FIFTH EDITION

Fishman's Pulmonary Diseases and Disorders

Mc Graw Hill Education

ON THE COVER

The background image was obtained using three-dimensional, micro-computed tomography (micro-CT) on a lung specimen from a normal donor. Airways and blood vessels are shown penetrating alveolar ducts and alveoli. Imaging was performed at 8-µm isotropic resolution (McDonough JE, Yuan R, Suzuki M, et al. Small-airway obstruction and emphysema in chronic obstructive pulmonary disease. *N Engl J Med.* 2011;365(17):1567–1575. PMCID: PMC3238466). The clinical CT images in the insets are still frames captured from the corresponding online video, which can be accessed by scanning the adjacent QR code. The top image, a maximum-intensity projection of a reformatted coronal section, shows contrast-enhanced pulmonary vasculature. The bottom image, a volume rendering of a similar reformatted coronal section using inverted gray scale, reveals the airways.

The initial portion of the video, comprised of a coronal view from a contrast-enhanced chest CT scan obtained from a normal, 25-year-old woman, shows volume rendering of the bony thorax and pulmonary vasculature. The video transitions to volume rendering of the lungs, trachea, and bronchi. Shown subsequently is a rotating tomographic section of the distal airways. A red box in the section indicates the general location from which a lung specimen was obtained from a separate, normal donor for micro-CT imaging. The last segment of this portion of the video shows rectangular volume rendering of the specimen, which then transitions to a rotating tomographic depiction. Blood vessels *(solid arrow)*, alveolar ducts *(dashed arrow)*, and alveoli *(dotted arrow)* are identified. The second portion of the video demonstrates an unenhanced CT scan from a 63-year-old female lung transplant recipient who had severe COPD. The patient's chest x-ray is shown on the left and axial CT images on the right. The red box indicates the location from which a specimen was obtained from the explanted emphysematous lung for micro-CT imaging. The micro-CT segment in the video includes rectangular volume rendering of the emphysematous lung specimen and, subsequently, a rotating tomographic section of the tissue sample. Loss of alveolar structure is evident. Blood vessels *(solid arrow)*, alveolar ducts *(dashed arrow)*, and alveoli *(dotted arrow)* are noted. In this specimen, blood vessels are filled with residual blood.

Fishman's Pulmonary Diseases and Disorders

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Fishman's Pulmonary Diseases and Disorders

Fifth Edition

EDITOR-IN-CHIEF

Michael A. Grippi, MD

Vice Chairman, Department of Medicine
Pulmonary, Allergy, and Critical Care Division
Perelman School of Medicine at the University of Pennsylvania
Chief Medical Officer, GSPP Specialty Hospital
Philadelphia, Pennsylvania

Alfred P. Fishman, MD, 1918–2010

Alfred P. Fishman, MD, was a husband, father, scientist, clinician, author, and consummate editor. The breadth and depth of his intellectual curiosity were great, and his contributions to pulmonary medicine and science of real consequence. He was an exacting task master who set a high bar for all of us, as well as for himself; his commitment to excellence was steadfast. The editors of the fifth edition dedicate this work to Dr. Fishman—the man, the mentor, and the driving force behind the origins of *Pulmonary Diseases and Disorders*.

CONTENTS

Contributors xiii
Preface xxvii

PART 1: Perspectives

1 **Milestones in the History of Pulmonary Medicine** 2
Michael A. Grippi

PART 2: Scientific Basis of Lung Function in Health and Disease

SECTION 1 Genetic, Cellular, and Structural Basis of Normal Lung Function

2 **Functional Design of the Human Lung for Gas Exchange** 20
Matthias Ochs / Ewald R. Weibel

3 **The Respiratory Muscles** 63
Ghislaine Gayan-Ramirez / Marc Decramer

4 **Molecular Regulation of Lung Development** 73
Wellington V. Cardoso / Jining Lu

5 **Pulmonary Surfactant and Disorders of Surfactant Homeostasis** 83
Jeffrey A. Whitsett / Timothy E. Weaver

6 **Mucociliary Clearance** 93
Burton F. Dickey / Michael R. Knowles / Richard C. Boucher

7 **The Genetic Basis of Respiratory Disorders** 104
Micheala A. Aldred

8 **Stem Cells and Respiratory Disease: Prospects for the Future** 117
Darrell N. Kotton

9 **Personalized Pulmonary Medicine** 124
Benjamin A. Raby / Kelan G. Tantisira

SECTION 2 Physiological Principles of Normal Lung Function

10 **Pulmonary Mechanics** 137
Murray D. Altose

11 **Control of Ventilation** 148
Frank J. Jacono / Xavier Soler / Atul Malhotra

12 **Circadian Rhythms and Sleep Biology** 158
Allan I. Pack

13 **Pulmonary Circulation** 167
Robert Naeije

14 **Ventilation, Pulmonary Blood Flow, and Ventilation–Perfusion Relationships** 183
Peter D. Wagner

15 **Blood-Gas Transport** 195
Adrian Shifren / Robert A. Klocke

16 **Diffusion, Chemical Reactions, and Diffusing Capacity** . . . 199
Robert A. Klocke / Adrian Shifren

17 **Acid–Base Balance** 207
Stanley Goldfarb / Kumar Sharma

SECTION 3 The Lungs in Different Physiological States

18 **Respiratory System Response to Exercise in Health** 219
Jerome A. Dempsey / Anthony J. Jacques

19 **Aging of the Respiratory System** 233
Edward J. Campbell

SECTION 4 Lung Immunology

20 **Innate and Adaptive Immunity in the Lung** 246
Charles S. Dela Cruz / Jonathan L. Koff

21 **Lymphocyte- and Macrophage-Mediated Inflammation in the Lung** 259
Praveen Govender / Frederic F. Little / Kevin C. Wilson / David M. Center

22 **Mast Cells and Eosinophils** 275
Edward S. Schulman / Peter H. S. Sporn

23 **Leukocyte Accumulation in Pulmonary Disease** 292
Nicholas W. Lukacs / Peter A. Ward

24 **Antibody-Mediated Lung Defenses and Humoral Immunodeficiency** 303
Homer L. Twigg III

SECTION 5 Lung Injury and Repair

25 **T Lymphocytes in the Lung** 318
Lauren E. Cohn

26 **Chemokines, Adipokines, and Growth Factors in the Lung** 327
Marcus W. Butler / Paul McLoughlin / Michael P. Keane

27 **Redox Signaling and Oxidative Stress in Lung Diseases** . . . 341
Jessy Deshane / Victor J. Thannickal

28 **Fibroblasts in Lung Homeostasis and Disease** 359
Yong Zhou / Victor J. Thannickal

PART 3: Symptoms and Signs of Respiratory Disease

SECTION 6 Clinical Approach to the Patient

29 **Approach to the Patient with Respiratory Symptoms** 374
Michael A. Grippi / Robert M. Senior / Jeffrey P. Callen

CONTENTS

SECTION 7 Diagnostic Procedures

30 Modern Approach to Thoracic Imaging Diagnosis 412
Eduardo J. Mortani Barbosa Jr. / Warren B. Gefter

31 Thoracic Ultrasonography 468
Lisa Chen / Paul H. Mayo

32 Physiologic and Metabolic Study of Pulmonary Disorders Using Conventional Imaging Techniques and Positron Emission Tomography 477
Ghassan El-Haddad / Søren Hess / Daniel Worsley / Abass Alavi

33 Pulmonary Function Testing 502
Michael A. Grippi / Gregory Tino

34 Principles and Applications of Cardiopulmonary Exercise Testing 537
Karl T. Weber / Kevin P. Newman

35 Diagnostic Bronchoscopy, Transthoracic Needle Biopsy, and Related Procedures 553
Anil Vachani / Daniel H. Sterman

36 Interventional Bronchoscopy 572
Andrew R. Haas / Daniel H. Sterman

37 Diagnostic Thoracic Surgical Procedures: Thoracoscopy, VATS, and Thoracotomy 583
Robert E. Merritt

38 Evaluation of Respiratory Impairment and Disability 586
Akshay Sood

PART 4: Obstructive Lung Diseases

SECTION 8 Chronic Obstructive Pulmonary Disease

39 Pathology of Chronic Obstructive Pulmonary Disease: Diagnostic Features and Differential Diagnosis 600
Joanne L. Wright / Andrew Churg

40 Chronic Obstructive Pulmonary Disease: Epidemiology, Pathophysiology, Pathogenesis, and α1-Antitrypsin Deficiency 613
Robert M. Senior / Richard A. Pierce / Jeffrey J. Atkinson

41 Cigarette Smoking and Smoking Cessation 636
Stephen I. Rennard / David M. Daughton

42 Course and Treatment of Chronic Obstructive Pulmonary Disease 650
M. Bradley Drummond / Robert A. Wise

43 Rehabilitation in Chronic Obstructive Pulmonary Disease and Other Respiratory Disorders 664
Andrew L. Ries

SECTION 9 Asthma

44 The Biology of Asthma 673
Matthew C. Bell / William W. Busse

45 Asthma: Epidemiology 687
Augusto A. Litonjua / Andrea J. Apter / Scott T. Weiss

46 Asthma: Clinical Presentation and Management 700
Omar S. Usmani / Peter J. Barnes

47 Aspirin- and Exercise-Induced Asthma 715
Jose L. Gomez / Geoffrey L. Chupp / Gregory P. Geba

48 Allergic Bronchopulmonary Aspergillosis (Mycosis) and Severe Asthma with Fungal Sensitivity 730
Geoffrey L. Chupp

SECTION 10 Other Obstructive Disorders

49 Upper Airway Obstruction in Adults 738
Christine Won / Gaetane Michaud / Meir H. Kryger

50 Cystic Fibrosis 757
Judith A. Voynow / Maria Mascarenhas / Andrea Kelly / Thomas F. Scanlin

51 Bronchiolitis 778
Gary R. Epler

52 Bullous Disease of the Lung 787
Fernando J. Martinez

53 Bronchiectasis 800
Alan F. Barker / Steven L. Brody

PART 5: Interstitial and Inflammatory Lung Diseases

SECTION 11 Immunologic and Interstitial Diseases

54 Interstitial Lung Disease: A Clinical Overview and General Approach 810
Danielle Antin-Ozerkis

55 Systemic Sarcoidosis 823
David R. Moller / Edward S. Chen

56 Idiopathic Pulmonary Fibrosis 842
Robert M. Tighe / Eric B. Meltzer / Paul W. Noble

57 Idiopathic Interstitial Pneumonias Other Than Idiopathic Pulmonary Fibrosis 859
Erica L. Herzog / Ami N. Rubinowitz / Mridu Gulati

58 Hypersensitivity Pneumonitis 875
Alex H. Gifford / Richard I. Enelow

59 Radiation Pneumonitis 883
Kenneth B. Roberts / Roy Decker / Sara Rockwell

60 Pulmonary Manifestations of the Collagen Vascular Diseases 902
Gregory P. Cosgrove / Marvin I. Schwarz

61 Pulmonary Langerhans' Cell Histiocytosis 919
Sergio Harari / Olga Torre / Talmadge E. King Jr. / Joel Moss

62 Pulmonary Lymphangioleiomyomatosis 928
Angelo M. Taveira-DaSilva / Talmadge E. King Jr. / Joel Moss

63 Benign Metastasizing Leiomyoma 939
Gustavo Pacheco-Rodriguez / Angelo M. Taveira-DaSilva / Joel Moss

64 Depositional Diseases of the Lungs 945
Robert J. Homer

PART 6: Drug-Induced Lung Diseases

65 Pulmonary Toxicity Related to Chemotherapeutic Agents 956
Lynn T. Tanoue / John McArdle / Jennifer Possick

66 Drug-Induced Pulmonary Disease Due to Nonchemotherapeutic Agents 975
Hilary C. Cain

PART 7: Other Infiltrative and Airspace Disorders

67 The Lungs in Patients with Inborn Errors of Metabolism 994
Timothy Craig Allen

68 Alveolar Hemorrhage Syndromes 1001
Joseph P. Lynch / Michael C. Fishbein / Tisha Wang

69 Aspiration-Related Pulmonary Disorders 1018
Paul E. Marik

70 Pulmonary Alveolar Proteinosis Syndrome 1028
Bruce C. Trapnell / Takuji Suzuki

71 The Eosinophilic Pneumonias 1037
Carolyn L. Rochester

PART 8: Disorders of the Pulmonary Circulation

72 Pulmonary Arterial Hypertension 1064
Darren B. Taichman / Jess Mandel / Kimberly A. Smith / Jason X.-J. Yuan

73 Pulmonary Thromboembolic Disease 1110
Peter F. Fedullo / Gordon L. Yung

74 Pulmonary Vasculitis 1134
Ulrich Specks

75 Pulmonary Arteriovenous Malformations 1148
Daniel M. Goodenberger / Murali Chakinala

PART 9: Disorders of the Pleural Space

76 Nonmalignant Pleural Effusions 1164
John E. Heffner

77 Malignant Pleural Effusions 1188
Steven A. Sahn / John T. Huggins

78 Pneumothorax 1197
S. Rodrigo Burguete / Daniel T. DeArmond / Nilam J. Soni / Jay Peters

PART 10: Diseases of the Mediastinum

79 Malignant Mesothelioma and Other Primary Pleural Tumors 1216
Edmund K. Moon / Leslie A. Litzky / Daniel H. Sterman

80 Nonneoplastic Disorders of the Mediastinum 1236
Cameron D. Wright

81 Congenital Cysts of the Mediastinum: Bronchopulmonary Foregut Anomalies 1248
Alberto de Hoyos / Malcolm M. DeCamp Jr.

82 Benign and Malignant Neoplasms of the Mediastinum . . . 1259
Bryan M. Burt / Joseph B. Shrager

PART 11: Disorders of the Chest Wall, Diaphragm, and Spine

83 Nonmuscular Diseases of the Chest Wall 1274
George E. Tzelepis / F. Dennis McCool

84 Effects of Neuromuscular Diseases on Ventilation 1289
Gerard J. Criner / Nathaniel Marchetti

85 Management of Neuromuscular Respiratory Muscle Dysfunction 1313
John R. Bach

PART 12: Occupational and Environmental Disorders

SECTION 12 Occupational Disorders

86 Asbestos-Related Lung Disease 1322
William N. Rom

87 Chronic Beryllium Disease and Hard-Metal Lung Diseases 1334
Mary Elizabeth Kreider / Milton D. Rossman

88 Coal Workers' Lung Diseases and Silicosis 1342
Robert C. Stansbury / Edward L. Petsonk / John E. Parker

89 Occupational Asthma, Byssinosis, and Industrial Bronchitis 1360
J. Allen D. Cooper

90 Acute and Chronic Responses to Toxic Inhalations 1369
Jian Jing / David A. Schwartz

SECTION 13 Environmental Disorders

91 Indoor and Outdoor Air Pollution 1386
David Q. Rich / Jonathan M. Samet / Mark J. Utell

92 High-Altitude Physiology and Clinical Disorders 1412
Kingman P. Strohl / Cynthia M. Beall / Nikolaus C. Netzer

93 Diving Injuries and Air Embolism 1420
Christopher Logue

94 Thermal Lung Injury and Acute Smoke Inhalation 1428
Perenlei Enkhbaatar

PART 13: Pulmonary Complications of Nonpulmonary Disorders

95 Noninfectious Pulmonary Complications of Hematopoietic Stem Cell and Solid Organ Transplantation 1442
Bekele Afessa / Steve G. Peters / Robert M. Kotloff

96 Pulmonary Complications of Sickle Cell Disease 1463
Roberto F. Machado / Mark T. Gladwin

97 Pulmonary Disorders and Pregnancy 1479
Ghada Bourjeily / Jeffrey Mazer / Andrew Levinson

98 Pulmonary Complications of Intra-abdominal Disease . . . 1496
Sonja D. Bartolome / Michael J. Krowka

PART 14: Sleep and Sleep Disorders

99 Sleep Apnea Syndromes: Central and Obstructive 1510
Grace W. Pien / Ilene M. Rosen / Barry G. Fields

100 Sleep-Related Hypoventilation Syndromes 1551
Richard J. Schwab / Bernie Young Sunwoo

CONTENTS

101 Changes in the Cardiorespiratory System During Sleep 1561
Indira Gurubhagavatula

102 Differential Diagnosis and Evaluation of Sleepiness 1567
Mithu Sen / Meir H. Kryger

PART 15: Surgical Aspects of Pulmonary Medicine

103 Perioperative Respiratory Considerations in the Surgical Patient 1578
Horace M. DeLisser / Michael A. Grippi

104 Acute Respiratory Failure in the Surgical Patient 1592
Robert M. Kotloff

105 Perioperative Care of the Patient Undergoing Lung Resection 1606
Robert J. Cerfolio / Ayesha S. Bryant

106 Thoracic Trauma 1618
Nathan T. Mowery / J. Wayne Meredith

107 Lung Transplantation 1624
Allan R. Glanville

PART 16: Neoplasms of the Lungs

SECTION 14 Lung Cancer

108 Genetic and Molecular Changes in Lung Cancer: Prospects for a Personalized Pharmacological Approach to Treatment 1652
Howard Li / Jeffrey A. Kern

109 Epidemiology of Lung Cancer 1667
Charles S. Dela Cruz / Lynn T. Tanoue / Richard A. Matthay

110 Approach to the Patient with Pulmonary Nodules 1684
David Ost

111 The Pathology of Bronchogenic Carcinoma 1700
Leslie A. Litzky

112 Clinical Evaluation, Diagnosis, and Staging of Lung Cancer 1722
Lydia Chang / M. Patricia Rivera

113 Treatment of Non–Small-Cell Lung Cancer: Surgery 1733
Scott I. Reznik / W. Roy Smythe

114 Treatment of Non–Small-Cell Lung Cancer: Chemotherapy 1747
Laurie L. Carr / James R. Jett

115 Treatment of Non–Small-Cell Lung Cancer: Radiation Therapy 1758
Tithi Biswas / Mitchell Machtay

116 Small Cell Lung Cancer: Diagnosis, Treatment, and Natural History 1770
Jonathan E. Dowell / David E. Gerber / David H. Johnson

117 Primary Lung Tumors Other than Bronchogenic Carcinoma: Benign and Malignant 1786
Alla Godelman / Steven M. Keller

118 Extrapulmonary Syndromes Associated with Lung Tumors 1797
Nicholas J. Pastis / Nichole T. Tanner / Gerard A. Silvestri

119 Pulmonary Metastases: The Role of Surgical Resection 1810
Loretta Erhunmwunsee / Thomas A. D'Amico

SECTION 15 Lymphoproliferative Disorders

120 Lymphoproliferative and Hematologic Diseases Involving the Lung and Pleura 1816

Hilary C. Cain, MD
Associate Professor
Section of Pulmonary and Critical Care Medicine
Department of Internal Medicine
Yale University School of Medicine
VA Connecticut Healthcare System
West Haven, Connecticut
Chapter 66

Jeffrey P. Callen, MD
Professor of Medicine (Dermatology)
Chief, Division of Dermatology
University of Louisville
Louisville, Kentucky
Chapter 29

Edward J. Campbell, MD
HerediLab, Inc.
Salt Lake City, Utah
Chapter 19

Wellington V. Cardoso, MD, PhD
Professor of Medicine and Genetics & Development
Director, Columbia Center for Human Development
Department of Medicine
Columbia University Medical Center
New York, New York
Chapter 4

Laurie L. Carr, MD
Assistant Professor of Medicine
National Jewish Health
Denver, Colorado
Chapter 114

David M. Center, MD
Gordon and Ruth Snider Professor of Pulmonary Medicine
Professor of Medicine and Biochemistry
Associate Provost for Translational Research
Chief, Pulmonary, Allergy, Sleep and Critical Care Medicine
Boston University School of Medicine
Boston Medical Center
Chapter 21

Robert J. Cerfolio, MD, MBA
Professor of Surgery
James H. Estes Endowed Chair Lung Cancer Research
Birmingham, Alabama
Chapter 105

Murali Chakinala, MD, FCCP
Associate Professor of Medicine
Director, Pulmonary Hypertension Center
Co-Director HHT Center
Division of Pulmonary and Critical Care Medicine
Department of Medicine
Washington University School of Medicine
St. Louis, Missouri
Chapter 75

Georgios Chamilos, MD
Department of Internal Medicine
School of Medicine, Stavrakia, Voutes
University of Crete Heraklion
Crete, Greece
Chapter 133

Lydia Chang, MD
Assistant Professor of Medicine
Division of Pulmonary and Critical Care Medicine
University of North Carolina
Chapel Hill, North Carolina
Chapter 112

Lisa Chen, DO
Attending Physician
North Shore University Hospital
Manhasett, New York
Chapter 31

Edward S. Chen, MD
Assistant Professor of Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland
Chapter 55

Asha N. Chesnutt, MD
Pulmonary and Critical Care Physician
Pulmonary, Critical Care and Sleep Medicine
The Oregon Clinic, PC
Portland, Oregon
Chapter 140

Jason D. Christie, MD
Associate Professor of Medicine and Epidemiology
Division of Pulmonary, Allergy, and Critical Care Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 141

Geoffrey L. Chupp, MD
Associate Professor of Medicine, Yale School of Medicine
Director, Yale Center for Asthma and Airway Disease
Director, Pulmonary Function Laboratory, Yale New Haven Hospital
New Haven, Connecticut
Chapters 47 and 48

Andrew Churg, MD
Professor, University of British Columbia
Pathologist, Vancouver General Hospital
University Hospital
Vancouver, BC Canada
Chapter 39

Lauren E. Cohn, MD
Associate Professor of Medicine
Co-Director, Yale Center for Asthma and Airway Diseases
Section of Pulmonary, Critical Care and Sleep Medicine
Yale University School of Medicine
New Haven, Connecticut
Chapter 25

J. Allen D. Cooper Jr., MD
Division of Pulmonary, Allergy and Critical Care Medicine
University of Alabama Medical School
Chief, Pulmonary Section
Birmingham Department of Veterans Affairs Medical Center
Birmingham, Alabama
Chapter 89

Ryan Cooper, MD, MPH
Assistant Professor
Division of Infectious Diseases
University of Alberta
Edmonton, Alberta
Chapter 131

Gregory P. Cosgrove, MD, FCCP
Chief Medical Officer, Pulmonary Fibrosis Foundation
Interstitial Lung Disease Program
Associate Professor
National Jewish Health
University of Colorado-Denver
Denver, Colorado
Chapter 60

Gerard J. Criner, MD
Professor of Medicine
Florence P. Bernheimer Distinguished Service Chair
Chief, Division of Pulmonary and Critical Care
Temple University School of Medicine
Philadelphia, Pennsylvania
Chapter 84

Thomas A. D'Amico, MD
Gary Hock Endowed Professor and Vice-Chair of Surgery
Chief, Section of General Thoracic Surgery
Program Director, Thoracic Surgery
Duke University Medical Center
Durham, North Carolina
Chapter 119

David M. Daughton, MS
Behavioral Researcher, Retired
Pulmonary and Critical Care Medicine
Department of Internal Medicine
Nebraska Medical Center
Omaha, Nebraska
Chapter 41

Daniel T. DeArmond, MD
Assistant Professor
Director of Minimally Invasive Thoracic Surgery
Division of Thoracic Surgery
Department of Cardiothoracic Surgery
University of Texas Health Science Center San Antonio
San Antonio, Texas
Chapter 78

Malcolm M. DeCamp Jr., MD
Fowler McCormick Professor of Surgery
Northwestern University Feinberg School of Medicine
Chief, Division of Thoracic Surgery
Northwestern Memorial Hospital
Chicago, Illinois
Chapter 81

Roy Decker, MD, PhD
Associate Professor of Therapeutic Radiology
Yale University School of Medicine
Attending Physician, Yale-New Haven Hospital
Chapter 59

Marc Decramer, MD, PhD
Professor of Medicine
Chief Executive Officer
University Hospital
University of Leuven
Leuven, Belgium
Chapter 3

Charles S. Dela Cruz, MD, PhD
Assistant Professor
Section of Pulmonary, Critical Care, and Sleep Medicine
Department of Internal Medicine
Yale University School of Medicine
New Haven, Connecticut
Chapters 20 and 109

Horace M. DeLisser, MD
Associate Professor of Medicine
Department of Medicine
Perelman School of Medicine
Translational Research Laboratories
University of Pennsylvania
Philadelphia, Pennsylvania
Chapters 103 and 153

Jerome A. Dempsey, PhD
John Robert Sutton Professor Emeritus of Population Health Sciences
Director, John Rankin Laboratory of Pulmonary Medicine
University of Wisconsin
Madison, Wisconsin
Chapter 18

Jessy Deshane, PhD
Assistant Professor
Department of Medicine
Division of Pulmonary Allergy and Critical Care Medicine
University of Alabama
Alabama, Birmingham
Chapter 27

Clifford S. Deutschman, MS, MD, FCCM
Vice-Chair, Research
Department of Pediatrics
Professor of Pediatrics and Molecular Medicine North Shore-Long Island
Jewish-Hofstra School of Medicine
Steven and Alexandra Cohen Children's Medical Center
New Hyde Park, New York
Investigator
Feinstein Institute for Medical Research
Manhasset, New York
Chapter 142

Burton F. Dickey, MD
Department of Pulmonary Medicine
University of Texas MD Anderson Cancer Center
Houston, Texas
Chapter 6

Karen Doucette, MD, MSc (Epi)
Associate Professor
Division of Infectious Diseases, University of Alberta
Edmonton, Alberta
Chapter 131

Jonathan E. Dowell, MD
Associate Professor
Department of Internal Medicine (Division of Hematology and Oncology)
UT Southwestern Medical Center
Chief, Section of Hematology/Oncology
Dallas Veterans Affairs Medical Center
Dallas, Texas
Chapter 116

M. Bradley Drummond, MD, MHS
Assistant Professor, Pulmonary and Critical Care Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland
Chapter 42

Ghassan El-Haddad, MD
Assistant Member of Interventional Radiology
H. Lee Moffitt Cancer Center and Research Institute
Assistant Professor of Oncologic Sciences and Radiology
University of South Florida
Tampa, Florida
Chapter 32

Richard I. Enelow, MD
Professor of Medicine, Microbiology, and Immunology
Geisel School of Medicine at Dartmouth
Section of Pulmonary and Critical Care Medicine
Dartmouth-Hitchcock Medical Center
Lebanon, New Hampshire
Chapter 58

Kyle B. Enfield, MD, MS
Assistant Professor of Medicine
Division of Pulmonary and Critical Care Medicine,
Department of Medicine, University of Virginia School of Medicine
Attending Physician and Medical Director, Medical Intensive Care Unit,
University of Virginia Health System
Charlottesville, Virginia
Chapter 127

Perenlei Enkhbaatar, MD, PhD, FAHA
Professor, Department of Anesthesiology
Director of Translational Intensive Care Unit
University of Texas Medical Branch
Galveston, Texas
Chapter 94

Gary R. Epler, MD
Clinical Associate Professor
Harvard Medical School
Pulmonary and Critical Care Medicine
Brigham and Women's Hospital
Boston, Massachusetts
Chapter 51

Loretta Erhunmwunsee, MD
Chief Resident in Thoracic Surgery
Duke University Medical Center
Durham, North Carolina
Chapter 119

Peter F. Fedullo, MD
Director, Medical Intensive Care Unit
Professor of Clinical Medicine
University of California
San Diego, California
Chapter 73

Barry G. Fields, MD
Assistant Professor of Medicine
Division of Pulmonary, Allergy, and Critical Care Medicine
Department of Medicine
Emory University School of Medicine
Atlanta, Georgia
Chapter 99

Thomas M. File Jr., MD, MSc
Chair, Infectious Disease Division
Summa Health System
Akron, OH
Professor, Internal Medicine
Master Teacher, Chair, Infectious Disease Section
Northeast Ohio Medical University
Rootstown, Ohio
Chapter 126

Michael C. Fishbein, MD
Piansky Professor of Pathology and Medicine
Department of Pathology and Laboratory Medicine
UCLA Center for the Health Sciences
Los Angeles, California

Jay A. Fishman, MD
Associate Director, MGH Transplantation Center
Director, Transplant Infectious Disease & Compromised Host Program
Massachusetts General Hospital
Professor of Medicine, Harvard Medical School
Boston, Massachusetts
Chapters 122, 123, 135, and 137

Douglas B. Flieder, MD
Professor of Pathology
Fox Chase Cancer Center
Philadelphia, Pennsylvania
Chapter 120

Barry D. Fuchs, MD
Associate Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Perelman School of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Chapters 147 and 152

Ghislaine Gayan-Ramirez, PhD
Department of Pneumology
Katholieke Universiteit Leuven
Leuven, Belgium
Chapter 3

Gregory P. Geba, MD, MPH, DrPH, FACP, FCCP, FAAAAI
Vice President, Clinical Development and Regulatory Affairs
Regeneron Pharmaceuticals, Inc.
Tarrytown, New York
Chapter 47

Warren B. Gefter, MD
Professor of Radiology
Chief, Cardiothoracic Imaging Division
Associate Chair, Department of Radiology
Perelman School of Medicine at University Pennsylvania
Philadelphia, Pennsylvania
Chapter 30

David E. Gerber, MD
Associate Professor
Department of Internal Medicine
(Division of Hematology and Oncology)
Co-Leader, Experimental Therapeutics Program
Harold C. Simmons Cancer Center
UT Southwestern Medical Center
Dallas, Texas
Chapter 116

Alex H. Gifford, MD
Assistant Professor of Medicine
Geisel School of Medicine at Dartmouth
Dartmouth-Hitchcock Medical Center
Chapter 58

Timothy D. Girard, MD, MSCI
Division of Allergy, Pulmonary, and Critical Care Medicine
Center for Health Services Research
Center for Quality of Aging
Department of Medicine, Vanderbilt University School of Medicine
Geriatric Research, Education and Clinical Center (GRECC) Service,
Department of Veterans Affairs Medical Center,
Tennessee Valley Healthcare System
Nashville, Tennessee
Chapter 150

Mark T. Gladwin, MD
Professor of Medicine
Division Chief, Pulmonary, Allergy and Critical Care Medicine
Director, Heart, Lung, Blood and Vascular Medicine
Department of Medicine
Institute of University of Pittsburgh and UPMC Montefiore Hospital
Pittsburgh, Pennsylvania
Chapter 96

Allan R. Glanville, MBBS, MD, FRACP
Director Thoracic Medicine
Medical Director Lung Transplantation
St.Vincent's Hospital
Darlinghurst, Australia
Chapter 107

Alla Godelman, MD
Department of Radiology
Montefiore Medical Center
Assistant Professor of Radiology
Albert Einstein College of Medicine
Chapter 117

Stanley Goldfarb, MD
Associate Dean for Curriculum
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 17

Mitchell Goldman, MD, FACP
Program Director, Internal Medicine Residency
Professor of Medicine
Division of Infectious Diseases
Indiana University School of Medicine
Indianapolis, Indiana
Chapter 134

Jose L. Gomez, MD, MS
Instructor
Pulmonary, Critical Care and Sleep Section
Yale University School of Medicine
New Haven, Connecticut
Chapter 47

Daniel M. Goodenberger, MD
Professor of Medicine, Washington University School of Medicine
Chief, Medical Service, St. Louis VAMC
Medical Director Emeritus, HHT Centers of Excellence
Washington University and University of Texas Southwestern
St. Louis, Missouri
Chapter 75

Emily K. B. Gordon, MD
Assistant Professor
Department of Anesthesiology and Critical Care
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 142

Praveen Govender, MD
Assistant Professor of Medicine
Pulmonary, Allergy & Immunology
Associate Director, Sarcoidosis Center at Boston Medical Center
Boston, Massachusetts
Chapter 21

Michael A. Grippi, MD
Vice Chairman, Department of Medicine
Pulmonary, Allergy, and Critical Care Division
Chief Medical Officer, GSPP Specialty Hospital at Rittenhouse
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapters 1, 29, 33, 103, 139, and 152

Mridu Gulati, MD, MPH
Departments of Internal Medicine, Section of Pulmonary,
Critical Care and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
Chapter 57

Indira Gurubhagavatula, MD, MPH
Associate Professor of Medicine
Perelman School of Medicine
University of Pennsylvania
Director, Sleep Disorders Clinic
Philadelphia VA Medical Center
Philadelphia, Pennsylvania
Chapter 101

Andrew R. Haas, MD, PhD
Assistant Professor of Medicine
Chief, Section of Interventional Pulmonology and Thoracic Oncology
Division of Pulmonary, Allergy and Critical Care Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 36

Chadi A. Hage, MD
Assistant Professor of Medicine
Indiana University School of Medicine
Pulmonary-Critical Care Medicine
Thoracic Transplant program
Methodist Professional Center-1
Indianapolis, Indiana
Chapter 134

C. William Hanson III, MD
Professor of Anesthesiology and Critical Care
Surgery and Internal Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 146

Sergio Harari, MD
Director of Pulmonary Division and Department of Medicine
Unità Operativa di Pneumologia e Terapia Semi-Intensiva Respiratoria
Servizio di Fisiopatologia Respiratoria e Emodinamica polmonare
Ospedale San Giuseppe MultiMedica
Milano, Italy
Chapter 61

John E. Heffner, MD
Professor of Medicine
Garnjobst Chair, Department of Medicine
Oregon Health and Science University
Providence Portland Medical Center
Portland, Oregon
Chapter 76

Erica L. Herzog, MD
Department of Internal Medicine, Section of Pulmonary,
Critical Care and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
Chapter 57

Søren Hess, MD
Associate Professor, Department of Nuclear Medicine
Odense University Hospital
Denmark
Chapter 32

Robert J. Homer, MD, PhD
Professor of Pathology and Internal Medicine (Pulmonary)
Yale University School of Medicine
New Haven, Connecticut
Pathology and Laboratory Medicine Service
VA CT HealthCare System
West Haven, Connecticut
Chapter 64

Alberto de Hoyos, MD, FCCP, FACS
Director of Alton Ochsner Lung Cancer Center
Director of Thoracic Oncology
Ochsner Medical Center
New Orleans, Louisiana
Chapter 81

Gary B. Huffnagle, PhD
Professor of Medicine
Division of Pulmonary and Critical Care Medicine
University of Michigan Medical Center
Ann Arbor, Michigan
Chapter 121

John T. Huggins, MD
Associate Professor of Medicine
Division of Pulmonary, Critical Care, Allergy and Sleep Medicine
Department of Medicine
Medical University of South Carolina
Charleston, South Carolina
Chapter 77

Louise C. Ivers, MB, BCh, BAO, MPH, DTM&H
Associate Professor of Global Health and Social Medicine
Associate Professor of Medicine
Harvard Medical School
Division of Global Health Equity
Brigham and Women's Hospital
Boston, Massachusetts
Chapter 136

Frank J. Jacono, MD
Associate Professor of Medicine
Division of Pulmonary, Critical Care and Sleep Medicine
Case Western Reserve University
Louis Stokes Cleveland VA Medical Center
Cleveland, Ohio
Chapter 11

Anthony J. Jacques, BS
Department of Population Health Sciences
John Rankin Laboratory of Pulmonary Medicine
University of Wisconsin
Madison, Wisconsin
Chapter 18

James R. Jett, MD
Professor of Medicine
National Jewish Health
Denver, Colorado
Chapter 114

Jian Jing, MD, PhD
Post-Doctoral Fellow
Department of Medicine
University of Colorado School of Medicine
Aurora, Colorado
Chapter 90

David H. Johnson, MD, MACP
Donald W. Seldin Distinguished Chair in Internal Medicine
Professor and Chairman, Department of Internal Medicine
UT Southwestern School of Medicine
Dallas, Texas
Chapter 116

Joshua B. Kayser, MD, MPH
Division of Pulmonary, Allergy and Critical Care
Perelman School of Medicine
University of Pennsylvania
Interim Chief of Medicine
Director, Medical Intensive Care Unit
Philadelphia VA Medical Center
Philadelphia, Pennsylvania
Chapter 153

Michael P. Keane, MD, FRCPI
Professor of Medicine
Chair of Medicine and Therapeutics
University College Dublin
Consultant Respiratory Physician
St Vincent's University Hospital
Dublin, Ireland
Chapter 26

Steven M. Keller, MD
Director Thoracic Surgery, Weiler Hospital
Professor Cardiothoracic Surgery
Albert Einstein College of Medicine
Bronx, New York
Chapter 117

Andrea Kelly, MD
Division of Endocrinology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania
Chapter 50

Steven G. Kelsen, MD
Professor of Medicine and Physiology
Division of Pulmonary and Critical Care Medicine
Department of Medicine
Temple University School of Medicine
Philadelphia, Pennsylvania
Chapter 143

Jeffrey A. Kern, MD
Professor of Medicine
Chief, Division of Oncology
Director, Lung Cancer Center
Department of Medicine
National Jewish Health
Denver, Colorado
Professor of Medicine
Pulmonary Sciences and Critical Care Medicine
Department of Medicine
University of Colorado—Denver
Aurora, Colorado
Chapter 108

Talmadge E. King Jr., MD
Julius R. Krevans Distinguished Professor in Internal Medicine
Chair, Department of Medicine
University of California, San Francisco
San Francisco, California
Chapters 61 and 62

Robert A. Klocke, MD
Emeritus Professor and Chair
Department of Medicine
University at Buffalo
Buffalo, New York
Chapters 15 and 16

Michael R. Knowles, MD
Professor of Pulmonary and Critical Care Medicine
Department of Medicine
Marsico Lung Institute/Cystic Fibrosis Center
University of North Carolina
Chapel Hill, North Carolina
Chapter 6

Kenneth S. Knox, MD
Associate Professor of Medicine and Immunobiology
Division Chief, Division of Pulmonary, Allergy,
Critical Care and Sleep Medicine
Department of Medicine, University of Arizona
Tucson, Arizona
Chapter 134

Jonathan L. Koff, MD
Director, Adult Cystic Fibrosis Program
Section of Pulmonary, Critical Care, and Sleep Medicine
Department of Internal Medicine
Yale University School of Medicine
New Haven, Connecticut
Chapter 20

Marin H. Kollef, MD
Director, Critical Care Research
Director, Respiratory Care Services
Barnes-Jewish Hospital
Virginia E. and Sam J. Golman Chair in
Respiratory Intensive Care Medicine
Professor of Medicine Division of Pulmonary and
Critical Care Medicine Washington
University School of Medicine
St. Louis, Missouri
Chapter 129

Dimitrios P. Kontoyiannis, MD, ScD, FACP, FIDSA
Frances King Black Endowed Professor, Infectious Diseases
Deputy Head
Division of Internal Medicine
The University of Texas MD Anderson Cancer Center
Adj Professor Baylor College of Medicine
Adj Professor University of Houston
Houston, Texas
Chapter 133

Robert M. Kotloff, MD
Chair, Department of Pulmonary Medicine
Cleveland Clinic
Cleveland, Ohio
Chapters 95 and 104

Darrell N. Kotton, MD
Professor of Medicine and Pathology
Director, Center for Regenerative Medicine (CReM)
Boston University and Boston Medical Center
Boston, Massachusetts
Chapter 8

Camille Nelson Kotton, MD
Infectious Diseases Division
Massachusetts General Hospital
Boston, Massachusetts
Chapter 138

Mary Elizabeth Kreider, MD, MSCE
Associate Chief for Education and Fellowship Director
Division of Pulmonary and Critical Care Medicine
Clinical Director ILD Program
The Perelman School of the Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 87

Michael J. Krowka, MD
Professor, Pulmonary and Critical Care Medicine
Mayo Clinic
Rochester, Minnesota
Chapter 98

Meir H. Kryger, MD, FRCPC
Professor, Pulmonary, Critical Care and Sleep Medicine
Yale School of Medicine
Director, Sleep Medicine Fellowship Program
Physician, VA Connecticut Healthcare System
West Haven, Connecticut
Chapters 49 and 102

Andrew Levinson, MD
Assistant Professor of Medicine (Clinical)
Pulmonary and Critical Care Medicine
The Warren Alpert Medical School of Brown University
The Miriam Hospital and Rhode Island hospital
Providence, Rhode Island
Chapter 97

Howard Li, MD
Assistant Professor
Division of Pulmonary Sciences and Critical Care Medicine
Department of Medicine
Denver VA Medical Center
Denver, Colorado
University of Colorado Anschutz Medical Campus
Aurora, Colorado
Chapter 108

Augusto A. Litonjua, MD, MPH
Associate Professor of Medicine
Channing Division of Network Medicine and
Division of Pulmonary and Critical Care Medicine
Department of Medicine
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts
Chapter 45

Frederic F. Little, MD
Assistant Professor of Medicine
Boston University School of Medicine
Program Director, Allergy/Immunology Fellowship
Medical Director, Pulmonary, Allergy, and Sleep Clinics
Boston Medical Center
Boston, Massachusetts
Chapter 21

Leslie A. Litzky, MD
Professor
Department of Pathology and Laboratory Medicine
Perelman School of Medicine of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapters 79, 111

Christopher Logue, MD
Hyperbaric Medicine Attending Physician
The Institute for Environmental Medicine
The Hospital of the University of Pennsylvania
Emergency Medicine Attending Physician
Penn Presbyterian Medical Center
Philadelphia, Pennsylvania
Chapter 93

Jining Lu, PhD
Assistant Professor of Medicine
Columbia Center for Human Development
Department of Medicine
Columbia University Medical Center
New York, New York
Chapter 4

Nicholas W. Lukacs, PhD
Godfrey Dorr Stobbe Professor of Pathology
Assistant Dean for Faculty Affairs
University of Michigan Medical School
Ann Arbor, Michigan
Chapter 23

Joseph P. Lynch, III, MD
Holt and Jo Hickman Endowed Chair of Advanced Lung Disease
and Lung Transplantation
Professor of Clinical Medicine, Step VIII
Associate Chief, Division of Pulmonary and Critical Care Medicine,
Clinical Immunology, and Allergy
David Geffen School of Medicine at UCLA
Los Angeles, California
Chapter 68

Roberto F. Machado, MD
Associate Professor of Medicine
Section of Pulmonary, Critical Care Medicine, Sleep and Allergy
University of Illinois Chicago
Chicago, Illinois
Chapter 96

Mitchell Machtay, MD
Vincent K. Smith Professor and Chair
Department of Radiation Oncology
Case Western Reserve University School of Medicine
University Hospitals Seidman Cancer Center
Cleveland, Ohio
Chapter 115

Atul Malhotra, MD
Kenneth M. Moser Professor of Medicine
Division of Pulmonary, Critical Care and Sleep Medicine
University of California San Diego
La Jolla, California
Chapter 11

Scott Manaker, MD, PhD
Associate Professor of Medicine
Pulmonary, Allergy, and Critical Care Division
Vice Chair for Regulatory Affairs
Department of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 145

Jess Mandel, MD
Professor of Medicine
Associate Dean for Undergraduate Medical Education
UCSD School of Medicine
La Jolla, California
Chapter 72

Nathaniel Marchetti, DO
Associate Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Temple University School of Medicine
Philadelphia, Pennsylvania
Chapter 84

Paul E. Marik, MD
Chief, Pulmonary and Critical Care Medicine
Department of Internal Medicine
Eastern Virginia Medical School
Norfolk, Virginia
Chapter 69

Thomas J. Marrie, MD, FRCPC, MACP, FRSC
Dean, Faculty of Medicine
Dalhousie University
Halifax, Nova Scotia
Chapter 128

Stanley I. Martin, MD
Associate Professor, Clinical Internal Medicine
Director, Infectious Diseases Fellowship Program
Division of Infectious Diseases
Transplant Infectious Diseases Service
The Ohio State University Wexner Medical Center
Columbus, Ohio
Chapter 135

Fernando J. Martinez, MD, MS
Executive Vice Chairman
Gladys and Roland Harriman Professor of Medicine
Joan and Sanford I. Weill Department of Medicine
Weill Cornell Medical College
NewYork-Presbyterian Hospital/Weill Cornell Medical Center
New York, New York
Chapter 52

Maria Mascarenhas, MD
Division of Gastroenterology, Hepatology and Nutrition
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania
Chapter 50

Richard A. Matthay, MD
Boehringer Ingelheim Emeritus Professor of Medicine and
Senior Research Scientist in Medicine
Pulmonary and Critical Care Medicine Section
Department of Internal Medicine
Yale University School of Medicine
New Haven, Connecticut
Chapter 109

Michael A. Matthay, MD
Professor, Medicine and Anesthesia
Associate Director, Intensive Care Unit, University of California,
San Francisco
Senior Associate, Cardiovascular Research Institute
San Francisco, California
Chapter 140

Paul H. Mayo, MD
Academic Director Critical Care
Long Island Jewish Medical Center
New Hyde Park, New York
Professor of Medicine
Hofstra North Shore-LIJ School of Medicine
Hempstead, New York
Chapter 31

Jeffrey Mazer, MD
Assistant Professor of Medicine
Pulmonary and Critical Care Medicine
The Warren Alpert Medical School of Brown University
The Miriam Hospital
Providence, Rhode
Chapter 97

John McArdle, MD
Assistant Clinical Professor of Medicine, University of Connecticut
Connecticut Multi-Specialty Group
Hartford, Connecticut
Chapter 65

F. Dennis McCool, MD
Professor of Medicine
Pulmonary Critical Care and Sleep Medicine
Alpert Medical School of Brown University
Memorial Hospital of Rhode Island
Pawtucket, Rhode Island
Chapter 83

Paul McLoughlin, MB, BCh, MRCPI, PhD
Professor of Physiology
University College Dublin
School of Medicine and Medical Sciences
Conway Institute of Biomedical and Biomolecular Research
St. Vincent's University Hospital
Dublin, Ireland
Chapter 26

Eric B. Meltzer, MD
Adjunct Assistant Professor of Medicine
Division of Pulmonary, Allergy and Critical Care Medicine
Department of Medicine
Duke University Medical Center
Durham, North Carolina
Chapter 56

J. Wayne Meredith, MD, FACS
Department of Surgery
Wake Forest Medical Center
Winston-Salem, North Carolina
Chapter 106

Robert E. Merritt, MD
Associate Professor of Surgery
Division of Thoracic Surgery
Ohio State University Medical Center
Columbus, Ohio
Chapter 37

Gaetane Michaud, MS, MD, FRCPC
Associate Professor of Medicine
Yale School of Medicine
New Haven, Connecticut
Chapter 49

Mark E. Mikkelsen, MD, MSCE
Assistant Professor of Medicine
Pulmonary, Allergy and Critical Care Division
Perelman School of Medicine at the University of Pennsylvania
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 152

David R. Moller, MD
Professor of Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland
Chapter 55

Edmund K. Moon, MD
Assistant Professor of Medicine
Section of Interventional Pulmonary and Thoracic Oncology
Division of Pulmonary, Allergy, and Critical Care
Department of Medicine
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 79

Joel Moss, MD, PhD
Deputy Chief, Cardiovascular and Pulmonary Branch
National Heart, Lung, and Blood Institute
National Institutes of Health
Bethesda, Maryland
Chapters 61, 62, and 63

Nathan T. Mowery, MD, FACS
Associate Professor of Surgery
Department of Surgery
Wake Forest Medical Center
Winston-Salem, North Carolina
Chapter 106

Robert Naeije, MD, PhD
Professor and Chairman of the Department of Physiology
and Pathophysiology
Director, Pulmonary Hypertension Clinic, Erasme University Hospital
Department of Physiology
Erasme Campus
Free University of Brussels
Brussels, Belgium
Chapter 13

Patrick J. Neligan, MD, FJFICM
Director of Critical Care Services
Consultant in Anaesthesia and Intensive Care
Galway University Hospitals and National University of Ireland,
Galway, Ireland
Chapter 147

Nikolaus C. Netzer, MD, PhD
University Professor
Hermann Buhl Institute for Hypoxia Research and Sleep Medicine Research
University of Ulm, Department of Internal Medicine, Germany
Faculty of Psychology and Sports Science, University Innsbruck
Innsbruck, Austria
Chapter 92

Kevin P. Newman, MD
Professor of Medicine
Division of Cardiovascular Diseases
University of Tennessee Health Science Center
Memphis, Tennessee
Chapter 34

Michael S. Niederman, MD
Professor of Medicine
SUNY at Stony Brook
Pulmonary and Critical Care
Winthrop-University Hospital
Mineola, New York
Chapter 125

Paul W. Noble, MD
Professor of Medicine
Chair of Medicine
Department of Medicine
Cedars Sinai Medical Center
Los Angeles, California
Chapter 56

Matthias Ochs, MD
Professor and Chair
Institute of Functional and Applied Anatomy
Hannover Medical School
Hannover, Germany
Chapter 2

David Ost, MD, MPH
Professor of Medicine
The University of Texas MD Anderson Cancer Center
Houston, Texas
Chapter 110

Gustavo Pacheco-Rodriguez, PhD
Staff Scientist, Cardiovascular and Pulmonary Branch
National Heart, Lung, and Blood Institute
National Institutes of Health
Bethesda, Maryland
Chapter 63

Allan I. Pack, MBChB, PhD
John Miclot Professor of Medicine
Chief, Division of Sleep Medicine/Department of Medicine
Director, Center for Sleep and Circadian Neurobiology
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
Chapter 12

John E. Parker, MD
Professor and Chief, Section of Pulmonary and Critical Care Medicine
Health Sciences Center
West Virginia University Healthcare
Morgantown, West Virginia
Chapter 88

Nicholas J. Pastis, MD
Assistant Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Department of Medicine
Medical University of South Carolina
Charleston, South Carolina
Chapter 118

Jay Peters, MD
Professor and Chief
Division of Pulmonary and Critical Care Medicine
Department of Medicine
University of Texas Health Science Center San Antonio
San Antonio, Texas
Chapter 78

Steve G. Peters, MD
Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Mayo Clinic
Rochester, Minnesota
Chapter 95

Edward L. Petsonk, MD
Professor, Section of Pulmonary and Critical Care Medicine
West Virginia University Healthcare
Health Sciences Center
Morgantown, West Virginia
Chapter 88

Julie V. Philley, MD
Assistant Professor of Medicine
Department of Pulmonary and Critical Care Medicine
University of Texas Health Science Center
Tyler, Texas
Chapter 132

Grace W. Pien, MD, MSCE
Assistant Professor of Medicine
Division of Pulmonary and Critical Care Medicine
Department of Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland
Chapter 99

Gerald B. Pier, PhD
Professor of Medicine (Microbiology and Immunobiology)
Division of Infectious Diseases
Department of Medicine
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts
Chapter 124

Richard A. Pierce, PhD
Division of Pulmonary and Critical Care
Department of Medicine
Washington University School of Medicine
St. Louis, Missouri
Chapter 40

Jennifer Possick, MD
Assistant Professor of Medicine
Section of Pulmonary, Critical Care and Sleep Medicine
Yale School of Medicine
New Haven, Connecticut
Chapter 65

Bala Prakash, MD
Assistant Professor of Medicine
Pulmonary, Critical Care and Sleep Medicine
Hofstra North Shore- LIJ School of Medicine
Manhasset, New York
Chapter 125

Gregory P. Priebe, MD
Associate Professor
Division of Critical Care Medicine
Department of Anesthesiology, Perioperative and Pain Medicine
Division of Infectious Diseases
Department of Medicine
Boston Children's Hospital
Division of Infectious Diseases
Department of Medicine
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts
Chapter 124

Benjamin A. Raby, MD, MPH
Associate Professor of Medicine
Channing Division of Network Medicine and the Division of Pulmonary and Critical Care Medicine
Director, BWH Pulmonary Genetics Center
Department of Medicine

PREFACE

This, the fifth edition of *Fishman's Pulmonary Diseases and Disorders*, represents a substantial departure in content and style from the previous four editions. Notably, this is the first edition in which the founding editor, Alfred P. Fishman (1918–2010), is no longer at the helm. Dr. Fishman, a legend in pulmonary science and medicine, leaves a legacy based on a long and distinguished career. Incredibly, he served as sole editor of the first two editions of the textbook, which initially appeared in print in 1980. Subsequently, he enlisted a number of coeditors, including several from the current group. Those of us who had the opportunity to work with him on the prior two editions remain grateful for his leadership, editorial style, and unrelenting commitment to excellence. His memory inspired us in preparing the current volume. We can only hope that it measures up to his exacting standards.

While many of the elements of the book have changed, one aspect remains firmly entrenched: The book represents a coupling of the body of knowledge of pulmonary and critical care medicine with the underlying basic and applied science upon which the clinical material is based. The book is designed to appeal both to clinicians and investigators who are interested in the science of medicine, including relevant respiratory biology and underlying cellular and molecular mechanisms. We hope that readers will find it authoritative, well referenced, and a suitable platform from which to launch additional inquiry.

The body of knowledge and level of detail in the fifth edition have evolved substantially since the last edition, published in 2008. In virtually all areas of pulmonary medicine, notable advancements have been made, and each is discussed in detail. For example, tremendous progress has occurred in our understanding of the genetics of respiratory disease; indeed, the era of "personalized medicine" is upon us. A full chapter has been devoted to the genetics of pulmonary disease and another to personalized pulmonary medicine—additions from the previous edition. Similarly, growth in immunology and immunosuppressive management, along with technical advances in lung transplantation, has been amply documented in the literature over the last 5 years and is presented in detail. Advances in the science and treatment of pulmonary hypertension have been noteworthy. This area, which was one of great interest to Dr. Fishman, is discussed in a comprehensive chapter on the subject. In addition, the rapid evolution of cardiovascular and pulmonary imaging techniques has been dramatic, and multiple examples of such advanced imaging populate many of the chapters. Utilization of the technology and its attendant costs constitute the basis for considerable debate and ongoing studies regarding applicability in screening patients for underlying pulmonary disease (e.g., lung cancer screening using low-dose CT scanning in at-risk patients). Finally, as another example of noteworthy progress, developments in interventional bronchoscopic techniques continue to evolve and have become increasingly sophisticated over the last 5 years. They are discussed in two related chapters on diagnostic and interventional bronchoscopy.

Within the realm of critical care medicine, significant advances have been reported in the early diagnosis and management of sepsis, multiple organ dysfunction syndrome (MODS), acute respiratory distress syndrome (ARDS), and the newly defined entity of "chronic critical illness." These advances have translated into improved survival of patients with disorders that, at one time, were largely fatal. Patient survival, particularly in the setting of chronic and, sometimes, debilitating, organ dysfunction has generated debate on the appropriateness of application of the technology and affordability of the healthcare thereby engendered. Such considerations inform a discussion of the organization of intensive care units and long-term acute care facilities, topics which have been included in this edition.

Not all of the news has been good. For example, challenges in the medical management of advanced interstitial lung disease, particularly idiopathic pulmonary fibrosis, have remained all too evident. Therapy has been disappointing. Notably, however, several recently completed clinical trials have improved prospects for management.

Those responsible for generating the content of the fifth edition include 278 contributors. They are drawn from among the world's experts in the areas about which they have written. One hundred fifty-nine contributors are new from the last edition, including many from outside the United States, reflecting the vast array of expertise available globally in the areas of pulmonary science and medicine.

Organization and content are not the only metrics that have changed with the fifth edition. Footnoted references are now incorporated extensively. Supplemental content and illustrations are made available by accessing QR codes embedded on the printed pages. Production constraints created by page limitations have been curtailed significantly. Notably, the fifth edition is being made available in an electronic version accessed via the World Wide Web.

An additional technological advance over the prior edition is incorporation of a number of videos designed to complement and, at times, accentuate information contained within the text. Not surprisingly, most of the videos relate to procedures or imaging. They are designed to reflect common or unique findings drawn from "real life" clinical experiences. They, too, are accessible using a QR code reader.

With all of the technological advances in play, at the end of the day, the compilation and synthesis of the information contained within this textbook are a reflection of the commitment, untiring effort, and professionalism of many contributing authors. The editors are enormously grateful for their willingness to "dig deep" and generate authoritative discussions of the complex and expanding fields of pulmonary and critical care medicine.

These same, appreciative editors have, themselves, contributed enormous boluses of time in editing and authoring the chapters that comprise the book. Personally, I found the willingness of my colleagues to step up and orchestrate its preparation extraordinarily gratifying.

Finally, on behalf of all of the editors, I wish to express our thanks for the commitment of key individuals in preparing the fifth edition, including Brian Belval, Executive Editor at McGraw-Hill; Peter Boyle, Sr Project Development Editor; Priscilla Beer, Sr Media Project Manager; and Sarah M. Granlund, Project Manager. Their ability to keep the train on the track was nothing short of exceptional.

Perspectives

1 **Milestones in the History of Pulmonary Medicine** 2

CHAPTER 1

Milestones in the History of Pulmonary Medicine*

Michael A. Grippi

The current level of clinical, scientific, and technologic sophistication of medicine has evolved over more than 2000 years. From the inception of medicine, pulmonary medicine has been an integral part of its growth and development. About 300 years ago, progress toward scientific medicine accelerated markedly, and it has continued to gain speed ever since. In the 17th century, research and experimentation began to tilt clinical medicine toward the exact sciences; by the 18th century, pathology had become an integral part of clinical medicine, and clinical–pathologic correlations succeeded empiricism, dogmatism, and metaphysics. The age of the great clinicians dawned in Europe early in the 19th century, when autopsies became legally permissible and socially acceptable, and when physicians who cared for patients actually performed the autopsies.

The road to our current understanding and practice of pulmonary medicine and science has been somewhat convoluted.[1–3] Progress has been punctuated by delays, detours, and reversals. However, it is possible to retrace the scientific trail by examining iconic figures and addressing milestones in drawing the map (Table 1-1). This chapter uses these milestones to trace the course of scientific pulmonary medicine over the last two millennia. By necessity, what follows constitutes a limited overview of *selected* aspects of the history of the field, including alveolar–capillary gas exchange, lung volumes, mechanics of breathing, control of breathing, ventilation–perfusion relationships, and scientific advancements impacting clinical medicine, including chest imaging, lung transplantation, bronchoscopic techniques, and advances in critical care. Indeed, much of the content of the book addresses the many advances in respiratory disorders achieved over the last 50 years.

ALVEOLAR–CAPILLARY GAS EXCHANGE

In reflecting on the history of the science and thinkers largely responsible for our current understanding of the central role of the lungs in gas exchange, the following are considered: the ancient Greeks, William Harvey and the Oxford physiologists, the "phlogiston theory," theories of blood gas diffusion and "secretion" of oxygen, and the physical chemistry of blood gas transport.

■ ANCIENT GREEK MEDICINE

The beginnings of scientific medicine can be traced to ancient Greece in the sixth century BC. At that time, natural philosophers speculated that air, or some essential ingredient in air, was inspired to generate a "vital essence" for distribution throughout the body.

Hippocrates, the "father of medicine," is as much a symbol of the Greek physician of the fifth and fourth centuries BC as the name of a real figure (Fig. 1-1). As an individual, he exemplified the caring physician who kept accurate records, made cautious inferences, and relied more on nature, rest, and diet than on drugs for treatment. His name has been immortalized by affixing it to three major components of Greek medicine, even though none appears to be the work of a single individual.

The first is the *Hippocratic corpus*, a collection of about 70 works that includes case reports, textbooks, lectures, and notebooks. The collection contains a description of Cheyne–Stokes breathing and the use of *Hippocratic succussion* for the diagnosis of fluid and air in the pleural cavity. The second is a collection of aphorisms—a compilation of brief generalizations related to medicine. The third, which is more likely attributable to Pythagoras (c. 530 BC) than Hippocrates (who lived about a century later), is the *Hippocratic oath*, which not only represents the spirit of the physician of ancient Greece, but which has endured to modern times as a reflection of the physician's code of ethics.

Another Greek, Aristotle, not only had an enduring influence on the intellect of humankind in his own time, but also for two millennia, thereafter. Not until the 17th century were Aristotle's doctrine of the four elements (earth, air, fire, and water) and that of Hippocrates (blood, phlegm, yellow bile, and black bile) laid to rest, thereby clearing the way for modern scientific medicine.

Soon after Aristotle, in about 300 BC, an extraordinary medical school was founded at Alexandria in Egypt. One of the first teachers at the school, Erasistratus, postulated that the "pneuma," or spirit essential for life, is generated from interplay between air and blood.

About four centuries after Erasistratus, Galen (Fig. 1-2) drew upon the medical, philosophic, and anatomic knowledge of his day to fashion a remarkable physiologic schema.[3,4] His construct was largely teleologic. Unfortunately, it was so convincing that even though it was ultimately proved to be fanciful, it sufficed to retard scientific progress for a millennium and a half. Galen was a talented individual who was well educated, well read, and well positioned in society to popularize his beliefs. Moreover, his concepts fit well into the tenets of Christianity, which was then in its ascendency; to controvert his authority was tantamount to blasphemy. Among his long-lasting, albeit erroneous, postulates, were the following: invisible pores in the ventricular septum that enabled the bulk of the blood to flow from the right ventricle to the left ventricle, thereby bypassing the lungs; a diminutive pulmonary circulation that served only to nourish the lungs; and two-way traffic in the pulmonary veins that enabled inspired air and "effluent waste vapors" to go their respective ways (Fig. 1-3).

Voices raised in protest to Galen's theories were without lasting effect. In the 13th century, Ibn al-Nafis, writing in his *Canon of Avicenna*, objected that blood does not traverse the ventricular septum from right to left, as Galen had proposed. However, this insight attracted little attention. Three hundred years later, Vesalius voiced similar misgivings. In the 16th century, Michael Servetus, a polymath trained in theology, geography, and anatomy, pictured the pulmonary circulation as the vehicle by which the "inhaled spirit" could be distributed throughout the body. In his theologic treatise, *Christianismi Restitutio*, he pointed out that blood could not traverse the septum between the right and left ventricles, and that the lumen of the pulmonary artery was too large for a nutrient vessel. He became a hunted heretic, wanted for execution by both the Catholic Church and Calvin. He was warned by Calvin to stay out of Geneva. Both Servetus and Calvin then behaved predictably: Servetus showed up at a church where Calvin was preaching and Calvin had him captured and burned at the stake. In 1559, Realdus Columbus of Cremona, a pupil of Vesalius, rediscovered the pulmonary circulation, as did Andreas Caesalpinus in 1571. Despite these challenging observations, Galen's schema was to last for more than another half century—until the physiologic experiments of William Harvey.

■ WILLIAM HARVEY AND THE OXFORD PHYSIOLOGISTS

William Harvey (Fig. 1-4) was led to the discovery of the circulation of the blood[5] by anatomic observations on the valves in systemic

*This chapter constitutes an updated revision of the original chapter written by Alfred P. Fishman.

TABLE 1-1 Landmark Figures in the Evolution of Modern Pulmonary Medicine

Alveolar–Capillary Gas Exchange

Ancient Greek Medicine
- Hippocrates of CoS (c. 460–359 BC)
- Aristotle (384–322 BC)
- Erasistratus of Chios (c. 300–250 BC)
- Galen of Pergamon (AD 129–99)
- Ibn al-Nafis (c. 1210–1288)
- Leonardo da Vinci (1452–1519)
- Miguel Servetus (1511–1553)
- Andreas Vesalius of Brussels (1514–1564)
- Realdus Columbus of Cremona (1516–1559)
- Andreas Caesalpinus of Pisa (1519–1603)

William Harvey and the Oxford Physiologists
- Galileo Galilei (1564–1642)
- William Harvey (1578–1657)
- Giovanni Alfonso Borelli (1608–1679)
- Marcello Malpighi (1628–1694)
- Robert Boyle (1627–1691)
- Richard Lower (1631–1691)
- Robert Hooke (1635–1703)
- John Mayow (1640–1679)

Phlogiston: The Rise and Fall
- Georg Ernst Stahl (1660–1734)
- John Black (1728–1799)
- Joseph Priestley (1733–1804)
- Carl Wilhelm Scheele (1742–1782)

Respiration and Metabolism
- Antoine Laurent Lavoisier (1743–1794)
- John Dalton (1766–1844)
- Julius Robert von Mayer (1814–1878)
- Carl von Voit (1831–1908)
- Nathan Zuntz (1847–1920)

The Blood Gases
- Joseph Black (1728–1799)
- John Dalton (1766–1844)
- Heinrich Gustav Magnus (1802–1870)
- Felix Hoppe-Seyler (1825–1895)
- Paul Bert (1833–1886)
- Christian Bohr (1855–1911)
- John Scott Haldane (1860–1936)
- August Krogh (1874–1949)

Diffusion or Secretion of Oxygen
- Joseph Barcroft (1872–1947)
- Marie Krogh (1874–1943)

The Physical–Chemical Synthesis
- Lawrence J. Henderson (1878–1942)

Mechanics of Breathing
- John Hutchinson (1811–1861)
- Karl Ludwig (1816–1895)
- Franciscus Cornelius Donders (1818–1889)
- Fritz Rohrer (1888–1926)
- Wallace Osgood Fenn (1893–1971)

Control of Breathing

The Central Respiratory Centers
- Thomas Lumsden (1874–1953)
- Hans Winterstein (1878–1963)
- Merkel Henry Jacobs (1884–1970)

veins made by his mentor, Fabricus ab Aquapedente. Harvey's small book, *De Motu Cordis*, published in 1628, not only corrected a self-perpetuating error in Galenical teaching, but also marked the birth of modern physiology. The time, however, was not yet ripe to relate the function of the heart to the physiology of breathing. To his dying day, Harvey clung to the idea that the main function of breathing is to cool the heart. Moreover, since he made no use of the microscope, he could not picture how the pulmonary arteries made connections with the pulmonary veins. Galileo invented the compound microscope in 1610. In 1661, using the compound microscope, Marcello Malpighi reported that alveoli were covered by capillaries and that blood and air were kept separate by the continuous alveolar–capillary barrier.

Figure 1-1 The Hippocrates of Ostia. This damaged bust is believed to represent Hippocrates as perceived in antiquity. It was found in a family tomb in excavations near Ostia. *(Used with permission of Dr. Dickinson W. Richards.)*

Figure 1-2 Galen of Pergamon as depicted in medieval times. No authentic reproduction exists of Galen in ancient times. *(Used with permission of Galen's Therapeutica, published in Venice in 1500.)*

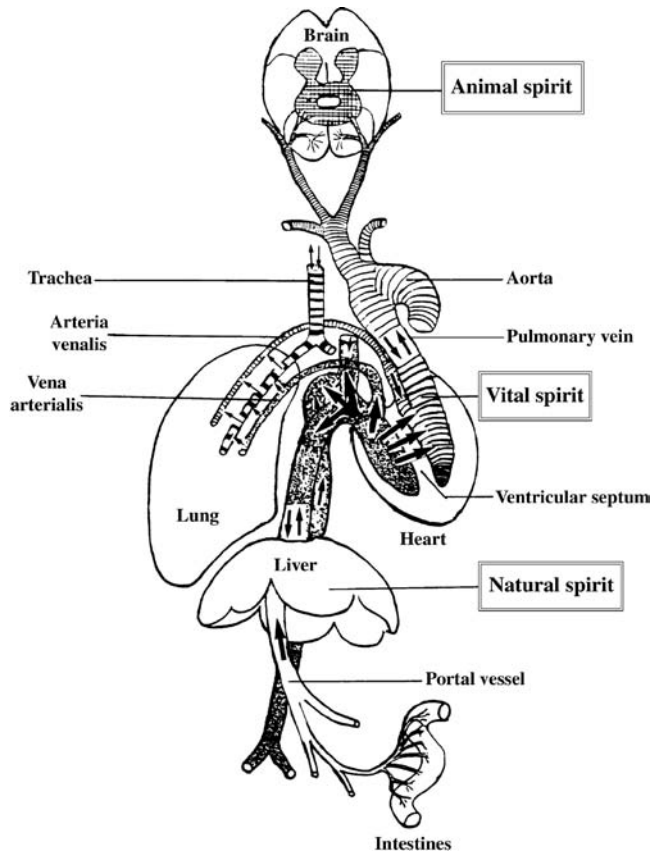

Figure 1-3 Galen's scheme of the circulation. The diagram shows the source and distribution of the three types of spirits. The validity of this scheme depended on invisible pores in the ventricular septum, two-way traffic in the pulmonary vein, and selective permeability of the mitral valve for sooty wastes but not for spirit-containing blood. Vena arterialis, pulmonary vein; arteria venalis, pulmonary artery. *(Modified with permission from Singer C. A Short History of Scientific Ideas to 1900. London: Oxford University Press; 1959.)*

Figure 1-4 William Harvey (1578–1657). This portrait of William Harvey is part of a family group in which William Harvey and his five brothers are gathered around their father, William Harvey.

Figure 1-5 Robert Boyle (1627–1691). This engraving, from an original painting by Johann Kerseboom, hangs in the Royal Society, London. Boyle's invention of a pneumatic air pump and his publications concerning "the spring of air and its effect" stimulated considerable research on the physical properties of air and its role in respiration and combustion. He strongly influenced Hooke, Lower, and Mayow at Oxford.

Harvey's description in 1628 of the circulation of the blood had three major consequences for pulmonary medicine: (1) it oriented pulmonary medicine toward the basic sciences and away from philosophy and empiricism; (2) it demolished the Galenic concept of the movement of the blood; and (3) it set the stage for an upcoming generation of physiologists at Oxford University to explore breathing in chemical and physical terms.

The physiologists working at Oxford in the 1660s were greatly impressed by Harvey's disciplined approach to scientific inquiry. Many were medical practitioners who conducted research as a sideline. Four, in particular, began the systematic study of air and its constituents, thereby laying the foundations for contemporary respiratory physiology and medicine: Robert Boyle (Fig. 1-5), Robert Hooke, Richard Lower, and John Mayow.

In 1660, Robert Boyle proved by means of his air pump that air is necessary for life. In 1667, Robert Hooke showed that insufflation of the lungs with air while breathing movements were arrested could keep an open-chest animal alive, that is, that movement of the lungs was not essential for life. Richard Lower, the first to practice blood transfusion, took advantage of Hooke's continuously inflated lung preparation in the dog to observe that dark venous blood becomes bright red as it traverses lungs insufflated with air. In 1674, Mayow interpreted the change in the color of blood from venous to arterial as due to the uptake of "nitroaerial particles" (later to be called "oxygen") from the air.

PHLOGISTON: THE RISE AND FALL

Unfortunately, the discoveries and insights of the Oxford physiologists went largely unnoticed during the century that followed, overshadowed by the "phlogiston theory" of combustion. The theory, advanced by Stahl, postulated that all combustible materials were composed of two ingredients: phlogiston, a principle that transformed into fire when heated, and an ash that was left behind after the fiery phlogiston escaped. The phlogiston theory was sufficiently malleable to accommodate almost every new discovery that could have overthrown it, including the rediscovery of carbon dioxide in 1754 by John Black, and the independent discoveries of oxygen by Priestley and Scheele. Although the respiratory gases had been discovered by the end of the 18th century and many of their properties characterized, the discoveries were misapplied to support, rather than destroy, the phlogiston theory. The phlogiston theory was finally demolished by the experiments of Lavoisier.

RESPIRATION AND METABOLISM

From the time of Hippocrates until early in the 20th century, debate had continued about the site of heat production in the body. In 1777, Lavoisier suggested that air was composed of one respirable gas (which he later named "oxygine") and another (nitrogen) that remained unchanged in the course of respiration. Between 1782 and 1784, Lavoisier and Laplace concluded, on the basis of calorimetric experiments on guinea pigs, that "respiration is therefore a combustion, admittedly very slow, but otherwise exactly similar to that of charcoal" (Fig. 1-6). The similarity between respiration and combustion had previously been recognized by the Oxford physiologists, especially Mayow.[6] By 1783, Lavoisier was accumulating evidence against the phlogiston theory and began to replace it with an entirely new system of chemistry.

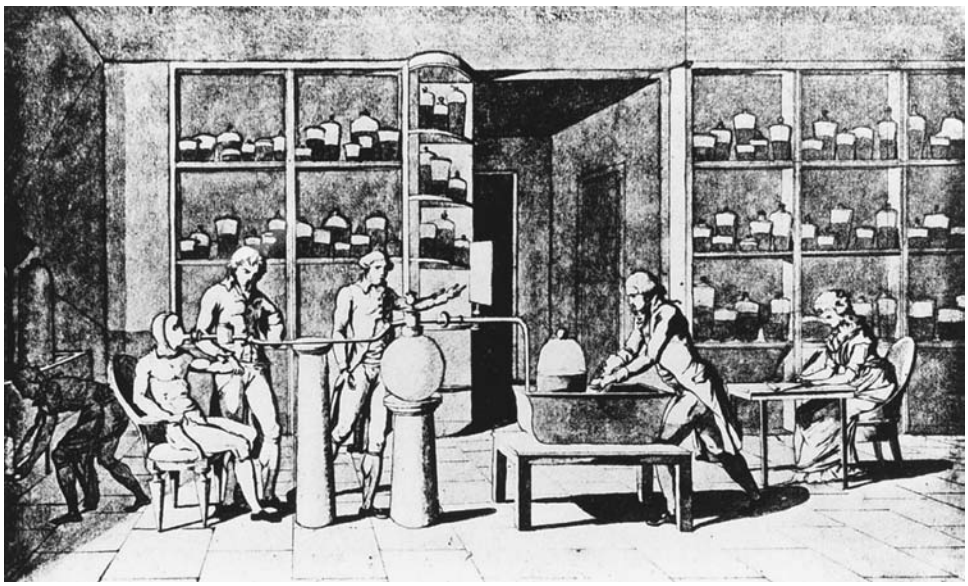

Figure 1-6 Scene from the laboratory of Antoine Laurent Lavoisier (1743–1794). His wife is acting as his assistant, and Sequin is the subject. Studies such as this led to the conclusion that respiration and circulation are similar processes.

As noted previously, the ancients pictured the heart as the heat generator. Lavoisier favored the lungs. Others held that combustion occurred in the blood. Although Spallanzani had shown in the 18th century that isolated tissues take up oxygen and evolve carbon dioxide, the idea that combustion occurred in the tissues was slow to gain acceptance. However, the hypothesis gained strength through the work of Pflüger in 1878. He measured oxygen consumption and carbon dioxide production in dogs and calculated respiratory quotients. His research substantiated a concept that had been enunciated, but not named, by Lavoisier.[7]

Once the idea that oxidation occurred in the tissues had become generally accepted, investigators delved into the processes involved in utilization of foodstuffs by the tissues, energetics, growth, and repair. Carl von Voit and Max von Pettenkofer, using a respiration chamber, drew upon chemical balances and respiratory quotients in humans to distinguish the nature of the foodstuffs being burned and to show that the amounts of fat, protein, and carbohydrate burned varied with the mechanical work done by the subject. Between 1842 and 1845, Julius Robert von Mayer formulated the law of conservation of energy. Subsequently, Max Rubner showed that the law applied to the living body, and Herman von Helmholtz showed that its relevance to metabolism could be demonstrated experimentally. Application of these principles at the bedside was greatly facilitated by the development of a portable metabolic apparatus by Nathan Zuntz. Pioneering bedside studies of metabolic states were conducted by a succession of distinguished investigators, including Magnus-Levy, Graham Lusk, F. G. Benedict, and Eugene F. DuBois.

THE BLOOD GASES

The Oxford physiologists set the stage for the discovery of the blood gases. Using his vacuum pump, Robert Boyle extracted "air" from blood. John Mayow came close to discovering oxygen by showing that only part of air was necessary for life, and that this part, his "nitroaerial spirits," was removed both by respiration and fire (combustion). One of his famous experiments entailed enclosing a mouse and a lighted lamp in an airtight container; the lamp went out first and then the mouse died. However, Mayow did not realize that the "nitroaerial spirits" could be isolated as a gas.[6]

One hundred years after Mayow, Joseph Priestley (Fig. 1-7) exposed a mouse to the gas released from heated mercuric oxide and found that the gas supported life better than air did; he also noticed that a flame burned more vigorously in this gas than in air. Priestley was not alone in his preoccupation with flame. In 1773, about a year before Priestley had obtained oxygen by heating mercuric oxide, Scheele discovered oxygen independently because of his interest in fire, and he designated oxygen as "fire air."

In 1662, Van Helmont, a Capuchin friar and talented chemist, as well as a mystic with a drive to quantify, discovered carbon dioxide, coined the word *gas*, and called carbon dioxide "wild gas" ("gas sylvestre"). In 1755, Joseph Black rediscovered carbon dioxide. He showed that calcium carbonate (limestone) and magnesium carbonate (magnesia alba) lost weight on heating, releasing "fixed air" (CO_2) in the process. This fixed air extinguished both flame and life. Lavoisier knew of the observations of Black and of Priestley and Scheele. He decided in 1778 that the gas obtained from heating

Figure 1-7 Joseph Priestley (1733–1804), the discoverer of oxygen. This figure shows a silver medal struck in his honor in 1783. A Presbyterian minister, he was radical in his religious and political beliefs, inventive in science, and conservative in the interpretation of his findings. *(Reproduced with permission from Fishman AP, Richards DW. At work in his laboratory, Bohr *(far right)* and his associates systematically explored the interplay between the respiratory gases and hemoglobin that led to the discovery of the "Bohr effect." *(Reproduced with permission from Fishman AP, Richards DW. Circulation of the Blood: Men and Ideas. New York: Oxford University Press; 1964.)*

mercuric oxide was not "fixed air" or "common air," but "highly respirable air" (oxygen).

The story of hemoglobin, the essential element in the transport of the respiratory gases by the blood, begins with Hoppe-Seyler, who, between 1866 and 1871, crystallized hemoglobin, explored its chemical properties, and assigned it a proper role in the transport of oxygen by the blood. At the turn of the 19th century, Dalton reported his experiments with the respiratory gases, which led to the development of his atomic theory. In 1872, taking advantage of Dalton's law, Paul Bert published the first oxygen dissociation curve, that is, oxygen content at different barometric pressures; he pictured the curve as hyperbolic. Christian Bohr (Fig. 1-8) subsequently identified its s-shaped contour, and in 1904, together with Hasselbach and August Krogh, showed that increasing carbon dioxide tension in blood drives out oxygen, that is, the "Bohr effect." Shortly thereafter, the influence of various factors, for example, temperature and electrolytes, on the affinity of oxygen for hemoglobin (and, consequently, on the position of the oxygen dissociation curve) was explored in detail by Barcroft and associates. In 1914, Christiansen, Douglas, and Haldane reported that an increase in the oxygen tension of the blood drives out carbon dioxide, that is, the "Haldane effect." In 1967, a new dimension was added to the understanding of the position and configuration of the oxygen dissociation curve by the demonstration that diphosphoglycerate, a chemical constituent of red cells, regulates the release of oxygen from oxyhemoglobin.

DIFFUSION OR SECRETION OF OXYGEN

Bohr is a central figure as an investigator and mentor in respiratory physiology.[8] In 1904, he raised a troublesome issue that was not easily resolved, primarily because of limitations in methodology at the time. He postulated that even though diffusion could account for oxygen uptake at rest, it could not suffice during strenuous exercise, particularly at altitude. He held that oxygen *secretion* had to be involved.[9] He held to this misconception during his lifetime, a conviction supported by two major lines of evidence. The first was indirect: Oxygen secretion by the swim bladder of fish showed by extrapolation that active transport of oxygen in the lungs was possible. The second was based on observations made during Bohr's expedition to Pike's Peak in 1912, during which it was erroneously demonstrated that with exercise at altitude, arterial oxygen tension exceeded alveolar oxygen tension.

However, even before the report from high altitude, Bohr's former assistant, August Krogh, and his wife, Marie Krogh (Fig. 1-9) had marshaled new evidence to show that "the absorption of oxygen and the elimination of carbon dioxide in the lungs takes place by diffusion and diffusion alone." The final blow to the secretion theory was delivered by Marie Krogh.[10] Based on the single-breath carbon monoxide method for determining diffusing capacity that she and her husband had developed in 1910,[11] she was able to account for oxygen uptake in the lungs by diffusion alone, even during strenuous exercise under conditions of low oxygen tension. Refinements in the carbon monoxide method by Roughton and others extended

Figure 1-9 August and Marie Krogh in 1922, at the time of their first visit to the United States so that August Krogh could deliver the Silliman Lecture at Yale. They demonstrated that diffusion, without secretion, could account for the transfer of O_2 and CO_2 across the alveolar–capillary membranes of the lungs. *(Used with permission of their daughter, Dr. Bodil Schmidt-Nielsen.)*

Figure 1-10 Two founders of contemporary respiratory physiology in 1936. Sir Joseph Barcroft (1872–1947) *(left)* proved, in experiments on himself, that diffusion was the mechanism for gas exchange in the lungs and pioneered current understanding of the respiratory functions of the blood. Lawrence J. Henderson (1878–1942) *(right)* provided a mathematical analysis of blood as a physiochemical system and stimulated research on the complex interplay involved in respiratory gas exchange during exercise. *(From Fishman AP, Richards DW. Circulation of the Blood: Men and Ideas. New York, NY: Oxford University Press; 1964, with permission.)*

its clinical applicability and provided further evidence against the secretion theory.[12] Despite these observations, Haldane would not let go. Throughout his life, despite mounting evidence to the contrary, he adhered to the idea that oxygen was secreted by the alveolar membrane.

The issue was finally settled by Joseph Barcroft (Fig. 1-10). Using a chamber to reproduce the circumstances of hypoxia and strenuous exercise assessed during the Pike's Peak expedition, he found that under all conditions, the oxygen saturation of arterial blood was less than that of arterial blood exposed to a sample of alveolar gas obtained at the same time. He subsequently confirmed these results by experiments done at high altitude at Cerro de Pasco (1921–1922).

THE PHYSICAL–CHEMICAL SYNTHESIS

Lawrence J. Henderson undertook the herculean task of depicting the reactions of oxygen and carbon dioxide in blood, not as cause and effect, but as interplay among physiochemical variables and functions (Fig. 1-10). His theoretical considerations and practical applications in the Fatigue Laboratory at Harvard University were greatly abetted by close collaboration with Van Slyke, Wu, and McLean at the Rockefeller Institute in New York, who were exploring the exchanges of blood constituents between red cells and plasma. In 1828, Henderson presented his synthesis in the form of a d'Ocagne nomogram that displayed changes in the various elements that entered into the exchange of the respiratory gases between alveolar gas and blood: plasma; the red cell; hemoglobin; and chloride, bicarbonate, and hydrogen ions. He presented nomograms not only for the normal subject at rest and during exercises, but also for individuals with anemia, nephritis, diabetic coma, and other major clinical entities. Henderson dealt with steady-state observations. Roughton and associates enlarged the physiochemical horizons further by discovering carbonic anhydrase in the red cell and addressing transient phenomena related to transport of respiratory gases and carbon monoxide in blood.

LUNG VOLUMES

Although Humphrey Davy had determined his own lung volume using hydrogen as the test gas in 1800,[13] it was not until the 1840s that John Hutchinson laid the groundwork for modern pulmonary function testing. He devised a spirometer and used it to determine the subdivisions of the lung in a large number of healthy subjects, relating the measurements to height and age (Fig. 1-11). The many refinements since then are too numerous for mention in this chapter. A big step forward was the invention of the body plethysmograph many years later, which made possible the determination of the thoracic gas volume and airway resistance.

MECHANICS OF BREATHING

The ancients wondered how air moved into and out of the lungs; as far back as the time of Erasistratus, the diaphragm was recognized as involved in breathing. Galen was aware that the lungs fill the chest cavity and are moved by the actions of the thorax, and that the large airways enlarge and lengthen during inspiration. He marveled at the long course of the nerves to the diaphragm and the innervation of the intercostal muscles. After Galen, interest in the mechanics of breathing waned except for sporadic observations and experiments by anatomists, notably Leonardo da Vinci and Andreas Vesalius. Interest in respiratory mechanics resumed in the 16th century, largely as a result of progress in physics and mathematics, as exemplified in the works of Borelli and Galileo.

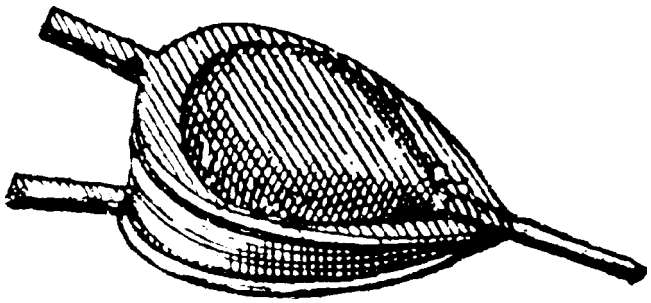

Figure 1-12 Mayow's model of the chest and lungs. The bellows encloses a bladder, the neck of which opens to the outside. A glass window on the upper side makes it possible to observe the bladder during inflation and deflation. *(Reproduced with permission from Mayow J: Medico-Physical Works, Crum A, Brown, Dobbin L (trans). Edinburgh, Alembic Club, Reprints, no 17, 1957. (Translated from Tractatus quinque medico-physics, 1674))*

THE RESPIRATORY MUSCLES

Mayow, one of the Oxford physiologists, drew heavily on the work of colleagues, including Boyle and Hooke, to develop considerable insight into the mechanics of breathing. He also built the first model on record of the chest as a bellows, which contained a bladder within it (Fig. 1-12). He understood that air moved into the lungs as the chest expanded because of the pressure and elasticity of ambient air; he also appreciated that the chest expands because of the action of the intercostal muscles (internal and external), that the diaphragm is the primary muscle of inspiration, and that normal expiration is passive. After Mayow, little research was done on the role of the respiratory muscles in breathing until the mid-19th century, when Donders distinguished between the respective roles played by the inspiratory muscles and elastic forces.

ELASTIC PROPERTIES OF LUNGS AND CHEST

Until the 20th century, observations on the elastic properties of the lungs and chest cage in humans were fragmentary. Access to the pleural space was the major limiting factor. With few exceptions – notably Neergaard and Wirz, who used pleural pressures to determine elastic recoil in normal human subjects, and Christie, who recorded pleural pressures to demonstrate loss of pulmonary elasticity in emphysematous patients – measurements in humans were largely confined either to therapeutic interventions, for example, induction of a pneumothorax or aspiration of pleural fluid, or experiments done at autopsy. The number of observations on the mechanical properties of the lungs increased dramatically when it was shown by Buytendijk, in 1949, and again by Dornhurst and Leathart, in 1952, that esophageal pressures provided an accurate measure of pleural pressures.

The role of alveolar surface tension in determining the elastic forces in the lungs began to be widely appreciated in the late 1950s, although the stage had been set long before. In 1812, Laplace had published the law of surface tension. The implications of this law for the lungs was appreciated initially in 1929 when Neergaard compared pressure–volume curves of lungs filled with air with those filled with fluid. He concluded that unopposed surface tensions would favor alveolar collapse. Then, between 1954 and 1960, a remarkable outpouring of papers from different laboratories showed that a unique surfactant lined the alveoli, and this material was absent in premature infants with hyaline membrane disease (and alveolar collapse); these papers prompted extensive research on the chemical and physical properties of surfactant and on its sites of formation and removal.

AIRWAY RESISTANCE

A giant step forward occurred in 1916 when Rohrer, as part of his doctoral dissertation, presented a conceptual framework for determining flow and resistance in airways. His equations were based on precise anatomic measurements of airway dimensions in a human cadaver, coupled with aerodynamic principles. During the following decade, he and his coworkers, Neergaard and Wirz, applied Poiseuille's law for laminar flow and his equations to the determination of airway resistance. Use of Fleisch's pneumotachygraph, coupled with periodic interruptions of airflow, permitted measurement of alveolar pressure. Clinically useful measurements of alveolar pressure became available in 1956 with the introduction by DuBois and associates of the whole-body plethysmograph, which they coupled with the application of Boyle's law.

SYNTHESIS OF MECHANICS

During the decade between 1915 and 1926, Rohrer and his colleagues provided a remarkably comprehensive synthesis of respiratory mechanics that included a description of the static pressure–volume characteristics of the respiratory system and the work of breathing; they also developed the principle of optimal frequencies of breathing to minimize respiratory work. Together with von Neergaard and Wirz, Rohrer developed and tested, experimentally, concepts involving pressures, flows, and volumes. The full significance of Rohrer's work was not appreciated until the publications by Fenn and his group at the University of Rochester, starting in the 1940s. The contributions of W. O. Fenn, H. Rahn, and A. B. Otis to our present understanding of the mechanics of breathing are significant, and there is little doubt that this group shaped much of the contemporary thinking of respiratory physiologists and pulmonary physicians.[14–17]

CONTROL OF BREATHING

The control of breathing is a complex process that depends on the integrity of the entire respiratory system—lungs, airways, circulation, and control systems.[18] Two dominant control systems exist. One is in the central nervous system; the other is outside the brain. Control mechanisms in the central nervous system are influenced by the state of wakefulness or alertness and are subject to voluntary control. These mechanisms are also influenced reflexively by a variety of peripheral receptors.

LOCALIZATION OF THE CENTRAL RESPIRATORY CENTERS

In 1812, Legallois, apparently intrigued by the gasping movements of the head after decapitation, identified an area in the medulla that was essential for life. In 1923, Lumsden systematically explored the effects of serial sectioning of the brain stem on respiration, marking the beginning of the era of contemporary research on rhythmic breathing. He designated an area in the caudal pons responsible for a sustained inspiratory drive as the "apneustic center," and an area in the rostral and lateral portions of the pons that presumably inhibited the apneustic drive as the "pneumotaxic center"; sectioning of the vagi exaggerated the inhibition of the apneustic drive by the pneumotaxic center. Sixteen years later, Pitts et al.[19], using stereotactic stimulation of the cat medulla, identified inspiratory and expiratory centers and proposed a theory that could account for both rhythmic breathing and apneusis.

CHEMICAL STIMULATION OF THE RESPIRATORY CENTERS

The chemical stimuli to breathing have been known for more than a century. In 1885, Miescher-Ruesch showed in humans that ventilation at rest is primarily regulated by carbon dioxide. Between 1887 and 1901, cross-perfusion experiments by Leon Fredericq underscored the role of carbon dioxide. However, it was not until 1905

to 1909 that Haldane, Priestley, and Douglas paved the way to the modern understanding of the role of carbon dioxide under a variety of experimental conditions.[20] In their experiments on humans, they relied heavily on the Haldane gas analyzer and an alveolar gas sampler of their own invention. However, their experiments did not distinguish clearly between CO_2 and H^+ in the stimulation of the respiratory centers. Winterstein, and later Gesell,[21] advanced the idea that the chemical regulation of respiration is determined by the concentration of hydrogen ions within the respiratory centers.

The Winterstein theories[22] provide a good example of the evolution of ideas prompted by new discoveries and inventions. The original theory in 1911 attributed increments in ventilation caused by hypoxic or hypercapnic inspired mixtures to a single mechanism, that is, acidification of arterial blood by either carbonic acid or lactic acid. In 1921, Jacobs' demonstration of the rapid diffusion of carbon dioxide into starfish eggs implicated acidity within the respiratory centers,[23] as well as arterial blood acidity, as the sites of stimulation. To account for the stimulation of breathing by hypoxia (the peripheral chemoreceptors had not yet been discovered), he invoked the release of asphyxiating substances *(Erstickungsstoffen)* within the respiratory centers themselves. A third theory, postulated in 1949, attempted to incorporate the discovery of the peripheral chemoreceptors, and it finally gave way in 1955 to his fourth theory, which explained the effects of acid or hypoxia on both the central and peripheral chemoreceptors.

A major consequence of Winterstein's research was an impetus to subsequent exploration of the chemical control of breathing. These studies led to the identification of central chemoreceptors, distinct from mechanoreceptors, on the ventral surface of the medulla, and clarification of the role of hydrogen ion activity as the central stimulus to breathing. The studies also prompted a search for a unifying theory for the chemical control of breathing.

THE REFLEX REGULATION OF BREATHING

A considerable and diverse number of peripheral receptors can influence breathing reflexively by supplying information to respiratory centers located in the brain. These include pain receptors, stretch receptors in the muscles and distensible thoracic structures, and organs and chemoreceptors in major systemic arteries.

MECHANORECEPTORS

Until the work of Hering and his student, Breuer, little was known about the role of afferent impulses to the central control mechanisms in the control of breathing, other than the fact that electrical stimulation of the vagus nerves influenced respiration.[24] In 1868, Hering and Breuer reported that inflation of the lungs stopped respiration in expiration and promoted expiration, and that, conversely, a decrease in lung volume ended expiration and promoted inspiration. They inferred that inflation mechanically stimulated nerve endings in the lungs and that the resulting impulses ascending the vagi were inhibitory to inspiration.

PERIPHERAL CHEMORECEPTORS

In 1841, Volkmann suggested the existence of chemoreceptors in the systemic circulation that were sensitive to blood-borne stimulants to respiration. In 1927, J. F. Heymans and C. Heymans first showed that the aortic bodies served this function, and in 1930, C. Heymans and Bouckaert demonstrated the peripheral chemoreceptive function of the carotid bodies. These were physiologic observations that tallied well with the observations of F. De Castro, a student, and later a colleague, of Ramón y Cajal, who was sufficiently impressed by the histologic structure, location, and rich innervation of the carotid body to propose that it might be stimulated by blood-borne substances (Fig. 1-13).[25]

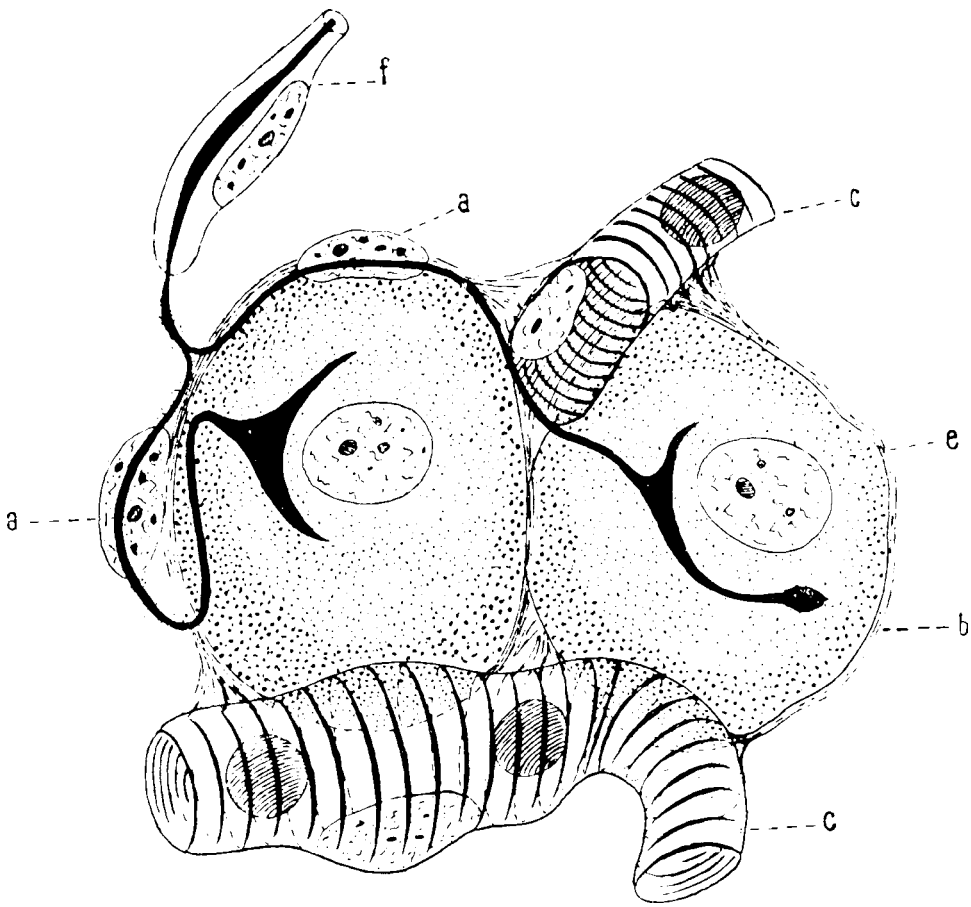

Figure 1-13 Drawing by De Castro showing the structure of the chemoreceptor. The glomus cells (*e*) present an ample cytoplasmic surface for contact with the perfusing blood delivered by the capillary (*c*); sensory nerve fiber (*f*) with sheath of myelin; Schwann cells (*a*) surround the unmyelinated fibers which form the terminal menisci; cell membrane (*b*). *(Reproduced with permission from De Castro F: Sur la structure de la synapse dans les chemocepteurs: leur mécanisme d'Excitation et R™ le dans la circulation sanguine locale. VENTILATION–PERFUSION RELATIONSHIPS

In 1946, William Dock attributed the apical localization of tuberculosis to hypoperfusion of well-ventilated alveoli in the lung apices in the upright position.[26] Shortly thereafter, ventilation–blood flow relationships were described in quantitative terms in papers by two separate groups: Rahn and Fenn[27] and Riley and Cournand.[28–30]

SCIENTIFIC BASIS OF CLINICAL PULMONARY MEDICINE

Five remarkable figures serve to illustrate different stages in the evolution of the scientific basis of pulmonary medicine: Morgagni, Laënnec, Koch, Cournand, and Richards. They represent key scientists in the areas of pathologic anatomy, microbiology, and physiology.

■ PATHOLOGIC ANATOMY

Morgagni and Laënnec, almost a century apart, made major contributions to the field of pathologic anatomy. Morgagni (Fig. 1-14), who lived in the 18th century and was a student of Valsalva, veered away from the undisciplined case reports of his predecessors. Instead, he adopted a logical system for relating findings at autopsy to their clinical manifestations. At age 79, he published a compilation of his lifelong experience in his famous work, *De Sedibus et Causis Morborum per Anatomen Indagatis. De Sedibus* includes about 700 cases. The clinical–pathologic correlations in this work benefited greatly from the fact that Morgagni was both a seasoned clinician and a pathologist. One of the compilation's five books is devoted to diseases of the thorax. Among his descriptions were those of a tubercle undergoing liquefaction and the hepatization stage of pneumonia.

René Théophile Laënnec is, perhaps, best known for inventing the stethoscope in 1816 (Fig. 1-15).[31,32] At that time, clinical medicine in Europe, especially in France, was turning from metaphysical concepts and doctrinal systems to pathology as its scientific foundation. Eminent physicians, such as Bichat, Bayle, and Corvisart in France, and William and John Hunter and Baillie in England, were turning to anatomic findings at autopsy to understand the signs and symptoms of their patients. Percussion had been rediscovered by Corvisart. Although Auenbrugger had reported in Latin his "new invention" in 1761, the idea had not caught on until Corvisart – eminent clinician and teacher and personal physician to Napoleon – published a translation in French in 1808. Corvisart's approach to medicine strongly influenced Laënnec. Laënnec applied the stethoscope and Corvisart's "sounding of the chest" to study individual patients with diseases of the lungs and heart throughout their clinical course, along with anatomical examination at autopsy. This was no simple matter. Since there were no pathologists in those days, the physician not only had to provide continuous care during the patient's lifetime, but he also had to arrange for, and perform, the autopsy; he then had to gather all that he had seen and learned and prepare it for publication.

In 1819, two years after the invention of the stethoscope, Laënnec published his famous monograph, *De l'Auscultation médiate*, which drew lessons from carefully documented cases that were studied throughout their clinical course and at autopsy. In this work, Laënnec built upon the monumental tome of Morgagni, who, a generation before, had related the clinical features of the diseases he described to the morbid anatomy, but who had not been able to take the next step of relating the clinical course of individual patients to the anatomic findings after death.

Laënnec's monograph contains descriptions of physical signs, clinical–pathologic correlations for tuberculosis, pneumonia, bronchiectasis, emphysema, and cancer of the lung, and instructions for the treatment of these conditions. The descriptions of tuberculosis were an outstanding contribution to the field and were reported prior to Koch's discovery of the causative agent.

■ MICROBIOLOGY

Tuberculosis provides a remarkably illuminating example of the impact of a novel basic science on clinical medicine.[33–35] The disease

can be traced back to the ancients, who were familiar with the diverse clinical syndromes that we now take for granted as due to tuberculosis; however, they had no way to relate them to a common etiologic agent. A synthesis by Morton in 1685 of all that was then known about tuberculosis focused on cavitary lesions, emaciation ("consumption"), and the tubercle, but it was shrouded in Galenic humors. An understanding of the disease accelerated in the 18th century when clinicians, such as William Cullen, began to sort out the various syndromes relating to phthisis, including hemoptysis, empyema, catarrh, and asthma.

The tempo of discovery increased dramatically in the 19th century after the French Revolution. During the Napoleonic era, distinguished Parisian clinicians, including Bichat, Bayle, Louis, Broussais, and Laënnec, reported clinical–pathologic correlations of tuberculosis (Notably, both Bayle and Laënnec died of tuberculosis.). However, little advance was made in understanding the pathogenesis of tuberculosis until Villemin, who, impressed by the analogy between glanders and syphilis on the one hand, and tuberculosis on the other, and the fact that two of the three diseases had been shown to be infectious in origin, undertook experiments demonstrating that tuberculosis was an infectious disease that could be transmitted from humans to animals, and from animals to animals.

KOCH

In 1876, Koch was a general practitioner in the German township of Wollestein in the province of Posen, where he was responsible for the health care of 4000 inhabitants (Fig. 1-16). Between obstetrical deliveries and satisfying the medical and surgical needs of patients of all ages, he managed to conduct research on the microbial causes of communicable diseases. His laboratory was homemade—based in either the barn or his living room; his major instrument was a microscope used to examine bacteriologic and tissue specimens. In pursuing his research, he kept in mind the dictum of Jacob Henle, one of his teachers in medical school, who counseled that, "before microscopic organisms can be regarded as the cause of contagion in man, they must be found constantly in the contagious material, they must be isolated from it and their strength tested." This lesson was to become the keynote of the future "Koch postulates."

In 1876, Koch, the busy medical practitioner, sent a letter to Professor Ferdinand Cohn, director of the Botanical Institute in Breslau, indicating that he had discovered "the process of development of bacillus anthracis" and requesting permission to present his findings to Professor Cohn, "the foremost authority on bacteria." Koch had discovered the spores of anthrax bacilli. Cohn arranged for him to present his results before a room full of formidable, distinguished scientists, including Julius Cohnheim, Carl Weigert, Moritz Traube, Ludwig Lichtheim, and Leopold Auerbach. Koch's demonstration of the complete life history of the anthrax bacillus, including sporulation, was entirely convincing to these scientists. After the meeting, Cohnheim, upon his return home, announced to his colleagues, "This man has made a splendid discovery which is all the more astonishing because Koch has had no scientific connections and has worked entirely on his own initiative and has produced something absolutely complete. There is nothing more to be done. I consider this the greatest discovery in the field of bacteriology."

During the next 2 years, Koch described novel procedures for the examination, preservation, and photography of bacteria and demonstrated the role of microorganisms in traumatic infections, while continuing his dual existence as a country doctor and an independent investigator. In 1880, Cohn and Cohnheim arranged for him to move to Berlin as a member of the Imperial Sanitary Commission. The move freed more time for research. By 1881, he made another breakthrough—the pour-plate method for isolating pure cultures. The opportunity that this technique afforded to produce transparent solid media, coupled with Koch's invention of new staining methods, paved the way for him to tackle the microbial cause of tuberculosis.

Figure 1-16 Robert Koch (1843–1910), announcing his discovery of the tubercle bacillus as the cause of tuberculosis, Berlin, March 28, 1882. *(Reproduced with permission from Knight D: Robert Koch: Founder of Bacteriology. New York: Franklin Watts, Inc.; 1961:10.)*

Koch's scientific approach, which has been immortalized as "Koch postulates," consisted of four essential steps: (1) To prove that a microbe is the cause of a disease, it must be present in all cases of the disease (Koch showed this for the tubercle bacillus using methylene blue and a counter stain), (2) the microbe must be grown outside of the body in pure culture. (Koch devised blood-serum jelly as a culture medium for the slow-growing tubercle bacillus.), (3) the pure culture must be capable of causing the disease in healthy animals (Koch proved this initially by inoculation and, subsequently, by allowing animals to breathe contaminated air.), (4) the same microbe must then be isolated from the inoculated (infected) animal and grown outside of the body in pure culture.

Koch's discovery of the tubercle bacillus and its modes of transmission revolutionized the treatment of tuberculosis. Before the discovery, tubercular patients were treated in sanitaria, which offered fresh air and altitude. Those who ran the sanitaria did not know that tuberculosis was a contagious disease: Sanitation was unregulated, and neither sterilization nor fumigation was practiced; diagnostic capabilities were limited. Koch's discovery of the tubercle bacillus revolutionized therapy. For the rest of his life, while pursuing the causes of other diseases around the world – rinderpest in South Africa, Texas fever, tropical malaria, blackwater fever, and bubonic plague in Bombay – Koch maintained his interest in tuberculosis.

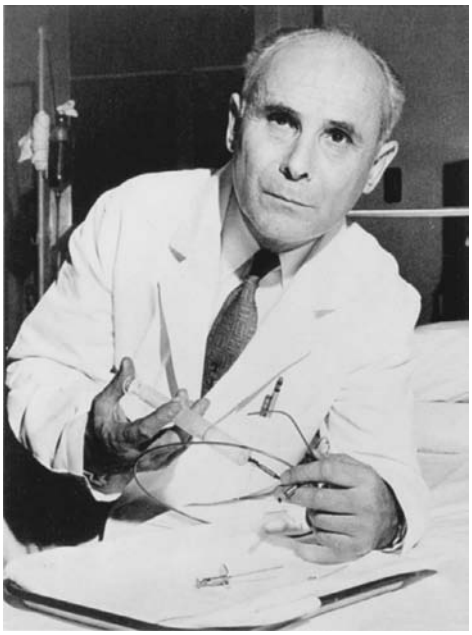

Figure 1-17 André Frederic Cournand (1895–1988) and Dickinson W. Richards (1895–1973). After Forssman's report of the uneventful catheterization of his own right heart, Cournand and Richards pioneered the use of cardiac catheterization for the study of the normal and the abnormal pulmonary circulation and the standardization of pulmonary function tests.

This interest, however, led him into a major mistake—advocacy of tuberculin as a vaccine instead of as a diagnostic test. In 1905, he was awarded the Nobel Prize. On April 7, 1910, the year of his death, he delivered a final address on the epidemiology of tuberculosis before the Berlin Academy of Sciences.

■ PHYSIOLOGY OF THE PULMONARY CIRCULATION

Starting with William Harvey,[5] studies of the pulmonary circulation have gone hand in hand with advances in pulmonary physiology and medicine. For many years, research on the pulmonary circulation was confined to animal experimentation. A giant step forward was made with the introduction of cardiac catheterization in humans.

Accurate measurement of pulmonary blood flow is a sine qua non for assessing pulmonary and cardiac performance in health and disease. The use of nitrous oxide in humans by Krogh and Lindhard was an important beginning in this direction, but not until mixed venous blood could be sampled for application of the Fick principle could reliable determinations of pulmonary blood flow be made.

Claude Bernard in 1846 and Chauveau and Marey in 1861 had catheterized the right side of the heart in animal experiments. Whether this technique could be used safely in humans was not known until 1929, when Werner Forssmann, a young surgeon in Germany, introduced a ureteral catheter into his own right atrium. In the 1940s, Cournand, Richards, and their colleagues resorted to right heart catheterization to obtain mixed venous blood for the determination of cardiac output by application of the Fick principle (Fig. 1-17). The technique opened the way not only to the accurate determination of cardiac output, but also to exploration of the heart and lungs in a wide variety of clinical disorders.

Until 1946, when von Euler and Liljestrand reported the effects of hypoxia and hypercapnia on the pulmonary circulation in an open-chest preparation of an anesthetized cat, (Fig. 1-18)[36] there was little understanding of the regulation of the pulmonary circulation. However, these studies, coupled with the proposition of local control of the pulmonary circulation by local concentrations of the respiratory gases, paved the way to understanding pulmonary hypertension and the behavior of the pulmonary circulation in normal individuals at rest, after birth, during exercise, and at altitude, and in individuals with heart or lung disease.

The interposition of the pulmonary circulation between the right and left sides of the heart is a prerequisite for gas exchange. However, it also serves a variety of other functions, for example, a

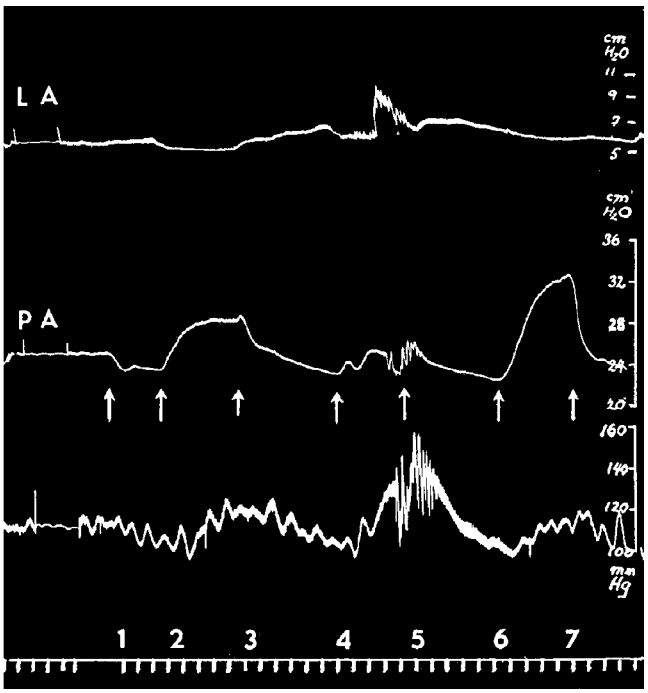

Figure 1-18 Effects of the blood gases on pulmonary arterial pressure in the open-chest cat, artificial respiration. LA, left atrial pressure; PA, pulmonary arterial pressure; lower trace, systemic arterial blood pressure. Numbers along the baseline represent the administration of test gases: 1, O_2 (from air); 2, 6.5% CO_2 in O_2; 3, O_2; 4, 18.7% CO_2 in CO_2; 5, O_2; 6, 10.5% O_2 in N_2; 7, O_2. *(Reproduced with permission from Von Euler, US and Liljestrand, G: Observations on the pulmonary arterial blood pressure in the cat. Acta Physiol Scand. 1946;12(4):301–320.)*

mechanical role, as a filter for particulate matter in blood returning to the heart, and a metabolic role, effecting the synthesis, uptake, and breakdown of biologic compounds. Extensive studies have been conducted in recent decades on the nonrespiratory functions of the lungs. From these studies has emerged considerable understanding of the diverse functions served by the branching pulmonary circulation and its components, including the endothelium and smooth muscle and their interplay.

TECHNOLOGIC ADVANCES THROUGH THE EARLY 20TH CENTURY

The road to contemporary pulmonary medicine could be just as easily traced by using technologic advances as landmarks, instead of people and discoveries. For example, the introduction of the manometer for pressure recording, the use of chambers to simulate high altitude, the development of accurate blood gas analyzers, and the application of sophisticated optical systems for viewing the lumens of the airways and the inside of the chest cavity are all notable milestones. However, probably no better example exists than the discovery of radiographs and the application of this discovery to the diagnosis, prevention, and management of pulmonary tuberculosis.

Wilhelm Conrad Roentgen discovered radiographs in 1895 while experimenting with cathode ray tubes in his physics laboratory at the University of Wurzburg. Although others before him had seen radiographs as early as 1890, Roentgen was apparently the first to grasp the full significance of the discovery, and his publication, quite unpretentious, immediately attracted worldwide attention because of its prospects for the study of anatomic structures and pathologic changes.

Within 2 years after Roentgen's discovery, fluoroscopy of the chest had been introduced into clinical practice, and its value in the early detection of tuberculosis and the diagnosis of pleural effusions was appreciated. In 1901, an atlas of chest radiographs was published, and the use of chest radiography increased greatly with each subsequent improvement in hot cathode radiograph tubes and intensifying screens. The radiographic evaluation of tuberculosis was superior to physical examination for diagnosis and characterization of the disease. By 1910, all patients admitted to sanatoriums had a chest radiographic examination, and by 1917 tuberculosis was classified according to radiographic findings.

MAJOR DEVELOPMENTS SINCE THE MID-20TH CENTURY

Many notable developments have occurred over the last 60 years in pulmonary medicine and the related field of critical care. Measured against the metric of having a broad and deep impact on clinical care, several are particularly noteworthy: advances in thoracic imaging, lung transplantation, bronchoscopy and interventional bronchoscopic techniques, and advances in management of the critically ill.

■ ADVANCES IN THORACIC IMAGING

Following Roentgen's discovery of the x-ray at the turn of the 20th century, another major diagnostic leap forward in pulmonary medicine occurred with development of computerized tomography (CT) in the 1960s.[37–39] In 1967, the first experimental CT scan was generated, with computer reconstruction of an image of a mouse taking 9 days to complete. The first human application was a head CT which demonstrated a brain tumor (Fig. 1-19). In 1973, Dr. Godfrey Hounsfield published a description of CT scanning in the British Journal of Medicine. Along with Dr. Allan Cormack, Hounsfield (Fig. 1-20) was awarded a Nobel Prize in 1979.

Application of CT to lung imaging arose in the mid-1970s; high-resolution techniques were developed in the 1980s. Multislice CT scanning now permits rapid acquisition of high-resolution images

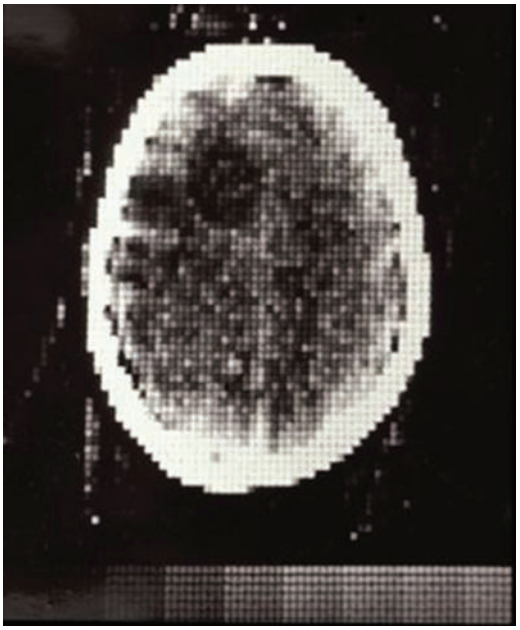

Figure 1-19 The first clinical CT scan, obtained in 1971. The grainy image shows a brain tumor in a frontal lobe (*left side* of image). Advances in image quality over the last four decades have been dramatic. *(Source: impactscan.org.)*

from which multiplanar reconstructions can be derived (Fig. 1-21). Elegant characterization and classification of a variety of interstitial and airway diseases is now possible using CT. In addition, when coupled with intravenous contrast injection (CT angiography), rapid, high-resolution scanners provide for the highly accurate diagnosis

Figure 1-20 Dr. Godfrey Hounsfield, inventor of computerized tomography (CT). Along with Dr. Allan Cormack, Hounsfield was awarded a Nobel Prize in 1979. *(Source: Visible Proofs, National Library of Medicine, National Institutes of Health.)*

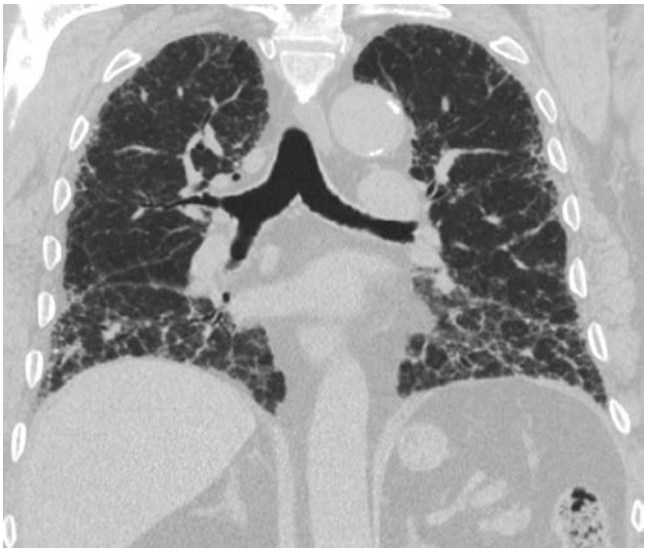

Figure 1-21 A modern day, coronal reconstruction of the chest using CT in a patient with idiopathic pulmonary fibrosis (IPF). Current scanners are capable of rapidly generating high-resolution images from which a variety of computer-generated reconstructions can be derived. *(Used with permission of Dr. Eduardo J. Mortani Barbosa, Jr.)*

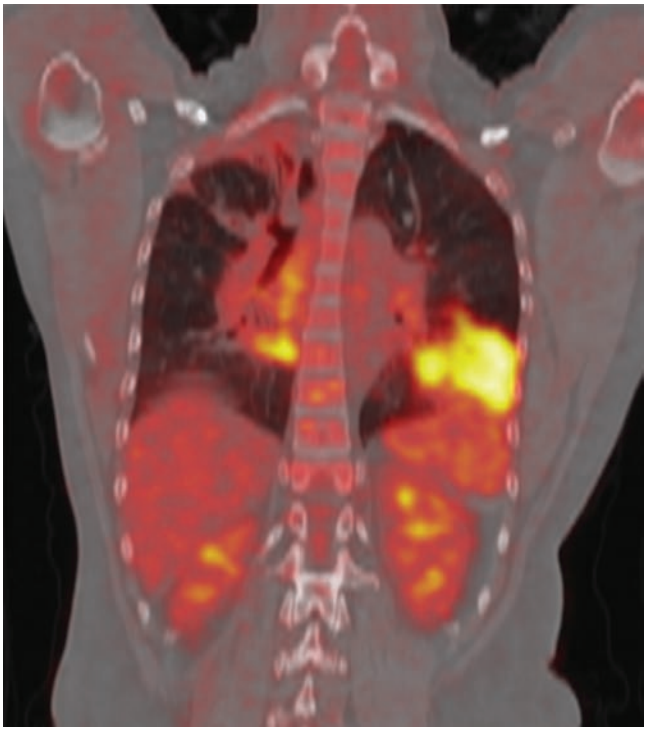

Figure 1-22 A coronal PET/CT image demonstrating metastatic lung cancer, evident as bright areas (in *yellow*) at the left base and the right hilum. The PET and CT images are aligned ("in register") to create precise anatomic localization of the heightened metabolic activity noted in the PET image. *(Used with permission of Dr. Eduardo J. Mortani Barbosa, Jr.)*

of pulmonary embolism[40] and other pulmonary vascular disorders. Advances in multislice techniques (e.g., development of 256-slice or 320-slice scanners) offer the promise of even higher quality imaging.

More recently, aligning the anatomic detail provided by CT with functional images afforded by positron emission tomography (PET) has generated useful information on the staging and clinical assessment of bronchogenic carcinoma, particularly non–small-cell carcinoma.[41–45] Positively charged electrons (positrons), emitted from injected radionuclides are destroyed by electrons and, in the process, produce photons which are detected and imaged by the PET scanner. Malignant cells, by virtue of having increased numbers of cell membrane–based glucose transporters compared with normal cells, accumulate greater levels of the radionuclide,[18] F-fluorodeoxyglucose (F-FDG), which cannot be metabolized further and is trapped within the cells. The tracer-enriched collection of malignant cells stands out against the background of normal tissue. Coupling of the PET-based and CT images provides precise localization of the area of abnormality (Fig. 1-22). PET/CT imaging has been used to evaluate solitary pulmonary nodules, assess local extent of disease (particularly mediastinal and pleural involvement) in lung cancer, and evaluate distant anatomic sites for metastatic disease.

■ LUNG TRANSPLANTATION

Following on the heels of pioneering animal experimentation conducted by Vladimir Demikhov,[46] the first reported human lung transplantation was conducted by Dr. James Hardy and colleagues in 1963.[47,48] However, it was not until the 1980s that clinically meaningful outcomes were achieved by Dr. Joel Cooper and colleagues with single-lung[49] and bilateral-lung[50] transplantation.

Since the advent of lung transplantation, more than 32,000 procedures have been performed worldwide. Survival of recipients has improved from 4.0 years in the late 1980s and early 1990s to 5.7 years in the last decade. Contemporary, overall survival rates are 79% at 1 year, 63% at 3 years, 52% at 5 years, and 29% at 10 years.[51]

Lung transplantation is associated with improvements in lung function, exercise tolerance, and hemodynamic parameters. Currently, the primary diagnoses for which lung transplantation is most commonly conducted include (in descending order of frequency) idiopathic pulmonary fibrosis (IPF), chronic obstructive pulmonary disease (COPD), cystic fibrosis (CF), and other disorders, including alpha-1-antitrypsin deficiency, sarcoidosis, non-CF bronchiectasis, lymphangioleiomyomatosis (LAM), and primary pulmonary hypertension.[51,52]

Despite tremendous advances in the field, complications of lung transplantation are common and include primary graft dysfunction (noncardiogenic pulmonary edema without other apparent cause occurring in the first 72 hours following transplantation); bronchial stenosis developing at the anastamotic site; a broad array of infectious complications, including CMV infection; acute rejection (occurring in over one-third of recipients); and chronic allograft dysfunction due to bronchiolitis obliterans.[51]

Improved surgical techniques in lung transplantation have been important. However, critical to advances in solid organ transplantation, including lung transplantation, has been development of effective immunosuppressive regimens.The earliest regimens included a limited repertoire of drugs, for example, corticosteroids and azathioprine. Development of calcineurin inhibitors, including cyclosporine in 1977 and tacrolimus in 1983, substantially advanced the field.[53]

While technical and pharmacologic advances in lung transplantation afford many patients with advanced lung disease improved quality of life, a limited supply of suitable donor organs persists. Various approaches have been employed in an attempt to ameliorate the continuous shortage. In addition to obtaining organs from brain-dead donors as the primary source, more recently, many transplant programs have embarked on the somewhat controversial program of donation after cardiac death (DCD) or donation from "non–heart-beating donors," who undergo controlled withdrawal of life support in an operating room. In addition, new technologic developments in organ "reconditioning" offer hope for enlarging the supply of transplantable lungs.[54–56]

■ BRONCHOSCOPY AND INTERVENTIONAL BRONCHOSCOPIC TECHNIQUES

Application of bronchoscopic techniques, both rigid and flexible, has revolutionized the field of pulmonary medicine, from both diagnostic and interventional perspectives. Credit for invention of the rigid bronchoscope is given to Gustav Killian (Fig. 1-23) in Germany in the late 19th century;[57] in the United States, the field of rigid bronchoscopy was pioneered by Chevalier Jackson in Philadelphia (Fig. 1-24).[58] The next major wave in bronchoscopy arose with development of the flexible fiberoptic technique by Shigeto Ikeda in Japan.[59,60] Since then, significant advances in optics, digital technology, and a variety of interventional techniques, including those based on the fiberoptic method, have been reported.

■ ADVANCES IN CRITICAL CARE

In parallel with the previously noted advances in imaging, transplantation, and bronchoscopy, significant progress in the management of critically ill patients has occurred over the last several decades. One of the most notable is application of mechanical ventilation.[61–63]

The era of the "iron lung," the first widely used negative pressure ventilator, dates back to 1928 (Fig. 1-25).[64–66] Restricted access to the patient was a major limitation to use of the device. The advent of positive pressure ventilators, dramatically evident during the polio epidemic in Copenhagen in 1952, ushered in the "modern" era of mechanical ventilation.[67] Indeed, the clustering of paralyzed patients needing ventilatory support paved the way for development of medical intensive care units. Subsequent invention of the Bennett valve, a result of efforts to establish a means of facilitating high-altitude flight for military purposes, further enhanced clinical use of positive pressure ventilation.[68–71] Many additional refinements in mechanical ventilation, including microprocessor-controlled functions, have evolved over the last quarter century. One noteworthy development in the field deserves special consideration: use of the "low-stretch protocol."

Based on recognition that application of traditionally used tidal volumes of 10 to 15 mL/kg body weight may cause stretch-induced injury in patients with acute lung injury (ALI) and acute respiratory distress syndrome (ARDS), a multicenter prospective trial was undertaken to address whether use of smaller tidal volumes (6 mL/kg), that is, a "low-stretch protocol," would improve outcomes. Indeed, in a landmark study published in 2000, an approximate 25% reduction in mortality using a low-stretch protocol was demonstrated.[72] Additional refinements, including use of higher levels of positive end-expiratory pressure (PEEP)[73] and the so-called "lung recruitment maneuvers"[74] have been added to the contemporary ventilator management scheme for these patients.

In addition to advances in mechanical ventilation, other notable recent refinements in critical care include recognition of the value of venous thromboembolism prophylaxis, prophylaxis against gastrointestinal bleeding, semierect patient positioning to minimize aspiration risk, good (but not excessive) glycemic control, application

of spontaneous breathing trials and sedation interruption, and early patient mobilization. However, one particular development warrants special mention: use of early goal-directed therapy (EGDT) in sepsis.

Sepsis is a severe, systemic response to infection and is associated with high mortality. A reflection of the systemic inflammatory response syndrome (SIRS), sepsis may progress to severe sepsis (end-organ dysfunction in the setting of documented or suspected infection) or septic shock (severe sepsis with hypotension unresponsive to intravenous fluid administration). An important study published in 2000 addressed the value of EGDT in the management of septic patients. Such therapy focuses on early and aggressive fluid administration titrated to a goal central venous pressure (CVP), mean arterial blood pressure (MAP), and target central venous oxygen saturation (Scv_{O_2}), and incorporates use of vasoactive agents and transfusion of packed red blood cells as necessary. Application of EGDT has been shown to reduce mortality by as much as one-third[75] and constitutes one of the cornerstones of management of critically ill patients with sepsis, as comprehensively discussed in the "Surviving Sepsis Campaign Guidelines for Management of Severe Sepsis and Septic Shock."[76]

CHAPTER 2

Functional Design of the Human Lung for Gas Exchange

Matthias Ochs
Ewald R. Weibel

At the end of a deep breath, about 80% of the lung volume is air, 10% is blood, and only the remaining 10% is tissue. Because this small mass of tissue is spread over an enormous area – nearly the size of a tennis court – the tissue framework of the lung must be extraordinarily delicate. It is indeed remarkable that the substance of the lung manages to maintain its integrity in the face of the multitude of insults that inevitably accompany a lifetime of exposure to ambient air and the complex necessity of keeping air and blood in intimate contact, but separate, for the sake of gas exchange.

Part of this success is undoubtedly attributable to the unique design of the lung, which ensures mechanical stability as well as nearly optimal conditions for the performance of the lung's primary function: to supply the blood with an adequate amount of oxygen even when the body's demands for oxygen are particularly high, as during heavy work.

THE LUNG AS AN ORGAN

At total lung capacity, the lung fills the entire chest cavity and can reach a volume, in the adult human, of some 5 to 6 L, largely depending on body size. Upon expiration, the lung retracts, most conspicuously from the lower parts of the pleural cavity, the posterior bottom edge of the lung moving upward by some 4 to 6 cm. This preferential lifting of the bottom edge is caused by retraction of the tissue throughout the entire lung, the surfaces of which are freely movable within the thoracic cavity.

The structural background for this mobility of a healthy lung is the formation, during morphogenesis, of a serosal space that is lined on the interior of the chest wall and on the lung surface by a serosa, the parietal and visceral pleurae, respectively (Fig. 2-1). However, this serosal space is minimal, since the visceral pleura is closely apposed to the parietal pleura, with only a thin film of serous fluid intercalated as a lubricant between the two surfaces.[1] Both pleural surfaces are lined by a squamous epithelial layer, often called mesothelium (due to its mesodermal origin), whose surface is richly endowed with long microvilli. The apical microvilli increase the surface area available, suggesting that pleural mesothelial cells are capable of participating in active transserosal transport of solutes. The total volume of pleural fluid is about 15 to 20 mL, with approximately 1700 cells/mm^3 (75% macrophages, 23% lymphocytes, 1% mesothelial cells). The volume and composition of the pleural fluid have to be tightly controlled to ensure an efficient mechanical coupling between chest wall and lung. Pleural fluid originates from pleural capillaries through microvascular filtration. Drainage occurs partly via lymphatic stomata in the parietal pleura. Transcytosis through mesothelial cells in both directions represents another mechanism involved in pleural fluid homeostasis.[2–6]

The connective tissue of the visceral pleura consists of three layers. A superficial layer of predominantly elastic fibers follows the mesothelium, thereby forming an elastic "bag" that enwraps each lobe. A deep sheet of fine fibers follows the outline of alveoli and extends into the depth of the lung. Between these sheets lies a bed of loose connective tissue, containing free cells (histiocytes, plasma cells, and mast cells), that is often close to lymphatics and systemic arterial branches from the bronchial arteries.

The lung is maintained in a stable position within the chest by the hilum, where airways and blood vessels enter from the mediastinum, and by the pulmonary ligament, a long, narrow band of attachment between visceral and mediastinal pleura that extends downward from the hilum. Because of these attachments, a pneumothorax causes the lung to retract and form a lump of tissue that is attached to the mediastinal wall of the thoracic cavity.

The shape of the lung is congruent with that of the fully expanded pleural cavity. This shape is preformed in lung tissue and is hence also evident if an excised lung is inflated, revealing its three faces: the convex thoracic face apposed to the rib cage, the concave diaphragmatic face modeled by the diaphragmatic dome, and the mediastinal face, on which the contours of the heart are impressed beneath the hilum.

As the lung retracts during deflation, the acute edges between the thoracic face and the diaphragmatic and (anterior) mediastinal faces of the lung withdraw; the thoracic and diaphragmatic leaflets of the parietal pleura become apposed, thereby forming a costodiaphragmatic recess on each side (Fig. 2-1). Similarly, as the ventral edge of the lung retracts, the costal and mediastinal pleurae form a

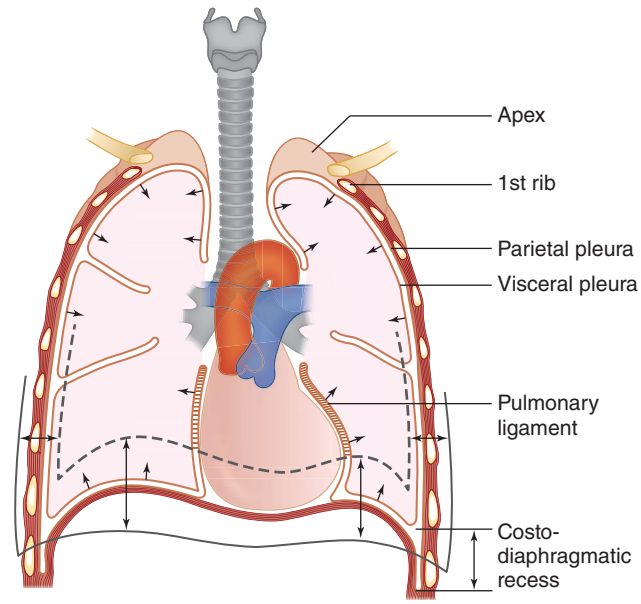

Figure 2-1 Frontal section of chest and lung showing pleural space. *Single arrows* indicate retractive force. *Double arrows* show the excursion of the lung bases and periphery between deep inspiration and expiration.

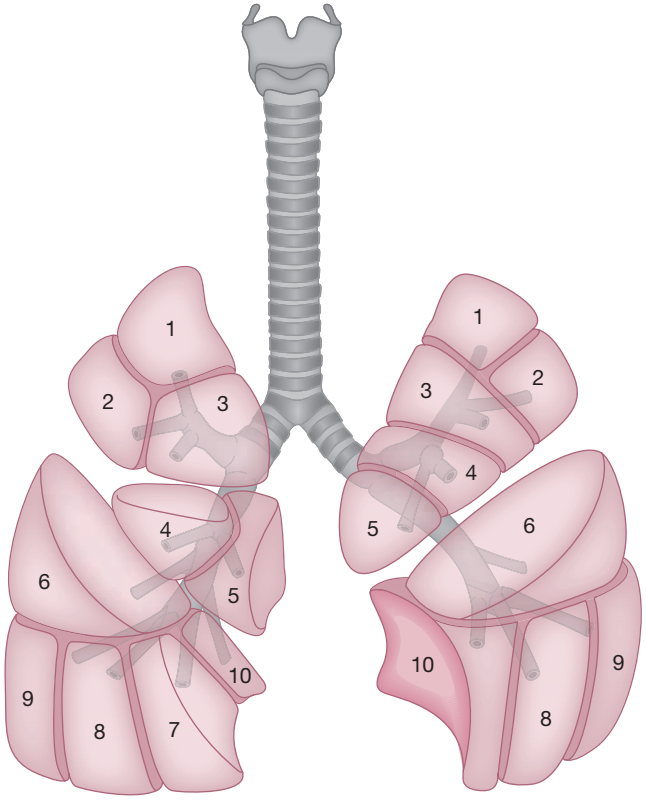

Figure 2-2 Bronchopulmonary segments of human lung. Left and right upper lobes: (1) apical, (2) posterior, (3) anterior, (4) superior lingular, and (5) inferior lingular segments. Right middle lobe: (4) lateral and (5) medial segments. Lower lobes (6): superior (apical), (7) medial–basal, (8) anterior–basal, (9) lateral–basal, and (10) posterior–basal segments. The medial–basal segment (7) is absent in the left lung. (Note: The lungs are represented as turned inward slightly to display part of the lateral face.)

recess on each side, corresponding topographically to the borders of the sternum.

The port through which airways and blood vessels enter the lung is the hilum, that is, the attachment of lung tissue to the mediastinum (Fig. 2-1). The airways reach the two hili by the mainstem, or principal, bronchi (Figs. 2-1 and 2-2). The left mainstem bronchus is longer than the right because it must pass under the aortic arch before it reaches the lung. The two principal bronchi course downward and begin to divide sequentially shortly after entering the lung, first releasing the lobar bronchus to the upper lobe (Fig. 2-2). Since a middle lobe is formed only on the right side, there is no middle lobe bronchus on the left; instead, the corresponding parts form the lingula, which receives its airways from the superior bronchus of the upper lobe (Fig. 2-2). The last branch of the stem bronchus goes to the lower lobe.

The branching pattern of the human bronchial tree and of the pulmonary artery and veins are shown in a resin cast in Figure 2-3. The pulmonary artery joins the bronchi while still in the mediastinum (Fig. 2-4A); its trunk lies to the left of the ascending aorta, and the right pulmonary artery turns dorsally to course between ascending aorta and right principal bronchus. In the hilum, the right pulmonary artery lies anterior to the right principal bronchus; the left pulmonary artery, however, "rides" on the principal bronchus and crosses over the superior lobar bronchus to the posterior side. From there on, the pulmonary artery branches in parallel with the bronchi; characteristically, each bronchus is associated with one closely apposed pulmonary artery branch, and this relationship

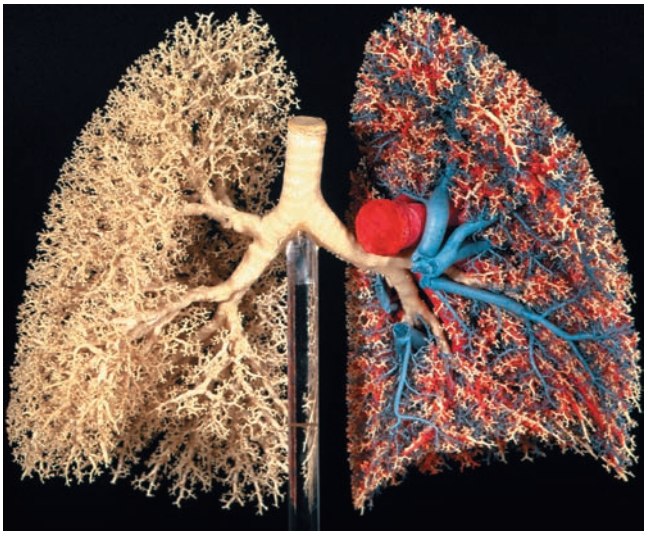

Figure 2-3 A resin cast of the human airway tree shows the dichotomous branching of the bronchi from the trachea and the systematic reduction of airway diameter and length with progressive branching. In the left lung the pulmonary arteries *(red)* and veins *(blue)* are also shown.

is strictly maintained to the periphery, that is to the respiratory bronchioles.

In contrast, the pulmonary veins (Fig. 2-4B) follow a course independent of the bronchial tree; rather, they lie about midway between two pairs of bronchi and arteries; this position is maintained to the periphery of the airway system. In the hilum, these veins are collected into at least two main veins on either side, which lead into the left atrium located at the back of the heart.

The airways systematically branch over an average of 23 generations of dichotomous branching,[7,8] ending eventually in a blind sac (Fig. 2-5). The last nine generations of these airways are connected to tightly packed alveoli, airway chambers in which gas exchange takes place, whereas the central airways serve the function of conducting the air to the gas-exchange parenchyma. In such a system of sequential branching, the unit of lung parenchyma could be defined according to the portion of parenchyma that is supplied by a particular branch of the bronchial tree, and it is possible to conceive of as many types of units as there are generations unless clear definitions for such units are proposed. However, two units appear to be natural:

1. The lobes, which are demarcated by a more or less complete lining of pleura. There are three lobes on the right (superior, middle, and inferior lobes), and two on the left (superior and inferior lobes).
2. The acinus, which is defined as the parenchymal unit in which all airways have alveoli attached to their wall and thus participate in gas exchange. Along the airway tree, the acinus begins with a transitional bronchiole (Fig. 2-5).[9,10]

Since all other units are somewhat arbitrarily defined, it is not surprising that some ambiguity exists in the literature about their meanings. Nonetheless, a certain convention has been adopted with respect to the following:

1. The lung segments, which are considered as the first subdivisions of lobes. Figure 2-2 shows the location and distribution of the segments to the various lobes. The symmetry is imperfect because on the left the two segments corresponding to the right middle lobe are incorporated into the superior lobe as the lingula (segments 4 and 5) and because the medial–basal segment of the lower lobe is generally missing on the left (segment 7).

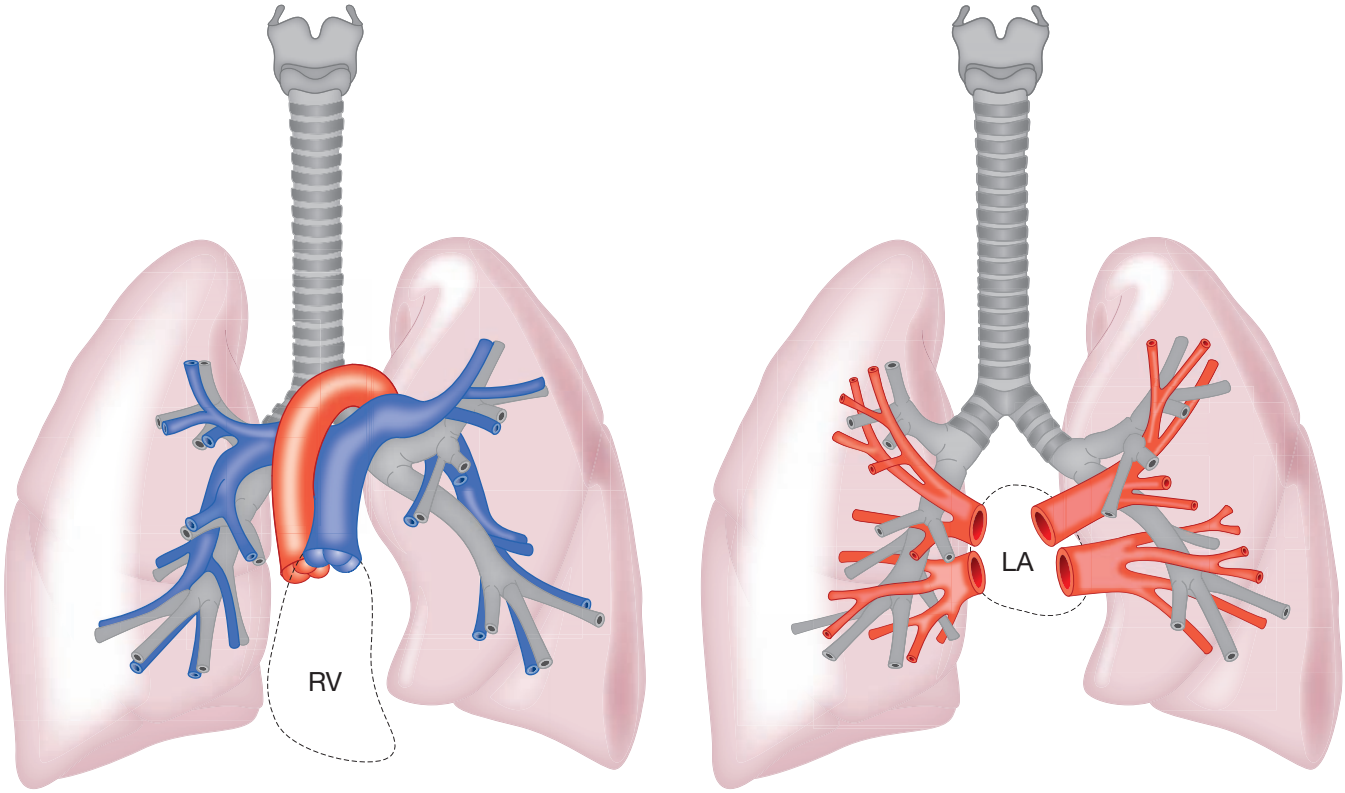

Figure 2-4 Schematic diagrams of the relation of the main branches of pulmonary arteries (**A**) and pulmonary veins (**B**) to the bronchial tree. The arteries follow the airways. Two mainstems of pulmonary vein penetrate independently into the lung on each side. LA, left atrium; RV, right ventricle.

2. The secondary lobule, an old anatomic unit. It was introduced in the 19th century because "lobules" of about 1 cm^3 are visible on the surface of the lung. These lobules are delineated by connective tissue septa that are connected to the pleura. The secondary lobule is difficult to define in terms of the bronchial tree, but it does seem to comprise about a dozen acini. With reference to bronchograms, secondary lobules are supplied by airway branches that are about 1 mm in diameter.

The pulmonary blood vessels show a characteristic relationship to these units (Figs. 2-3 and 2-4). The pulmonary arteries, following the airways, course through the centers of the units and finally fan out into the capillaries located in the delicate alveolar septa of lung parenchyma. In contrast, the veins lie in the boundary between units and collect the blood from at least two or three adjacent units. This arrangement applies to acini and secondary lobules as well as to lung segments.

Therefore, it is evident that the units of lung parenchyma are bronchoarterial units, which share their venous drainage with neighboring units. This architecture has important functional and practical consequences. Except for the lobes, none of the units is separated from each other by complete connective tissue septa.

ORGANIZATION OF LUNG TISSUE

■ BASIC STRUCTURAL ELEMENTS

While looking at the tissue organization of the lung, we must first consider that the airways and the blood vessels each have their own lining by an uninterrupted cell layer. These layers extend all the way out to the gas-exchange region, but they show different properties in conducting as compared with respiratory structures. Likewise, the connective tissue forms a continuum throughout the lung all the way out to the pleura, but it, too, will be differently organized in the different functional zones; whereas it is reduced to a minimum in the alveolar walls, it contributes a number of different ancillary structures to the wall of conducting airways and blood vessels, such as smooth muscle sheaths or cartilage. This connective tissue space also houses the nutritive vessels and nerves as well as the elaborate defense system related to lymphatic vessels. In the gas-exchange region, however, very few of these accessory structures are found.

The complexity of lung structure is also reflected at the cell biologic level. There is no such thing as a standard "lung cell." Instead, we find some 40 different cell types, highly specialized both structurally and functionally, in the lung.[11–13]

A word of caution is also necessary with respect to the extrapolation of structural findings in experimental animals, especially rodents, to the human lung. Noteworthy species differences include the bronchial circulation, the presence of respiratory bronchioles, the ultrastructural composition and distribution of nonciliated bronchiolar epithelial cells and their protein expression pattern, the frequency of certain cell types like alveolar brush cells and lipid-containing interstitial cells (lipofibroblasts), and the ultrastructural organization of lamellar bodies in type II alveolar epithelial cells. All these structural elements have features characteristic of the human lung that are not found in rodents.[14]

■ WALL STRUCTURE OF CONDUCTING AIRWAYS

The wall of conducting airways consists of three major components (Figs. 2-6 and 2-7): (1) a mucosa composed of an epithelial and a connective tissue lamina; (2) a smooth muscle sleeve; and (3) an enveloping connective tissue tube partly provided with cartilage.[15]

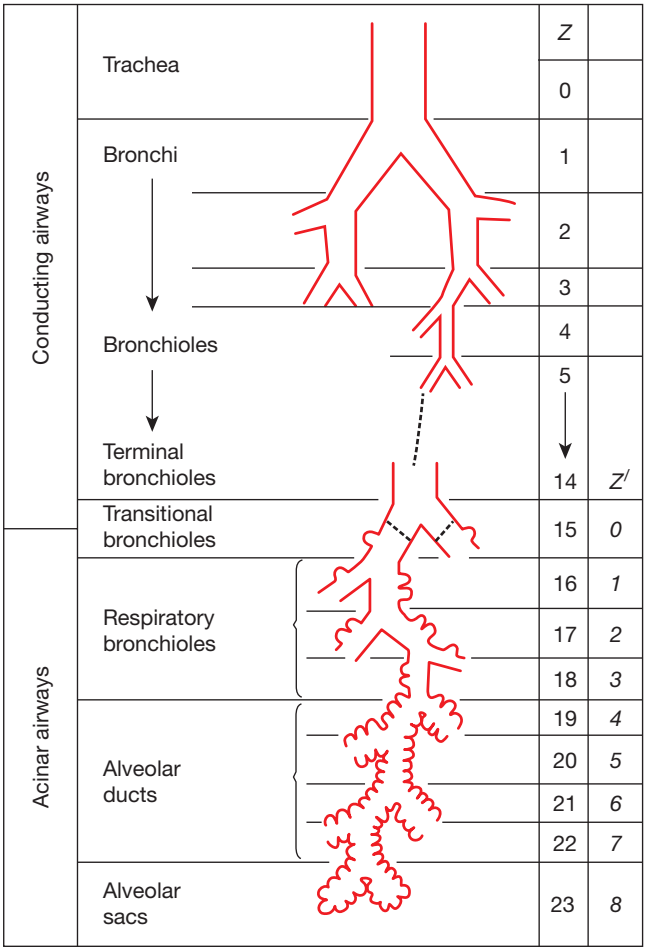

Figure 2-5 Model of airway branching in human lung by regularized dichotomy from trachea (generation z = 0) to alveolar ducts and sacs (generations 19–23). The first 14 generations are purely conducting; transitional airways (generation 15) lead into the acinar airways with alveoli that branch over 8 generations (z′). *(Modified with permission from Weibel ER: Morphometry of the Human Lung. Heidelberg: Springer-Verlag; 1963.)*

EPITHELIUM

Although derived from same anlage,[16,17] the airway epithelium modifies its differentiation characteristics as we proceed from large bronchi over bronchioles to the alveolar region (Fig. 2-6). A simple epithelium exists as a lining of smaller bronchioles: As we move upward toward larger bronchi, the epithelium becomes higher and some basal cells appear, making the epithelium pseudostratified. At the point of transition into the gas-exchange region – that is, at the entrance into the complex of alveoli – the epithelium abruptly becomes extremely thin. Figure 2-6 also shows that the epithelium is not made of a uniform cell population but that it is, at each level, rather a mosaic of at least two cell types, in that secretory cells as well as some rarer special cells are interspersed into the complex of lining cells.[15,18]

If we first have a closer look at the epithelium of larger conducting airways, we see that the lining cells are provided with a tuft of kinocilia at their apical cell face, whereas the secretory cells are goblet cells that produce and discharge to the surface a sticky mucus (Figs. 2-7–2-9). This mucus spreads out as a thin blanket on top of the cilia, which are embedded in a periciliary layer containing a dense network of mucins and mucopolysaccharides tethered to the cilia.[19] The mucus layer is capable of trapping dust particles that are still contained in the air entering the lung. Kinocilia (Fig. 2-10) are motile cell extensions that are known to beat rhythmically in a given direction and at a frequency of about 12 to 20 Hz.[20,21] In the airway epithelium, the cilia are oriented in such a fashion that their beat is directed outward. It is interesting that the cilia of airway epithelia develop at their tip fine claws with which they can grasp the mucus blanket in the phase of their forward beat, whereas on their return to the upright position they glide past the mucus blanket. The result of this is that the mucus blanket, together with trapped foreign material, moves outward or "up the airways" in a steady stream, a feature appropriately called the mucociliary escalator. Since the lining by ciliated cells is uninterrupted from the bronchioles, up the bronchi, to the trachea, this mucociliary escalator ends at the larynx, so that the normal fate of bronchial mucus is to be steadily discharged into the pharynx, whence it is swallowed, usually unnoticed. Only when an excessive amount of mucus accumulates in the trachea or in larger bronchi do we have to assist the system by coughing.

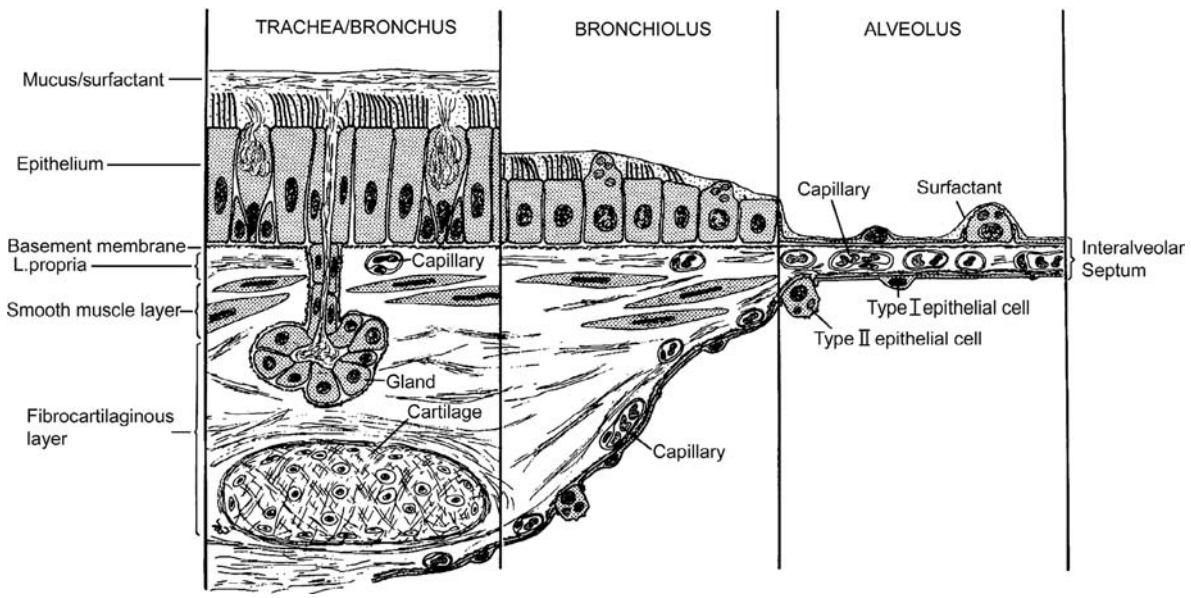

Figure 2-6 Airway wall structure at the three principal levels. The epithelial layer gradually becomes reduced from pseudostratified to cuboidal and then to squamous but retains its organization as a mosaic of lining and secretory cells. The smooth muscle layer disappears in the alveoli. The fibrous layer contains cartilage only in bronchi and gradually becomes thinner as the alveolus is approached.

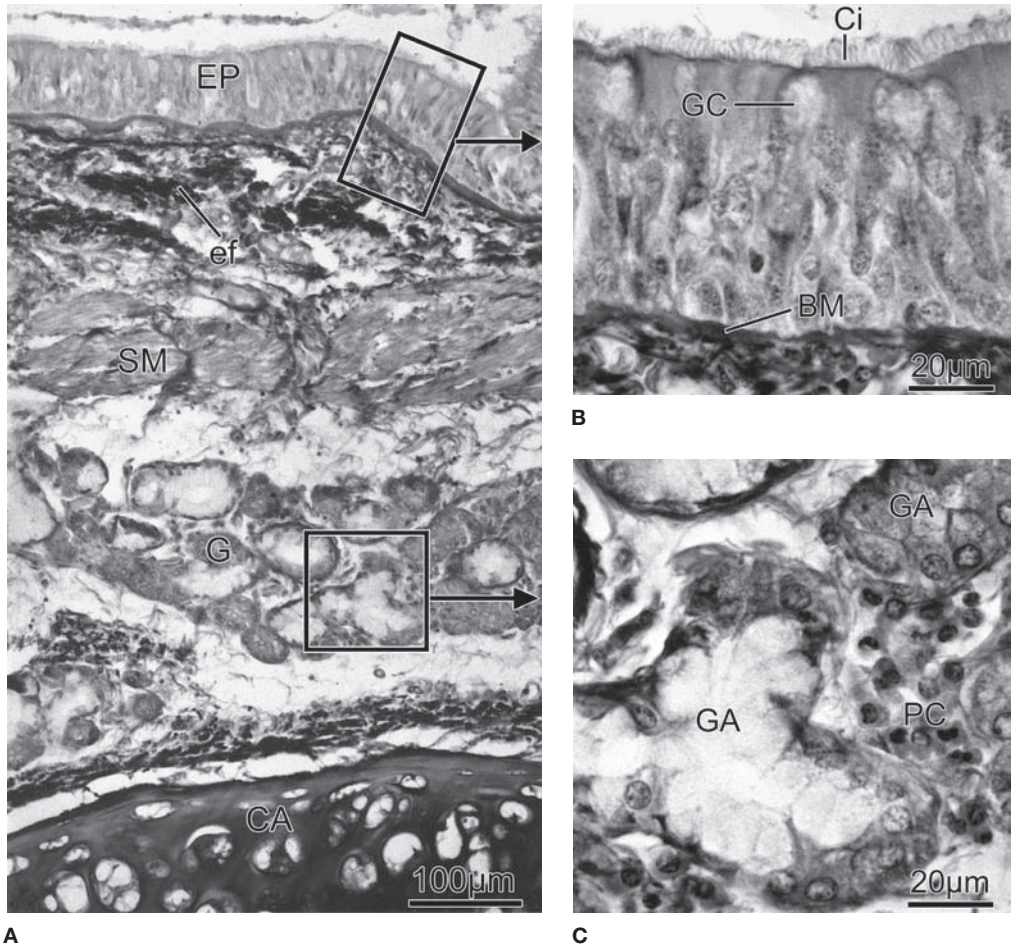

Figure 2-7 Light micrographs of bronchial wall. **A.** The layers from epithelium (EP) to cartilage (CA) with elastic fibers (ef), smooth muscle bundles (SM), and glands (G). **B.** Higher power of pseudostratified epithelium with cilia (Ci). **C.** Details of gland with acini (GA) associated with groups of plasma cells (PC). BM, basement membrane; GC, goblet cell.

The secretory cell population shows a number of specialized features. In the bronchi of all sizes and in larger bronchioles, one finds goblet cells interspersed between the ciliated cells; they form the mucus in their endoplasmic reticulum and Golgi complex, store it as droplets in their apical part, and discharge it in bulk (Figs. 2-8 and 2-9). In larger bronchi, one finds, in addition, small mucus glands located in the connective tissue; they are connected to the bronchial surface by long and narrow ducts (Figs. 2-6 and 2-7). In the normal bronchus, the glandular acini are relatively small and composed of serous and mucus cells; enlargement of the acini and a relative increase of mucus cells are characteristics of chronic bronchitis.

Finally, a special nonciliated secretory cell appears in the smaller bronchioles, the club cell (Clara) (Fig. 2-11).[22,23] This cell population is very heterogeneous, thus displaying both interspecies and intraspecies variations.[24–28] In the human lung, club cells account for about

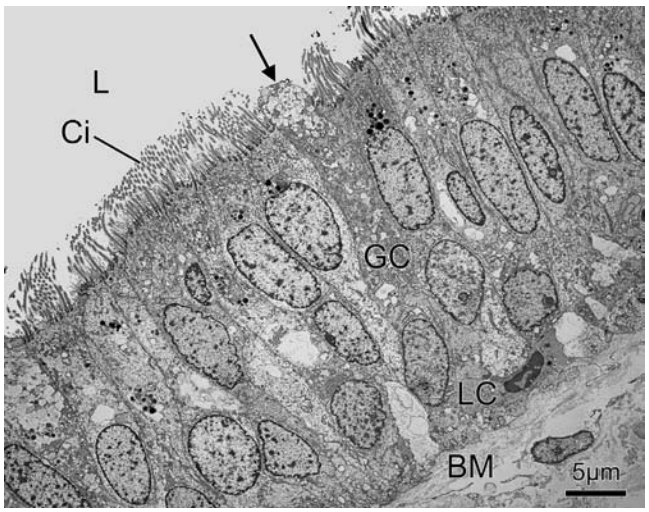

Figure 2-8 Electron micrograph of section across human bronchial epithelium made of high-columnar cells, most of which are ciliated (Ci). A goblet cell (GC) is cut lengthwise; note mucus droplets in process of accumulating at cell apex *(arrow)* and leukocyte (LC) caught in epithelium in process of diapedesis. BM, basement membrane; L, lumen.

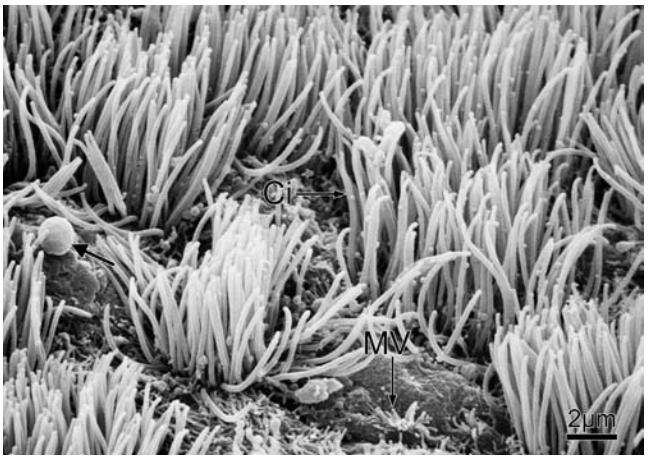

Figure 2-9 Surface view of bronchiolar epithelium shows tufts of cilia (Ci) forming on individual ciliated cells and microvilli (MV) on other cells. Note secretion droplet in process of release from goblet cell *(arrow)*.

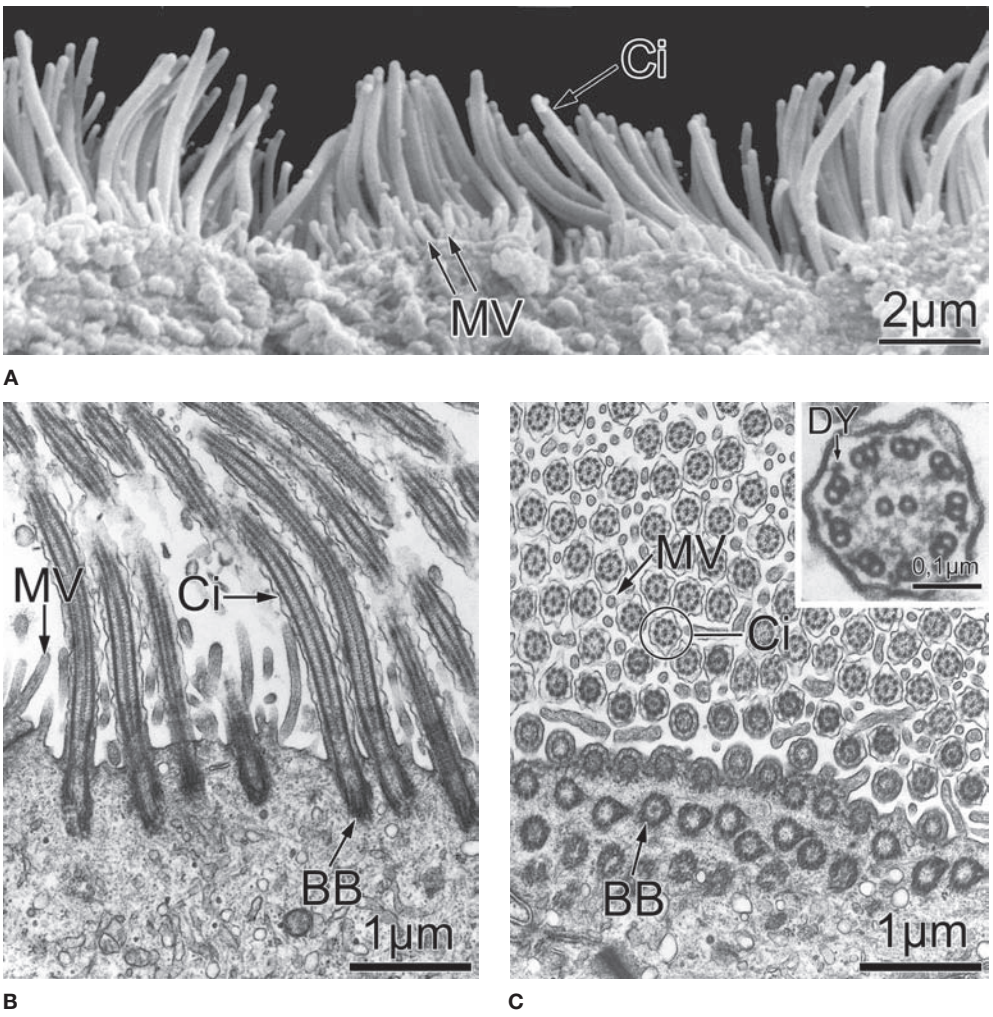

Figure 2-10 Cilia (Ci) from human bronchial epithelium seen on sections of epithelial cells in scanning electron micrograph (**A**), and on thin sections in longitudinal (**B**), and oblique cross section (**C**). They are implanted in the epithelial cell by a basal body (BB). Cross-sectioned cilium at high power (*inset*, **C**) reveals its membrane, which is enveloping a typical set of two axial tubules and nine peripheral duplex tubules with dynein arm (DY) attached. Note abundant short microvilli (MV) interspersed between cilia.

11% and 22% of the total epithelial cell number in terminal and respiratory bronchioles, respectively.[29] Besides the absence of cilia, club cells in conventional preparations are characterized by their dome-shaped apex that protrudes into the airway lumen. In contrast to that in rodents, where this cell is rich in smooth endoplasmic reticulum, club cells in the human lung lack significant amounts of smooth ER. They possess short lateral cytoplasmic extensions while their basal surface that rests on the basement membrane is practically free of infoldings. Membrane-bound electron-dense granules of about 500 to 600 nm diameter are present, which underlines their secretory activity. Our understanding of the functions of club cells is still incomplete. In many aspects, they appear to be functionally related to the secretory cell type of the alveoli, the type II alveolar epithelial cell; ultrastructural features and expression patterns of lung adenocarcinoma cells show characteristics of both club and type II cells. Club cell secretions add to the lining layer of the distal lung. Club cells synthesize and secrete the club cell secretory protein (CCSP),[22] which has been shown to be structurally similar to rabbit uteroglobin. The exact function of CCSP in the human lung still remains to be elucidated. CCSP levels in BAL fluid are decreased in smokers and in patients with COPD or interstitial lung diseases.[30] Animal studies suggest immunomodulatory functions for CCSP.[28] Within the lung, the club cell is the primary site of cytochrome P450 monooxygenase activity. Thus, they are heavily involved in detoxification of xenobiotics. Normal bronchiolar epithelial homeostasis is maintained by proliferation of club cells, whereas a cell population termed "variant Clara cells" or "variant CCSP-expressing cells," which is associated with neuroepithelial bodies or localized at bronchioloalveolar duct junctions, appears to act as progenitor cells for the bronchiolar epithelium under certain pathologic conditions.[28,31]

There are also some additional rarer cells. Neuroendocrine cells are capable of secreting mediators (amines and neuropeptides) into subepithelial capillaries. Prior to secretion, the bioactive substances are stored in dense-cored vesicles (Fig. 2-12). Occasionally, but only rarely in the adult human lung, these cells are organized in extensively innervated groups, and then termed "neuroepithelial bodies." Although it seems clear that neuroepithelial bodies have sensory, most likely oxygen-sensing, properties, their exact physiologic function is still poorly understood.[32–36] Another rare cell type of the airway epithelium is the brush cell. These cells are characterized by the presence of an apical tuft of blunt, broad, and straight microvilli with root-like structures composed of filaments extending into the cytoplasm (Fig. 2-13). Glycogen granules, vesicles, and smooth endoplasmic reticulum are usually present as well. There is species variation in the occurrence of brush cells. While common in rodents (in rats even present in the proximal alveolar epithelium[37]) they are only rarely found in the human lung. Their function is only partly explored. Owing to their ultrastructure and their strategic localization in the airways and at alveolar duct bifurcations, sensory/chemoreceptor as well as sentinel/immune surveillance functions have been proposed.[38,39] Recent evidence suggests that brush cells "taste" the chemical composition of the airway lining fluid.[40,41]

INTERSTITIUM

The layer of connective tissue in the bronchial mucosa consists predominantly of elastic fibers that are oriented longitudinally;

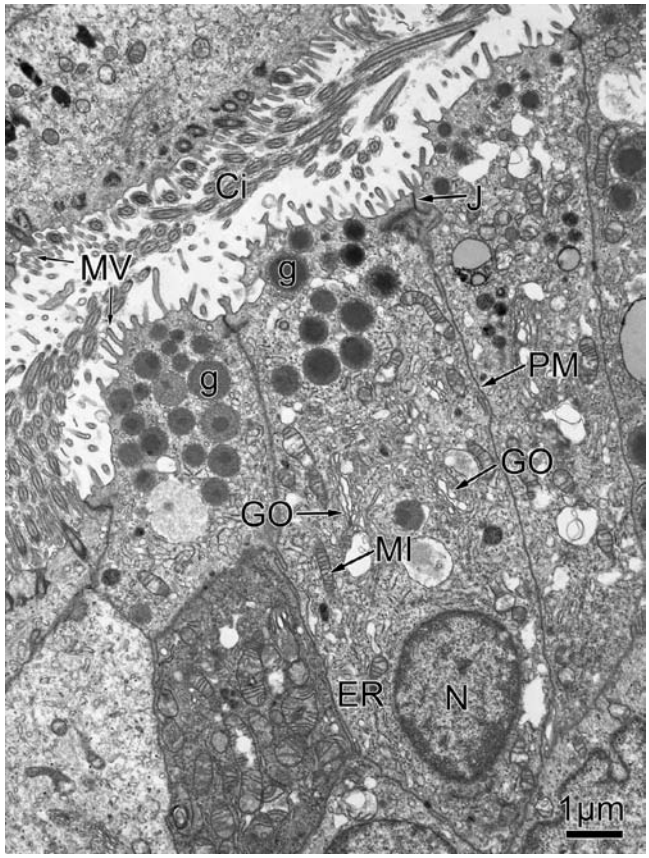

Figure 2-11 Club cells from human bronchiolar epithelium contain dense secretion granules (g) at apex. Note abundant cytoplasmic organelles such as mitochondria (MI), Golgi complex (GO), or endoplasmic reticulum (ER) as well as microvilli (MV) at surface. Cell membranes are closely apposed and form tight junctions (J) at apical edge. Ci, cilia; N, nucleus; PM, plasma membrane.

these fibers serve to maintain a smooth outline of the longitudinal profile of the bronchial lumen no matter how much the bronchi are stretched as the lungs are inflated. In this connective tissue lamina there are foci of lymphoid cells; often they form small lymphoid follicles.[42] However, bronchus-associated lymphoid tissue (BALT) is usually absent in normal adult human lungs and develops only after stimulation when inducible BALT might organize local immune responses.[43–46]

Smooth muscle bundles form a continuous sleeve in the connective tissue underlying the epithelial tube that extends from the major bronchi to the respiratory bronchioles; beyond the respiratory bronchioles, the bundles extend into the wall of alveolar ducts where the muscle fibers lie in the alveolar entrance rings. The bundles have an oblique course and encircle the mucosal tube in a criss-cross pattern; hence, their contraction results primarily in a narrowing of the lumen.

In the small bronchioles there is little else to the airway wall; the smooth muscle layer is ensheathed by a layer of delicate connective tissue that is in direct contact with adjacent alveoli (Fig. 2-6). In the larger bronchioles and even more in the bronchi, the outer connective tissue sheath forms a strong layer of fibers; in the bronchi, rings or plates of cartilage are incorporated into this layer.

The wall structure in the respiratory bronchioles is identical to that of terminal bronchioles except that in some regions the cuboidal epithelium is replaced by an alveolar epithelium of squamous cells (type I cells) closely apposed to capillaries. Very often, these single alveoli constitute outpouchings in these regions; sometimes

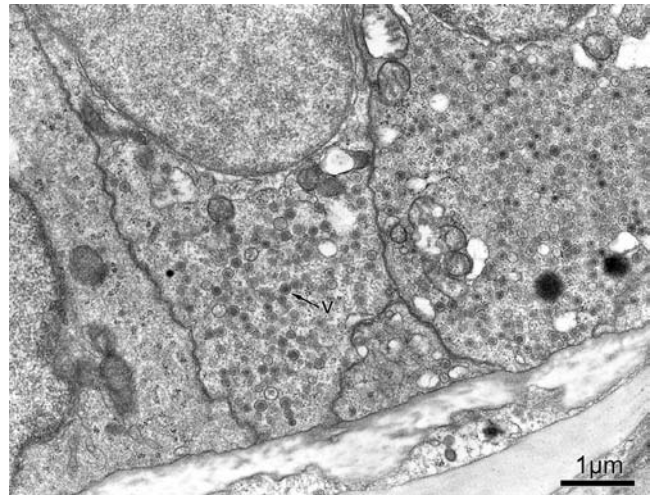

Figure 2-12 Basal part of neuroendocrine cell of human bronchiolar epithelium showing dense-cored vesicles (v). *(Reproduced with permission from Weibel ER. Lung cell biology, in Fishman A, Fisher AB, eds. Handbook of Physiology. Section 3: The Respiratory System. vol 1. Bethesda, MD: American Physiological Society; 1985:47–91.)*

simple "respiratory patches" form in the bronchiolar wall (see below).

■ WALL STRUCTURE OF CONDUCTING BLOOD VESSELS

The endothelial lining of pulmonary arteries and veins differs from that of capillaries by some site-specific structural and functional differences.[47–49] The endothelium of conducting blood vessels is thicker, and parts of its cytoplasm are richly endowed with organelles of various kinds (Fig. 2-14). Clearly, these cells are metabolically more active than those of the capillary endothelium. They are particularly rich in membrane-bound rod-shaped granules termed Weibel–Palade bodies,[50,51] which represent the regulated secretory organelles of endothelial cells (Fig. 2-14). The lumen of

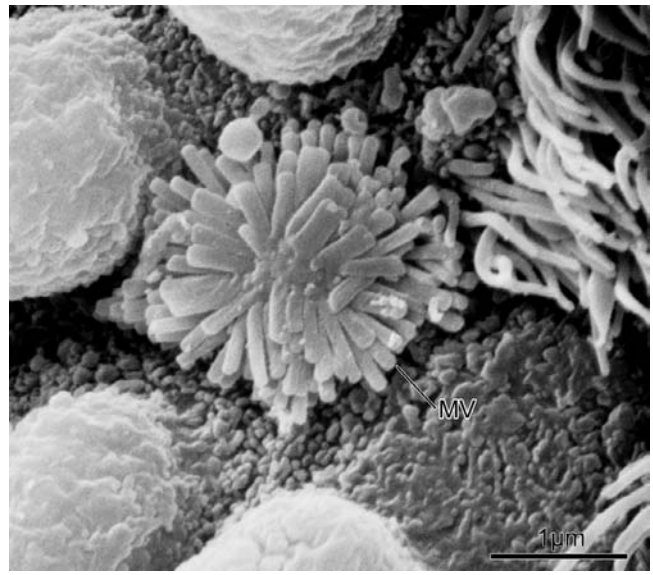

Figure 2-13 Brush cell from small bronchiole of rat lung containing broad microvilli (MV). *(Reproduced with permission from Weibel ER: Lung cell biology, in Fishman A, Fisher AB, eds. Handbook of Physiology. Section 3: The Respiratory System. vol 1. Bethesda, MD: American Physiological Society; 1985:47–91.)*

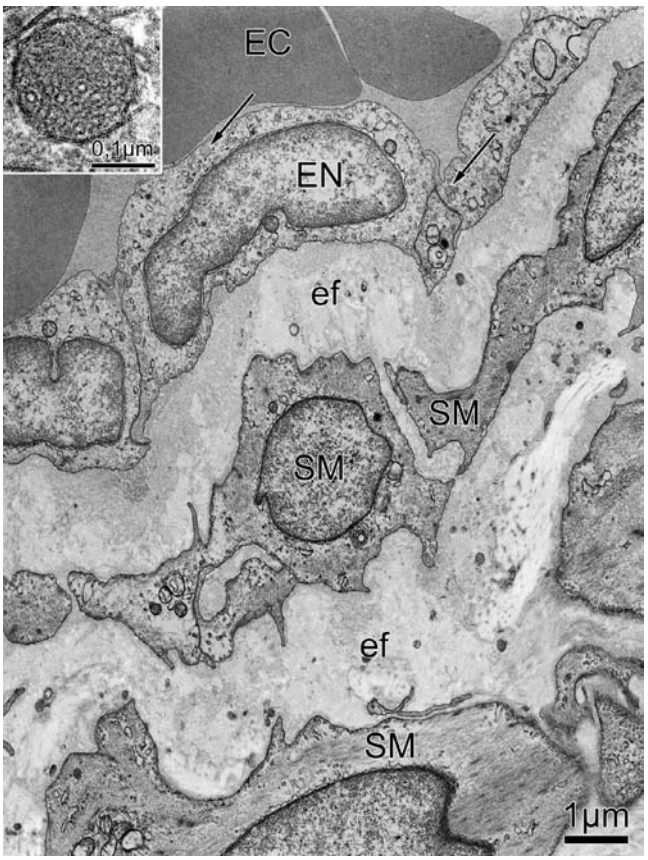

Figure 2-14 Part of wall of pulmonary artery from human lung. Endothelial cells (EN) form thick layer; their cytoplasm is rich in organelles. Specific granules of endothelium *(arrows),* a cross-section of one of which is shown at high power in the inset, are enveloped by a membrane and contain tubules. The arterial wall is of the elastic type, formed of alternating layers of smooth muscle (SM) and elastic fibers (ef). EC, erythrocyte.

Weibel–Palade bodies is filled with longitudinally arranged tubules. These tubules represent von Willebrand factor,[52] packed in a highly organized spiral that allows rapid secretion into the blood. Other components of Weibel–Palade bodies include tissue-type plasminogen activator, endothelin-1, the leukocyte adhesion receptor P-selectin, interleukin-8, the tetraspanin CD63/LAMP-3, and the small GTPase Rab27a. Thus, Weibel–Palade bodies are actively involved in hemostasis as well as in vasoactive and inflammatory responses.[53–56]

Many of the nonrespiratory metabolic functions of the lung – particularly the transformation of certain bioactive substances, such as angiotensin and prostaglandins – are performed in endothelial cells. Caveolae (or plasmalemmal vesicles) have been implicated in these processes.[57,58] Caveolae are plasma membrane invaginations and associated vesicles with an outer diameter of about 50 to 70 nm. Depending on fixation, the shape of these invaginations appears omega- or cup-like.[59] Their structural framework consists of members of the caveolin family of proteins associated with cholesterol and sphingolipids. Caveolae perform transport and signaling functions and are involved in membrane organization. All endocytic activity mediated by caveolae (thereby bypassing the clathrin-coated vesicle pathway) is pooled under the term potocytosis.[60–63]

Accessory structures develop in the wall in accord with the functional properties of the vessels. Thus, the walls of the major pulmonary arteries that are close to the heart, and therefore exposed to the pressure oscillations of large amplitude prevailing in the outflow tract of the right ventricle, are of the elastic type, that is, layers of elastic lamellae are interconnected with smooth muscle cells as in the aorta; the tone of the smooth muscle regulates the elastic modulus of the vessel wall, thereby controlling the shape of the pulse wave. In the pulmonary arterial tree, this pattern prevails out to branches of about 1 mm diameter.

In contrast, branches less than l mm in diameter are of the muscular type, that is, the smooth muscle fibers encircle the vessel lumen; they can modify the vessel's cross-section and can thus regulate blood flow through this vessel. Compared with systemic arteries, the thickness of the pulmonary arterial wall is reduced about in proportion to systolic pressure, that is, by about a factor of 1:5; in pulmonary hypertension, the wall becomes thicker. Although arterioles are a well-defined entity in the systemic vascular bed, where they constitute the major site of arterial resistance, pulmonary arterioles are more difficult to locate and define. A single muscle layer – the histologic definition of an arteriole – does occur in branches about 100 µm in diameter, but the arterial bed continues out to the precapillaries, which consist of vessels 20 to 40 µm in diameter that are enwrapped by an incomplete smooth muscle sheath. This poverty of smooth muscle contributes importantly to the low resistance to blood flow that is normally afforded by the pulmonary arterial tree.

The structure of pulmonary veins is similar to that of systemic veins in the upper half of the organism. Their walls are rich in connective tissue and contain irregular bundles of smooth muscle. Larger veins contain a large amount of elastic tissue. More extensive in rodents, but to a certain degree also in humans, cardiac muscle tissue from the left atrial myocardium forms sleeves in the adventitia of pulmonary veins where they overlap with the smooth muscle of the venous wall. The arrangement of the myocardial sleeves correlates with the distribution of foci of ectopic beats initiating atrial fibrillation.[64–67]

■ NUTRITIVE VESSELS AND NERVES

The tissue of lung parenchyma is very well supplied with blood; the fact that it is venous is of no disadvantage, because O_2 is easily obtained from the air. Thus, nutrient supply from pulmonary arteries combined with O_2 supply from air appears to suffice not only for the parenchyma but also for bronchioles and the smaller pulmonary vessels, whose outer surface is almost directly exposed to air. The thicker-walled bronchi, with their glands and cartilage, require a nutrient blood supply from bronchial arteries.[15,68,69] These derive in part directly from anterior branches of the aorta and partly from the upper intercostal arteries. They course alongside the esophagus and penetrate on both sides into the hilum. The bronchial arteries extend to the most peripheral bronchi but not into the walls of bronchioles. On the other hand, some branches supply large pulmonary vessels as vasa vasorum, whereas others course along larger septa to reach the pleura. Some bronchial arteries form anastomoses with peripheral branches of the pulmonary arteries. There have been long discussions about the role that such anastomoses may play. It seems that in the normal lung their importance has been overrated. However, in certain pathologic conditions, such as bronchiectasis and tumors, the bronchial arteries and perhaps the bronchopulmonary anastomoses appear to play an important role. They also enlarge to form a collateral circulation when branches of the pulmonary artery are obliterated. The peribronchovascular space around larger pulmonary artery branches and bronchi with its capillaries from the bronchial circulation has also been proposed as a unique compartment since it is a preferential site of leukocyte infiltration and edema formation under pathologic conditions.[70] Furthermore, the bronchial circulation attenuates ischemia–reperfusion lung injury. Consequently, interruption of the bronchial circulation without revascularization during lung transplantation often leads to bronchial anastomotic complications.

Except for a few bronchial veins in the hilar region, the bronchial system does not have its own venous drainage into the systemic veins. Instead, the bronchial veins, which begin as a peribronchial venous plexus, drain into pulmonary veins; this drainage seems to constitute one source of normal venous admixture to arterial blood.

The lung is innervated by the autonomic nervous system. The parasympathetic fibers are derived from the vagal nerves and the sympathetic fibers from the upper thoracic and cervical ganglia; together they form the pulmonary nervous plexus in the region of the hilum before entering the lung. The fiber bundles follow the major bronchi and blood vessels, finally penetrating into the acini; some nerves also supply the pleura. In addition, motor nerves influence the smooth muscle tone of airways and blood vessels, and sensory nerves are involved in reflex functions (e.g., cough reflex, Hering–Breuer reflex). Moreover, the secretory function of glands as well as of type II alveolar epithelial cells is at least partly under control of this nervous system. Nerve fibers are easily found in the wall of bronchioles and bronchi, where they often follow the course of bronchial arteries. However, fibers in alveolar septa are small and scarce.

THE CELLS OF THE ALVEOLAR REGION

■ BASIC DESIGN OF THE GAS-EXCHANGE BARRIER

Efficient gas exchange in the lung depends on a very thin barrier of very large surface between air and blood.[16,71] Actually, the barrier is so thin that it cannot be resolved into its constituents by light microscopy. Nevertheless, this barrier must be built of the three minimal tissue layers: an endothelium lining the capillaries, an epithelium lining the airspaces, and an interstitial layer to house the connective tissue fibers. The guiding principle in designing these cells must evidently be to minimize thickness and maximize extent. However, there is definitely a limit to this, set by the need to make the barrier and its constituent cells strong enough to resist the various forces that act on it: capillary blood pressure, tissue tension, and surface tension, in particular. Furthermore, the barrier must remain intact for a lifetime, and this requires continuous repair and turnover of the cells and their components. As a result, about half of the surface of the air–blood barrier is optimized for gas exchange in that the thin epithelial and endothelial cell extensions are only separated by a fused basement membrane. These areas are termed the thin parts of the air–blood barrier. Cell nuclei and connecting tissue fibers are concentrated in the so-called thick parts of the air–blood barrier.

In spite of this delicacy of tissue structure, we find that three-quarters of all the lung cells by volume or weight are contained in the lung parenchyma (Table 2-1). We also note that epithelium and endothelium make up about one-quarter each of the tissue barrier in the alveolar walls, whereas interstitial cells amount to 35%; the interstitial space with the connective tissue fibers makes up no more than 15% of the barrier.[11,72]

■ ALVEOLAR EPITHELIUM

The alveolar epithelium is a mosaic of different cell types. The vast majority of the total surface is lined by a single layer of squamous cells; the remaining fraction – only about 3% (Table 2-2) – is occupied by cuboidal secretory cells; one usually calls the squamous lining cells type I and the secretory cells type II alveolar epithelial cells or pneumocytes. Type I and II cells occur with a numerical frequency of about 1:2. A very rare third cell type, the brush cell, can be found in some specific regions near the entrance of the acinus (see above).

The fine structural details of the different types of alveolar epithelial cells can only be fully visualized by electron microscopy, whereas molecular markers selective for either type I or II cells or some of their constituents can be detected and localized by light microscopy (Fig. 2-15; Table 2-3).

TABLE 2-1 Estimated Cell Volumes in the Human Lung

Cell or Tissue	Volume (mL)	Percent Septal Tissue
Tissue (excl. blood)	284	—
Nonparenchyma	99	—
Alveolar septa	185	—
Cells	213	—
Nonparenchyma	50	—
Alveolar septa	163	—
Parenchymal cells	163	—
Alveolar epithelium type I	23	12.6
Alveolar epithelium type II	18	9.7
Capillary endothelium	49	26.4
Interstitial cells	66	35.8
Alveolar macrophages	7	3.9

Type I Alveolar Epithelial Cells

At first glance, the squamous type I cells show rather simple design features (Fig. 2-16). Their small, compact nucleus is surrounded by a slim rim of cytoplasm, where one finds a modest basic set of organelles, a few small mitochondria, and some cisternae of endoplasmic reticulum, seemingly the picture of a quiescent cell with no great metabolic activity.[11,73]

At the edge of the perinuclear region, a very attenuated cytoplasmic leaflet emerges (Fig. 2-16) and spreads out broadly over the basal lamina. This leaflet is made essentially of the two plasma membranes forming the apical and basal cell face, respectively, with a very small amount of cytoplasmic ground substance interposed (Fig. 2-17). Here one rarely finds any organelles except for the numerous plasmalemmal vesicles implied in the transcellular transport of molecules. In fact, besides capillary endothelial cells, type I alveolar epithelial cells are among the richest in caveolae.

TABLE 2-2 Morphometric Characteristics of Cell Population in Human Pulmonary Parenchyma

Cell Population	Percent of Total Cell Number[a]	Average Cell Volume (μm^3)	Average Apical Cell Surface (μm^2)
Alveolar epithelium			
Type I	8	1764	5098
Type II	16	889	183
Endothelium	30	632	1353
Interstitial cells	36	637	—
Alveolar macrophages	10	2492	—

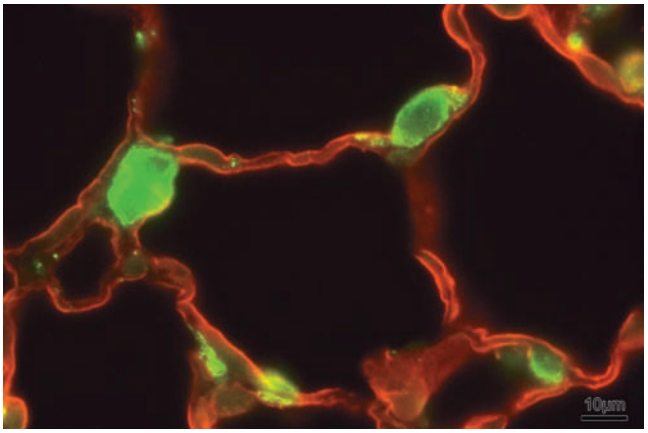

Figure 2-15 Immunofluorescent double labeling of alveolar epithelial cells. Type I cells are stained for Lycopersicon esculentum lectin *(red)*, type II cells are stained for SP-D *(green)*. Compare with Table 2-3. *(Micrograph used with permission of H. Fehrenbach.)*

The surface covered by one type I epithelial cell is about 4000 to 5000 µm^2. In some texts one may find the type I cell called the "small alveolar cell" because of its small nucleus; clearly this is a misnomer, as the type I cell is a rather large cell indeed, with respect to both surface and cell volume (Table 2-2). Terminal bars are formed where the cytoplasmic leaflets of epithelial cells meet (Fig. 2-18). If one looks at the surface of the alveolar epithelium in scanning electron micrographs (Fig. 2-19), one notes that the patches covered by single type I cells are variable in size and that even the largest are much smaller than the 4000 to 5000 µm^2 given earlier, a number derived by dividing the total alveolar surface by the total number of type I cell nuclei. Why is this? There seem to be three to four times as many type I cell domains encircled by terminal bars as there are nuclei. Indeed, this observation was already made some 130 years ago by Albert Kölliker; his interpretation was that part of the alveolar surface was lined by "nonnuclear" cytoplasmic plates rather than by complete cells. It turns out that an alternative explanation is possible. One finds that type I cells are not simple squamous cells but rather branched cells with multiple apical faces, as shown diagrammatically in Figure 2-20. Thus, what appears as nonnucleated plates are cytoplasmic domains connected to the perinuclear region by a stalk, spreading out on one side of the alveolar wall or the other; it is evident that several such domains may share a nucleus.[74]

Although type I cells cover about 97% of the alveolar surface area, they have long been neglected as being "silent," providing solely a barrier function. Although their overall function in the human lung remains to be determined, recent animal and in vitro studies strongly suggest that type I cells are actively involved in alveolar ion and fluid homeostasis.[75–77]

TABLE 2-3 Markers for Alveolar Epithelial Cells

Type I Cell	Type II Cell
HTI-56 (human)	Surfactant proteins:
T1α/RTI-40 (rat, mouse)	SP-A
Aquaporin 5	SP-B
Caveolin 1	SP-C
Receptors for advanced glycation end products	SP-D
(RAGE)	ABCA3
Carboxypeptidase M	HTII-280 (human)
Lectins:	RTII-70 (rat)
Lycopersicon esculentum	MMC4 (rat)
Bauhinia purpurea	Alkaline phosphatase
Ricinus communis 1	CD44
	Lectins:
	Maclura pomifera

These markers allow a selective distinction between type I and type II alveolar epithelial cells and can be visualized at a light microscopic level by immunohistochemistry, enzyme histochemistry, or lectin histochemistry. However, other cell types of the distal bronchiolar and alveolar region, e.g., Club cells, capillary endothelial cells, or alveolar macrophages, might also stain positive for some of these markers. Figure 2-16 A type I alveolar epithelial cell (EP1) from human lung. The nucleus (N) is surrounded by very little cytoplasm, which extends as thin leaflets *(arrows)* to cover the capillaries (C). Note the basement membranes (BM) of the epithelium and endothelium (EN), which become fused in a minimal barrier. Interstitial space contains fibroblast processes (F).

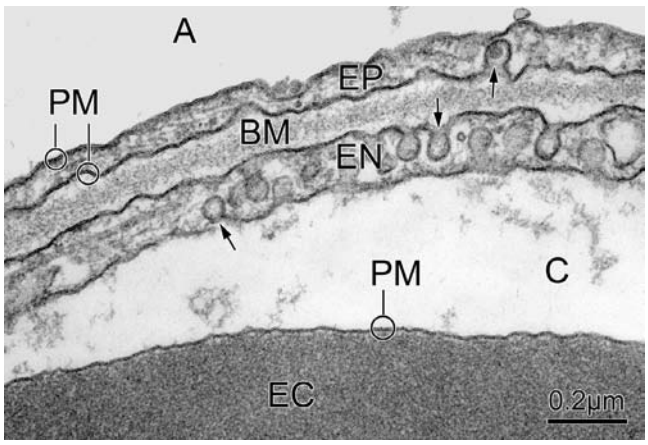

Figure 2-17 Thin, minimal tissue barrier between alveolar air (A) and capillary blood (C) is made of cytoplasmic leaflets of epithelium (EP) and endothelium (EN), joined by fused basement membranes (BM). Note that the epithelial and endothelial leaflets are bounded by plasma membranes (PM), as is the erythrocyte (EC). *Arrows* point to pinocytotic vesicles/caveolae. *(Reproduced with permission from Weibel ER: The Pathway for Oxygen. Cambridge, MA: Harvard University Press; 1984.)*

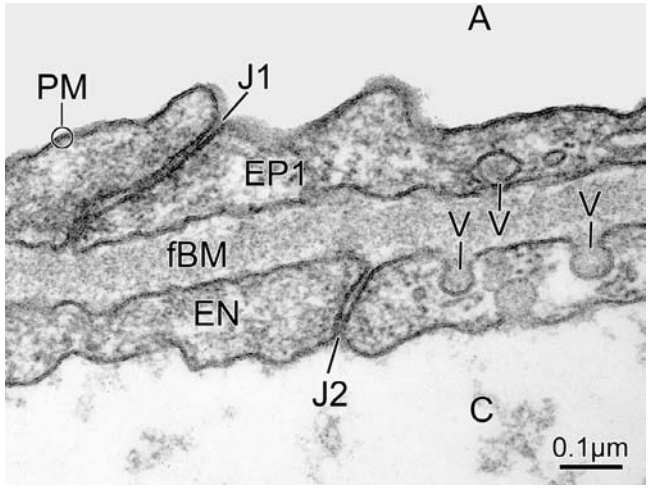

Figure 2-18 Minimal barrier part showing intercellular junctions. Between type I epithelial cells, a "tight" junction (J1) is formed by close apposition of the cell membranes over a comparatively wide band; the junction between endothelial cells (J2) is "leaky" because membranes become apposed over a narrow strip only. Note trilaminar structure of plasma membranes (PM), the occurrence of pinocytotic vesicles/caveolae (V) in both epithelium and endothelium (EN), and the fused basement membranes (fBM). A, alveolus; C, capillary; EP1, type I epithelial cell.

Type I cells are easily damaged, particularly because of their extensive surface area and their complex branching architecture. However, there is an additional problem: one finds that type I cells are not capable of multiplying by mitosis in vivo, neither during lung growth when more cells are needed to coat the expanding alveolar surface nor upon damage in the adult lung when cells need to be replaced. In both instances new type I cells are made by mitotic division and transformation of type II cells, a process that takes about 2 to 5 days.

This seems to work under normal circumstances. There are, however, conditions where this repair mechanism is too slow to cope with excessive damage, so that a syndrome of severe catastrophic

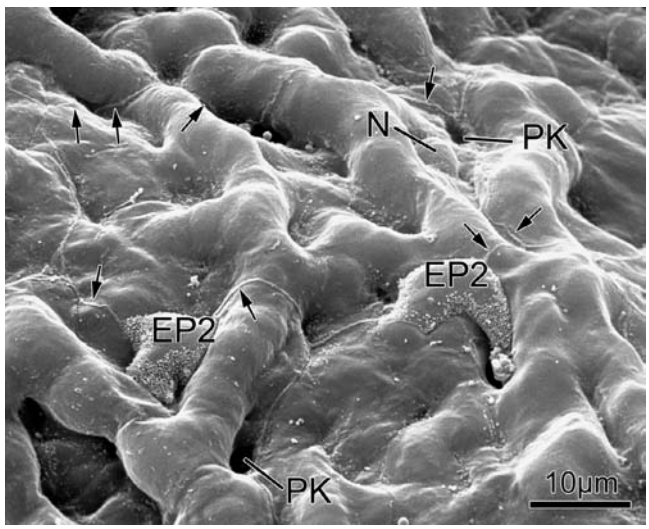

Figure 2-19 Surface of the alveolar wall in the human lung seen by scanning electron microscopy reveals a mosaic of alveolar epithelium made of type I and type II (EP2) cells. *Arrows* indicate boundary of the cytoplasmic leaflet of the type I cell which extends over many capillaries. Note the two interalveolar pores of Kohn (PK). N, nucleus of type I cell.

respiratory failure, acute respiratory distress syndrome (ARDS), develops, which requires intensive care treatment. In such patients one finds large parts of the type I cell lining of the alveolar surface to be destroyed. As a consequence, the barrier has become leaky and the alveoli fill with alveolar edema, so that they can no longer take part in gas exchange.[78,79]

With proper medical care, this alveolar edema can often be resolved within a few days. The alveoli become again filled with air, but in spite of this, gas exchange does not improve. What has happened is that the repair of the severely damaged alveolar epithelium requires a lot of new cells to be made by division of type II cells.[80] These form a rather thick cuboidal lining of the barrier surface, a phenomenon termed cuboidal metaplasia, and this thick barrier offers a high resistance to O_2 flow. It takes several weeks until a thin barrier is restored by transformation of the cuboidal cell lining into delicate type I cells. During this process, the cells go through intermediate stages where they are often positive for both type II and type I cell markers.[81,82]

Type II Alveolar Epithelial Cells

The type II alveolar epithelial cell is a conspicuous but in fact relatively small cell whose mean volume is less than half that of the type I cell (Table 2-2), although it is often called the "large alveolar cell."[11] Its shape is cuboidal, the apical cell surface bulges toward the lumen and is provided, mostly around its periphery, with a tuft of microvilli (Figs. 2-21 and 2-22). Often, type II cells seem to be preferentially located in the corners of alveoli or in

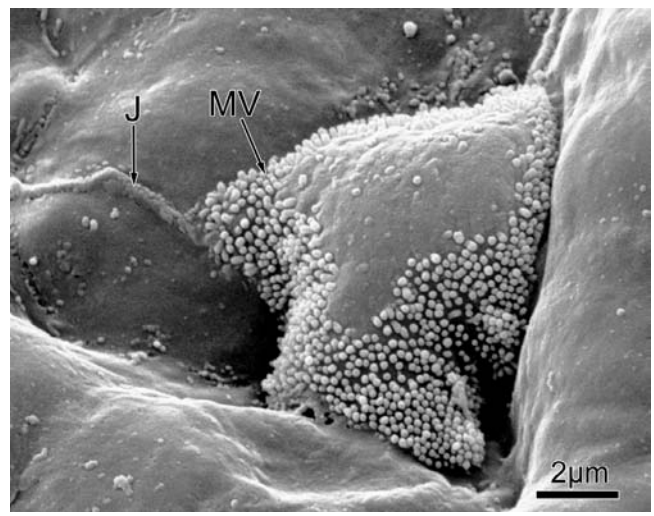

Figure 2-21 Higher magnification of a type II cell reveals a "crown" of short microvilli (MV) and a central "bald patch." Note junction lines of type I cells (J) meeting with the type II cell.

close proximity to interalveolar pores of Kohn. They are usually found as solitary cells; only in cases of alveolar epithelial damage, proliferation of type II cells leads to focal clusters during the repair process. Occasionally, a single type II cell might supply two or even three adjacent alveoli with its apical surface. The basement membrane beneath type II cells is occasionally interrupted. Through these apertures, foot processes of type II cells can extend to the interstitium and come in close proximity to interstitial cells.[83]

Type II cells contain a wealth of cytoplasmic organelles of all kinds (Fig. 2-22): mitochondria, a lot of endoplasmic reticulum with ribosomes, and a well-developed Golgi complex surrounded by a set of small lysosomal granules among which so-called multivesicular bodies – membrane-bounded organelles containing a group of small vesicles – stand out (Fig. 2-23). In addition, one finds the characteristic lamellar bodies, larger membrane-bounded secretory organelles that contain densely packed phospholipid lamellae. There are notable species differences in the ultrastructural organization of lamellar bodies. In rodents, the lamellae are mostly arranged in parallel stacks whereas in humans, concentrically arranged lamellae are mostly found, which are attached to a projection core consisting of randomly arranged short stacks of densely packed membrane segments (Fig. 2-24).[84] The periodicity of the lamellae is in the range of 4 to 6 nm. One human type II cell contains between 200 and 500 lamellar bodies, making up a total volume of about 2 cm^3 in the entire lung. With a diameter of approximately 1 µm, lamellar bodies are among the largest secretory organelles of all cells in the body. Owing to their equipment with lysosomal enzymes (e.g., acid phosphatase, cathepsins) and proteins (e.g., members of the lysosomal membrane protein (LAMP) family and their acidic pH of about 5.5, lamellar bodies are regarded as secretory lysosome-related organelles.[85]

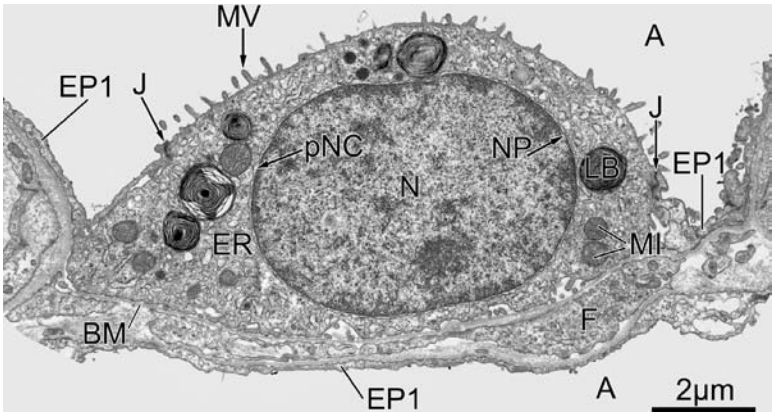

Figure 2-22 A type II epithelial cell from the human lung forms junction (J) with type I epithelial cells (EP1). Its cytoplasm contains osmiophilic lamellar bodies (LB) and a rich complement of organelles: mitochondria (MI), endoplasmic reticulum (ER), and so on. The nucleus (N) is surrounded by a perinuclear cisterna (pNC) which is perforated by nuclear pores (NP). A, alveolus; BM, basement membrane; F, fibroblast; MV, microvilli.

Type II cells have two main functions: they serve as the cellular source of pulmonary surfactant and they contribute to the regeneration of the alveolar epithelium under physiologic and pathologic conditions. These properties form the basis of the concept of the type II cell as the "defender of the alveolus."[86–88]

Surfactant prevents alveolar atelectasis by a surface area–dependent reduction of the alveolar surface tension (see below).[89–92] Another function of surfactant as a result of the reduction of alveolar surface tension is to prevent the formation of intra-alveolar edema.[93] In addition, certain surfactant components have important immunomodulatory functions in the innate host defense system.[94,95] Taken together, the main functions of surfactant might be summarized as to keep alveoli open, dry, and clean. Surfactant is composed of around 90% lipids, mainly saturated phosphatidylcholine, and around 10% proteins, including the surfactant apoproteins termed SP-A, SP-B, SP-C, and SP-D. Besides its biochemical complexity, surfactant is also morphologically very heterogeneous, consisting of different surfactant subtypes with highly organized structure that represent different stages in metabolism (Figs. 2-24–2-26).[84,96]

The alveolar epithelium (including interalveolar pores of Kohn) is lined by a thin but apparently continuous fluid layer inserted between the apical cell membrane and the surface film, thus forming a duplex lining layer.[97,98] Surfactant functions in and on this layer. It is synthesized, stored, secreted, and to a large extent recycled by type II cells.[84,87,99] Therefore, an intracellular surfactant pool present in type II cells and an intra-alveolar surfactant pool present at the surface of the fluid alveolar lining layer as well as within its hypophase can be distinguished. The intracellular storage form of surfactant is represented by lamellar bodies. Prior to storage, the synthesis of surfactant material involves endoplasmic reticulum, (at least partly) Golgi complex, and multivesicular bodies. In type II cells, multivesicular bodies participate in the posttranslational processing of surfactant proteins as well as in endocytosis and subsequent recycling and/or degradation of surfactant material; thus, most probably representing the junction point between the biosynthetic and endocytotic pathway. In addition, transitional forms between multivesicular bodies and lamellar bodies, termed composite bodies, have been described. Surfactant material present in lamellar bodies is secreted into the alveolar lumen via exocytosis (Figs. 2-25 and 2-26).

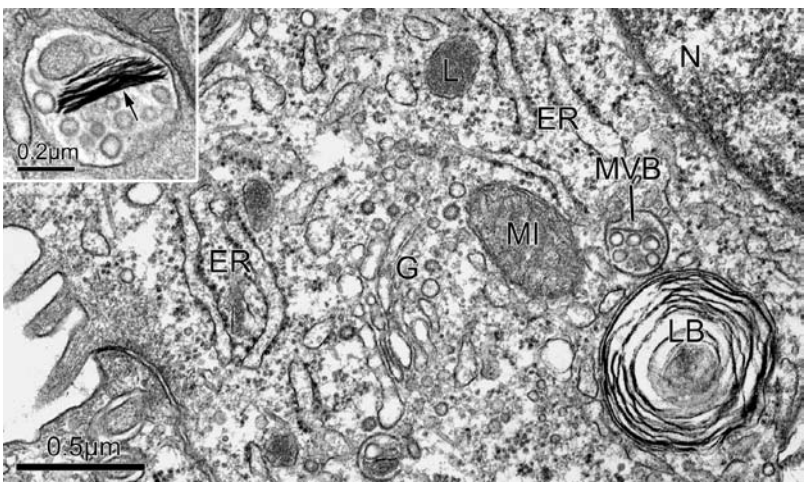

Figure 2-23 Cytoplasmic organelles of the type II cell implicated in the synthesis of surfactant are the endoplasmic reticulum (ER), Golgi complex (G), lysosomes (L), multivesicular bodies (MVB), and finally lamellar bodies (LB). The *inset* shows a large composite body with a stack of phospholipid lamellae *(arrow)*. N, nucleus. *(Reproduced with permission from Weibel ER: The Pathway for Oxygen. A

B

Figure 2-24 Immunogold labeling for SP-A (5-nm gold particles) and SP-B (15-nm gold particles) in the human lung. **A.** Within type II cells, SP-B is localized in the projection core (PC) of lamellar bodies (LB). **B.** In the alveolar lumen, SP-A is associated with tubular myelin figures (TM) whereas SP-B is found in the projection core (PC) of freshly secreted lamellar bodies (LB) and dense core particles *(arrow)* close to tubular myelin. UV, unilamellar vesicle.

Most surfactant components are assembled in lamellar bodies prior to secretion (Figs. 2-24–2-26)—at least the lipid fraction and the hydrophilic surfactant proteins SP-B and SP-C, whereas the hydrophilic surfactant proteins SP-A and SP-D seem to be secreted independently via a constitutive pathway bypassing the regulated exocytosis of lamellar bodies. Lamellar body secretion starts with the fusion of its limiting membrane with the apical plasma membrane, followed by formation of a fusion pore, and finally the slow release of surfactant material through the pore. The diameter of the pore is considerably smaller than that of the lamellar body. Thus, surfactant seems to be squeezed through the pore.[100] The mechanisms that regulate surfactant secretion in vivo are still not fully elucidated. It seems that, among the various stimuli that can act via several different signaling pathways, mechanical stretch during ventilation – either as a direct effect on type II cells or indirectly via type I cells or capillary endothelial cells which may act as "strain sensors" – is the physiologically most relevant.[87,99,101,102]

Intra-alveolar surfactant consists of several subtypes, namely freshly secreted lamellar body-like forms, tubular myelin, the surface film, and small unilamellar vesicles. After secretion, lamellar body-like forms in the hypophase associate with SP-A, which is separately secreted by type II cells,[103] and undergo a major

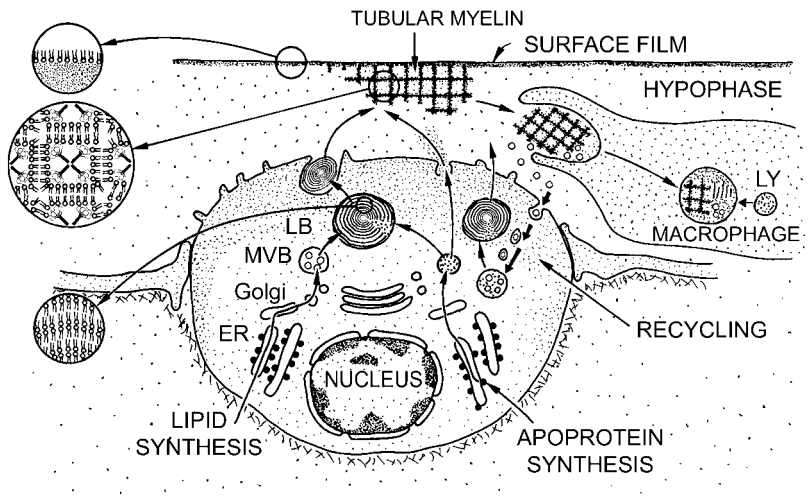

Figure 2-25 Schematic diagram of pathways for synthesis and secretion of surfactant lipids and apoproteins by a type II cell, for their recycling by type II cells, and for their removal by macrophages. Note the arrangement of phospholipids and apoproteins in the lamellar bodies, in tubular myelin, and in the surface film. *(Reproduced with permission from Weibel ER: The Pathway for Oxygen. Cambridge, MA: Harvard University Press; 1985.)*

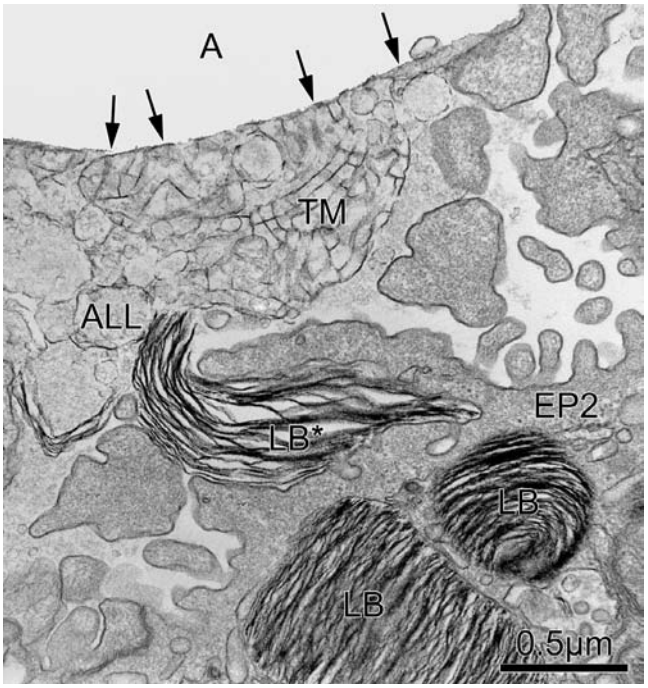

Figure 2-26 Apical part of type II cell (EP2) with lamellar bodies (LB); one of these (LB*) is seen in the process of being secreted into the alveolar surface lining layer (ALL). The free surface of the lining layer is covered by a thin black film of lipids *(arrows)*, which is connected with tubular myelin (TM) in the hypophase. *(Reproduced with permission from Weibel ER, Gil J: Structure-function relationships at the alveolar level, in West JB, ed.: Bioengineering Aspects of the Lung. New York: Springer-Verlag; 1977.)*

structural transformation into tubular myelin figures with a unique lattice-like structure.[104] The precise physiologic function of tubular myelin, however, is still unclear. Tubular myelin is thought to be the immediate precursor of the surface film, although the existence of an additional multilayered surface-associated surfactant reservoir underneath the surface film has been suggested.[96,105] "Spent" surfactant components are found in the hypophase as small unilamellar vesicles. The major route of surfactant clearance is reuptake by type II cells. Within type II cells, surfactant material can either be recycled or degraded. Other routes of surfactant clearance include ingestion and lysosomal degradation by alveolar macrophages and clearance via the airways.

After differential centrifugation of intra-alveolar surfactant material harvested by bronchoalveolar lavage, surface active large aggregates (LA), ultrastructurally largely corresponding to lamellar body-like forms and tubular myelin, and inactive small aggregates (SA), ultrastructurally largely corresponding to unilamellar vesicles, can be distinguished. Thus, the SA/LA ratio can be used to assess the biophysical activity of surfactant.[90,91]

A surfactant film, most likely mainly transported upward from the alveoli, is also present in the airways. Here, surfactant prevents collapse of smaller airways, prevents transepithelial fluid influx, enhances mucociliary transport, and interacts with inhaled pathogens and particles. At least some of the surfactant proteins are also synthesized and secreted by club cells. Club cells express SP-B, but not SP-C, which is exclusively expressed by type II cells. There is some controversy whether club cells express SP-A and SP-D. Although this is obviously the case in rodents, club cells in the normal adult human lung most likely express very low or no SP-A and SP-D.[103,106,107] It seems that club cells are not involved in reuptake or recycling of surfactant components.[108] However, their overall role in surfactant biology is not yet defined.

The surfactant apoproteins as the "smart molecules in the surfactant system"[109] have important functions in surfactant subtype assembly, surfactant biophysics, surfactant homeostasis, and innate immunity.[110–114] The hydrophilic proteins SP-A and SP-D belong to the collectin protein family involved in innate immunity. In addition, SP-A, together with SP-B, is important for tubular myelin formation, thus stabilizing active surfactant forms, whereas the hydrophobic proteins SP-B and SP-C and, in conjunction, SP-A enhance the adsorption of phospholipids into the surface film. SP-A might also inhibit surfactant secretion and stimulate surfactant reuptake by type II cells.

Differences in the ultrastructural organization of intracellular and intra-alveolar surfactant subtypes between humans and rodents are also reflected by a different distribution of surfactant proteins (Fig. 2-24).[84] In the human lung, SP-A within type II cells is mainly found in small vesicles and multivesicular bodies and only rarely at the periphery of lamellar bodies. In the alveolar lumen, SP-A is associated with peripheral membranes of lamellar body-like forms in close proximity to tubular myelin, in the corners of the tubular myelin lattice structure, and partly at the surface film and unilamellar vesicles.[103] SP-B in the human lung is localized in the projection core of lamellar bodies within type II cells and in dense core particles associated with tubular myelin in the alveolar lumen.[115]

The crucial role of the surfactant system for the maintenance of the functional integrity of the lung is clearly demonstrated by surfactant dysfunction disorders, which can be caused either at birth by developmental deficiency (owing to lung immaturity or mutations affecting surfactant synthesis or secretion) or later by acquired dysfunction (owing to damage of type II cells or inhibition/inactivation of intra-alveolar surfactant).[90,91,116] A primary deficiency of surfactant in the immature lungs causes the respiratory distress syndrome of premature neonates (RDS). Surfactant dysfunction mutations causing either acute respiratory failure or chronic lung disease after birth have been identified in the genes encoding for SP-B, SP-C, and the ATP-binding cassette transporter ABCA3, which is present at the limiting membrane of lamellar bodies. Impairment of an originally intact surfactant system is involved in the pathogenesis of a variety of other lung diseases, such as acute lung injury/ARDS as well as obstructive, infectious, and interstitial lung diseases. Mechanisms leading to impaired surfactant activity include apoptotic or necrotic cell death of type II cells, damage of surfactant proteins and lipids by reactive oxygen and nitrogen species, and enzymatic damage by phospholipases or neutrophil elastase. In addition, plasma proteins entering the alveolar space during edema formation are also known to inactivate surfactant.

With a turnover time of about 4 to 10 hours and only a rather small intracellular surfactant reserve available for secretion onto the large alveolar surface, the ability to cope with a lack of active surfactant during lung injury is limited. Hence, there is a rationale to supplement the surfactant material available in cases of surfactant deficiency or damage. One of the major advances in neonatology in our time has been the development of surfactant replacement therapy for the treatment of RDS. The story of the treatment of premature babies with exogenous surfactant is indeed a paradigmatic example in which discoveries from basic research were successfully applied to an important clinical problem.[91,117–119] The indications for surfactant replacement therapy have widened in recent years, with promising results in forms of respiratory failure not caused by a primary deficiency of endogenous surfactant but rather by impairment of an originally intact surfactant system. In these cases, however, the efficacy of exogenous surfactant therapy very much depends on the ability of the surfactant preparation to resist the inhibition/inactivation that caused alterations of the endogenous system.

■ CAPILLARY ENDOTHELIUM

The alveolar septa of the adult lung contain a single capillary network. The capillary endothelium is of the continuous (non-fenestrated) type. Alveolar capillaries are provided with pericytes, but they are rarer and less densely branched than pericytes of the systemic circulation.[120] Pericytes are related to vascular smooth muscle cells in that they both are contractile perivascular cells. Thus, pericytes protect microvessel wall integrity by providing some mechanical support. However, in contrast to vascular smooth muscle cells, pericytes are embedded within the endothelial basement membrane, frequently forming contacts with capillary endothelial cells. They seem to contribute components to the capillary basement membrane and extracellular matrix and secrete vasoactive substances. In addition, pericytes are thought to be involved in the regulation of endothelial cell proliferation and differentiation and to act as progenitor cells for other cell types.[121–124]

Capillary Endothelial Cells

At first glance, capillary endothelial cells resemble type I alveolar epithelial cells, but in contrast to type I cells with their complex branching architecture, capillary endothelial cells form simple sheets (Fig. 2-27).[57] Moreover, compared with the tight occluding junctions between alveolar epithelial cells that constitute a powerful seal of the intercellular cleft, the occluding junctions between capillary endothelial cells are rather leaky, allowing a nearly uninhibited exchange of water, solutes, and even some smaller macromolecules between the blood plasma and the interstitial space (Fig. 2-18). Occluding junctions between capillary endothelial cells are often located at the transition of the thin to the thick part of the air–blood barrier and are often covered by pericytes.

There is another notable and important difference between the two basically similar lining cells on the epithelial and endothelial side of the gas-exchange barrier: their size. Although the capillary surface is some 10% to 20% smaller than the alveolar surface, the capillary endothelial cells are about four times more numerous than type I cells[72]; this means that the surface covered by one type I epithelial cell must be about four times larger, namely 4000 to 5000 μm^2, as compared with about 1000 μm^2 in endothelial cells (Table 2-2).

Numerous caveolae are found in capillary endothelial cells (Figs. 2-17 and 2-18). However, at the bulging part of the capillaries, some parts of the endothelial cell extensions are free of caveolae and are thinned down to a thickness of about 20 to 30 nm, basically consisting of the two plasma membranes with only a minute amount of cytoplasm in between. These areas, rarer in human lungs than in rodents, are termed the avesicular zone of the alveolar capillary endothelium.[11,57] In contrast to the endothelium of conducting vessels, Weibel–Palade bodies are missing in capillary endothelial cells, thereby underscoring the structural and functional differences between alveolar and extra-alveolar endothelial cells.[11,49,125,126]

■ INTERSTITIUM

The interstitium of the alveolar septum is for the most part extremely thin. At the thick parts of the air–blood barrier where epithelial and endothelial basement membranes are separated, one finds elastic fibers and bundles of collagen fibrils in the extracellular matrix as well as interstitial cells, mainly fibroblasts, the cells responsible for production of extracellular matrix components (Figs. 2-28 and 2-29).

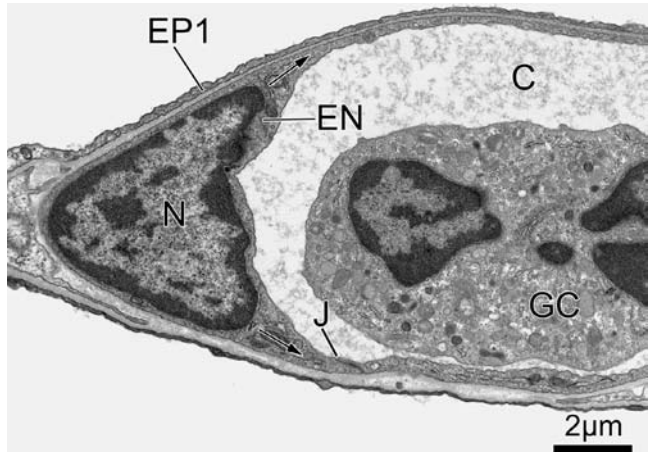

Figure 2-27 An endothelial cell (EN) of capillary (C) is similar in basic structure to a type I epithelial cell (EP1). The nucleus is enwrapped by little cytoplasm but thin leaflets extend as capillary lining *(arrows)*. Note the intercellular junction (J) and a white blood cell/granulocyte (GC), in the capillary. *(Modified with permission from Weibel ER: The Pathway for Oxygen. Cambridge, MA: Harvard University Press; 1984.)*

The precise arrangement of the connective tissue fibers will be discussed later in relation to the mechanical properties of the lung.

Interstitial Cells

The resident interstitial cells of the alveolar septum comprise fibroblasts and contractile cells (myofibroblasts, lipofibroblasts, smooth muscle cells, and pericytes) (Fig. 2-28). Free interstitial cells are part

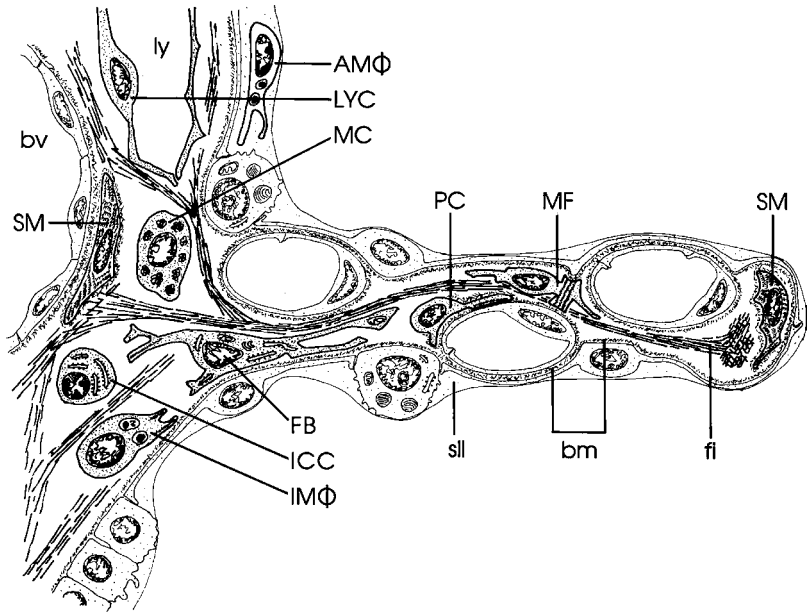

Figure 2-28 Schematic diagram of the structural organization of the alveolar interstitium. The alveolar septum extends between a free edge *(right)* and a perivascular connective tissue sleeve *(left)*, enwrapping a blood vessel (bv). Basement membranes (bm) are associated with epithelium and endothelium, and they bound the interstitial space. Fiber strands (fi) form a continuum. Interstitial cells include: fibroblasts (FB), myofibroblasts (MF), smooth muscle cells (SM), pericytes (PC), various kinds of immune competent cells (ICC), mast cells (MC), lymphatic endothelial cells (LYC), and histiocytes or interstitial macrophages (IMΦ). Alveolar macrophages (AMΦ) are submerged in the alveolar surface lining layer (sll), ly, lymphatic capillary. *(Reproduced with permission from Weibel ER, Crystal RG: Structural organization of the pulmonary interstitium. of the defense system usually found in the juxta-alveolar connective tissue sleeves (see below) and include interstitial macrophages (histiocytes), mast cells, and under certain conditions, lymphocytes, plasma cells, and granulocytes.

Fibroblasts are a heterogeneous cell population. Many fibroblasts have notable contractile properties; therefore, they have been termed myofibroblasts. Myofibroblasts contain bundles of microfilaments anchored in patches beneath the plasma membrane. These filament bundles span the entire width of the cell. At the places where the microfilament bundles are connected to the plasma membrane, attachments to the epithelial and/or endothelial basement membrane exist.[11,127,128] Through holes in the basement membranes, myofibroblasts directly link alveolar epithelial and capillary endothelial cells.[83]

Some contractile fibroblasts are equipped with nonmembrane–bound lipid bodies, thus termed lipid interstitial cells or lipofibroblasts.[129,130] These cells are more common in rodent than in human lungs and occur particularly during alveolar development and growth. Lipid bodies consist of an osmiophilic rim of amphipathic phospholipids, glycolipids, sterols and specific proteins, and a hydrophobic core of neutral lipids. In many cell types, lipid bodies represent specialized domains for the synthesis of eicosanoid mediators.[131] Pulmonary lipofibroblasts seem to be related to the lipid-containing perisinusoidal cell (Ito cell) in the liver in that they might serve as a storage depot for retinoids.[130,132] Under certain conditions, lipofibroblasts might provide fatty acid substrates for surfactant synthesis in type II cells.[130]

The occurrence of smooth muscle cells in the alveolar septa is mostly restricted to the free septal edges where they contribute to the network of alveolar entrance rings (Figs. 2-28 and 2-29). Pericytes abut alveolar capillaries (see above).

STRUCTURAL ASPECTS OF THE DEFENSE SYSTEM OF THE LUNG

The large and delicate alveolar surface is constantly challenged by inhaled microorganisms and particulate matter. Thus, normal lung function critically depends on an efficient defense system.[94,113,133–136] At the alveolar level, the primary defense barrier is the alveolar lining layer. Here, alveolar macrophages are the sentinel phagocytic cells of the innate immune system, as we shall discuss later. In addition, protein components of the innate immune system, including the lung collectins SP-A and SP-D as well as a variety of other antimicrobial peptides (e.g., lysozyme, lactoferrin, defensins, cathelicidins), are present in the alveolar lining layer.

Another set of macrophages forms a second defense line just beneath the alveolar epithelium; that is, in the interstitial space of the lung parenchyma. In the normal lung, these interstitial macrophages (histiocytes) are not found in alveolar septa; instead, they occur only in the connective tissue sleeves at the periphery and in the center of acini where the peripheral fiber system connects with the adventitial sheath of bronchioles and pulmonary arteries (Fig. 2-30). Thus, they are found in regions where lymphatics begin their course toward the major airways in the hilar region where lymph nodes are found. In these juxta-alveolar regions of connective tissue, we usually find the common elements of the defense system (Figs. 2-30 and 2-31). These include lymphatic vessels and several mobile cells. Interstitial macrophages are constantly being replenished by blood monocytes migrating into the interstitial space. Sometimes they become permanent residents in the form of storage cells for "indigestible" foreign matter, such as carbon particles and silicates. The relationship

between interstitial macrophages and dendritic cells (see below) is under discussion.[137,138] Lymphocytes are less common and are mostly present as T cells whereas B cells and natural killer cells are rare in the normal lung. Granulocytes (neutrophils, eosinophils, and basophils) are present in the human lung, but they are also very rare. Mast cells contain granules storing heparin and histamine as well as peptidases such as tryptases and chymases[139] that, in the human, show a characteristic scroll-like substructure (Fig. 2-32) as well as lipid bodies. According to their anatomic location, they show site-specific characteristics, thus displaying considerable heterogeneity.[140] Antigen-presenting dendritic cells possess long branched dendritic cell processes (hence, their name) and an irregular, folded nucleus. Phagolysosomes are absent. Once activated, dendritic cells migrate to lymph nodes where they induce the proliferation of antigen-specific T cells; thus, providing a link between innate and adaptive immunity. In addition to their presence within the lung parenchyma, dendritic cells are found within the tracheal and bronchial epithelium where they seem to form a network comparable to the Langerhans cells in the epidermis. Like Langerhans cells, airway dendritic cells are characterized by pentalaminar plate-like organelles (Birbeck granules).[141–143] In the ciliated epithelium of bronchi and bronchioles diapedesis is seen; that is, lymphocytes and other leukocytes in the process of penetrating the epithelium to reach the mucus blanket. Plasma cells occur in relatively high numbers around the acini of the seromucous glands of bronchi (Fig. 2-7); hence, it is likely that antibodies are being secreted into the mucus blanket by these glands by a process similar to that occurring in the salivary glands or in the glands of the nasal mucosa.

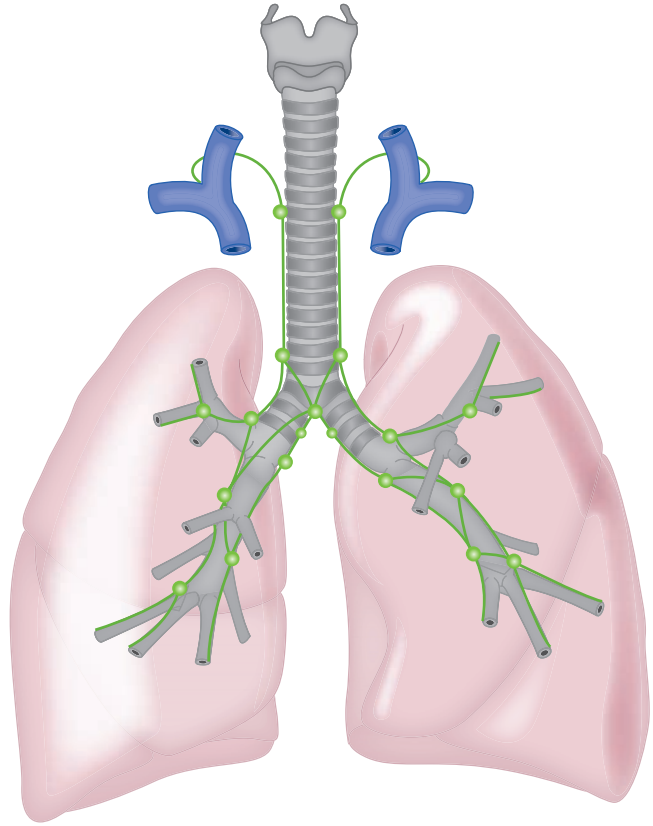

Figure 2-33 Schematic diagram of distribution of lymph nodes and main lymphatic channels along bronchial tree.

The third defense line is constituted by the lymph nodes, which are arranged along the major bronchi and extend to subsegmental bronchi about 5 mm in diameter (Fig. 2-33). The most peripheral lymph nodes are tiny, a mere 1 to 2 mm in diameter, but closer to the hilum they become larger, reaching 5 to 10 mm in diameter in the region of the tracheal bifurcation and along the trachea. The lymph nodes from adult human lungs often appear gray or even black because of deposition in the medullary cords of large numbers of macrophages loaded with carbon pigment. This material entered the lung via the airways, primarily as smoke, soot, or coal dust; depending on the size of the particles, they were either deposited on the surface of conducting airways or reached the alveoli. The further down the deposition, the greater the likelihood that this material cannot be eliminated while in the airways, that is, within the mucus blanket. The only exit from the lung parenchyma then is via the lymphatics, but this exit ultimately leads to the blood, a circumstance that is obviously to be avoided. Filtering the lymph in lymph nodes and providing a depository in the medullary cords protects the blood and hence the entire organism from dissemination of indigestible foreign matter and also, in most instances, of infective agents.

Thus, the lymphatic "circulation" in the lung plays an important defense role.[6,42] It is unidirectional. It begins as interstitial fluid that seeps from the capillaries and is efficiently drained along the connective tissue fibers toward those connective tissue sleeves in the center and at the periphery of acini where lymph capillaries begin. From there, lymphatic vessels, endowed with valves and an irregular smooth muscle wall, course in septal structures, in the pleura, and peribronchial and perivascular sheaths toward the hilar region (Fig. 2-33). Lymph nodes are intercalated in the course of the lymphatics, which lead the lymph toward the tracheal bifurcation and then along the trachea into the right and left mediastinal lymph channels. The right channel drains into the right subclavian vein;

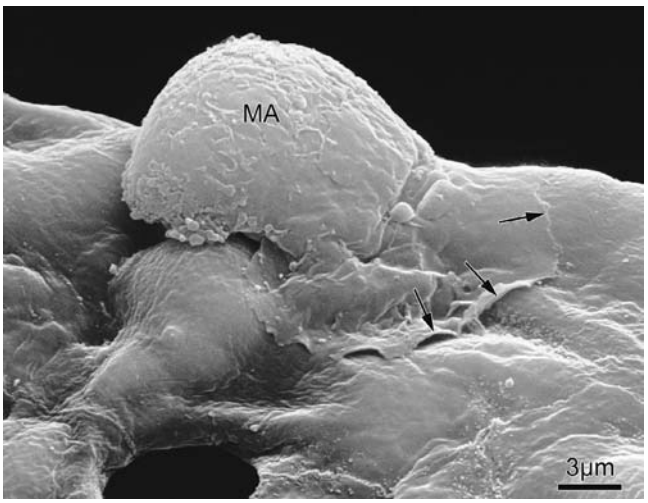

Figure 2-34 Alveolar macrophage (MA) seen sitting on epithelial surface of human lung. Note cytoplasmic lamella *(arrows)* which represents the advancing edge of the cell.

the left, together with the thoracic duct, into the left subclavian vein. Because of the many anastomoses connecting parallel lymphatics, a particular lymph node receives lymph from various lung regions, but the closest regions tend to predominate.

■ ALVEOLAR MACROPHAGES

Lung macrophages can be differentiated into several populations according to the compartment they are found in: intravascular, interstitial, airway, and alveolar macrophages.[144–146] Of these, the alveolar macrophages, the cell population of the surface lining layer, are of particular importance. They are free cells, endowed with a high phagocytic capacity, which are transiently attached to the surface of the alveolar epithelium by pseudopodia and can crawl over this surface by amoeboid movement (Fig. 2-34). Occasionally, alveolar macrophages can be observed during the passage through an interalveolar pore of Kohn. However, they are submerged beneath the surface film of phospholipids (Fig. 2-35) and, therefore, are part of the surface lining layer of alveoli, more specifically of its hypophase. Alveolar macrophages exert their phagocytic activity within the surface lining layer (Fig. 2-25). Hence, it is not surprising that their vacuoles contain large amounts of ingested surfactant material, in part even tubular myelin. The importance of alveolar macrophages for surfactant removal is underscored by the acquired form of pulmonary alveolar proteinosis, where a defect in surfactant catabolism by alveolar macrophages caused by autoantibodies against granulocyte/macrophage colony-stimulating factor (GM-CSF) leads to an accumulation of surfactant material in the alveoli.[147]

Alveolar macrophages are derived from monocytes – indirectly, therefore, from bone marrow cells – and probably reach the alveoli in two steps: first, by settling in the pulmonary interstitial tissue, and second, by migration from the interstitial tissue into the alveoli where they constitute a partly self-reproducing cell population. Their removal seems to involve two different pathways: (1) some of the macrophages undoubtedly move up the bronchial tree in the mucus blanket and eventually appear in the sputum; and (2) others possibly return into the interstitial space. In the normal lung, however, the second path seems to occur exclusively in those alveoli that abut the connective tissue sleeves around larger vessels and conducting airways or on interacinar septa; that is, where the lymphatic capillaries are located. A preferred location appears to be in the respiratory bronchioles at the entrance into the acinus or in the center of the acinus, where one often finds congregations of dust-laden macrophages; this may be at the origin of centroacinar damage observed in smokers, which lead to progressive emphysema. In these places, macrophages either settle as carbon pigment-loaded histiocytes, or they leave the lung parenchyma via lymphatics (Fig. 2-31) to settle in the lymph nodes. The way in which macrophages and/or their ingested material are transferred from the alveolar surface to the interstitial space is still unknown.

FUNCTIONAL DESIGN OF THE LUNG

From the preceding section it has become apparent that the lung is built of a multitude of cells and tissue elements that all serve specific functions in support of the lung's main function: the exchange of oxygen and carbon dioxide between the air and the blood. But it takes more than cells to make a good lung.[148] The lung's multiple component structures must be integrated to make an efficient and stable gas exchanger, and this demands a blueprint for the integral architecture of the human lung.[7] This must first ensure that the airways and blood vessels are adequately correlated topologically and quantitatively to allow well-matched ventilation and blood flow. It must also realize a complex organization that allows air ventilation, blood perfusion, and gas exchange to function in the most efficient manner. The design principles that govern the architecture of the human lung toward that goal can be characterized as *Complexity, Correlativity, and Connectivity*. Complexity means that the microscopic gas-exchange units are an integral part of the macroscopic airways and vessels; their architectural correlation determines the efficient approximation of air and blood in the gas exchanger; and connecting all the parts into a whole is achieved with a fiber continuum that pervades the entire lung. The implementation of these principles during development is decisive for "making a good lung."

■ DESIGN OF THE BRANCHING AIRWAY TREE

The entrance to the lung's airways is the trachea (Fig. 2-3), a single tube, the gas-exchange elements where air and blood are brought into close contact are contained in several million units. Between entrance and periphery lies a meticulously designed system of branching airways that serve to conduct the inspired air into those peripheral channels that carry alveoli in their walls and can thus contribute to the exchange of gases between air and blood (Fig. 2-5).[8]

In the mammalian and human lung the airways are built as dichotomous trees.[149] This is the result of lung morphogenesis where the end bud of each airway tube gives rise to two daughter branches. In the human lung this goes on for 23 generations, on average, and, since the number of branches doubles with each generation, there are 2^{23} or about 8 million end branches, generally called alveolar sacs.[8] This is an average value; in reality the number of branching generations needed to reach the alveolar sacs is quite

variable, ranging from about 18 to 30. This variability results from the fact that the airways form a space-filling tree (Fig. 2-3) whose endings must be homogeneously distributed in space and reach into every corner and into every gap in the available space, determined by the form of the chest cavity into which the lung develops. Some spaces are filled rapidly and the airways cannot continue to divide, whereas in other places more branches are needed to fill the space.

This branching process is accompanied by growth in length and diameter of the airway segments, the tubes between the branching nodes. The length of the tubes is adjusted to cover the distances needed to fill the space homogeneously with endings, whereas the diameter is, grossly speaking, made proportional to the volume of peripheral lung that is supplied by this branch.

Figure 2-36 shows a portion of a cast of the airway tree from a human lung. It is evident that the airways branch by dichotomy and that the length and the diameter of the tubes become gradually reduced with each generation. At first sight, the airway branching seems quite regular, but there is a certain degree of asymmetry in the sense that the two daughter branches differ in length and diameter; in animal lungs asymmetry is more pronounced than in human lungs.

Despite asymmetric branching some general rules govern the progression of dimensions along the tree. The diameter of daughter branches is smaller than that of the parent in the sense that the diameter reflects the volume of peripheral lung it supplies with air: larger airways serve larger lung units, smaller airways smaller units. The progression of airway diameters follows the law of Hess (1917)[150] and Murray (1926)[151] that, in a dichotomous tree, the diameters of the daughter branches, d_1 and d_2, are related to the parent branch d_0 as:

$$d_0^{\,3} = d_1^{\,3} + d_2^{\,3}$$

a law that predicts optimization of the airway diameters for convective air flow, providing lowest resistance for lowest dead space.

For a symmetric tree in which $d_1 = d_2$ this becomes:

$$d_1 = d_0 \cdot 2^{-1/3}$$

which means that the airway diameter becomes reduced by a factor of cube root of 1/2 or about 0.79 with each generation. Considering the progression of airway dimensions along the tree this law should apply to all successive generations so that we predict the average diameter in generation z to be:

$$d(z) = d_0 \cdot 2^{-z/3}$$

Figure 2-37 shows that this is approximately the case for the first 14 generations of conducting airways.

However, a closer look at the airways of the human lung shows that this is only approximately correct.[152] It appears that the smaller bronchioles (beyond generation 10) are provided with some safety factor in that the diameter is reduced by a factor of 0.83 rather than the physically optimal 0.79. This allows regulation of airway cross-section by contraction of the bronchiolar muscle sleeve without unduly increasing flow resistance which is very low in small airways (Fig. 2-38).[153] Design optimization is limited in favor of physiologic robustness.

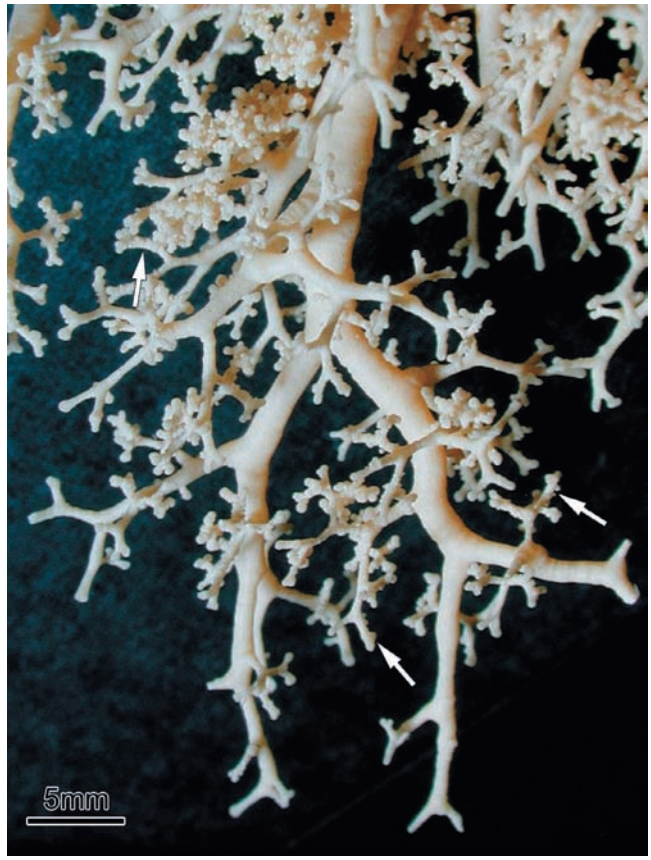

Figure 2-36 Peripheral portion of cast of human airway tree reaching out to the transitional bronchioles and some respiratory bronchioles *(arrows)*.

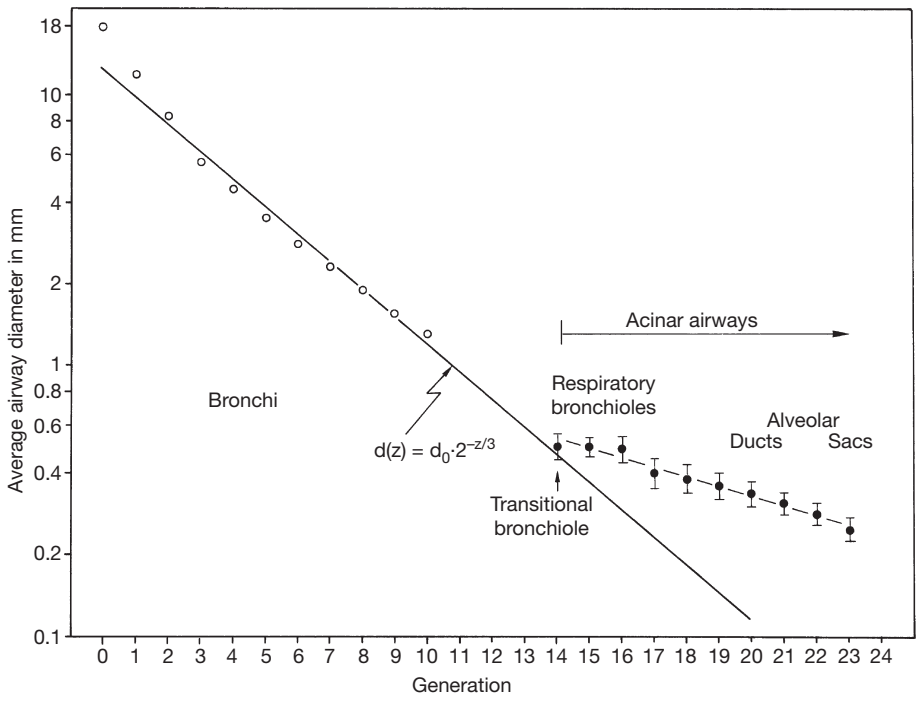

Figure 2-37 Average diameter of airways in human lung plotted by generations of regularized dichotomous branching. *(Reproduced with permission from Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec. 1988;220(4):401–414.)*

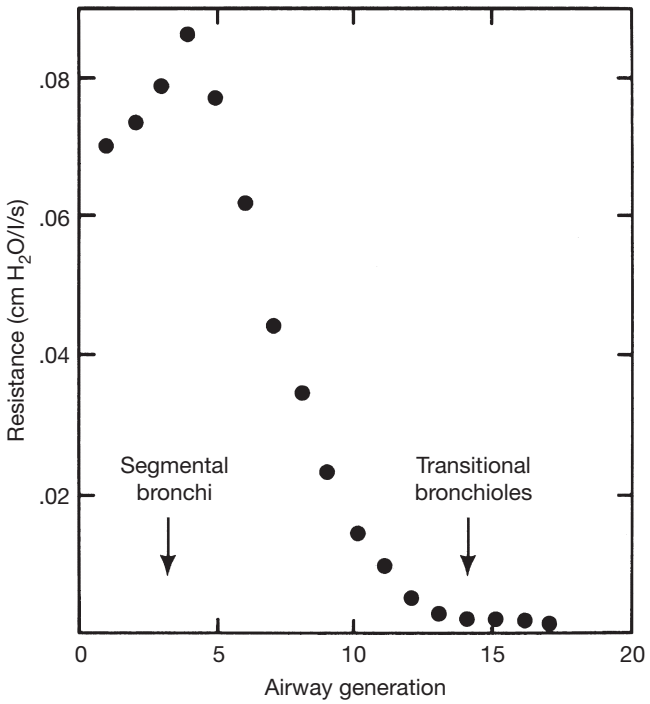

Figure 2-38 Airway resistance to mass air flow is located mostly in the conducting airways and falls rapidly toward the periphery. *(Redrawn with permission from Pedley TJ et al. The prediction of pressure drop and variation of resistance within the human bronchial airways. Respir Physiol. 1970;9(3):387–405.)*

This symmetric airway model reflects the typical pathway along the airway tree. It has been very useful in modeling the basic rules governing the distribution of air flow as well as the deposition of particles entering the lung. However, it disregards the effects of asymmetric branching. It is possible to construct models that take into account irregularities in branching, for example by considering the number of airways of a given diameter, d_u, that exist in each generation, and the length of the bronchial pathway that intervenes between the larynx and particular airways (Fig. 2-39).[8,154]

An alternative approach is to regard the airways as a system of tubes converging from the periphery, the acinus, toward the center, the trachea.[155] By using an ascending ordering system that is employed in analyzing rivers (Strahler system), branches are grouped into orders according to the sequence of convergence, beginning with the smallest most peripheral branches, designated as order l. This ordering pattern is particularly well adapted to a system of irregular dichotomy because the size of branches in one order varies less than with the generations-down model. This approach does not really account for the asymmetry of branching, however; it rather represents an attempt at extracting average data with less variability in each order. The degree of asymmetric branching is reflected in the branching ratio determined as the ratio of the number of branches in order μ to that in order $\mu + 1$. Remarkably, the progression of diameters through the various orders is again roughly proportional to the cube root of the branching ratio. Hence, from a functional point of view both models yield comparable results.

The general conclusion drawn from this type of analysis is that the diameters of the conducting airways are such as to assure optimal conditions for airflow but relaxing physical optimality conditions in the interest of physiologic robustness; the airways of the lung are thus well designed. The total volume of the conducting airways down to generation 14 (the anatomic dead space) is about 150 mL; it is rapidly flushed by simple gas flow in the course of inhaling 500 mL of fresh air during quiet inspiration. Therefore, for the larger airways, optimization for flow and its distribution to peripheral units are essential for good design.

These are the characteristics of the proximal airways built as smooth-walled tubes to distribute convective air flow into the lung. This design ends more or less abruptly when the airways reach lung parenchyma, the complex of alveoli that are arranged around peripheral airways (Fig. 2-40). The airway tree is thus subdivided into two major functional zones (Fig. 2-5): the first about 14 to 16 generations, on average, are designed as conducting airways where air flow is by convection; this is followed by about 8 generations of acinar airways where an axial channel, called alveolar duct, is enwrapped by a sleeve of alveoli with gas-exchange tissue on their surface.

In the human lung the transition is not abrupt. At some point the smooth bronchiolar wall becomes interrupted by one or two alveoli (Fig. 2-41). This so-called transitional bronchiole (Fig. 2-5) marks the entrance into an acinus.[9] It is followed by some three generations of respiratory bronchioles where an increasing fraction of the wall surface is occupied by alveoli, until the alveolar ducts are reached where the central air duct is completely surrounded by alveoli (Fig. 2-42). These acinar airways continue to branch by dichotomy. Their length and diameter decrease with each generation, but the slope does not follow the law of reduction by the cube root of 1/2; the diameters of respiratory bronchioles and alveolar ducts change very little with each generation.[9] Does this arrangement imply less than an optimal design? On the contrary, the cube-root-of-1/2 law relates to optimizing mass flow of a liquid or air. In the most peripheral airways, mass airflow is only part of the means of transporting O_2 toward the air–blood barrier. Since the airways are blind-ending tubes and since a sizable amount of residual air remains in the lung periphery after expiration, O_2 molecules must move into the residual air by diffusion (Fig. 2-43). However, diffusion of O_2 in the gas phase is best served by establishing as large an interface as possible between residual air and the fresh air that flows in from the trachea.[16] In fact, since the airway diameter remains nearly unchanged, the total airway cross section nearly doubles with each generation beyond generation 14.

The dimensions of the airway tree influence the ventilatory flow of air in a number of ways. First of all, airflow velocity falls along the airway tree because the total cross-sectional area of the airways increases with every generation (Fig. 2-44); whereas the cross-sectional area of the trachea is about 2.5 cm^2, that of the 1024 airways in the 10th generation taken together is 13 cm^2, and as we approach the acinar airways, the total cross section reaches 300 cm^2. However, since the same air volume flows through all generations, the flow velocity falls by more than 100-fold from the trachea to the acini: at rest, the mean flow velocity on inspiration is about 1 m s^{-1} in the trachea and less than 1 cm s^{-1} in the first-order respiratory bronchioles. In exercise, the flow velocities are up to 10 times greater, in proportion to the increased ventilation. This is discussed further when considering the relative importance of convection and diffusion in bringing O_2 to the alveolar surface for gas exchange.

The size of airways also determines the resistance to airflow. However, the overall resistance is rather small; it is given by the reciprocal of the ratio of ventilatory airflow to the pressure difference between the mouth and alveoli, which is normally no greater than about 1 cmH_2O (mbar) or less than 1 mm Hg. It is large enough, however, to potentially affect the distribution of ventilation to the many gas-exchange units. Because, in laminar flow, the resistance is inversely proportional to d^4 the distribution of air flow depends on a delicate balance of the size of parallel airway tracts. Even a slight narrowing of one of the two daughter branches at

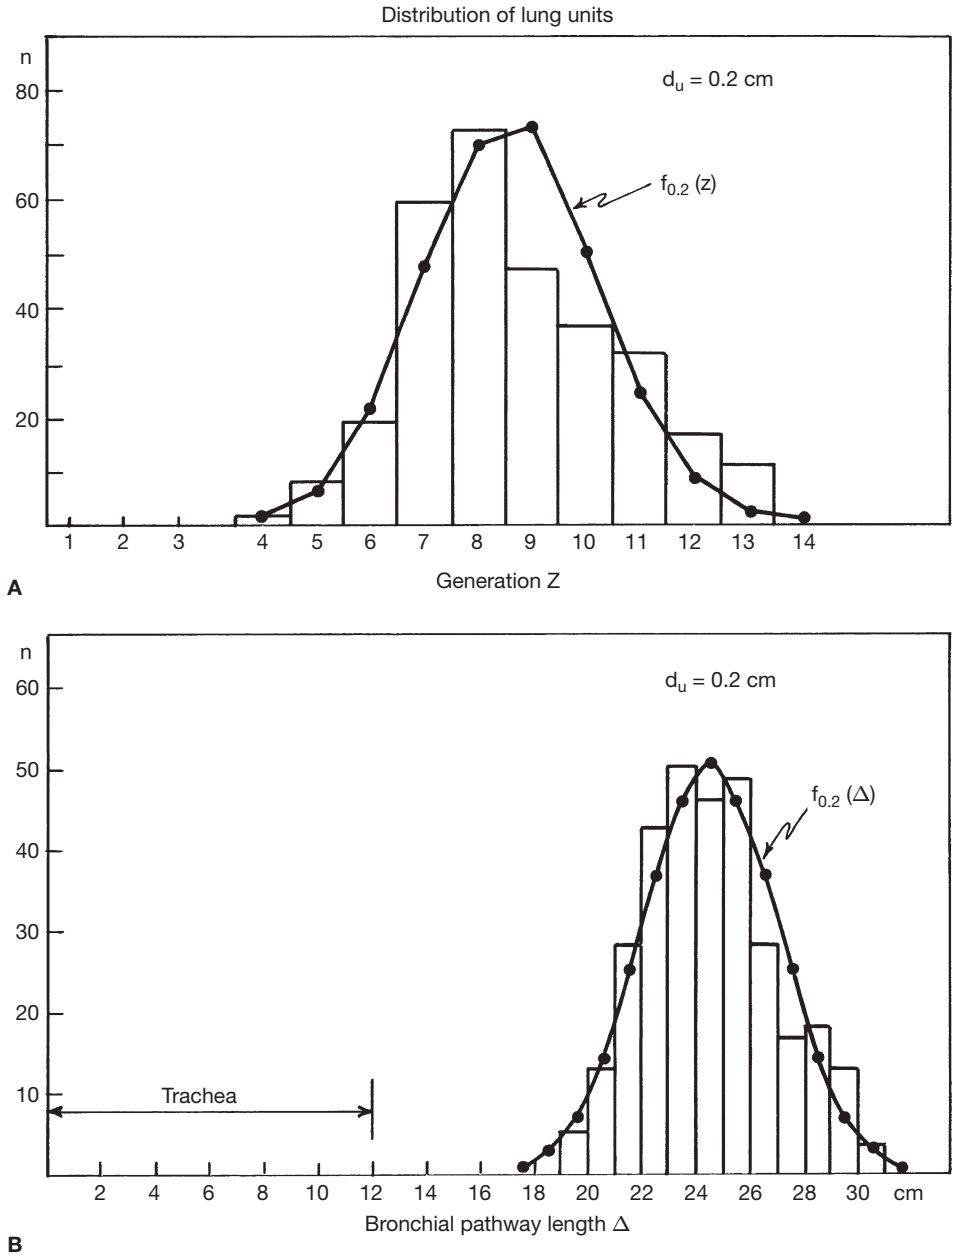

Figure 2-39 Distribution of airways of diameter d_u = 2 mm with respect to (**A**), generations of branching and (**B**), bronchial pathway lengths. *(Reproduced with permission from Weibel ER: Morphometry of the Human Lung. Heidelberg: Springer-Verlag; 1963.)*

a branch point will cause disproportionate air flow to the other branch and thus result in ventilation inhomogeneity.

Since the diameter of airways decreases as they branch (Fig. 2-37), one would suspect that their resistance increases toward the periphery. Apparently this is not the case, as the major pressure drop along the airways occurs in medium-sized bronchi; because the airway diameter decreases with a factor larger than the optimal 0.79 resistance becomes very low in the small bronchioles (Fig. 2-38).[153] This is further accentuated by the fact that the thin-walled bronchioles become widened as the lung expands on inspiration because they are subject to the tissue tensions in the coarse fiber system of the lung. Therefore, airway resistance is seen to fall as lung volume increases. When this effect of tissue tension is disturbed, as in emphysema, some small bronchioles may collapse. This causes ventilation of the peripheral lung units to become highly uneven.

This biophysical way of looking at the significance of the progression of airway dimensions has recently been complemented by the alternative notion that the airway and vascular trees could be determined by the laws of fractal geometry.[156] Fractal trees are formed by repeating the branching pattern from one generation to the next. If the proportion between parent and daughter branches remain the same this is called self-similar branching. In a dichotomous tree the diameter is ideally reduced by a factor of $2^{-1/D_f}$ where D_f is the fractal dimension. Since the airway tree is nearly space-filling $D_f \sim 3$, which means that the Hess–Murray law also follows from fractal geometry as a rule of optimal design, but because the reduction factor is somewhat larger than $2^{-1/3}$ it follows that the actual fractal dimension of the airway tree is a bit larger than 3; this is possible because the tree is "cut off" at the entrance to the acini and the "space" becomes filled with alveoli.[157,158]

DESIGN OF THE VASCULAR TREE

In many ways, the course and pattern of dimensional changes in the pulmonary blood vessels resemble those of the airways. Figure 2-3 shows that the pulmonary arteries follow the airways

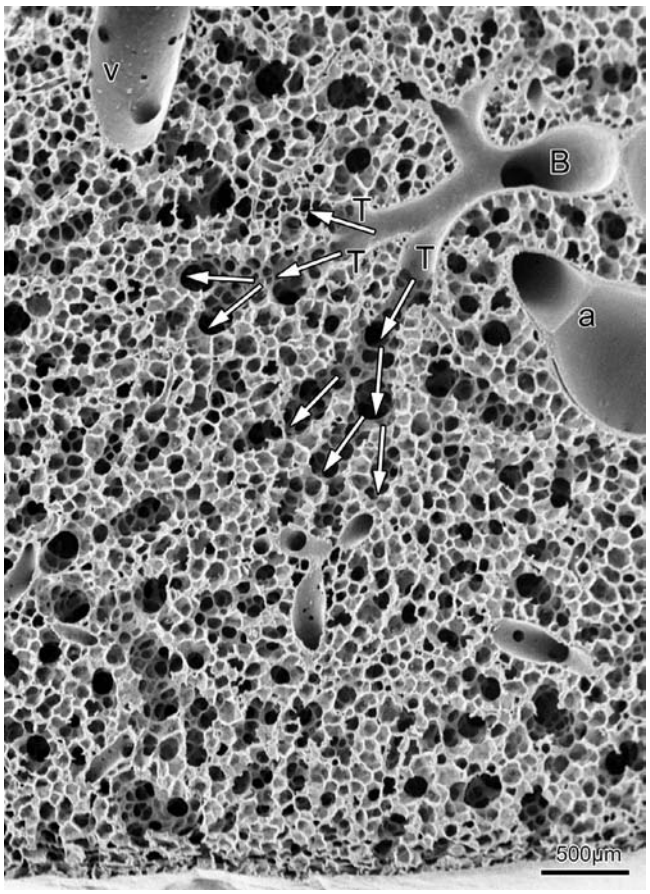

Figure 2-40 Scanning electron micrograph of lung shows branching of small peripheral bronchiole (**B**) into transitional bronchioles (T), from where the airways continue into respiratory bronchioles and alveolar ducts *(arrows)*. Note the location of the pulmonary artery (a) and vein (v) as well as visceral pleura *(bottom)*.

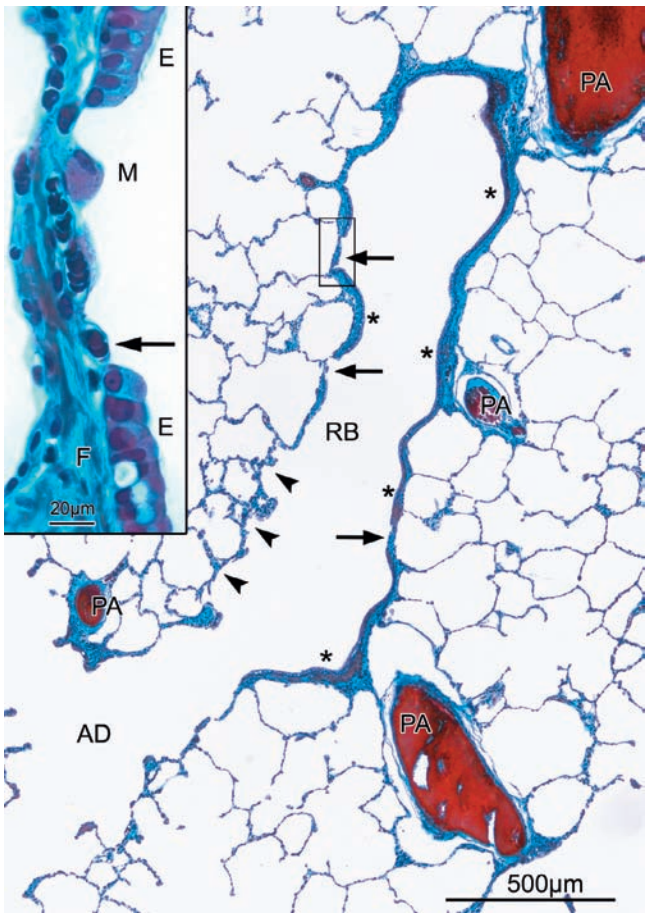

Figure 2-41 Respiratory bronchiole (RB) from human lung cut along its axis toward the transition to alveolar ducts (AD). Note lining by cuboidal airway epithelium *(asterisks)* and the occurrence of respiratory patches *(arrows)* before alveoli proper *(arrowheads)* appear. PA marks branches of pulmonary artery. *Inset:* Higher magnification of one of the respiratory patches in the wall of the respiratory bronchiole with capillaries *(arrow)* and alveolar macrophage (M). The cuboidal epithelium (E) with cilia is replaced by thin squamous epithelium of alveolar type 1 cell. Note thick fibrous layer (F) with smooth muscle cells.

closely, out to the smallest branches; together they form the axis of lung parenchymal units of varying order: acinus, lobule, segment, lobe. As indicated, the veins are differently disposed, lying in the boundary between two or three adjacent units (Figs. 2-30 and 2-45).

The diameter of each pulmonary artery branch also approximates closely that of the accompanying bronchus (Fig. 2-45A). Therefore, it is evident that the diameter law presented earlier for airways must also hold for the first 10 to 16 generations of pulmonary arteries (Fig. 2-37). However, the pulmonary arteries divide more frequently than the airways; very often, small branches leave the artery at right angles and supply blood to the parenchymal units adjacent to the bronchus (Fig. 2-45B). From a count of precapillaries, it seems that the pulmonary arteries divide, on the average, over 28 generations, as compared with 23 for the airways. The diameter of these terminal vessels is about 20 to 50 µm; if this range is plotted onto an extension of the graph of Figure 2-37 to generation 28, it falls on the curve that is obtained by extrapolation from the major branches[8,16]:

$$d(z) = d_0 \cdot 2^{-z/3}$$

This suggests that the pulmonary arteries abide to the cube-root-of-1/2 law from beginning to end. Evidently, the blood is transported to the capillary bed by mass flow only. Therefore, there is no reason to deviate from this fundamental law of design, which minimizes the loss of energy caused by blood flow.

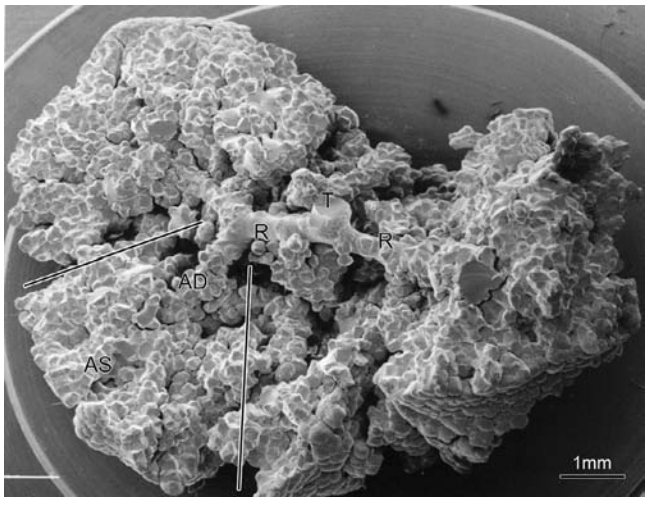

Figure 2-42 Scanning electron micrograph of a complete acinus from a silicon rubber cast of a human lung partly dissected to show transitional (T) and respiratory (R) bronchioles as well as alveolar ducts (AD) and alveolar sacs (AS). Lines mark approximate boundary of 1/8 subacinus. *(Reproduced with permission from Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec. 1988;220(4):401–414.)*

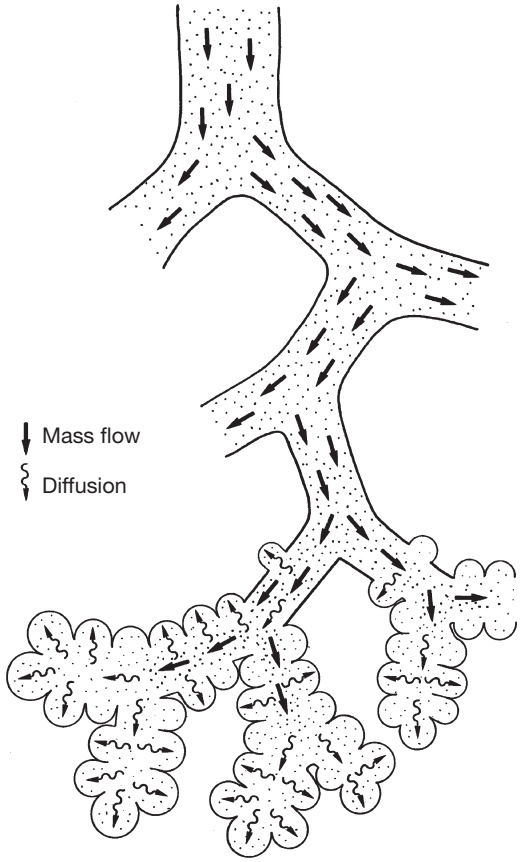

Figure 2-43 Oxygen molecules reach alveoli by combined mass airflow and molecular diffusion, the importance of diffusion increasing toward the periphery.

In a thorough analysis of the pulmonary vascular trees[159] conceived as fractal structures it has been shown that the fractal dimension of both arteries and veins is 2.71, thus somewhat less than 3. The diameter reduction factor is therefore slightly smaller than cube-root-of-1/2, and the diameters follow the regression:

$$d(z) = d_0 \cdot 2^{-z/2.71}$$

Therefore, in contrast to the airways, the resistance to blood flow increases along the pulmonary arteries and is highest in the most peripheral branches or arterioles. The resistance profile of the pulmonary arteries is thus the same as in the systemic circulation.

The alveolar capillary network of the lung is very different from that of the systemic circulation. Whereas in muscle, for example, long capillaries are found to be joined in a loose network, the capillaries of the alveolar walls form dense meshworks made of very short segments (Fig. 2-46).[8,160] The meshes are so dense that some people believe blood flows through the alveolar walls like a sheet rather than through a system of interconnected tubes. In this sheet-flow concept,[161] the sheet is bounded by two flat membranes, the air–blood barrier, connected by numerous "posts." When blood flows through this sheet, it is not channeled in a given direction but has freedom to move in a tortuous way between the posts. Although this concept oversimplifies the actual structural conditions, it does provide a useful description of the pattern of blood flow through the alveolar walls and explains why blood flow is not interrupted when some parts of the capillary bed become squashed flat at high inflation levels (see Fig. 2-58); the capillaries that remain open in the corners are simply some channels of this broad sheet. Furthermore, it is important to note that the capillary network or sheet is continuous through many alveolar walls (Fig. 2-46), probably at least throughout the entire acinus, if not for greater distances.[160] Consequently, it is not possible to isolate microvascular units. One finds, rather, that arterial end branches simply feed into this broad sheet at more or less even distances and that the veins drain these sheets in a similar pattern. However, now we must remember that the arteries reach the acinus along the airways, whereas the veins are in a peripheral location (Fig. 2-45). In principle, therefore, blood flows through the acinar capillary sheet from the center to the periphery of the acinar gas-exchange unit.

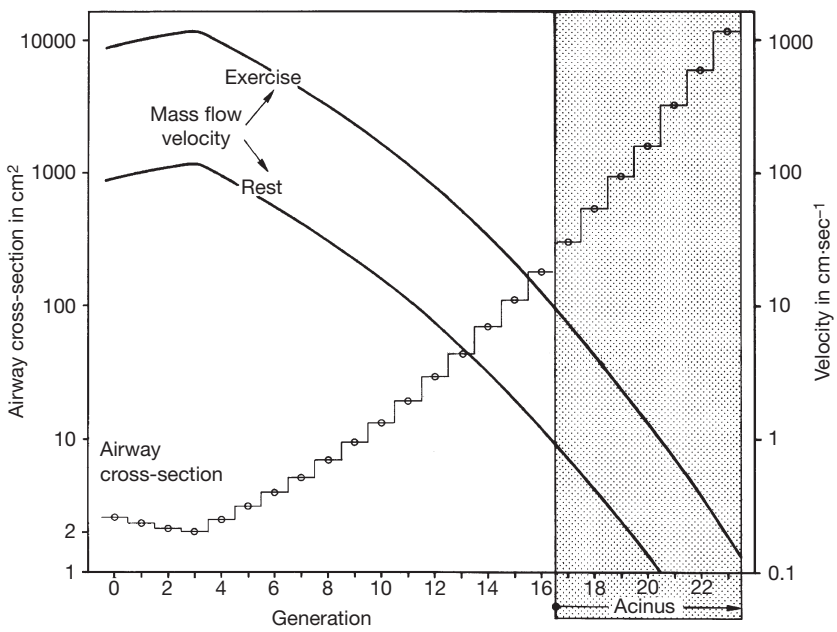

Figure 2-44 As total airway cross-section increases with the generations of airway branching, the mass flow velocity of inspired air decreases rapidly, falling below the molecular velocity of O_2 diffusion in air as we enter the acinus (see Fig. 2-66). *(Reproduced with permission from Weibel ER: The Pathway for Oxygen. Cambridge, MA: Harvard University Press; 1984.)*

DESIGN OF PULMONARY PARENCHYMA

■ ALVEOLI AND CAPILLARIES

The airspaces and blood vessels of lung parenchyma are designed to facilitate gas exchange between air and blood. To this end a very large area of contact between air and blood must be established; for the human lung it is sometimes compared with the area of a tennis court in size. Furthermore, the tissue barrier separating air and blood must be kept as thin as possible—it is found to be about 50 times thinner than a sheet of airmail stationery. This is important, because less than 1 second is available for loading O_2 onto the erythrocytes as they flow through the lung's gas-exchange region.[162]

The first design feature to this end is the formation of alveoli in the walls of all airways within the acinus—that is, in the ventilatory gas-exchange units beginning with a transitional bronchiole (see above) (Fig. 2-40). In the human lung, one estimates that there are about 30,000 acini,[9] and 400 million alveoli[163] so that each of

Figure 2-45 Casts of airways and blood vessels of human lung. **A.** shows how the pulmonary artery *(red)* closely follows the airways *(yellow)* to the periphery, whereas the pulmonary vein branches *(blue)* lie between the units. Note that the diameter of the pulmonary arteries is similar to that of the accompanying airway, but becomes relatively smaller toward the periphery *(arrow)*; small supernumerary arteries take off at right angles. **B.** Higher power view of group of acini *(circle)*, corresponding about to a secondary lobule, shows how artery penetrates into center of gas-exchange unit with veins collecting the blood around the periphery. *Arrowheads* point to alveolar pouches on transitional and respiratory bronchioles.

the ventilatory gas-exchange units contains some 13,000 alveoli, on average, connected to about seven to nine generations of acinar airways, respiratory bronchioles, and alveolar ducts.[9]

The alveoli are so densely packed that they occupy the entire surface of alveolar ducts; they are separated from each other by delicate alveolar septa that contain the capillary network (Fig. 2-47). About half the space of the septum is taken up by blood, which is thus exposed to the air in two adjacent alveoli (Fig. 2-48A). Although the barrier separating air and blood is extremely thin, we find the capillaries to be provided with a complete endothelial lining, as the alveolar surface of the septum is lined by an epithelium.[11] We have seen earlier that these two cell linings are very much attenuated over the greatest part of the surface.

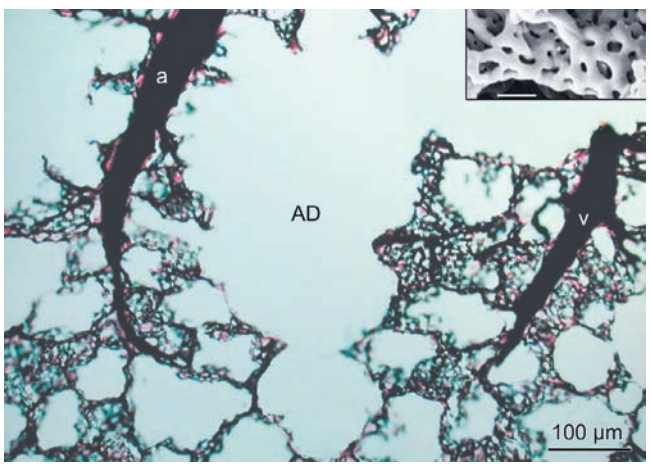

Figure 2-46 Alveolar capillary network demonstrated with gold labeling of blood plasma in a physiologically perfused preparation of a rabbit lung. The dense capillary network spans between end branches of pulmonary artery (a) and vein (v) and extend through many alveolar septa around alveolar duct (AD). *Inset:* Plastic cast shows the dense meshes of the network. Scale bar = 20 µm. *(Inset used with permission of P. Burri.)*

Figure 2-48 In the alveolar wall, shown in (**A**) in a scanning electron micrograph from a human lung, the capillary blood (C) with its erythrocytes (ec) is separated from the air by a very thin tissue barrier (B). *Short arrows* mark intercellular junctions of alveolar epithelium that course toward interalveolar pores of Kohn (K). The model (**B**) shows the capillary network *(red)* to be interwoven with the meshwork of septal fibers *(green)*, the course of which is marked by asterisks in (**A**). The epithelial lining *(yellow)* that crosses the septum at interalveolar pores (K) is removed on the upper surface of the septum to show the capillary. The septal fibers are anchored on the strong fiber bundle marking the free edge of the septum or the alveolar entrance ring (AE). *(Reproduced with permission from Weibel ER: The Pathway for Oxygen. Cambridge, MA: Harvard University Press; 1984.)*

To make the barrier very thin, the interstitial structures must also be reduced to the minimum required (Fig. 2-49). The septal interstitium contains very few cells, mostly slim fibroblast with long extensions; these contain fine bundles of contractile filaments that serve an as yet unknown mechanical function. The septal interstitium usually does not contain cells of the defense system or lymphatics.

INTERNAL SUPPORT OF PARENCHYMAL STRUCTURES: THE PULMONARY FIBER CONTINUUM

This extraordinary reduction of the tissue mass in the alveolar septa inevitably introduces a number of major problems. How is it possible to secure the mechanical integrity of the system if we consider that several forces act on the septal tissue with a tendency to disrupt it? The thin barrier must not only withstand the distending pressure of the capillary blood due to both hemodynamic forces and gravity, particularly in the lower lung zones, but must also keep the capillary bed expanded over a very large surface—a task that is made difficult because surface forces that act on the complex alveolar surface would tend to collapse alveoli and capillaries (see further below). This requires a very subtle, economical design of the fibrous support system.[164,165]

The problem of supporting the capillaries on connective tissue fibers with as little tissue as possible has been solved ingeniously:

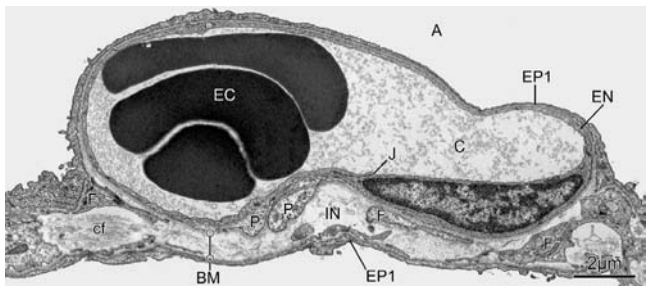

Figure 2-49 Alveolar septum from human lung lined by type I epithelium (EP1) with capillary lined by endothelial cell (EN) that is associated with processes of pericytes (P). Substantial interstitial space (IN) with collagen and elastic fibers (cf) and fibroblasts (F) occurs on one side only, whereas minimal air–blood barrier is formed on other side by fusion of basement membranes (BM) of endothelium and epithelium.

we find that the fiber network is interlaced with the capillary network.[166] Figure 2-48B shows that when the fibers are taut, the capillaries weave from one side of the septum to the other. This arrangement has a threefold advantage: (1) it allows the capillaries to be supported unit by unit directly on the fiber strands without the need of additional "binders"; (2) it causes the capillaries to become spread out on the alveolar surface when the fibers are stretched; and (3) it optimizes gas-exchange conditions by limiting the presence of fibers, which must interfere with O_2 flow, to half the capillary surface. The thin section of a capillary shown in Figure 2-49 reveals that an interstitial space with fibers and fibroblasts exists on only one side of the capillary, whereas on the other the two lining cells, endothelium and epithelium, become closely joined with only a single common basement membrane interposed. Therefore, over half the surface of the capillary blood is separated from the air merely by a minimal tissue barrier made of epithelial and endothelial cytoplasmic sheets with their basement membranes fused leaving no interstitial space that could enlarge with interstitial pulmonary edema (Fig. 2-17).

The principal structural "backbone" of the lung is a continuous system of fibers anchored at the hilum and put under tension by the negative intrapleural pressure that tugs on the visceral pleura.[165] The general construction principle follows from the formation of the mesenchymal sheath of the airway units in the developing lung; as the airway tree grows, its branches remain separated by layers of mesenchyme within which blood vessels form. When fiber networks develop within this mesenchyme, they enwrap all airway units and extend from the hilum right to the visceral pleura. The pulmonary fiber system hence forms a three-dimensional fibrous continuum that is structured by the airway system and is closely related to the blood vessels. By virtue of the design of this fibrous continuum, the lung becomes, in fact, subdivided into millions of little bellows that are connected to the airway tree, as represented schematically in Figure 2-50; these structures expand with expansion of the chest because the tension exerted on the visceral pleura by the negative intrapleural pressure becomes transmitted to the bellows' walls through that fiber system.

To try to put some order into this fiber system, we can first single out two major components that can be identified easily (Fig. 2-50).

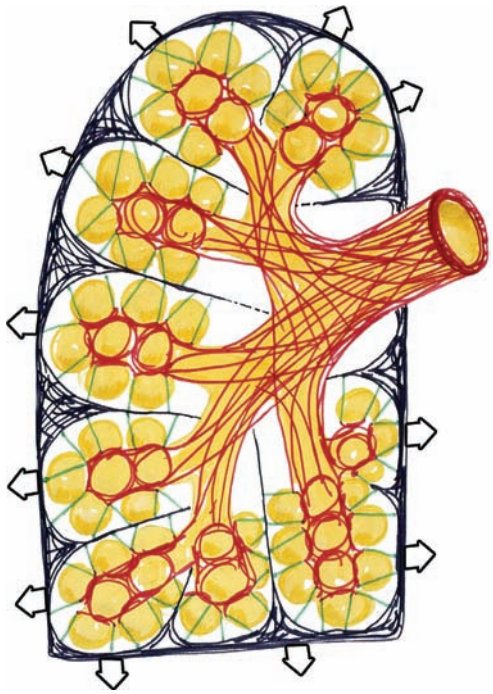

Figure 2-50 The lung's fiber continuum: axial fibers *(red)* extend from airways into the alveolar ducts as a network of entrance rings into alveoli *(yellow)*; peripheral fibers *(black)* extend from the pleura to interlobular septa; the septal fibers *(green)* in the alveolar walls are anchored in peripheral and axial fibers. Arrows indicate the traction on the pleura exerted by thorax and diaphragm. *(Reproduced with permission from Weibel ER: Looking into the lung: What can it tell us? Am J Roentgenol. 1979;133(6):1021–1031.)*

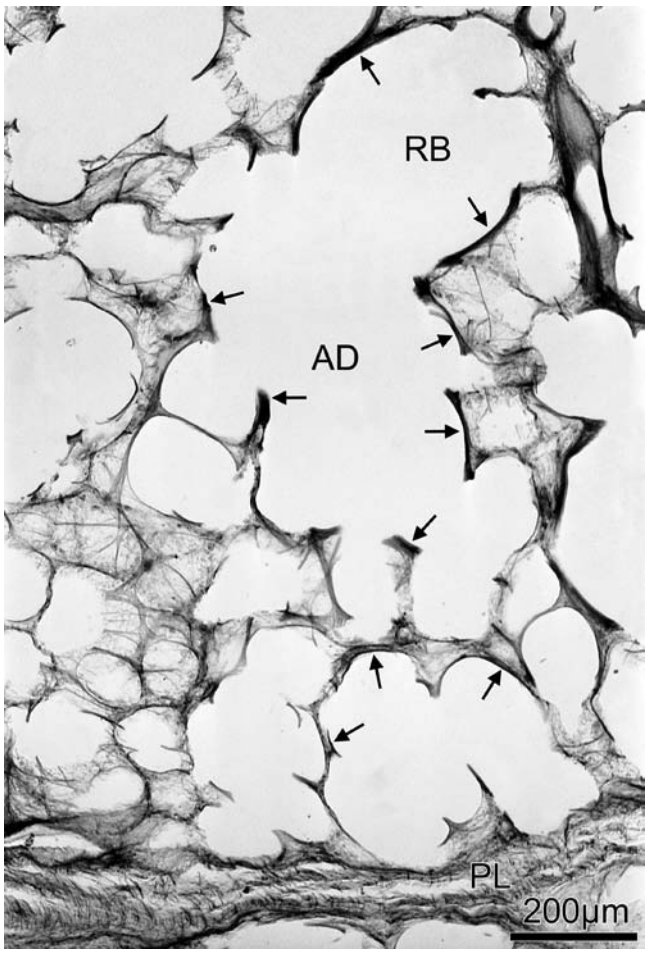

Figure 2-51 Connective tissue stain reveals the strong fiber rings *(arrows)* that demarcate the alveolar ducts (AD) and respiratory bronchioles (RB). Pleura (PL) extends as peripheral fibers into parenchyma. *(Reproduced with permission from Weibel ER: The Pathway for Oxygen. Cambridge, MA: Harvard University Press; 1984.)*

First we find that all airways – from the mainstem bronchus that enters the lung at the hilum out to the terminal bronchioles and beyond – are enwrapped by a strong sheath of fibers. These fibers constitute the axial fiber system; they form the "bark" of the tree whose roots are at the hilum and whose branches penetrate deep into lung parenchyma, following the course of the airways. A second major fiber system is related to the visceral pleura, which is made of strong fiber bags enwrapping all lobes. We then find connective tissue septa penetrating from the visceral pleura into lung parenchyma, separating units of the airway tree. We call these fibers the peripheral fiber system because they mark the boundaries between the units of respiratory lung tissue.

The peripheral fiber system subdivides the lung into a number of units that are not simple to define because they form a continuous hierarchy in accordance with the pattern of airway tree branching. However, as we have seen, two such units appear to be natural: the lobes, which are demarcated by a more or less complete lining by visceral pleura with a serosal cleft interposed (Fig. 2-1); and the acinus, the parenchymal unit in which all airways participate in gas exchange.

The acinus is the functional unit of the pulmonary parenchyma. The airway that leads into the acinus, the transitional bronchiole, continues branching within the acinus for about 6 to 10 additional generations (Figs. 2-5 and 2-40). These intra-acinar airways, called respiratory bronchioles and alveolar ducts, also carry in their wall relatively strong fibers of the axial fiber system, which extend to the end of the duct system. However, since the walls of intra-acinar air ducts are densely settled with alveoli, these fibers are reduced to a kind of delicate network that constitutes the "wall" of the alveolar ducts. The meshes of this network that encircle the alveolar mouths are generally called alveolar entrance rings; it is this fiber network that allows alveoli to be formed as open chambers with free edges of the alveolar septa (Figs. 2-47 and 2-51).[148] These fiber rings are associated with some smooth muscle cells (Fig. 2-29), and they serve as a scaffold for a network of finer fibers that spread within the alveolar septa (Figs. 2-48B and 2-51). However, in a fiber system there may be no loose ends. Accordingly, the septal fiber system must be anchored at both ends—on the network of axial fibers around the alveolar ducts, and on extensions of the peripheral fibers that penetrate into the acinus from interlobular septa. Thus, the fiber system of the lung becomes a continuum that spans the entire space of the lung, from the hilus to the visceral pleura (Fig. 2-50). It is put under varying tension as the pleural bag is expanded by the chest wall and diaphragm. It thus functions as a tensegrity structure where structural integrity is maintained only if the fiber continuum is under tension and undisrupted.[167,168]

The continuous nature of a well-ordered fiber system is an essential design feature of the lung.[148] This becomes evident in emphysema. When some fibers are disrupted, they cannot be kept under tension. They retract and larger airspaces form as the fiber system is rearranged near the damage. Small foci of emphysema form in most lungs in the course of time.

The fiber system serves mainly as a mechanical support for the blood vessels, with which it is intimately associated in an orderly fashion.[148] The pulmonary artery branches in parallel with the airway tree, but it is not related to the axial fiber system. Like the pulmonary veins the pulmonary arteries are associated with those parts of the peripheral fiber system that form an adventitial

sheath on the larger vessels of both types and also form a boundary sheath on the outer surface of bronchi where alveolar complexes touch on the bronchial wall. Therefore, it is justified to characterize the connective tissue surrounding bronchi and pulmonary arteries as a peribronchovascular space, which houses the lymphatics as well as the systemic bronchial arteries and their branches. In fact, this space is continuous with the septal connective tissue that enwraps the pulmonary veins (Fig. 2-30) and is continuous with the visceral pleura. However, whereas the arteries penetrate into the acinus, the veins remain at the periphery and are thus located between the airway units (Fig. 2-45). In the alveolar septa, the capillary network spreads out as a broad sheet of vessels whose paths are continuous throughout the system of interconnected alveolar septa (Fig. 2-46). We have seen that these capillaries are intimately related to the septal fiber system (Fig. 2-48B).

PARENCHYMAL MECHANICS AND TISSUE DESIGN

As in all connective tissue, the fibers of the lung are composed of collagen and elastic fibers.[164] The collagen fibers are bundles of fibrils bound together by proteoglycans; they are practically inextensible (less than 2%) and have a very high tensile strength; they rupture at loads of 50 to 70 dyn/cm^{-2}, which means that a collagen fiber of 1-mm diameter can support a weight of over 500 g. In contrast, elastic fibers have a much lower tensile strength but a high extensibility. They can be stretched to about 130% of their relaxed length before rupturing.

In the fiber system of lung parenchyma, collagen and elastic fibers occur in a volume ratio of about 2.5:1, whereas this ratio is 10:1 for the visceral pleura. In a relaxed state, one finds the collagen fibers to be longer than the accompanying elastic fibers, so that they appear wavy. Because of the association between "rubber-like" elastic and "twine-like" collagen fibers, the connective tissue strands behave like an elastic band. They are easy to stretch up to the point where the collagen fibers are taut, but from there on they resist stretching very strongly.

The elastic properties of the lung's fiber system can be studied by filling the airways with fluid so as to eliminate the effects of surface tension. This reveals that the lung's fiber system has a high compliance until high levels of inflation are reached, and that the retractive or recoil force generated by the fiber system amounts to no more than a few millibars at physiologic inflation levels. The actual recoil force in the air-filled lung, reflected by the negative pressure in the pleural space, is appreciably higher, but this is caused by surface tension rather than the retractive force of the fibers.

Surface tension arises at any gas–liquid interface because the cohesive forces between the molecules of the liquid are much stronger than those between the liquid and gas.[169] As a result, the liquid surface tends to become as small as possible. A curved surface, such as that of a bubble, generates a pressure that is proportional to the curvature and the surface tension coefficient γ. The general formula of Gibbs relates this pressure, P_s, to the mean curvature $\overline{K}$:

$$P_s = 2\gamma \cdot \overline{K}$$

In a sphere, the curvature is simply the reciprocal of the radius r (Laplace's law):

$$P_s = \frac{2\gamma}{r}$$

The most critical effect of surface tension is that it endangers stability of the airspace, because a set of connected "bubbles," the alveoli, is inherently unstable: The small ones should contract and the large ones expand. Since the 400 million alveoli are all connected with each other through the airways, the lung is inherently unstable: Why do the alveoli not all collapse and empty into one large bubble? There are two principal reasons.[16,170]

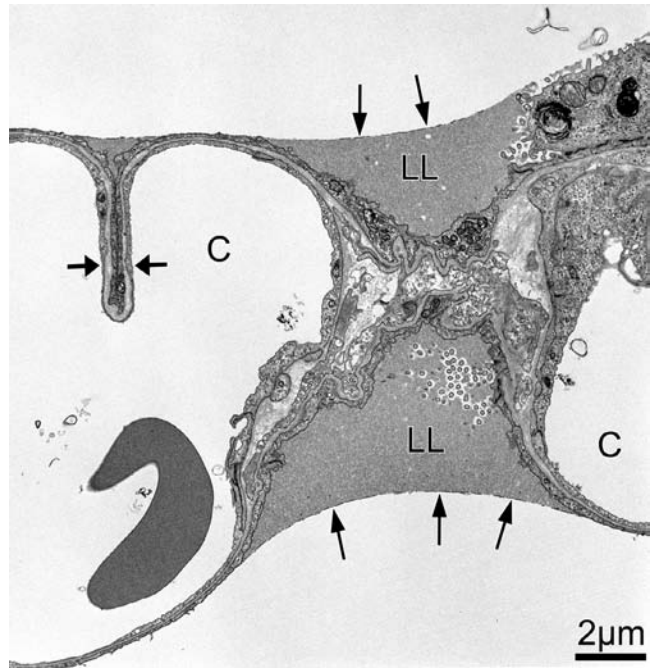

Figure 2-52 Alveolar septum of human lung fixed by perfusion through blood vessels shows alveolar lining layer (LL) in crevices between capillaries (C) topped by surfactant film that appears as a fine black line *(arrows)*. Note the type II cell with lamellar bodies and the fold in thin tissue barrier *(bold arrows)*. *(Used with permission of M. Bachofen and G. Wolff Basel.)*

The first reason is one of tissue structure. The alveoli are not simply soap bubbles in a froth. Rather, their walls contain an intricate fiber system, as we have seen. Thus, when an alveolus tends to shrink, the fibers in the walls of adjoining alveoli are stretched, and this prevents the alveolus from collapsing altogether. It is said that alveoli are mechanically interdependent and this stabilizes them.

The second reason is related to the fact that the alveolar surface is not simply water exposed to air but is lined by surfactant[171] (Figs. 2-25 and 2-52), which has peculiar properties in that its surface tension coefficient γ is variable.[169,172] From a large volume of evidence, it is now established that surface tension falls as the alveolar surface becomes smaller, and that it rises when the surface expands. Because of this feature, which is due to the phospholipoprotein nature of alveolar surfactant (see above), alveoli do not behave like soap bubbles whose surface tension remains constant. When an alveolus begins to shrink, the surface tension of its lining layer falls and the retractive force generated at the surface is reduced or even abolished. Combined with interdependence, this property of surfactant allows the complex of alveoli to remain stable.[170]

Which of the two factors for stabilizing lung structure is now the most important: interdependence or surfactant properties? It turns out that both are essential. If one depletes the lung of its surfactant lining by washing with a detergent, the pressure–volume curve changes dramatically[173] (Fig. 2-53). On deflation, lung volume falls rapidly. If we look at samples from lungs fixed at the same volume (60% total lung capacity) but derived from either normal or detergent-rinsed lungs, we find that surfactant depletion causes the alveoli to collapse. However, this causes the alveolar ducts to enlarge, stretching the strong fiber nets at the mouths of the collapsed alveoli. The ducts do not collapse because of interdependence between adjacent units.

In the normal air-filled lung, surfactant properties and interdependence owing to fiber tension both contribute to stabilizing the

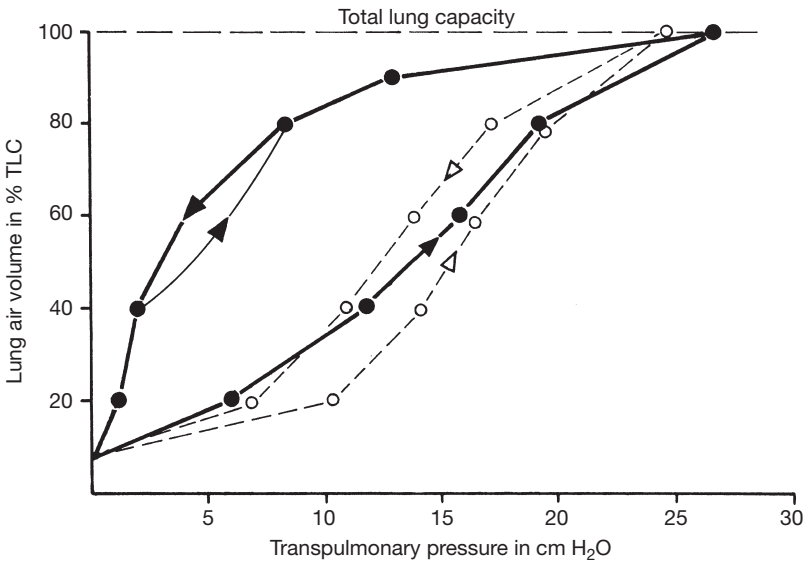

Figure 2-53 Comparison of pressure–volume curve of a normal air-filled rabbit lung *(heavy line)* with that of a surfactant-depleted lung *(broken line)*. The thin line with *paired arrows* represents small hysteresis when breathing between 40% and 80% TLC along the deflation curve.

complex of alveoli and alveolar ducts.[174] To understand this, let us examine Figure 2-54, which shows a highly simplified diagram of a parenchymal unit. Interdependence is established by the continuum of axial, septal, and peripheral fibers. Surface tension exerts an inward pull in the hollow alveoli, where curvature is negative. However, over the free edge of the alveolar septa, along the outline of the duct, the surface tension must push outward because there the curvature is positive.[16] The latter force must be rather strong, because the radius of curvature is very small on the septal edge; but this force is counteracted by the strong fiber strands, usually provided with some smooth muscle cells, that we find in the free edge of the alveolar septum (Figs. 2-29, 2-47, and 2-51). Thus, interdependence is an important factor in preventing the complex hollow of the lung, where negative and positive curvatures coexist, from collapsing. However, its capacity to do so is limited and requires low surface tensions, particularly on deflation when the fibers tend to slack. If surface tension becomes too high, the lung's foam-like structure will partly collapse in spite of fiber interdependence.

This is of considerable physiologic importance. It is sometimes claimed that alveoli pop open when the lung is inflated, collapsing on deflation. That is correct when starting with a deflated lung (Fig. 2-53): collapsed alveoli open up along the inflation curve. But that is not the way we breathe. The normal breathing cycle operates on the deflation slope of the pressure–volume curve (Fig. 2-53) with small hysteresis, a state that is maintained by taking a deep sigh intermittently up to TLC. In this condition the surface tension is kept low because the surfactant lining is spread out[172] and alveoli do not collapse. When we breathe in and out between 80% and 40% of total lung capacity, the range of normal breathing in exercise, alveoli change their size very little. In contrast to the twofold change in air volume the alveolar surface area changes by only about a factor of 1.2.[174] The reason for this is that the main change in air volume does not occur in alveoli, but predominantly in the alveolar ducts as shown in Figure 2-55, and this is very favorable for acinar ventilation. This differential volume change can be explained by the effect of surface forces: at 40% TLC surface tension γ is nearly 0 but it increases to 12 $mN \cdot m^{-1}$ at 80% TLC 2. As the lung inflates this causes the positive surface force to become strong on the free edge of alveolar septa (Fig. 2-54), thus causing the duct cross section to widen, while shrinking when the forces decrease on deflation (Fig. 2-55). In this process the alveolar septa become stretched on inflation by only a small degree, a mere 20% in area. The acinus is thus well ventilated whereas the gas-exchange surface is little affected by varying air volume.[148]

MICROMECHANICS OF THE ALVEOLAR SEPTUM

We must finally consider the mechanical factors that shape the alveolar septum in the air-filled lung. As we have seen, the alveolar septum is made of a single capillary network that is interlaced with fibers (Fig. 2-48). When the fibers are stretched, the capillaries bulge alternatingly to one side or the other, and this causes pits and crevices to occur in the meshes of the capillary network.

This irregular surface is to some extent evened out by the presence of an extracellular layer of lining fluid, which is rather thin over the capillaries but forms little pools in the intercapillary pits (Fig. 2-52).[175] This lining consists of an aqueous layer of variable thickness, called the hypophase, and surfactant, which forms a film on the surface of the hypophase. The hypophase seems to contain considerable amounts of reserve surfactant material, which occurs in a characteristic configuration called tubular myelin (Figs. 2-25 and 2-26).

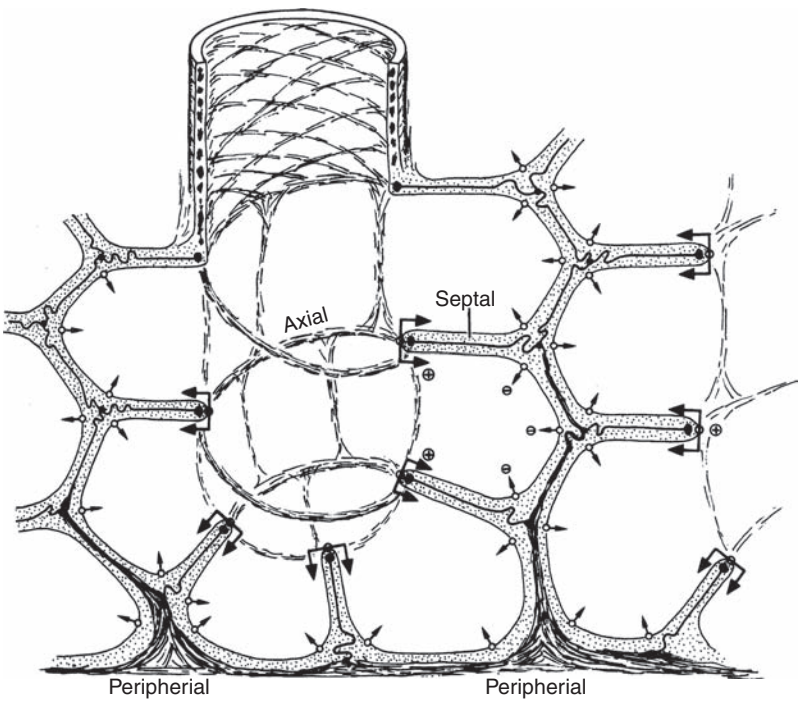

Figure 2-54 Model of the disposition of axial, septal, and peripheral fibers in an acinus showing the effect of surface forces *(arrows). (Reproduced with permission from Weibel ER: The Pathway for Oxygen. Cambridge, MA: Harvard University Press; 1984.)*

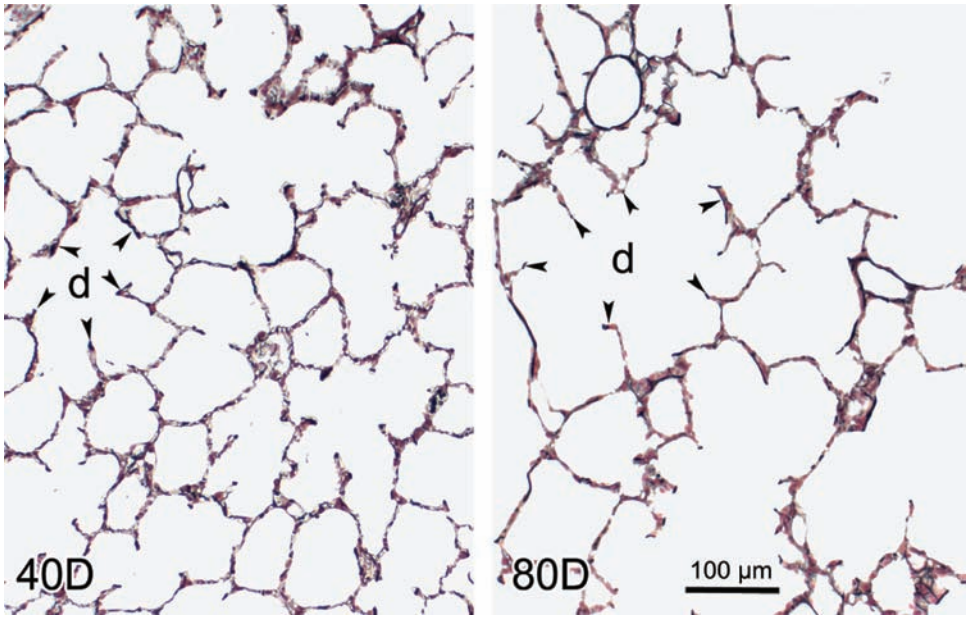

Figure 2-55 Light micrographs of sections of lung parenchyma in rabbit lungs perfusion fixed on deflation to 40% TLC (**A**), and 80% TLC (**B**), respectively (compare Fig. 2-53). Note that the size of the alveolar ducts (d) is markedly enlarged in 80D due to the surface forces acting on the free edges of alveolar septa *(arrow heads)*. *(Preparations used with permission of H. Bachofen, University of Bern.)*

In the alveolar septum, the tissue structures are extremely delicate, as we have seen. Therefore, its configuration is not exclusively determined by structural features but results from the molding effect of various forces that must be kept in balance. Figure 2-56 shows how the three principal mechanical forces – tissue tension, surface tension, and capillary distending pressure – interact in the septum.[16] The fibers of the alveolar septum are under a tension whose magnitude depends on the level of lung inflation. This tends to straighten out the fibers, so that a force (pressure) normal to the fiber axis results, which is responsible for shifting the capillaries to one side of the septum or the other (Figs. 2-48B and 2-56). The walls of the capillaries are exposed to the luminal pressure, which is the result of blood pressure in pulmonary arteries and veins but also depends on gravity, for one finds wider capillaries at the bottom of the lung than at the top. If this distending pressure acts homogeneously over the circumference of the capillary, it will push against the fibers on one side but will cause the thin barrier on the opposite side to bulge outward. This effect is to some extent counteracted by surface tension, which exerts a force normal to the surface (Fig. 2-56). This force depends on two factors. Its direction depends on the orientation of curvature, acting toward the alveolar space over concave regions (negative curvature) and toward the tissue over convexities (positive curvature); and its magnitude depends on the degree of curvature and on the value of the surface tension coefficient γ.

The alveolar septum achieves a stable configuration when all these interacting forces are in balance.[176] Combined forces tend to squash the capillary flat; this happens at high levels of lung inflation when the fibers are under high tension and the surface tension coefficient of surfactant reaches its highest value because of expansion of the surface. On deflation, the fibers are relaxed and surface tension falls drastically. The capillary distending pressure now exceeds both the tissue and the surface forces, with the result that the slack fibers are bent, weaving through the capillary network, whereas the capillaries bulge slightly toward the airspace. Surface tension is apparently so low as to permit a considerable degree of surface "crumpling" to persist (Fig. 2-57).

The importance of the balance between the forces that act on the septum is also shown in Figure 2-58.[177] The specimen of panel B was fixed under zone 3 perfusion conditions, where capillary pressure is larger than alveolar pressure, and all the capillaries are wide, partly bulging toward the airspace, as in Figure 2-57. This is different in panel A, which was fixed under zone 2 conditions where capillary pressure is close to alveolar pressure. In the flat part of the septum, the capillaries are squashed flat, because the surface and tissue forces now exceed the vascular distending pressure. However, it is interesting that the capillaries remain wide in the corners where three septa come together. The distribution of surface forces causes the internal pressure to be lower in the region of these corners, as we can see intuitively from Figure 2-54.

■ THE LUNG AS GAS EXCHANGER

The structures discussed so far are designed to ultimately serve the lung's main function, gas exchange between air and blood, in relation to the body's varying O_2 needs.[178] These are set by the energetic demands of the cells and their mitochondria when these produce ATP by oxidative phosphorylation to allow the cells to do work. This process requires a flow of O_2 to be maintained from the lung to the cells, as will be discussed later. It proceeds along the respiratory system through various steps: into the lung by ventilation, to the blood by diffusion, through the circulation by blood flow, from the blood capillaries by diffusion to the cells and

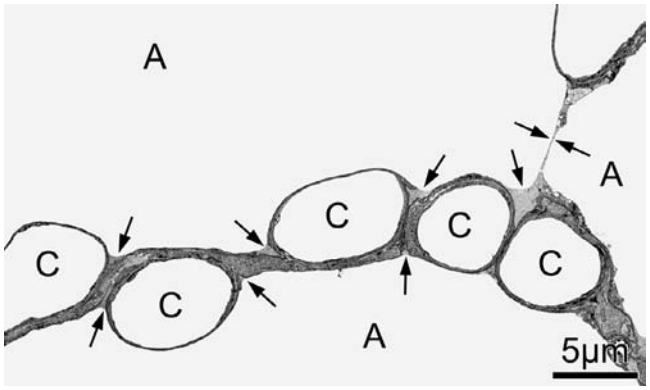

Figure 2-57 Alveolar septum of air-filled rabbit lung perfusion fixed at 60% TLC shows empty capillaries (C), which bulge toward the alveolar airspace (A). Note pools of surface lining layer in the crevices between capillaries *(arrows)* and film spanning across alveolar pore *(double arrows). (Reproduced with permission from Gil J et al. Alveolar volume-surface area relation in air- and saline-filled lungs fixed by vascular perfusion. J Appl Physiol Respir Environ Exerc Physiol. 1979;47(5):990–1001.)*

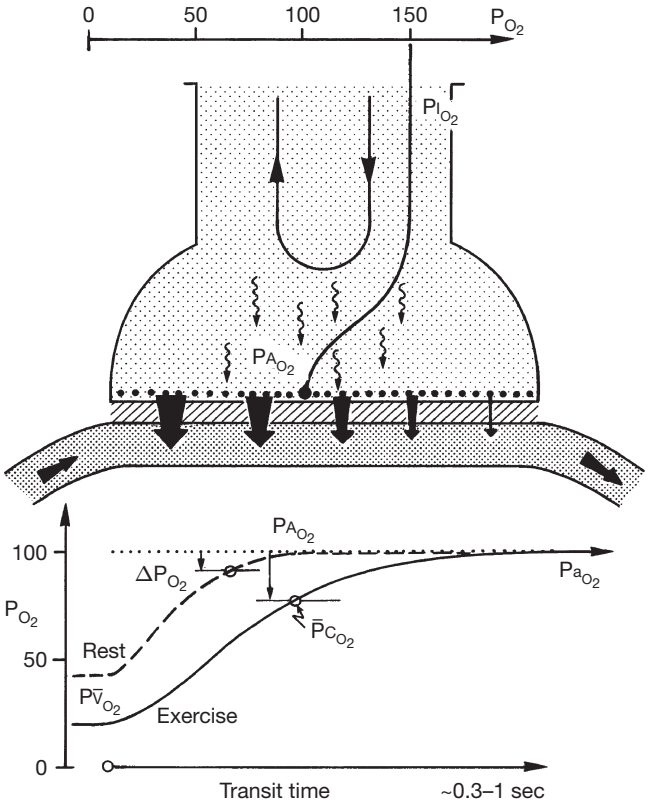

Figure 2-59 Model of gas exchange showing gradual rise of capillary P_{O_2} ($P_{C_{O_2}}$) as blood flows through capillary until it approaches alveolar P_{O_2} ($P_{A_{O_2}}$). *(Reproduced with permission from Weibel ER: The Pathway for Oxygen. Cambridge, MA: Harvard University Press; 1984.)*

mitochondria, where it disappears in the process of oxidative phosphorylation.[16] A number of basic features characterize this system[179]: (1) under steady-state conditions the O_2 flow rate, $\dot{V}_{O_2}$ is the same at all levels, that is, O_2 uptake in the lung is equal to O_2 consumption in the tissues; (2) the basic driving force for O_2 flow through the system is a cascade of O_2 partial pressure which falls from inspired P_{O_2} down to near zero in the mitochondria; (3) the O_2 flow rate at each step is the product of a partial pressure difference and a conductance which is related to structural and functional properties of the organs participating in O_2 transfer, as will be discussed below in detail.

With respect to gas exchange in the lung (Fig. 2-59), the O_2 flow rate is determined by the Bohr equation:[180]

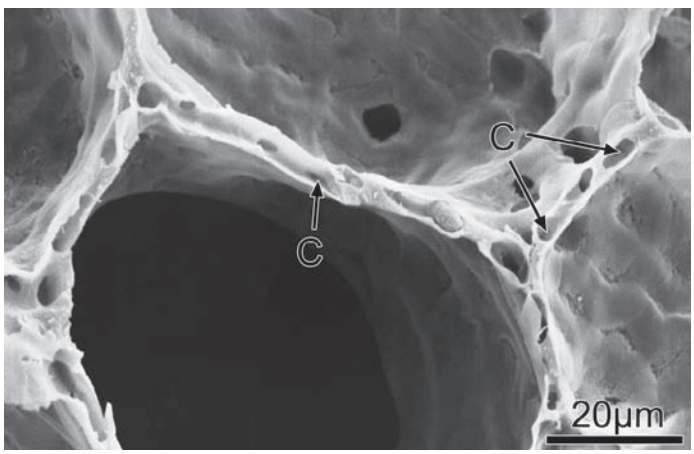
$$\dot{V}_{O_2} = (PA_{O_2} - P\bar{C}_{O_2}) \cdot DL_{O_2}$$

Where

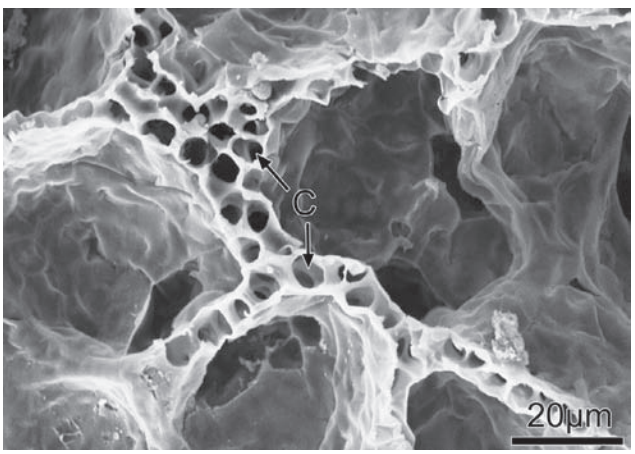
PA_{O_2} = P_{O_2} in alveoli,

$P\bar{C}_{O_2}$ = the mean P_{O_2} in pulmonary capillaries, and

DL_{O_2} = the pulmonary diffusing capacity or the lung's O_2 conductance



A



B

Figure 2-58 Scanning electron micrographs of alveolar walls of rabbit lungs fixed under (**A**), zone 2 and (**B**), zone 3 conditions of perfusion. Note that capillaries (C) are wide in zone 3 and slit-like in zone 2, except for "corner capillaries," which are wide in either case. *(Reproduced with permission from Bachofen H et al: Morphometric estimates of diffusing capacity in lungs fixed under zone II and zone III conditions. Respir Physiol. 1983;52(1):41–52.)*

The important point is now that all parameters to the right of this equation may be significantly affected by design features. We will see that $D_{L_{O_2}}$ is largely determined by the surface area and the thickness of the air–blood barrier. The O_2 partial pressure difference is established by ventilation and perfusion of the gas-exchange units, and this may be affected by the design of the airway and vascular trees, particularly in the acinus.[178]

THE PULMONARY DIFFUSING CAPACITY

In the equation mentioned earlier, $D_{L_{O_2}}$ is the total conductance of the gas exchanger for O_2 diffusion from the alveolar air into the capillary erythrocytes until it is bound to hemoglobin. It can be estimated physiologically if we can measure O_2 uptake $\dot{V}_{O_2}$ and estimate the effective P_{O_2} difference between alveolar air and capillary blood, not a trivial undertaking as the change in capillary P_{O_2} as O_2 is being taken up must be integrated (Fig. 2-59). On the other hand the conductance is a physical characteristic. Therefore, it should be possible to calculate a theoretical value of $D_{L_{O_2}}$ from the physical properties of the gas exchanger, its dimensions and material properties.[181,182] To do that we must consider the geometry of the structures involved, alveoli, tissue barrier, and capillary blood, in setting up a physical model of $D_{L_{O_2}}$. In the first step, we can break the process into two steps (Fig. 2-60):[183] (1) O_2 flow across the barrier or what has been called the membrane conductance $D_{M_{O_2}}$ and (2) O_2 binding to hemoglobin in the red blood cells or the conductance of capillary blood De_{O_2} These two conductances are in series. Accordingly their overall effect on O_2 flow is obtained by adding their resistances or the reciprocal of the conductance:

$$1/D_{L_{O_2}} = 1/D_{M_{O_2}} + 1/De_{O_2}$$

The two conductances $D_{M_{O_2}}$ and De_{O_2} are of very different nature. $D_{M_{O_2}}$ is the conductance of a diffusion barrier that offers "passive" resistance to diffusion and thus depends essentially on the material properties of the barrier, estimated by a diffusion coefficient K, and on the dimensions of the barrier. The larger the surface area S and the thinner the barrier thickness τ the greater $D_{M_{O_2}}$, according to the formula $D_{M_{O_2}} = K \cdot S/\tau$. In contrast, De_{O_2} is related to a more complex process that involves, besides diffusion, the binding of O_2 to hemoglobin, which is a nonlinear process.

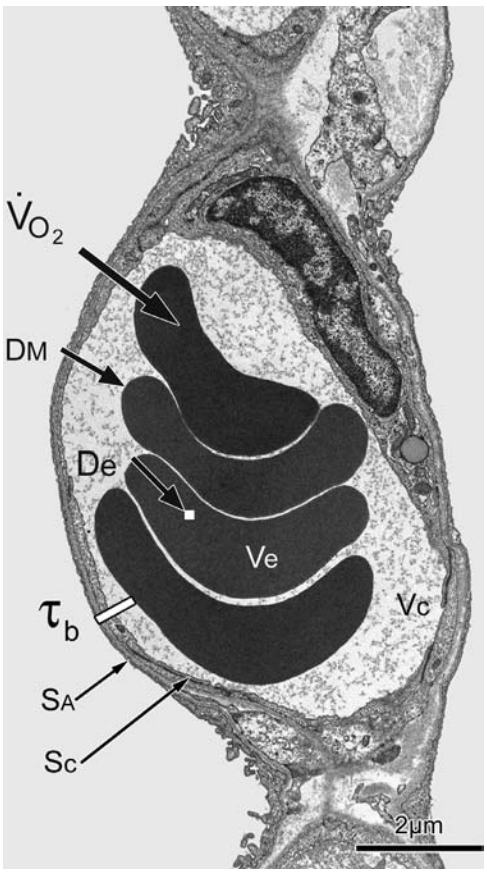


Figure 2-60 Morphometric model for calculating diffusion capacity, DL. Its two components are: (1) the membrane conductance DM, which extends from the alveolar surface (SA) to the nearest erythrocyte membrane traversing the tissue barrier, the capillary surface (Sc), and the plasma layer over the distance τ_b; and (2) the conductance of the erythrocyte interior, De, that depends on the capillary and the erythrocyte volume, Vc and Ve. (See text.)

The Membrane Conductance ($D_{M_{O_2}}$)

The structural characteristics of the membrane conductor are seen in Figure 2-60. It is made of the two layers that separate air in alveoli from the erythrocytes in the capillary: the tissue barrier and the layer of blood plasma. In addition, an alveolar lining layer of varying thickness spreads over the epithelial surface. Even though these layers have distinct characteristics; in effect they act as a single diffusion barrier.[182]

As discussed earlier in this chapter, the tissue barrier is a complex structure. Its two bounding surfaces are formed by independent cell layers, epithelium and endothelium, and they are related to two independent functional spaces, alveoli and capillaries. The two surfaces are not perfectly matched, and the thickness of the barrier varies considerably (Fig. 2-60). Over about half the surface the tissue barrier shows minimal thickness compatible with an intact structure: The thin cytoplasmic leaflets of type I epithelial cells are joined to the thin extensions of endothelial cells by the fused basement membranes leaving no interstitial space. In this region we also find the surface lining layer to be very thin. Over the other half the barrier is thicker because of the occurrence of supporting connective tissue fibers (Fig. 2-49) and the presence of cell bodies of epithelial and endothelial cells as well as fibroblasts, and the lining layer can form deeper pools (Fig. 2-52).

The plasma layer shows even greater variation in its thickness and distribution. Since erythrocytes are of about the same dimension as the capillaries, the plasma layer that separates them from the endothelium can be vanishingly thin where the red cell nearly touches the wall. However, erythrocytes are corpuscular particles and there are "plugs" of plasma of varying size that separate them in the direction of blood flow. Also their distortable disk shape causes the plasma layer between erythrocyte and capillary surface to be quite variable.[184] Furthermore, occasional leukocytes function like plasma plugs in regard to O_2 diffusion to the red cells. Therefore, the diffusion distance from the capillary wall to the red cell membrane can vary from a few nm to several µm.

Strictly speaking, these two layers of the barrier offer O_2 diffusion different resistances so their conductances should be calculated separately. However, this distinction does not appear to be important under normal conditions. Indeed, it is more reasonable to treat them as a single barrier. For one, the flow velocity of the plasma layer is much lower than the diffusion of O_2 so that plasma is quasistatic with respect to diffusion. Furthermore, under normal conditions the surface areas of alveoli, capillaries, and erythrocytes do not differ much, and the diffusion coefficients of tissue and plasma are also quite similar. Therefore, we prefer now to estimate the membrane diffusing capacity by considering O_2 diffusion from the alveolar surface to the erythrocyte membrane as:[182]

$$D_{M_{O_2}} = k_b \cdot S(b)/\tau_{hb} = K_b \cdot (S(A)+S(c))/2 \cdot \tau_{hb}$$

where K_b is Krogh's permeation coefficient estimated at 3.3×10^{-8} $cm^2\ min^{-1}\ mm\ Hg^{-1}$, τ_{hb} is the harmonic mean distance from the

alveolar surface to the nearest erythrocyte membrane, and S(b) is the surface area of the barrier that we estimate as the mean of the alveolar and capillary surface areas, S(A) and S(c), respectively, the two most robust measures of the area of air–blood contact. These parameters can be estimated on sections of properly sampled lung tissue by stereologic methods.[185–187]

We should also mention that the presence of a surface lining layer in the living lung may modify the geometry of the barrier as we see it on electron micrographs with the consequence that both the barrier thickness and the alveolar surface are reduced to a similar degree because some thicker parts of the barrier become shifted beneath the surfactant pools (Fig. 2-52).[177] Therefore, the effect on the estimate of $D_{L_{O_2}}$ is negligible.

Erythrocyte Conductance (De_{O_2})

As mentioned, the erythrocyte conductance is of a different nature in that it involves two coupled events,[183] that is, diffusion of molecular oxygen and oxyhemoglobin within the red blood cell as well as the chemical reaction of O_2 with hemoglobin. A way out of this is to obtain an empirical estimate of the rate at which O_2 is bound to whole blood, θ_{O_2}, and to express the erythrocyte conductance De_{O_2} as:

$$De_{O_2} = \theta_{O_2} Vc$$

where Vc is the total capillary blood volume, which can again be estimated on sections by stereologic methods.

The coefficient θ_{O_2} is estimated in vitro on whole blood, but this is difficult because of the effect of variable unstirred layers around the red cells.[188,189] In addition, θ_{O_2} depends on the hematocrit or hemoglobin concentration, and it is not a constant as it falls with increasing O_2–hemoglobin saturation; recent studies have shown that, as blood moves through alveolar capillaries, θ_{O_2} falls gradually from about 4 to 1 mL O_2 mL^{-1}, $torr^{-1}$ so that the correct value can only be found after Bohr integration of capillary P_{O_2}. For normal human lungs and a hemoglobin content of 15 g/100 mL of blood, a value $\theta_{O_2} = 1.8\ mL\,O_2 \cdot mL^{-1}, torr^{-1}$ is a reasonable estimate, but if the actual hemoglobin concentration [Hb] varies a corrected value can be obtained by multiplying this standard value with a factor c = [Hb]/15.

Morphometry of the Human Lung and Diffusing Capacity

With this model in hand, we can now attempt to estimate the diffusing capacity of the human lung on the basis of morphometric data, as listed in Table 2-4. These data, obtained by electron microscopic morphometry on seven young adults,[190] reveal the alveolar surface area to amount to 130 m^2 and the capillary surface to be about 10% smaller. These values are higher than those most commonly quoted in textbooks derived from light microscopic studies, which did not adequately resolve the alveolar surface texture. The harmonic mean thickness of the tissue barrier is 0.6 μm, whereas the total barrier, from alveolar to red cell surface (Fig. 2-60), measures 1.11 μm.[182] The capillary volume is estimated at about 200 mL. With these data we calculate $D_{L_{O_2}}$ for the adult human lung to be about 150 to 200 mL O_2 min^{-1} mm Hg^{-1}, the variation depending on the choice of θ_{O_2}.

These data also allow us to ask the question how the resistance to O_2 diffusion is distributed between the diffusion barrier and the red cells. Table 2-4 shows that the diffusion conductance of the "membrane" and that of the red cells are very similar, which means that the resistance to O_2 uptake is nearly equally divided between membrane and red cells.

These morphometric estimates of the diffusing capacity are based on model assumptions that are considered reasonable. The test of their validity must be to compare them with physiologic estimates. The standard physiologic value of $D_{L_{O_2}}$ of a healthy adult at rest is about 30 mL O_2 min^{-1} mm Hg^{-1}; thus, considerably less than what we find on the basis of morphometric estimates. However, this is not a valid comparison, because, under resting conditions, we take up only one-tenth the amount of O_2 that our lungs are capable of absorbing under conditions of heavy work. There have been a number of estimates of $D_{L_{O_2}}$ in exercising humans,[191] and these have yielded values of the order of 100 mL O_2 min^{-1} mm Hg^{-1}. This estimate should come closer to the "true capacity" of the lung for O_2 transfer to the blood than the value obtained at rest. The fact that this is only about 50% lower than the morphometric estimate is not disturbing, for we do not know whether the "true diffusing capacity" is completely exploited even in heavy exercise. Inhomogeneities in the distribution of ventilation and perfusion would, for example, limit the degree to which "true" $D_{L_{O_2}}$ can be exploited. One aspect of this type of limitation is discussed in the following when we consider the effect of the acinus design on gas exchange.

To test whether the morphometric estimate of $D_{L_{O_2}}$ is reasonable we performed, some years ago, a combined physiologic and morphometric estimation of pulmonary diffusing capacity on four species of canids ranging from 4 to 30 kg in body mass.[192]

Because it is difficult to estimate mean capillary P_{O_2} reliably, most physiologic measurements of the diffusing capacity use carbon monoxide (CO) as a tracer gas; CO binds to hemoglobin so avidly that, for practical purposes, the Pb_{CO} is zero, so that it suffices to measure CO uptake and alveolar CO concentration. It is also possible to revise the morphometric model of diffusing capacity to estimate the conductance for CO instead of O_2 by appropriately changing the permeability coefficients and the rate of CO binding to erythrocytes, θ_{CO}, whereas the morphometric parameters are not changed. In a study on dogs and on other canids, the calculated morphometric value of $D_{L_{O_2}}$ was found to be larger than the physiologic estimate by less than a factor of 1.5, thus confirming the observation made with respect to human lungs.

Therefore, we conclude that the pulmonary gas exchanger is designed with a certain amount of redundancy or excess capacity, but this is by no means unreasonable from an engineering point of view. Indeed, to design the pulmonary gas exchanger with a certain degree of redundancy may make a lot of sense. The lung forms the interface to the environment and its functional performance will thus depend on environmental conditions, such as the prevailing O_2 partial pressure, which falls as we go

TABLE 2-4 Morphometric Estimate of $D_{L_{O_2}}$ for Young, Healthy Adult Humans of 70-kg Body Weight, Measuring 175 cm in Height

Morphometric data (mean ± 1 SE)			
Total lung volume (60% TLC)	4340	±285	mL
Alveolar surface area	130	±12	m^2
Capillary surface area	115	±12	m^2
Capillary volume	194	±30	mL
Air–blood tissue barrier thickness			
Arithmetic mean	2.2	± 0.2	μm
Harmonic mean	0.62	±0.04	μm
Total barrier harmonic mean thickness	1.11	± 0.1	μm
Diffusing Capacity (mL/min/mm Hg)			
Membrane	$D_{M_{O_2}}$	350	
Total	$D_{L_{O_2}}$	158

from sea level to higher altitudes. It has been shown that goats, whose $D_{L_{O_2}}$ is about twice as large as seemingly required, can maintain their maximal level of exercise-induced $\dot{V}_{O_2}$ even under hypoxic conditions whereas the dogs that have very small excess $D_{L_{O_2}}$ cannot. It has also been suggested that human athletes exercising at high altitude may fully exploit their $D_{L_{O_2}}$. This suggests that the apparent redundancy in $D_{L_{O_2}}$ may be a safety factor to protect the good functioning of the pulmonary gas exchanger even when environmental conditions are not optimal. Recent studies with partial pneumonectomy in dogs have shown that the lung can achieve 85% of its maximal O_2 uptake even when 40% of lung tissue is removed after left pneumonectomy, making use of some of this reserve capacity; but when right pneumonectomy removes 60% of lung tissue, adequate function can be achieved only after compensatory growth of the residual lung tissue to restore diffusing capacity.[193–196]

DESIGN OF THE ACINUS AND GAS EXCHANGE

The preceding section considered the overall size of the gas exchanger of the entire lung to compare it with the global performance of this organ. In reality, the surface the size of a tennis court is subdivided into some 400 million gas-exchange units. These are individually perfused with blood because they correspond to the unit capillary network that spans between pulmonary arteriole and venule (Fig. 2-46). The diameter of such a roughly disk-shaped unit is about 500 μm and has a surface area that corresponds approximately to that of an alveolus, even though alveoli and the capillary unit are not congruent as the latter spans over several alveoli and each alveolus is in contact with several capillary units.[162]

These gas-exchange units are arranged along the terminal generations of the airway tree that form the pulmonary acinus (Fig. 2-61B). Note that this arrangement of gas-exchange units to the airway system differs from the common representation of the alveolar–capillary unit as a terminal "bubble" (Fig. 2-61A). This has potential functional consequences because ventilation of alveoli occurs in two steps:[197] (1) upon inspiration oxygen-rich air flows through the airways into the acinus carrying along O_2; (2) in the peripheral airways flow velocity slows down because the airway cross-section increases, and O_2 now moves toward the periphery by diffusion in the air phase, driven by the P_{O_2} gradient that becomes established as O_2 is absorbed at the alveolar surface (Fig. 2-62). Thus, in the peripheral airways diffusion along the airways is combined with diffusive permeation of O_2 into the alveoli and across the tissue barrier to the blood, the actual process of gas exchange. Whereas all capillary network units are individually perfused with venous blood the alveoli are not independent in terms of their O_2 supply, which depends on their location along the airway tree. Therefore, the design of the acinus has significant effects on the gas-exchange conditions.

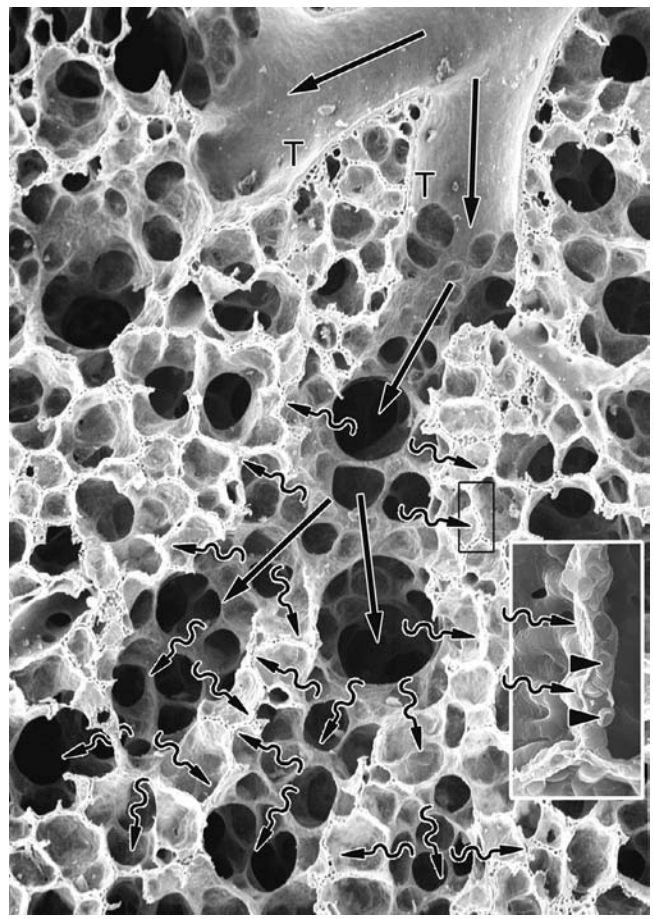

Figure 2-62 Central part of the acinar airways beginning with transitional bronchiole (T) and leading into the branched alveolar ducts. On inspiration air flows in by convection *(straight arrows)*, but as flow velocity falls diffusion of O_2 *(wiggly arrows)* becomes the dominant mechanism for bringing O_2 to the gas-exchange surface. All along acinar airways O_2 is absorbed by the capillary blood in the septa *(inset, arrowheads)*.

THE ACINAR AIRWAY SYSTEM CONNECTED TO THE GAS EXCHANGER

In a systematic study of human lungs[9] the mean volume of acini was found to be 187 mm^3 with a standard deviation of 79 mm^3. The branching pattern for an average size human acinus is shown in Figure 2-63. The segment lengths have been drawn to scale and the terminal clusters of alveoli of the alveolar sacs are marked by a dot. This acinus has been subdivided into eight subacini whose

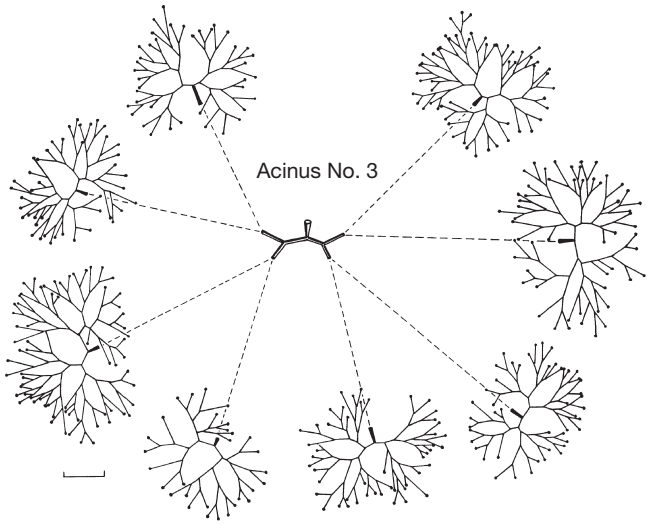

Figure 2-63 Graphic representation of branching pattern of acinar airways in one human acinus of 183 mm^3 volume with the segment lengths drawn to scale. The airways are separated at the third generation thus displaying the branching pattern within each 1/8 subacinus. *(Reproduced with permission from Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec. 1988;220(4):401–414.)*

substems are located in the third generation of acinar airways. The first three generations of acinar airways following on the transitional bronchiole are respiratory bronchioles, where there are only a few alveoli. In contrast, the alveolar ducts that follow are completely and densely lined with alveoli (Fig. 2-64). The 1/8 subacinus is a unit

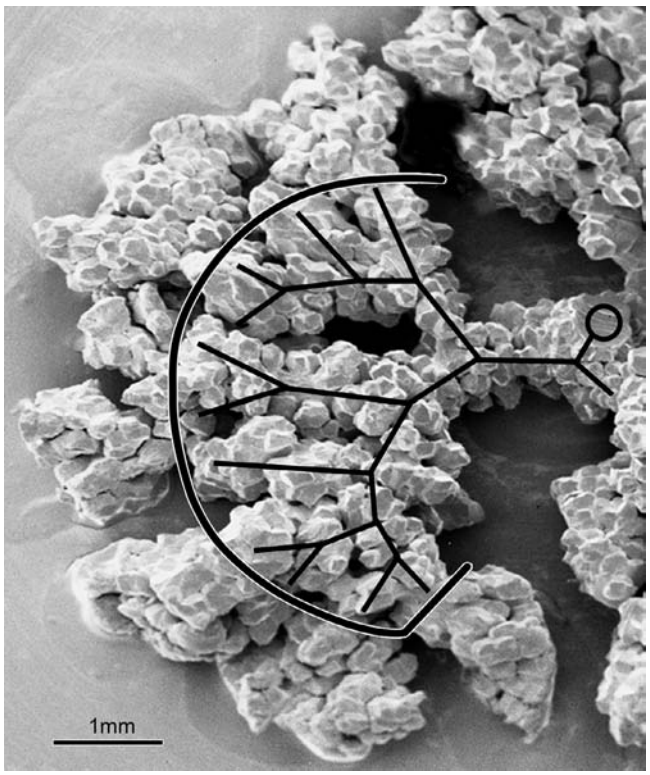

Figure 2-64 Airways of 1/8 subacinus of human lung beginning with generation 18 alveolar duct (circle). The silicon rubber cast has been spread out to show the course of the subsequent branchings. The curved line marks the approximate boundary to the last generation to show that this generation of alveolar sacs (see Fig. 2-5) comprises over half the gas-exchange area of the acinus.

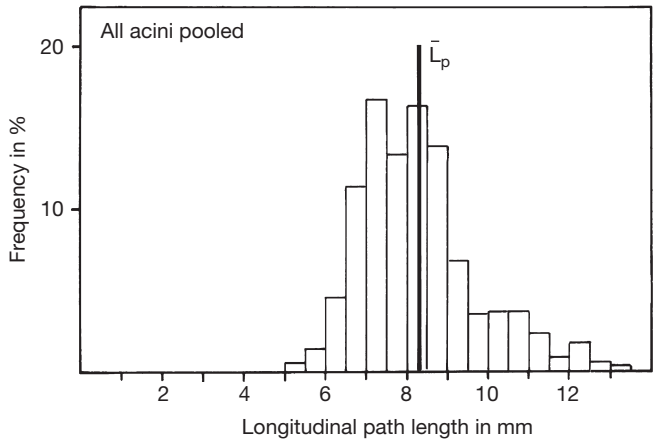

Figure 2-65 Frequency distribution of longitudinal path length from the transitional bronchiole to the alveolar sacs in the human lung. *(Reproduced with permission from Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec. 1988;220(4):401–414.)*

of functional significance, as we shall see. The intra-acinar airways branch by irregular dichotomy; terminal sacs are located in generations 6 to 11 so that the intra-acinar airways branch over an average of 8 generations (Fig. 2-5).

The morphometry of the intra-acinar airways of the human lung shows a number of characteristic traits. The inner diameter (d_{in}) that characterizes the cross-section of the duct tube decreases from about 490 μm at the transitional bronchiole to 270 μm in the last generations.[9] When this is plotted onto the graph relating airway diameter to generations of branching (Fig. 2-37), we note that this diameter falls less steeply than the cube-root-of-1/2 law we have observed for conducting airways. This is a significant finding in terms of the ventilation of alveoli by O_2 diffusion.

An important morphometric characteristic of acinar airways is the total path length for O_2 diffusion from the entrance at the transitional bronchiole to the terminal cluster of alveoli at the alveolar sac (Fig. 2-5). This path length is determined by two factors: the number of generations and the segment length. The length of alveolar ducts gradually decreases from 1330 to 640 μm in the peripheral generations, the alveolar sacs being a little bit longer. Since the number of branching generations varies somewhat, we can expect the path length to vary even within one acinus. In the human lung, the average longitudinal path length measures 8.3 ± 1.4 mm (Fig. 2-65).[10] Because of the decreasing length of acinar ducts 3.4 mm of this total path length are for the first three generations of respiratory bronchioles, whereas the path length of alveolar ducts and sacs comprised in the 1/8 subacinus (Fig. 2-64) averages 4.7 ± 0.88 mm.

Typical Path Model of Human Acinus

In view of assessing the effect of these structural features on the functional performance of the pulmonary gas exchanger we can attempt to develop what we may call a typical path model for an average human acinus[9,10]; the relevant morphometric data are given in Table 2-5. Such an acinus has a volume of 187 mm^3. Its airways branch over an average of eight generations to reach the terminal alveolar sacs. With each generation the number of branches doubles to end with some 256 terminal alveolar sacs in an average acinus (Fig. 2-63). Locating the transitional bronchiole ($z' = 0$) in generation 14 (Fig. 2-5) the terminal air sacs are in generation 23 of the typical path airway tree. From the estimates of the lengths and inner diameters of the airway segments we can derive overall parameters of functional significance, such as the total airway cross-section per generation, $A_d(z')$, which is a determinant of air flow velocity (Fig. 2-44). Finally,

TABLE 2-5 Typical Path Model of Human Acinus

Generation		Segments			Dimensions per Generation			Path Length
Airways z	Acinus z′	N(z′)	l mm	d_{in} mm	$A_d(z')$ mm^2	$V_d(z')$ mm^3	$S_{alv}(z')$ mm^2	$L_p(z')$ mm
15	0	1	1.4	0.50	0.20	0.32	7	1.4
16	1	2	1.33	0.50	0.39	0.52	23	2.73
17	2	4	1.12	0.49	0.75	0.84	67	3.85
18	3	8	0.93	0.40	1.00	0.93	129	4.78
19	4	16	0.83	0.38	1.81	1.50	219	5.61
20	5	32	0.70	0.36	3.26	2.28	349	6.31
21	6	64	0.70	0.34	5.81	4.07	661	7.01
22	7	128	0.70	0.31	9.11	6.38	1204	7.71
23	8	256	0.70	0.29	16.9	13.47	2720	8.41

Source: Modified with permission from Haefeli-Bleuer B, Weibel ER: Morphometry of the human pulmonary acinus. Anat Rec. 1988;220(4):401–414.

we can also estimate the distribution of alveolar surface area to the different generations in proportion to the duct surface $S_d(z')$, but adjusting for the fact that only part of this surface is associated with alveoli in the respiratory bronchioles (generations z′ = 1–3). For an estimated alveolar surface of 130 m^2 in the human lung (Table 2-4), there would be about 54 cm^2 of gas-exchange surface per average acinus. It is seen that half this gas-exchange surface is in the last generation (see also Fig. 2-64). A final check of this model is that the path length from the entrance into the transitional bronchiole to the end of the alveolar sacs is 8.4 mm, which agrees well with the mean path length estimated in the human acini (Fig. 2-65).

Implications of Acinar Design for Gas-Exchange Function: The Phenomenon of Diffusion Screening

The gas exchange in the pulmonary acinus involves several physicochemical phenomena that occur within the complex acinar geometry described in the preceding section.[197] As mentioned, in the distal regions of the lung, oxygen is transported toward the alveolar membrane both by convection and molecular diffusion. Oxygen then diffuses through the tissue membrane into the blood, where it is bound by hemoglobin. Several physical parameters govern oxygen uptake at the acinar level, such as air flow velocity, diffusion coefficient of oxygen in air, alveolar membrane permeability, blood hemoglobin content, and its reaction rate with oxygen. Conversely, carbon dioxide is discharged from the blood to the alveolar gas through diffusion across the membrane. It then diffuses backward along the airways to the zone, where convection becomes dominant, and is lastly expelled from the lung. In all these processes, the morphology of the system plays an essential role.

Since oxygen uptake into the blood is driven by the O_2 partial pressure at the alveolar surface we must ask whether this driving force is the same throughout the acinus or whether there could be differences between its central and peripheral parts. Some earlier studies had shown that concentration gradients may exist as a consequence of efficient capture of oxygen by hemoglobin. More recently,[197] we have come to realize that such gradients are strongly influenced by the finite permeability of the membrane that plays a dominant role in the effective properties of the acinus as the ventilatory gas-exchange unit. O_2 molecules entering the unit where diffusion prevails have a larger probability to hit the surface of the alveolar membrane near the entrance than in the more distal regions. If the membrane permeability is large, O_2 molecules are absorbed at the very first hits. As a consequence, O_2 is absorbed into the blood in the first parts of the acinar pathway, a process called *diffusional screening,* so that the gas-exchange units in the deeper part of the acinus would receive less O_2 (Fig. 2-61) or perhaps even not enough for gas exchange to occur. Blood perfusing these regions would not be oxygenated and would thus appear as a shunt. In contrast, if the permeability is small, molecules will be absorbed only after many collisions with the wall. They then have a fair chance to reach the deeper regions and the entire acinar surface can be effective for gas exchange.

To put this into the perspective of structure–function relations this process is related to the balance between two conductances:[197] a diffusion conductance Y_{cross} for O_2 to *cross* the barrier from alveolar air to capillary blood, and a diffusion conductance Y_{reach} for O_2 to *reach* the surface through the airspaces. Both these conductances are determined by the product of: (a) a physical parameter (the permeability coefficient for O_2 in tissue, and the diffusion coefficient for O_2 in air, respectively); and (b) a morphometric parameter (the gas-exchange surface, and the distance along the acinar airways, respectively). The physical coefficients are given quantities, except that the tissue permeability is also affected by the thickness of the tissue barrier, a parameter that varies very little between species. On the other hand, the size and surface of the acinus can be varied during evolution and growth to adjust the two conductances. We can predict that the design of the acinus is optimized if Y_{cross} and Y_{reach} are about equal as this means that both the gas-exchange surface and the acinar air volume, or the diffusion distance, are matched. If Y_{cross} were much smaller than Y_{reach} the low permeability of the gas exchanger would need to be compensated by a larger gas-exchange surface, and this would inevitably entail a larger volume of the acinus to accommodate the surface and by that a longer diffusion distance.

The morphometric study of acini in various mammalian species[9,197,198] revealed that the size of the acini is such that $Y_{cross} \sim Y_{reach}$ so that their morphology seems to be at least partially adapted to minimize the effects of screening. Note that the problem of screening occurs in that part of the acinus where O_2 moves to the surface by diffusion only (Fig. 2-62), in what is called the diffusion cell. The transition between convection and diffusion is determined by the Peclet number (Fig. 2-66), essentially the ratio between air flow and diffusion velocities[197]; diffusion is more effective than convection when the Peclet number is smaller than 1. In the human lung, under resting conditions, this transition occurs in generation 18 and that is the entrance to the 1/8 subacinus (Fig. 2-63); accordingly the diffusion cell corresponds to the 1/8 subacinus. In exercise, where O_2 consumption as well as ventilation is increased, convective transport of O_2 is effective out to generation 21 (Fig. 2-66). So in exercise there are only two to three generations of acinar airways that act as diffusion cell, but that is still highly significant because these generations accommodate 75% of the gas-exchange surface (Fig. 2-64 and Table 2-5).

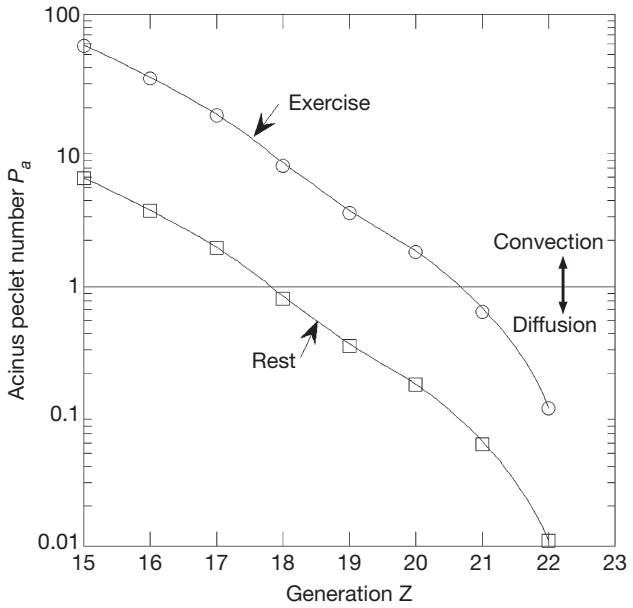

Figure 2-66 In the human acinus the Peclet number, reflecting the relation between convective flow velocity and diffusion velocity of O_2, falls as the airway cross-section increases. Below 1 diffusion becomes the dominant mechanism of alveolar ventilation. This transition point is about in generation 18 at rest and extends out to generation 21 in heavy exercise. *(Reproduced with permission from Sapoval B, Filoche M, Weibel ER. Smaller is better, but not too small: A physical scale for the design of the mammalian pulmonary acinus. Proc Natl Acad Sci USA. 2002;99(16):10411–10416. Copyright (2002) National Academy of Sciences, USA.)*

Note that what has been discussed so far relates essentially to about half the respiratory cycle, namely, inspiration when fresh O_2-rich air is actively brought into the acinus. During expiration things are in a way reversed: CO_2 that has diffused from the blood into the acinar air now dilutes O_2 and the convection–diffusion front is moved toward the bronchi. For this reason, the effective duty cycle of the gas-exchange system is smaller than 1, particularly under the conditions of high O_2 uptake rate in exercise. This must be considered when modeling gas exchange. Recent refined model studies using the same morphometric data together with reasonable assumptions on the physiologic conditions revealed that the size of the human pulmonary acinus is such as to avoid negative effects of diffusional screening.[199]

THE LUNG AS PART OF THE PATHWAY FOR OXYGEN

The lung's main function, gas exchange between air and blood, serves the body's varying O_2 needs as they are set by the energetic demands of the cells and their mitochondria when these produce ATP by oxidative phosphorylation to allow the cells to do work. This process requires a flow of O_2 to be maintained from the lung to the cells[16] which proceeds along the respiratory system through various steps from the lung to the blood, by circulatory blood flow to the cells and mitochondria (Fig. 2-67). A number of basic features characterize this system: (1) under steady-state conditions the O_2 flow rate, $\dot{V}_{O_2}$, is the same at all levels; (2) the basic driving force for O_2 flow through the system is a cascade of O_2 partial pressures, which fall from inspired P_{O_2} down to near zero around the mitochondria; (3) the O_2 flow rate at each step is the product of an O_2 partial pressure difference and a conductance G, which is related to structural and functional properties of the organs participating in O_2 transfer. In the preceding section we have seen that the principal design features of the lung that determine one of the key conductances, the pulmonary diffusing capacity, are sized to just yield a conductance that allows the O_2 uptake required to satisfy the demands of the whole body cell system at work, with a small margin of safety under normal conditions. Therefore, the lung appears designed to serve the body's needs efficiently and economically. The question we may now ask is whether the other parts of the respiratory system, from the heart to the mitochondria are also designed for economic functional performance.[200]

Let us first look at the overall functional performance of the system. We first note that O_2 consumption is highly variable, increasing by about a factor of 10 between resting conditions and heavy exercise when 90% of the O_2 is consumed in the locomotor muscles. Figure 2-68 shows that the oxygen consumption in muscle is proportional to the energy output,[201] measured for example as running speed, and that it reaches a limit $\dot{V}_{O_2max}$ beyond this the running speed can still be increased, but the additional energy required by the higher speed is then supplied through glycolysis or anaerobic ATP production with the result that lactic acid concentration in the blood gradually increases. It is now interesting to note that $\dot{V}_{O_2max}$ is a characteristic of the work capacity of an individual: well-trained athletes reach their $\dot{V}_{O_2max}$ at a higher running speed and a higher level of oxygen consumption, and lactic acid concentration in the blood also begins to increases at the higher performance levels corresponding to $\dot{V}_{O_2max}$ (Fig. 2-68).

One may now raise the question whether this variable limitation of oxidative metabolism is a result of variable functional constraints affecting the regulation of metabolic rate and circulatory transport, or whether it could be set by variations in design constraints characterizing the structural components of the pathway, one possible candidate being the pulmonary diffusing capacity. The answer to this question depends on an integrated study of structure and function of the respiratory system. For this we need a quantitative model of the oxygen pathway that identifies all the functional variables and the design parameters at the four levels of the system[202]: the lung, circulation of blood with the heart, capillaries, and mitochondria (Table 2-6). This model is a further development of the one shown in Figure 2-67 in the sense that, at each level, the equation describing oxygen flow rate sorts out the parameters of functional

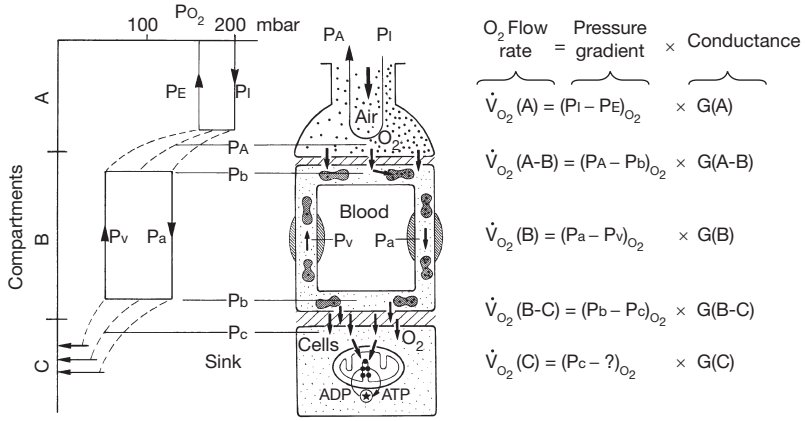

Figure 2-67 Model of the respiratory system from the lung to the cells. Oxygen flow is driven through the system by a cascade of P_{O_2} ranging from inspired $P_{I_{O_2}}$ to near zero at the mitochondria. At each level the flow rate is determined by a partial pressure difference and a conductance. *(Modified with permission from Taylor CR, Weibel ER: Design of the mammalian respiratory system. I. Problem and strategy, Respir Physiol. 1981;44(1):1–10.)*

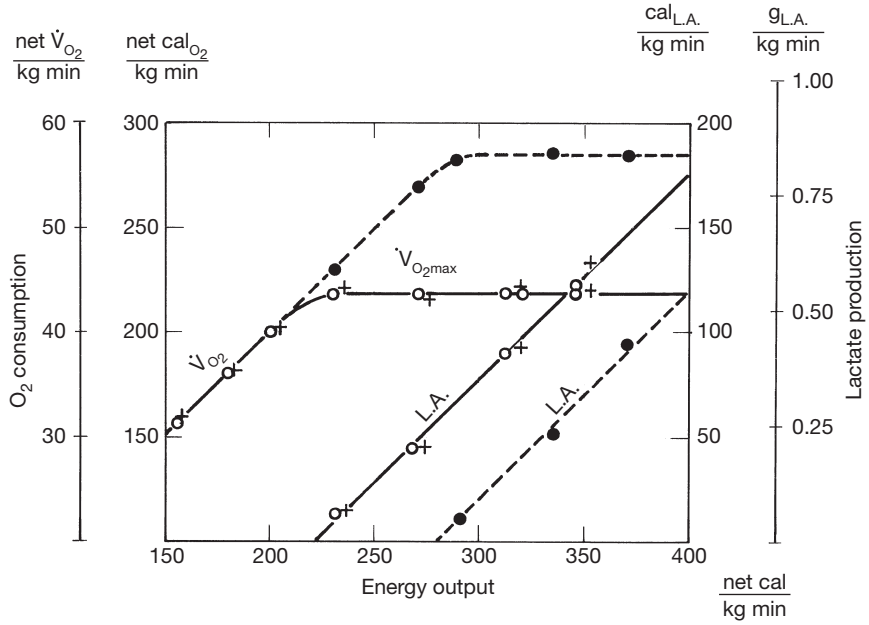

Figure 2-68 Rate of O_2 consumption *(left ordinate)* and lactic acid production *(ordinate at right)* in exercise are plotted as a function of the work intensity and, therefore, of the energy requirement *(abscissa)*. Oxygen consumption increases linearly up to a point corresponding to an energy requirement of 220 cal/kg min^{-1}; if work is pushed beyond that there is no further increase in O_2 consumption ($\dot{V}_{O_2max}$ is reached) but glycolysis now generates the required energy resulting in an increase in lactic acid production. The broken lines refer to athletes (middle- and long-distance runners) whose maximum oxygen consumption is higher; the line of the lactic acid for these subjects is correspondingly shifted to the right. *(Reproduced with permission from Margaria R, Cerretelli P, Diprampero PE, et al. Kinetics and mechanism of oxygen debt contraction in man. J Appl Physiol. 1963;18:371–377.)*

regulation and those of structural design. These are distinguished in the following sense: Functional variables are regulated according to need with short time constants (seconds), whereas structural design parameters are genetically determined static elements that can be adjusted to a certain extent, for example, by training, but with time constants of weeks to months.

Thus, design variables set the capacity of the system because they are determined by structures whose quantitative properties cannot be adjusted at short notice. If the system were designed according to the principle of symmorphosis we would predict that the design variables are adjusted to $\dot{V}_{O_2max}$ at all levels from the lung to the mitochondria.

The experimental test of this hypothesis requires the integrated measurement of $\dot{V}_{O_2max}$ of the relevant functional parameters, and of all the design parameters, which must then be correlated on the basis of the model of Table 2-6. This cannot be easily done in the human so that is where we can learn from studies in comparative physiology. We know that $\dot{V}_{O_2max}$ is highly variable among mammals. Some species such as dogs, horses, or pronghorn antelopes have a much higher level of $\dot{V}_{O_2max}$ than "normal" species of the same size such as goats or cows; this is called adaptive variation.[203] On the other hand body size matters so that small animals have a higher metabolic rate per unit body mass than large species, which is called allometric variation.[200] These are genetically determined variations, the result of evolution and selection by fitness, in contrast to the changes in overall work capacity and $\dot{V}_{O_2max}$ induced by exercise training in human athletes, which are epigenetic variations.[204,205] In all these cases we can ask how and to what extent the structural design parameters are adjusted to meet the different requirements for O_2 to cover the energetic need at the limit of the aerobic work capacity. If there is a bottleneck, then there will be one and only one parameter whose variation is perfectly matched to the variation in the limit of O_2 flow, $\dot{V}_{O_2max}$, whereas all the parameters that are overdesigned would appear in haphazard relations to the flow limit. On the other hand, if the limiting resistances are distributed all steps would have to be matched to the varying $\dot{V}_{O_2max}$. If we take the bold view that the organisms are economically designed we would predict that the structural parameters at all levels should be sized to the maximal total O_2 flow requirement with no unnecessary excess capacity because that would be a waste. We have called this design principle symmorphosis, meaning that there should be no more structure built into the system than required to serve the functional needs.[179]

TABLE 2-6 Model of Structure–Function Relations in Pathway for Oxygen Separating Functional and Structural Parameters in the Equations Defining O_2 Flow Rate Through Four Levels

FUNCTION • DESIGN	
$\dot{V}_{O_2}\ (\text{lung}) = (PA_{O_2} - Pb_{O_2})\{t_c, \theta_{O_2}\} \bullet DL_{O_2}\{S(A), S(c), V(c), \tau_{hb}\}$	(1)
$\dot{V}_{O_2}\ (\text{heart}) = (\sigma_a \cdot Pa_{O_2} - \sigma_{\bar{v}} \cdot P\bar{v}_{O_2}) \cdot f_H \bullet Vs\{V(LV)\} \cdots V_V(ec)$	(2)
$\dot{V}_{O_2}\ (\text{caps}) = (Pb_{O_2} - Pc_{O_2})\{tc\theta_{O_2}\} \bullet DT_{O_2}\{S(c), V(c), V_V(ec), \delta(c, mi)\}$	(3)
$\dot{V}_{O_2}\ (\text{mito}) = \dot{V}_{O_2}\{\dot{m}_{ATP}\} \bullet V(\text{mi})\ \{S_V(im, mi)\}$	(4)

The O_2 flow rate $\dot{V}_{O_2}$ is expressed as the product of functional and design parameters; parameters that affect the factors are shown in italics and placed in braces {.}. The functional parameters include: O_2 partial pressures (P_{O_2}), coefficients of "hematocrit-specific" O_2 capacitance (σ) which depend on O_2-hemoglobin dissociation, O_2 binding rate (θ), heart frequency (f_H), capillary transit time (tc), and mitochondrial O_2 consumption rate as function of ATP flux ($\dot{V}_{O_2}\{\dot{m}_{ATP}\}$). Design parameters include: diffusion conductances (D) of lung and tissue gas exchangers which depend on alveolar and capillary exchange surface areas ($S_{(A)}$, S(c)), capillary volumes (V(c)), hematocrit (V_V(ec)), harmonic mean barrier thickness (τ_{hb}), capillary-mitochondrial diffusion distance (δ(c,mi)), and mitochondrial volume (V(mi)) with inner membrane surface density (S_V(im,mi)).

Testing the Hypothesis of Symmorphosis

To test such a hypothesis we can first compare mammals that greatly differ in terms of their maximal O_2 consumption. The first type of this variation is found in comparing normal with athletic species, such as dogs with goats or horses with steers.[203] It has been found that such athletic animals can achieve a $\dot{V}_{O_2max}$ that is about

TABLE 2-7 Comparison of Morphometric and Physiologic Parameters of Muscle Mitochondria and Capillaries, and of Heart, Blood and Lung with Variation of $\dot{V}_{O_2max}$ in Three Pairs of Athletic and Sedentary Species. Data per Unit Body Mass

	Mitochondria		Blood	Capillaries		Heart			Lung
Design Function	$\dot{V}_{O_2max}/M_b$ mL·min^{-1}·kg^{-1}	V(mt)/Mb mL·kg^{-1}	V_V(ec)	V(c)/Mb mL·kg^{-1}	V(ec)/Mb mL·kg^{-1}	fH min^{-1}	Vs/M_b mL·kg^{-1}	$\dot{Q}$(ec)/Mb mL·min^{-1}·kg^{-1}	$D_{L_{O_2}}$/Mb mL·min^{-1}·mmHg^{-1} kg^{-1}

2.5 times higher than that of normal species of the same size. This is much more than what human athletes can achieve. The relevant morphometric data on such species are shown in Table 2-7 for three species pairs.[206] If we go through the respiratory system, beginning at the bottom with the mitochondria, we note that their total volume in the locomotor muscles is also 2.5 times greater in the athletic species with the result that, at $\dot{V}_{O_2max}$ the unit volume of mitochondria consumes the same amount of oxygen in all these six species, namely about 5 mL O_2 per minute and mL mitochondria. In the next level up, the muscle capillaries, we note that the capillary volume is only 1.7 times greater in the athletic species. However we note that in the athletes the hematocrit, that is, the concentration of erythrocytes in the blood, is larger so that as a result the capillary erythrocyte volume, the product of capillary volume with hematocrit, is 2.44 times greater, thus well matched to the mitochondrial O_2 demands. Note that this is what counts because oxygen is delivered exclusively from the capillary red blood cells. When we look at the determinants of total blood flow the heart is the central element. We notice that athletic species have larger hearts resulting in a larger stroke volume Vs, but that the maximal heart frequency is not different between the species pairs so that cardiac output is determined by the stroke volume. This is only 1.7 times greater in the athletic species. However, note that, here again, the hematocrit plays an important role as it determines the amount of O_2 that can be transported to the capillaries. If we calculate the cardiac erythrocyte output $\dot{Q}$ (ec) we find that it is again 2.4 times greater in the athletic species. Thus the design parameters of the internal steps of the O_2 transport cascade are quantitatively adjusted to the needs for O_2 flow under limiting conditions. Thus, it appears that the resistance to O_2 flow is distributed to all levels.

When we then consider the design of the pulmonary gas exchanger we note that the O_2 diffusing capacity of the lung of athletic species is only 1.7 times greater than that of normal species. Considering that we found that the human lung may have some excess capacity by about a factor of 1.5, this may signify that normal sedentary species such as goats or cows have a greater excess capacity than athletic species. Indeed, this can be shown to be the case in two ways:[207] (1) when one calculates the progression of O_2 loading on capillary blood (Bohr integration, Fig. 2-59) one finds that dogs reach saturation just before the blood leaves the capillaries into arterial blood, whereas the goats have some 30% reserve capacity; (2) when goats are run on a treadmill while breathing hypoxic air one finds that they can maintain their $\dot{V}_{O_2max}$ in contrast, dogs cannot run at their established $\dot{V}_{O_2max}$ under such conditions. We concluded from this observation that athletic species have designed a lung to match the requirements for maximal O_2 uptake with no excess capacity while normal sedentary species apparently allow for a certain safety margin which allows them to perform well also under unfavorable hypoxic conditions. If this is now applied to our observations on the human lung this may mean that the excess capacity of the normal lung may just be sufficient to allow athletes to increase their $\dot{V}_{O_2max}$ by training by a factor 1.5, just about what they can achieve (Fig. 2-67).

One has also found that highly trained athletes do not tolerate heavy exercise at very high altitudes as they cannot achieve O_2 saturation of their arterial blood. Thus, it seems that the pulmonary gas exchanger is now the limiting factor for O_2 transfer to the working muscles. The reason for this is that the lung of the adult cannot enlarge its gas-exchange surfaces to match the increased demands of trained muscles. So an athlete must make do with the lung she or he has developed during growth. This contrasts with the changes induced by exercise training in muscle with an increase in mitochondria and capillaries, and in the heart by enlargement of the ventricles, all well matched to the maximal

O_2 demands.[202] Therefore, it is fortunate – and perhaps a sign of good design – that the lung is designed with some excess diffusing capacity to allow the lower, internal, levels of the respiratory system to exploit their capacity to adapt to increased energetic needs.

CHAPTER 3

The Respiratory Muscles

Ghislaine Gayan-Ramirez
Marc Decramer

The respiratory muscles constitute a complex pump system. Several muscles comprise this system, represented schematically in Figure 3-1. Breathing under all circumstances requires a coordinated contraction of different respiratory muscles. The most important inspiratory muscle is the diaphragm. The conditions under which this respiratory muscle system weakens and eventually will fail are addressed in other chapters (see Chapters 83, 85, and 104). This chapter focuses on structural and functional properties of the respiratory muscles, respiratory muscle action, and respiratory muscle interaction.

STRUCTURAL AND FUNCTIONAL PROPERTIES OF RESPIRATORY MUSCLES

The respiratory muscles are skeletal muscles, and, in essence, their structural and functional properties are within the range of other skeletal muscles located in the limbs. Adaptations to their specific function, however, make them distinctly different from other skeletal muscles in a number of respects. First, limb muscles are essentially designed to produce movements, and hence, primarily work against inertial loads. Respiratory muscles mainly have to overcome resistive and elastic loads.

Second, peripheral muscles contract rhythmically during movements, whereas respiratory muscles contract rhythmically and continuously, and they are the only skeletal muscles on which life depends. These vital muscles thus have to be well equipped to sustain continuous rhythmic contraction. These adaptations include high fatigue resistance, high oxidative capacity, greater capillary density, and greater maximal blood flow, and they depend upon structural and functional properties of the muscles.

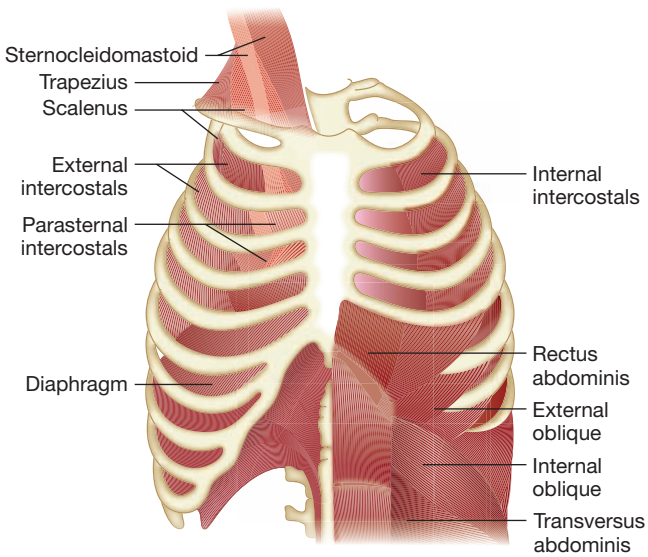

Figure 3-1 Idealized drawing of the respiratory muscles.

STRUCTURAL PROPERTIES

Structural properties of muscles in general, and respiratory muscles in particular, depend upon fiber types present in the muscle, morphological characteristics of the fibers, and motor unit organization.

Fiber Types

Four types of muscle fibers are usually present in skeletal muscles. They are distinguished on the basis of the myofibrillar myosin adenosine triphosphatase (ATPase) activity and its pH dependence and pretreatment with paraformaldehyde.[1,2] Thus, after acid preincubations at pH 4.5, type I fibers are stained dark, type IIa fibers are stained lighter than type IIb and type IIx fibers. In addition, pretreatment with paraformaldehyde after alkaline preincubation at pH 10.4 further allows the distinction between type IIb fibers staining lighter than type IIx fibers. Alternatively, muscle fibers may be distinguished through myosin heavy chain gene expression using electrophoresis and western blotting or via immunostaining.[3] This latter technique has the advantage of revealing the presence of coexpression of different myosin heavy chain isoforms within the same muscle fiber. It has also been revealed that myosin heavy chain 2b is not expressed in human muscle.[4] Type I fibers, or slow oxidative fibers, have a slow contraction profile but are high in endurance and rich in oxidative enzymes.[5] Type II fibers are fast-twitch fibers that develop tension rapidly. They either are fatigue resistant or glycolytic oxidative (IIa), or fatigable or glycolytic (IIb),[5] whereas resistance to fatigue for the type IIx fibers is intermediate between the IIa and IIb fibers. Type II fibers develop greater forces than do type I fibers. Muscles primarily composed of type I fibers have high endurance capacity, whereas those primarily composed of type IIb fibers are designed to develop high forces but have low endurance capacity.[5] Type IIa fibers are intermediate and combine relatively high force development with relatively long endurance.[5] In general, type I fibers have the smallest cross-sectional area, and type IIb fibers tend to have the largest.

The respiratory muscles are mixed muscles containing both fast-twitch and slow-twitch fibers. The human diaphragm contains about 55 ± 5% type I fibers, 21 ± 6% type IIa fibers, and 23 ± 3% type IIx fibers. Other respiratory muscles (i.e., intercostal muscles, abdominal muscles, sternomastoids) contain at least 60% highly oxidative fibers.[6] No data are available on the scalenes. The respiratory muscles thus are generally well equipped to sustain continuous rhythmic contraction.

Morphological Characteristics of the Fibers

The respiratory muscles consist of muscle bundles oriented in a parallel fashion. These bundles consist of hundreds of muscle fibers, each of which in turn consists of hundreds of myofibrils. These myofibrils are made up of hundreds of sarcomeres arranged in series, each sarcomere consisting of a number of myosin (thick filaments) and twice the number of actin (thin) filaments. The capacity of the muscle to produce forces depends upon the number of myofibrils in parallel, since the forces developed by all these myofibrils are additive, whereas the displacement and velocity of shortening depend upon the number of sarcomeres in series. Indeed, the displacements of these sarcomeres arranged in series are additive.

The density of mitochondria in each of the four fiber types tends to be greater than in the same fiber types in limb muscles.[5,7] In addition, in humans, the diaphragm is composed of about 80% oxidative fibers compared with 36% to 46% in the limb muscles of untrained men.[5,7] As a consequence, the volume density of mitochondria in the diaphragm is twofold greater than in the limb muscles.[5,7] Therefore, the oxygen uptake capacity of the diaphragm is considerably greater than that of limb muscles because of the high oxidative fiber content and the greater mitochondrial density.[5,7] Moreover, the maximal blood flow also considerably

exceeds that of limb muscles because of the greater capillary density, which is about twice the capillary density in the limb muscle. The diaphragm is thus well equipped to sustain rhythmic contraction at rest through its type I and IIa fibers: The type IIa fibers permit additional recruitment in power and rate during exercise, and the few type IIx fibers permit high power outputs necessary for sneezing and coughing.

Motor Unit Organization

Muscle fibers are organized by their innervations in motor units that vary in their mechanical and fatigue properties. In adults, all muscle fibers within a motor unit are the same fiber type. The muscle fibers within a given motor unit are broadly dispersed throughout a region of the diaphragm. Dispersion occurs both horizontally across the surface of the diaphragm and vertically with fibers at different depths. The innervation ratio (number of fibers supplied by a single motoneuron) is approximately 400 in rat diaphragm[8] compared with an estimated value of 2500 in humans.[9] There are four types of motor units in the respiratory muscles: a motor unit with slower contraction times and resistance to fatigue (type S) and three types of motor units displaying faster contraction times, with various degrees of fatigue resistance. The type S comprises fibers that express the slow isoform of myosin heavy chain. Fast motor units that are fatigue resistant (type FR) comprise muscle fibers expressing the myosin heavy chain 2a; those that are highly fatigable (type FF) comprise muscle fibers expressing myosin heavy chain 2b; and those that are fatigue intermediate (type FInt) comprise muscle fibers that express the myosin heavy chain 2x. Motor units composed of fast fibers are large and develop forces in the range of 110 millinewton (mN). These, however, are considerably smaller than in limb muscles. Motor units composed of slow fibers are smaller and develop forces in the range of 30 to 60 mN. The recruitment pattern of the diaphragm follows the size principle with the smallest motor units being recruited first.

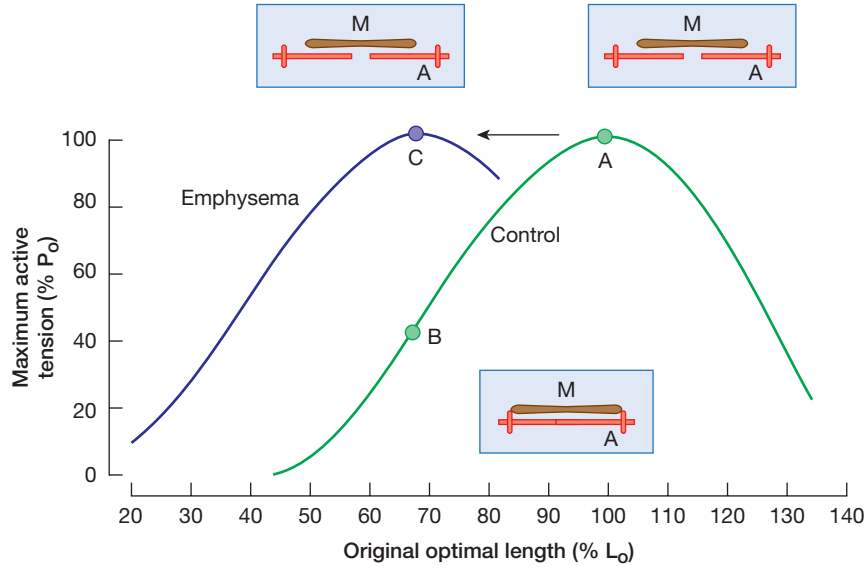

Figure 3-2 Diaphragmatic length–tension curve in normal hamsters and hamsters with elastase-induced emphysema. Tension is expressed as a percentage of maximum tetanic tension, P_o, and length is expressed as a percentage of original optimal length, L_o. The degree of filament overlap among actin (A) and myosin (M) filaments in control (**A**), acute (**B**), and chronic hyperinflation (**C**) is shown. Note that due to sarcomere adaptation in chronic hyperinflation, the degree of filament overlap is the same at a considerably shorter length. *(Reproduced with permission from Farkas G: Functional characteristics of the respiratory muscles. Sem Respir Crit Care Med. 1991;12(4):247–257.)*

■ FUNCTIONAL PROPERTIES

Functional properties of muscles are generally described in terms of force–length relationships, time-dependent characteristics of the twitch, force–frequency, force–velocity, and power–frequency relationships.

The force–length characteristics of the diaphragm are in essence similar to other muscles. Maximal tension is generated at the optimal length. Three aspects of the force–length curve of the diaphragm are potentially relevant to clinical medicine. First, with hyperinflation, the diaphragm shortens and its capacity to generate force is concomitantly reduced.[10] Second, when hyperinflation occurs chronically, adaptation occurs in the muscle. This adaptation consists of drop out of sarcomeres such that muscle shortening is then accommodated by a reduced number of sarcomeres rather than alterations in filament overlap within the sarcomeres.[11] As a consequence, the force-generating capacity is restored, at least in part, at foreshortened length.[10] This adaptation is summarized in Figure 3-2. The consequences of this adaptation to patients with hyperinflation are discussed in the section "Physiological Conditions Affecting Respiratory Muscle Interaction." Third, although less-than-optimal filament overlap is the primary reason for a reduction in force with muscle shortening, calcium deactivation due to T-tubular failure also plays a role.[12] This is potentially significant for treatment, since inotropic agents restore T-tubular function in foreshortened muscle.[13] Accordingly, inotropic agents exert much greater effects on foreshortened diaphragm than on diaphragm placed at its optimal length.[14] This concept opens up new perspectives for respiratory muscle pharmacotherapy in patients with severe hyperinflation. The length–tension curves of other respiratory muscles and their adaptation to hyperinflation have not been systematically studied.

A particularly interesting question is the relationship between the in situ operational length of the respiratory muscles and the optimal length in vitro. For the diaphragm, the length at functional residual capacity (FRC) comes close to the optimal length.[15,16] The length changes undergone by the diaphragm over the vital capacity range are large, 30% to 40%.[17,18] These length changes are considerably smaller for the parasternal intercostals, the scalenes, and the sternocleidomastoids.[19–21] For the parasternal intercostals, the length at FRC is clearly longer than optimal in supine dogs, so that with hyperinflation, the parasternal intercostals move toward their optimal length.[21,22] Subsequent experiments, however, indicate that the fall in pleural pressure caused by stimulation of the parasternal intercostals in dogs is reduced with increasing lung volume.[23] This discrepancy was shown to result from changes in orientation and motion of ribs with hyperinflation. The scalenes and sternocleidomastoids appear to operate on the ascending limb of their length–tension curves in supine dogs.[20] How hyperinflation in patients affects the force-generating capacity of these muscles remains unclear. According to an analysis, the changes in length during passive inflation are proportional to the mechanical advantage of a particular respiratory muscle.[24] In keeping with this analysis, the mechanical advantage of the diaphragm would be considerably greater than the mechanical advantage of other inspiratory muscles (see in the section "Physiological Conditions Affecting Respiratory Muscle Interaction").

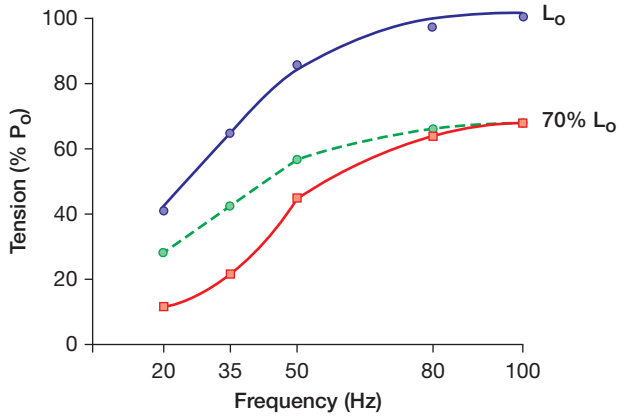

Figure 3-3 Force–frequency curve of human diaphragm at optimal length (L_0) and 70% L_0. Force is expressed as a percentage of maximal tetanic tension, P_0, and frequency is expressed in Hz. *Dashed line* is the predicted line at 70% L_0, whereas the *solid line* is the observed line. The predicted line is based on the assumption that a 30% change in length produces a 35% drop in force at all stimulation frequencies, as is observed for maximal tetanic force. Note that the decrease in force at lower stimulation frequencies is considerably greater than theoretically predicted. *(Reproduced with permission from Farkas G: Functional characteristics of the respiratory muscles. Sem Respir Crit Care Med. 1991;12(4):247–257.)*

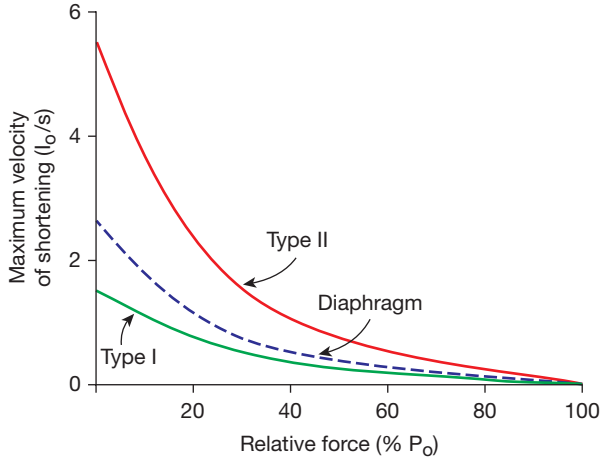

Figure 3-4 Force–velocity curve of human diaphragm *(dashed line)*, which is intermediate between the force–velocity curve of a typical slow muscle (type I) and a typical fast muscle (type II). Maximum velocity is expressed in optimal length (L_0), per second and relative force is expressed as a percentage of maximum tetanic force, P_0.

The force developed by a muscle increases with increasing frequency of stimulation. The increase in force is considerably steeper for a slow muscle in which fusion occurs at lower frequency because of the longer relaxation time than for a fast muscle. The diaphragm is intermediate, so that at in vivo stimulation frequencies (10–30 Hz), a fused tetanic contraction occurs. Particularly interesting is the effect of acute shortening on the force–frequency curve. Since acute shortening is associated with a downward shift of the force–frequency curve, the detrimental effect of acute shortening on the force-generating capacity of the diaphragm appears to be twofold.[10] With muscle shortening there is a clear reduction in maximal tetanic force. However, the decrease in force at submaximal stimulation frequencies is disproportionately greater (Fig. 3-3).

The force–velocity curve of the diaphragm is shown in Figure 3-4. With increasing loads, the velocity of contraction is reduced. The velocity of contraction is a direct function of myosin ATPase activity, and, hence, the force–velocity curve is primarily determined by the muscle fiber composition. The diaphragm is intermediate between the force–velocity curve of a fast and a slow muscle (Fig. 3-4).[6] The production of airflow into the lungs requires power output by the respiratory muscles. Power may be calculated as the product of the values of velocity and force according to the force–velocity relationship (Fig. 3-4). Instantaneous peak power occurs at 30% of maximal force and at 30% of maximal velocity. The frequency–isometric force relationship, frequency–shortening force, and frequency–power relationships show a similar dependency of force and power upon frequency of stimulation.

Fatigue also affects profoundly the force–length, force–frequency, force–velocity, and power–frequency characteristics of the diaphragm. The diaphragm, however, is more resistant to developing fatigue than limb muscles in vivo and in vitro.[25] Of note, the inspiratory muscles recover from fatigue 10 times faster than the elbow flexors performing a similar task.[26] The effects of fatigue on functional properties of the respiratory muscles are discussed in Chapters 84, 85 and 104. The factors determining the development of respiratory muscle fatigue are also discussed in these chapters.

ACTIONS OF RESPIRATORY MUSCLES

THE DIAPHRAGM

The diaphragm is the most important inspiratory muscle. It is innervated by the phrenic nerves supplied by the cervical nerve roots C3 to C5 in humans. It consists of two distinct parts, the costal and crural parts, which have separate actions on the rib cage, separate segmental motor innervations, and a different embryological origin. In respiratory activities, however, the diaphragm frequently operates as a functional unit, and in the following its action is described as such. Diaphragmatic action is schematically represented in Figure 3-5. Diaphragmatic contraction increases chest wall dimensions because of three distinct reasons. First, diaphragmatic descent increases the craniocaudal dimensions of the thorax. Diaphragmatic descent is tightly coupled to outward motion of the free abdominal wall.

Second, diaphragmatic contraction increases the dimensions of the lower rib cage because of the increase in abdominal pressure that it causes. This increase in abdominal pressure acts through the zone of apposition (i.e., the zone in which the diaphragm is immediately apposed to the rib cage) to expand the lower rib cage. This action is the appositional component of diaphragmatic action (Fig. 3-5).[27,28] The magnitude of the appositional component is determined by the magnitude of the zone of apposition, about 25% to 30% of the total internal surface area of the rib cage at FRC in standing humans, and by the magnitude of the increase in abdominal pressure caused by diaphragmatic contraction.[28]

Third, diaphragmatic contraction further increases lower rib cage dimensions because of its insertions into the lower rib cage. The diaphragmatic fibers are oriented axially, and their contraction causes pull on the lower rib cage in an axial direction, leading to cephalad motion and outward rotation of the lower rib and hence, to lower rib cage expansion. This is the *insertional component* of diaphragmatic contraction (Fig. 3-5).[27]

When the diaphragm acts in isolation during diaphragmatic contraction or pacing in high quadriplegics, in whom all inspiratory muscles, except for sternocleidomastoids, are paralyzed,[29,30] it exerts an expiratory effect on the upper rib cage during inspiration.[29,31] These data point out that in normal subjects, quiet inspiration is not accomplished by the diaphragm alone but rather results from the coordinated activity of the diaphragm with the rib cage inspiratory muscles and the abdominal muscles. Indeed, the pattern of chest

wall motion in quadriplegics shown in Figure 3-6 indicates that diaphragmatic contraction alone cannot be responsible for the pattern of chest wall motion observed during quiet breathing (see in the section "Physiological Conditions Affecting Respiratory Muscle Interaction") and hence, that other muscles assist the diaphragm in moving the chest wall during quiet breathing.

■ THE INTERCOSTAL MUSCLES

The functional anatomy of intercostal muscles is schematically represented in Figure 3-7. Between the chondral portions of the ribs only one layer of intercostal muscles, the parasternal intercostals, is present. Between the osseous portions of the ribs, two layers are present. The outermost layer runs obliquely downward and forward and is called the *external intercostal*. The innermost layer runs obliquely downward and backward and is called the *internal intercostal* (Fig. 3-7, left panel). Note that the internal intercostals and parasternal intercostals have the same fiber orientation. Dorsally only an external intercostal is present. Finally, the fusiform muscle running from the lateral border of the transverse processes of the thoracic vertebra and inserting caudally into the rostral border of the rib below is called the levator costae (Fig. 3-7, right panel).

The parasternal portion of the intercostal musculature, the "parasternals," is consistently active during quiet breathing both in animal and human subjects,[19,32] and is the most important inspiratory portion of the intercostal musculature. The parasternal intercostals have the greatest mechanical advantage, and their contraction produces about 60% of the cephalad motion of the rib during inspiration.[33,34] Within the parasternal intercostals, the medial fibers have a greater mechanical advantage and are activated more consistently and before the middle and lateral fibers.[35]

The action as well as the respiratory role of the interosseus intercostals remain the subject of a longstanding debate. The most commonly accepted view on intercostal muscle action is based on a theory of intercostal muscle fiber orientation and rib geometry. This theory states that the external intercostals are inspiratory in action, and the internal intercostals are expiratory in action.[36] Numerous experiments do not fit with this theory, although a finite element analysis largely confirmed these actions.[36] It is commonly believed that the interosseus intercostals constitute a reserve system that may be recruited with increased ventilatory load. The external intercostals are recruited predominantly during inspiration, primarily in the upper interspaces, whereas the internal intercostals are recruited predominantly during expiration primarily in the lower interspaces.[36] Wilson et al.[34] demonstrated

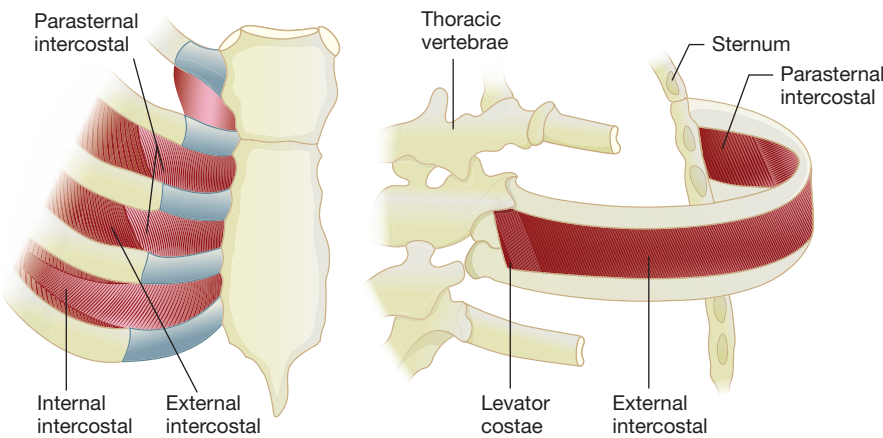

Figure 3-7 Diagram of the functional anatomy of the intercostal muscles, at their anterior *(left)* and posterior *(right)* aspects. Notice the parasternal, internal, and external intercostals, and the levator costae.

by the application of the reciprocity theorem of Maxwell, that the external intercostals in the dorsal portion of the costal interspaces have a large inspiratory mechanical advantage. This advantage decreases in the ventral and caudal directions such that in the ventral portion of the caudal interspaces it is reversed in an expiratory mechanical advantage.[36] Conversely, the internal intercostals in the caudal interspaces have a large expiratory mechanical advantage, but this advantage decreases in the cranial and ventral directions.[36] Because of this pattern of topographic distribution the pattern of neural activation is crucial for the function of these muscles.[36] This pattern was shown to match the pattern of distribution of mechanical advantage, such that the external intercostals have an inspiratory function and the internal intercostals have an expiratory function.[36]

Without question, the levator costae have an inspiratory action on the rib. It is frequently activated even during quiet inspiration in supine dogs.[37] The levator costae's contribution to inspiratory motion of the ribs during quiet breathing, however, appears substantially smaller than that of the parasternal intercostals. This contribution may further increase when the inspiratory motion of the ribs is appreciably increased.

THE SCALENES

The scalenes run between the transverse process of the five lower cervical vertebrae and the upper margin of the first (scalenus anterior) and second (scalenus medius and posterior) ribs. The action of these muscles is to raise the first two ribs. The orientation of their axis in the neck causes upward motion of these ribs ("pump handle" motion). Moreover, the scalenes are consistently active during quiet breathing in normal individuals and contribute to chest wall expansion.[38] They may be very important in the case of spinal cord injury. When the injury is below C4 to C8, the scalenes' function is entirely or partially preserved, and they contribute importantly to upper rib cage motion in these patients.[39]

THE STERNOCLEIDOMASTOIDS

The sternocleidomastoids run between the mastoid processes of the temporal bone and the manubrium sterni and medial portion of the clavicle. The pressure-generating ability of the sternocleidomastoid muscle in normal humans is about the same as that of the scalene muscles. In humans, these muscles are electrically silent during quiet breathing, but they may be recruited with increased ventilatory load. These muscles are particularly important in high quadriplegics in whom they preserve their function because they are innervated by the 11th cranial nerve and spinal nerves C1 to C2.[29,40] Through training the sternocleidomastoids may develop marked hypertrophy and contribute to several hours of ventilator independence in these patients.[40] They also may be recruited in patients with poliomyelitis and diaphragmatic dysfunction. These muscles are thought to be important in moving the upper rib cage in patients with chronic obstructive pulmonary disease (COPD), even though a clinical experimental study failed to demonstrate consistent activity in these muscles in these patients.[41]

THE SHOULDER GIRDLE AND NECK MUSCLES

Several shoulder girdle and neck muscles may contribute to inspiration under particular circumstances. Most of these muscles run from the rib cage to an extrathoracic extension. When the rib cage is fixed in the lean-forward position—a position commonly employed by patients with COPD—these muscles contribute to expansion of the rib cage during inspiration. Muscles that may contribute to inspiration include the trapezius, latissimus dorsi, pectoralis major and minor, erector spinae, teres major, serratus anterior, platysma, mylohyoid, and sternohyoid. Since these muscles commonly contribute to inspiration in patients with severe airflow obstruction, their further use for other activities (e.g., hair combing), may considerably increase dyspnea in these patients.[42]

THE CLAVICULAR HEAD OF PECTORALIS MAJOR

The clavicular head of the pectoralis major runs laterally and caudally from the medial half of the clavicle and manubrium sterni to the humerus. If the arms are fixed and braced, contraction causes downward motion of the ribs and sternum, increase in pleural pressure and, hence, expiration. Simultaneously, the lower rib cage and the abdomen move outward. Tetraplegics use this expiratory action when all other expiratory muscles are paralyzed.[43]

THE TRIANGULARIS STERNI

The triangularis sterni is the most important expiratory muscle of the rib cage.[44] The muscle runs at the inside of the thorax between the inner aspect of the sternum and the inner aspect of the five lower ribs (Fig. 3-8), and its action is to lower the ribs relative to the sternum and thus to cause expiration. The triangularis sterni is electrically silent in humans breathing quietly,[44] but it is recruited during expiration below FRC.[44] Its neural activation is also coupled with that of the abdominal muscles.[44] Its recruitment threshold is low, lower than the recruitment threshold of most other expiratory muscles.

THE ABDOMINAL MUSCLES

The abdominal muscles are composed of four different muscle layers (Fig. 3-1). Ventrally, a muscular sheet running between the lower costal cartilages and the sternum and the pubis, represents the rectus abdominis. This muscle is enclosed in a sheath formed by the aponeuroses of the other three muscles. Laterally, an oblique muscle runs obliquely downward and forward between the lower eight ribs and the iliac crest, inguinal ligament, and linea alba medially, the external oblique. At the inner surface of this muscle lies the internal oblique with a fiber orientation, which is 90 degrees perpendicular to the external oblique. These muscles are homologous to the external and internal intercostals. The innermost layer is the transversus abdominis, a circular muscular sheet surrounding the abdomen, with a fiber orientation that is parallel to the ribs. The transversus abdominis originates from the inner surface of the lower six ribs, where it interdigitates with the costal insertions of the diaphragm. It runs from this origin and the lumbar fascia, iliac crest, and inguinal ligament,

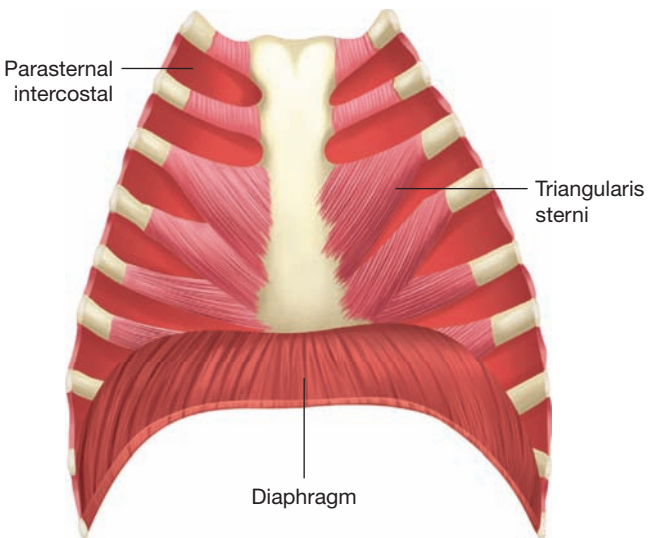

Figure 3-8 Diagram illustrating the functional anatomy of the parasternal intercostal muscles, the triangularis sterni, and the diaphragm.

circumferentially around the abdominal visceral mass to terminate ventrally in the rectus sheet. These muscles all have an expiratory action, by virtue of the inward pull of the abdomen they cause and of the insertions they have in the rib cage. In addition, however, rib cage expansion may occur with contraction of some of these muscles through the increase in abdominal pressure accompanying their contraction.[45]

The abdominal muscles are electrically silent during quiet breathing. Usually, however, tonic activity is present in the abdominal muscles in upright position, particularly in the upper segments.[27] During inspiratory loading, CO_2-induced hyperventilation, exercise, and forced expiration, these muscles are recruited. The transversus abdominis appears to have the lowest recruitment threshold.[46,47]

RESPIRATORY MUSCLE INTERACTION

RESPIRATORY MUSCLE INTERACTION DURING QUIET BREATHING

Respiratory muscle interaction is traditionally studied by means of a Konno–Mead diagram, relating rib cage diameter or cross-sectional area to abdominal diameter or cross-sectional area (Fig. 3-6). First, this relationship is determined in the absence of muscle contraction, during a relaxed expiration, yielding a relaxation line. During quiet breathing in the upright position, the chest wall moves along this relaxation line, which means that proportional expansion of rib cage and abdomen is occurring. In the supine position, abdominal movement is proportionally greater than rib cage movement. Since isolated diaphragmatic contraction in quadriplegics causes abdominal movement without rib cage motion or even inward movement of the upper rib cage (upper rib cage paradox), diaphragmatic contraction alone cannot be responsible for the pattern of motion occurring during quiet breathing (Fig. 3-6). Therefore, this motion requires concomitant contraction of other muscles (i.e., the parasternal intercostals and scalenes). These muscles actively contribute to chest wall motion and cause upper rib cage expansion, whereas diaphragmatic contraction alone would cause upper rib cage paradox. During quiet breathing, the diaphragm probably contributes about 60% to 70% of the tidal volume, and the parasternal intercostals and scalenes contribute the rest.[48]

Posture alters the interaction between the respiratory muscles. For the diaphragm, the resistance of the abdominal contents on diaphragmatic descent is the principal determinant of its action on the rib cage. When changing from a seated to a supine posture in humans, there is a marked increase in abdominal compliance[49] and changes in the diaphragm shape result in less rib expansion. The influence of posture on the lung-expanding action of the diaphragm has been confirmed in patients with upper cervical cord transaction. Indeed, when these patients were supine, the paced diaphragm was able to generate an adequate tidal volume but the latter was progressively and markedly reduced when the patients were gradually tilted head up.[29] The abdominal muscles[50,51] and also the triangularis sterni[44,52,53] are silent in the supine posture in healthy individuals and while the tonic activity of the abdominal muscles in the standing posture is not related to the phases of the respiration, the activity of the triangularis sterni is confined to expiration.[53] Active use of these two sets of expiratory muscles in the standing posture compensates for the adverse effect of this posture on the inspiratory muscles, in particular the diaphragm.

Sleep affects respiratory muscle function negatively but in healthy individuals these physiological changes are not clinically significant. Sleep is associated with a generalized postural muscle hypotonia that is most profound during the phasic events of rapid eye movement (REM) sleep.[54] Therefore, respiratory muscles with a dual respiratory and postural function like the intercostals lose activity during REM sleep whereas the diaphragm, a muscle with only a respiratory function, maintains and even increases its activity to maintain tidal volume during REM sleep.[55] In severe COPD patients where rib cage motion is mainly produced by the inspiratory muscles of the rib cage as the diaphragm is mechanically impaired by hyperinflation, the substantial decrease in the activity of the scalene and sternocleidomastoid muscle during REM sleep is expected to decrease inspiratory pressure development and to lead to hypoventilation.[56]

PHYSIOLOGICAL CONDITIONS AFFECTING RESPIRATORY MUSCLE INTERACTION

Respiratory muscle interaction present during quiet breathing and the chest wall motion resulting from it may be altered in a number of physiological circumstances in which ventilatory load is affected. Indeed, the respiratory muscles participate in tasks that, although not strictly ventilatory in nature, serve important respiratory functions. These tasks of daily life include speech, laughter, swallowing, gagging, vomiting, and coughing. In addition, the interaction of the respiratory muscles is also modified during nonventilatory tasks.

Speech and laughing require the coordination of respiration and structures involved in producing sound features. Spontaneous speech occurs primarily at volume levels below spontaneous end expiration.[57] There is, therefore, a successive recruitment of muscles of expiration to empty the rib cage: first the triangularis sterni muscle[44,57] and the internal intercostal muscles then the external oblique and other muscles of the lateral abdominal wall and finally the rectus abdominis.[46,58,59] At the very end of expiration, the latissimus dorsi is active too.[58,59] Abdominal contraction during speech can optimize the inspiratory function of the diaphragm obliged to contract rapidly between phrases, and will also prevent dissipation of the pressure developed by the rib cage muscles on paradoxical abdominal displacement.[57]

Laughing is a natural maneuver triggered by emotion necessitating the coordination of the laryngeal and respiratory systems to produce a characteristic sound pattern and phasic lung pressure variations superimposed on an active expiratory effort. Laughter generally takes place when lung volume is low, near FRC and is terminated near residual volume.[60] It is characterized by sudden repetitive expiratory efforts leading to a decrease in lung volume due to sudden and sustained increase in gastric and esophageal pressures. The triangularis sterni muscle is recruited during laughing.[44] Higher transdiaphragmatic pressure at the end of the consecutive expiratory efforts indicates that the diaphragm actively prevents part of the increase in abdominal pressure from being transmitted to the chest wall cavity, thereby protecting intrathoracic structures from further mechanical stress and compression.[60] A pilot study suggests that the pattern of diaphragm activation during laughter is different from that induced by coughing or sneezing.[61]

For swallowing, respiration needs to be interrupted. During swallowing, the passive expiration of the diaphragm is interrupted by static activity aimed at preserving respiratory volume for expiration after swallowing.[62] Abdominal activity increases throughout pre- and postswallowing expiration.[62]

Vomiting that is produced by changes in thoracic and abdominal pressures is generated by the coordinated action of the major respiratory muscles. During vomiting, the diaphragm and the external instercostal (inspiratory) muscles cocontract with abdominal (expiratory) muscles in a series of burst of activity that culminates in expulsion while the internal intercostal (expiratory) muscles contract out of phase with these muscles during retching and are inactive during expulsion (see review by Miller[63]). Finally, the portion of the diaphragm surrounding the esophagus relaxes during expulsion, presumably to facilitate rostral movement of the gastric content (see review by Miller[63]).

Coughing, sneezing, and gagging represent complex acts involving both inspiratory and expiratory phases during which most of the respiratory muscles are recruited. Importantly, during those

maneuvers, the maximal diaphragm force is reached.[64,65] Voluntary cough in humans is associated with a coordinated activation of the expiratory and accessory muscles. A graded increase in activity and burst duration proportional to cough flow rates is observed. Low cough flow rates are essentially produced by the activation of the expiratory muscles whereas accessory muscles become involved sequentially and increasingly with the production of higher flow rates.[66] The triangularis sterni muscle is actively recruited during coughing[44,67] and also during sneezing.[67]

Finally, understanding the level of muscle recruitment may be particularly relevant when testing respiratory muscle force to evaluate the degree of impairment in some diseases. Indeed, in untrained normal subjects, maximal inspiratory effort against a closed shutter (Müller maneuver or the maximal inspiratory pressure) mainly activates the intercostal muscle and the diaphragm as well as the sternomastoid.[68] The same holds true for the sniff maneuver through the nose.[68] The combined maneuver consisting in a maximal inspiratory maneuver combined with a maximal expiratory effort activates also the expiratory muscles (rectus abdominis) and produces the highest level of diaphragmatic strength as assessed by measuring transdiaphragmatic pressure.[68] The maximal electrical activity of the diaphragm is reached during the sniff maneuver.[68] These data indicate that the pressure generated by these maneuvers reflects a complex interaction between several groups of muscles.

All the above-mentioned effects pertain to ventilatory aspects of the respiratory muscles but, in addition to their respiratory role, the respiratory muscles also contract during postural tasks. The costal and the crural diaphragm are active with a single rapid movement of the contralateral upper limb in humans.[69] Electromyographic activity of the diaphragm increases prior to the onset of the activity of the muscle responsible for movement. This occurs irrespective of the phase of respiration[69] and is associated with an increase in transdiaphragmatic pressure with an initial reduction in length of the costal diaphragm. Similarly, during trunk rotation external and internal intercostal muscles show increased inspiratory activity superimposed on their postural tone[70,71] as do the parasternal intercostals.[72] During repetitive movement, the diaphragm contracts tonically throughout the respiratory cycle and phasic modulation of diaphragm activity at the frequency of limb movement is superimposed on its respiratory and tonic activation.[73] This was also observed in the transversus abdominis muscle.[73] Modulation of the intra-abdominal pressure that occurs through coordinated activity of the diaphragm, abdominal and pelvic floor muscles, may be important for the control of spinal stability when the limbs move.[69,73] When respiratory demand is increased, the activity of the diaphragm and the transversus abdominis associated with movement of an arm is reduced or even abolished, and the associated changes in gastric pressure are reduced.[74] In humans, the postural role of the diaphragm may also be impaired with specific fatigue of the inspiratory muscles.[75] The human triangularis sterni muscle also contracts during postural maneuvers such as head flexion, trunk rotation, and leg lift.[44]

PATHOLOGICAL CONDITIONS AFFECTING RESPIRATORY MUSCLE INTERACTION

Respiratory muscle interaction is profoundly affected by a number of pathological conditions including hyperinflation, reduced or loss of muscle activity.

Hyperinflation is a functional abnormality of lung diseases in which airflow obstruction or loss of elastic recoil are features. Hyperinflation may be particularly severe in patients with COPD, in whom the FRC often exceeds predicted total lung capacity (TLC). An overwhelming amount of evidence shows that hyperinflation reduces the diaphragmatic effectiveness as a pressure generator and reduces diaphragm contribution to chest wall motion. The contribution of the intercostal muscles and scalenes is likely to be increased, such that chest wall motion becomes exclusively or predominantly rib cage motion (Fig. 3-6). The ineffectiveness of the diaphragm may result from diaphragmatic shortening, geometrical alterations, alterations in diaphragm–rib cage interaction, alteration in mechanical arrangements among the costal and crural parts of the diaphragm, reduction in the zone of apposition.[76] Among these, diaphragmatic shortening appears to be the most important. Indeed, with inflation from FRC to TLC, the diaphragm shortens about 30% to 40%,[17,18] whereas the parasternal and upper external intercostal muscles shorten by only 10%,[19,77] the scalene by 2%,[78] and the sternomastoid muscle by 6%.[78] For the diaphragm, this shortening is expected to reduce significantly its pressure-generating capacity. Several studies indicate that diaphragmatic geometry is not affected significantly by hyperinflation, pointing out that the length–force properties of the diaphragm represents the most important factor for the pressure-generating capacity of this muscle.[79,80] The appositional component of diaphragmatic action is reduced substantially due to a reduction in the zone of apposition.[28] The insertional component is affected so that diaphragmatic contraction causes inward retraction of the lower rib cage. This may be noticed clinically in patients with severe hyperinflation.[81,82] The mechanical arrangement between the costal and crural parts of the diaphragm changes from a parallel arrangement at FRC to a series arrangement at TLC.[17] This is likely to further compromise the pressure-generating capacity of the diaphragm independently of its force–length characteristics.

Hyperinflation also impairs the pressure-generating capacity of the inspiratory intercostal muscles (the parasternals and the external intercostals). This effect is mainly related to the orientation and motion of the ribs.[23] The synergistic interaction between the diaphragm and the inspiratory intercostal muscles becomes prominent at high lung volumes.[23] The force-generating capacity of the neck muscles like the scalene and the sternomastoid muscle is maintained with hyperinflation.[78] In dogs, hyperinflation induces lengthening of the abdominal muscles, particularly the transverse abdominis and internal oblique muscle.[83] Consequently, the rise in abdominal pressure obtained by selective stimulation of the abdominal muscles at TLC is greater than that obtained at FRC.[84] This also happens in normal humans during magnetic stimulation of the abdominal muscles.[83]

It should be emphasized, however, that the above pertains to acute hyperinflation. In chronic hyperinflation, the diaphragm adapts to the chronically foreshortened state by dropping out of sarcomeres.[11] As a consequence, the filament overlap within each sarcomere is restored toward optimal overlap. This adaptation is shown in Figure 3-2. This adaptation, however, only partially restores diaphragmatic function. First, because part of the reduction in force with shortening is due to compression of the T-tubular system, blocking exit-electrolyte flow and impeding excitation–contraction coupling.[12] Whether adaptations in T-tubular function also occur with chronic foreshortening remains to be investigated. Second, sarcomere adaptation adapts only to the loss in diaphragmatic function associated with diaphragmatic shortening and not to the loss in function due to geometrical alterations, alterations in diaphragm–rib cage interaction, changes in mechanical arrangement among different parts of the diaphragm, or loss of zone of apposition. Third, although sarcomere adaptation restores the force-generating capacity of a foreshortened diaphragm, it reduces the number of sarcomeres in series. Consequently, sarcomere adaptation compromises the capacity of the diaphragm to undergo changes in length and, hence, its capacity to produce volume changes, presumably its most important function. The fiber length of the parasternal intercostal muscles[85] and of the scalenus muscle[86] are, however, not affected by chronic hyperinflation in animals.

Interventions aimed at reducing hyperinflation such as lung volume reduction surgery (LVRS) and lung transplantation improve diaphragmatic function. The effects of LVRS are primarily due to an increase in the zone of apposition, lengthening of the diaphragm,

and improved neuromechanical coupling.[87] To what extent complete sarcomere adaptation is present in patients with COPD and extreme hyperinflation is not clear from the clinical studies with LVRS. After lung transplantation the radius of curvature and the zone of apposition of the diaphragm are also restored. This is primarily due to mediastinal displacement toward the graft.

Expiratory muscle recruitment is frequently observed in COPD patients with severe airflow obstruction.[88] The transversus abdominis is frequently recruited. Expiratory muscle recruitment may contribute to the intrinsic positive end-expiratory pressure ($PEEP_i$) that is frequently observed in these patients. $PEEP_i$ is primarily caused by impaired pulmonary mechanics and consequent dynamic hyperinflation. The functional significance of this expiratory muscle activation is poorly understood. Indeed, in severe airflow obstruction, expiratory flow limitation is frequently present. In the presence of expiratory flow limitation, recruitment of expiratory muscles no longer contributes to expiratory flow.

In patients with pulmonary disease in general and COPD in particular, several factors may contribute to generalized muscle weakness, in which the respiratory muscles partake. These include hypoxemia and hypercapnia, malnutrition, cardiac failure, corticosteroid treatment, infection, electrolyte disturbances, and inactivity with consequent disuse atrophy. A recent study demonstrated that COPD exacerbations contribute to the development of this muscle weakness. Of particular importance appears to be treatment with corticosteroids in repetitive bursts, which is often inadvertently administered to COPD patients. Typically this causes a myopathic pattern characterized by scattered necrotic fibers with an increased number of central and subsarcolemmal nuclei, and generalized muscle fiber atrophy as seen on muscle biopsy[89] instead of selective type IIb fiber atrophy as is seen in animal studies.

The continuous patterns of motor activity associated with respiration make the diaphragm the most active muscle in the body. The daily duty cycle (ratio of active to inactive time) of the diaphragm in most species is about 45% compared to 2% for the extensor digitorum muscle (predominantly composed of type IIb fibers) and 14% for the soleus muscle (mainly a type I muscle).[90] Given the diaphragm is highly active, it is expected to be particularly sensitive to inactivity. It is therefore not surprising that serious diaphragm dysfunction develops rapidly during controlled mechanical ventilation, a situation in which the diaphragm is totally inactive.[91–93] Perturbations in respiratory muscle interaction are also marked in patients with cervical spinal cord injuries. In these patients, the intercostal and abdominal muscle contribution to respiratory function is lost. Diaphragm inspiratory capacity is also often compromised when injury is located at the C3 to C5 levels. During quiet breathing, tetraplegic subjects with injuries at C4 to C7 use their scalene[39,94] that becomes hypertrophied.[94] Patients with high tetraplegia use several neck muscles[40] in addition to the sternocleidomastoids and trapezii to breathe.[29] Quadriplegics are also predisposed to the development of inspiratory muscle fatigue because of reduced muscle strength and endurance.[95] Inspiratory muscle training in these patients increases both strength and endurance and protects against fatigue.[95] Diaphragm contracting alone through phrenic nerve pacing in subjects with upper cervical cord transaction or during spontaneous breathing in subjects with traumatic lower cervical cord transaction exerts both an expiratory action on the upper rib cage and an inspiratory action on the lower rib cage.[29,31,39] Finally because abdominal and expiratory rib cage muscles are paralyzed in subjects with tetraplegia, their ability to raise intrathoracic pressure is markedly reduced. Despite active use of the clavicular portion of the pectoralis major to deflate the rib cage during forced expiration,[43,96,97] cough is ineffective and the clearance of airway secretion is markedly impaired. Strength training of the pectoralis major improves expiratory function,[98] an effect that is expected to increase the effectiveness of coughing that might reduce the prevalence of bronchopulmonary infections in these subjects.

CONCLUSIONS

The act of breathing requires the coordinated action of a number of muscle groups. During quiet breathing, chest wall motion results from the action of the diaphragm but also from the other inspiratory muscles such as the parasternal intercostals and the scalenes in addition to the expiratory muscles. Those respiratory muscles are all well equipped to sustain continuous rhythmic contraction. Respiratory muscle interaction is affected by posture and sleep but also in a number of physiological circumstances in which ventilatory load is altered such as during speech, laughter, swallowing, gagging, vomiting, and coughing. In addition to their respiratory role, the respiratory muscles also contract during postural tasks such as limb muscle movement, leg lift, trunk rotation, and head flexion. Finally, several pathological conditions including hyperinflation, reduced or loss of activity caused by undernutrition, medical treatment (in particular corticosteroids), mechanical ventilation, or spinal cord injury may also affect the function and the interaction of the respiratory muscles. Strategies consisting in reducing hyperinflation (e.g., LVRS, lung transplantation), or improving muscle function through muscle training may help to some extent restoring respiratory muscle function.

ACKNOWLEDGMENTS

The authors thank Mr. Jean Sente for making excellent drawings. They further thank the Fonds voor Wetenschappelijk Onderzoek-Vlaanderen grants #G.0389.03, #G.0386.05, and #G.0197.07, Research Foundation KU Leuven grants #OT/02/44 and #OT/06/52 and Astra Zeneca Pharmaceuticals for their support of the research mentioned in this chapter.

CHAPTER 4

Molecular Regulation of Lung Development

Wellington V. Cardoso
Jining Lu

INTRODUCTION

This chapter focuses on the mechanisms that control the development of the respiratory tract from the specification of lung endoderm and tracheal progenitors to the formation of the bronchial tree and the alveolar region. Based essentially on histological criteria lung development can be described in four stages: *(a) Pseudoglandular*: Corresponding to the period of formation of the bronchial tree through branching morphogenesis, the lung exhibits a gland-like morphology with epithelial tubules separated by a thick mesenchymal layer; *(b) Canalicular*: Branching is nearly finished and distinct columnar and cuboidal epithelial cells are seen in proximal (large) and distal (small) airways, respectively. Epithelial tubules are separated by a thinner mesenchyme containing blood vessels; *(c) Saccular*: Primitive saccules are seen at the distal end of bronchial tree with widening of the lumens and the appearance of type I (flat-shaped) and type II (cuboidal, surfactant-producing) cells. The intimate approximation of the type I cell to the vascular structures (primitive alveolar–capillary barrier) allows gas exchange during the immediate postnatal period; *(d) Alveolar:* Primitive saccules undergo septation to form numerous smaller mature alveolar structures to increase gas exchange surface.[1,2]

The development of the respiratory system encompasses prenatal and postnatal life, although timing and duration of specific events vary among species. Lung development starts much earlier in humans than in mice and rats; alveolar formation initiates in the human lung by late gestation in contrast to the murine lung, in which alveolization is a postnatal process (see comparison in Fig. 4-1).

HOW RESPIRATORY PROGENITORS ARISE

The lung originates from the anterior portion of the gut tube (foregut), which also gives rise to organs, such as the thyroid, stomach, liver, and pancreas. Respiratory progenitors of the lung and trachea arise from the ventral foregut endoderm in mice at around embryonic day 9 (E9.0, midgestation) and in humans around the 3rd week of gestation. Studies in mice show that these cells can be readily recognized even before a lung primordial bud forms by the expression of Nkx2–1 (Ttf1, thyroid transcription factor 1); this gene, however, is not lung specific and also labels progenitor cells of the thyroid seen in more anterior (cranial) regions of the foregut (Fig. 4-2A).[3] Nkx2–1 is essential for lung cell fate as disruption of this gene in mice results in severe inhibition of branching and no evidence of epithelial cells expressing surfactant protein or other differentiation marker genes typically found in the lung.[3] Questions remain whether in these mutants lung progenitors are never specified or just cannot be maintained in the absence of Nkx2–1. How are these progenitors specified? There is strong evidence that Fgf and Wnt signaling play a key role in this process. Studies in organ culture suggest that Fgf2 at high concentrations is able to induce lung cell fate in the early foregut endoderm.[4] High levels of Fgf1 and 2 are found in the cardiac mesoderm immediately adjacent to the ventral foregut endoderm (Fig. 4-2A). These observations suggest a model in which high levels of Fgfs diffusing from the developing heart induces Nkx2–1-expressing lung progenitor cells.[4] Interestingly, canonical Wnt pathway is also required for lung specification. Both Wnt2 and Wnt2b are present in the foregut mesoderm at the prospective site of lung formation. Loss of canonical Wnt or their ligands prevents the appearance of Nkx2–1-expressing cells.[5,6] Moreover, there is a role for Bmp signaling in the maintenance or expansion of Nkx2–1-expressing lung progenitors.[7]

FORMATION OF THE LUNG AND TRACHEAL PRIMORDIA

Once the Nkx2–1-expressing progenitor cells are specified in the prospective lung region of the foregut, they are subsequently expanded to generate the tracheal and the lung primordia. The primordial lung is identified in human embryos at the beginning of gestation (around the 4th week), much earlier compared to mice (midgestation at E9.5). The two primordial lung buds arise as lateral outgrowths of the ventral foregut endoderm and fuse at the midline, the site where tracheal primordium also starts to form (Fig. 4-2B–D). From then on, the trachea and the digestive tube separate through a mechanism still poorly understood that involves formation of a tracheoesophageal septum.[8,9] Primary lung bud formation is crucially dependent on the local expression of Fgf10 (fibroblast growth factor 10) in the foregut mesoderm.[10,11] Fgf10 diffuses to the nearby endoderm at the prospective lung region and activates Fgfr2b signaling in Nkx2–1-expressing progenitor cells leading to epithelial proliferation and migration toward the Fgf10 source.[12,13] Fgf10-null mice die at birth and have multiple defects. Strikingly, lungs do not form but tracheal development occurs.[10,11] This raises the possibility that tracheal and lung progenitors, although originating from a population of Nkx2–1-expressing endodermal cells, are different at least in their requirement for Fgf10 signaling for expansion or survival.

How is the expression of Fgf10 controlled? How is positioning of the lung primordium along the anteroposterior (AP) axis of the foregut determined? There is accumulated evidence that signaling

At E9.5, these Nkx2–1-positive cells give rise to the tracheal primordium and primary lung buds. **B.** Ventral–dorsal (V–D) differences in gene expression in the foregut at the onset of lung development. **C.** V–D foregut patterning and tracheoesophageal separation (Es, esophagus). **D.** Regulation of primary lung bud formation in the foregut: Gene network in the mesenchyme *(yellow)* and epithelium (*blue*; highest levels of Nkx2–1 and Shh in the distal bud).

by the vitamin A–derivative retinoic acid (RA) is a major regulator of Fgf10 expression at the onset of lung development.[14] RA synthesis and RA receptor (RAR) activity is prominent in the E8.5–9.5 mouse foregut.[15] Disruption of RA signaling by vitamin A deficiency, or genetic disruption of key components of the RA pathway, or RA antagonists in organ cultures leads to multiple developmental abnormalities, including lung agenesis.[14,16–18] RA integrates multiple pathways in the foregut to regulate primary lung bud morphogenesis. RA signaling in the foregut mesoderm allows activation of the Wnt pathway by suppressing expression of the Wnt inhibitor Dkk1 (Dickkopf-1)[19]; RA also inhibits Tgfβ signaling.[20] The balanced activity of Wnt and Tgfβ leads to proper mesodermal Fgf10 expression required for formation of the lung primordium (Fig. 4-2D). Thus, the disruption of Wnt/Tgfβ/Fgf10 interactions is likely to represent the molecular basis for the failure to form the lung classically reported in vitamin A deficiency. The role of Wnt in the expression of Fgf10 is further supported by the lack of Fgf10 expression in the lung field mesenchyme of foregut in Wnt2a/Wnt2b double null mice.[5]

Other essential regulators of early events associated with the lung primordium are T-box (Tbx) and Gli transcription factors (Fig. 4-2B–D). Multiple T-box genes are expressed in the foregut and particularly Tbx2–Tbx5 have been reported in the developing lung mesenchyme.[21] Studies in chick embryo show that Tbx4 is expressed in the foregut mesoderm at the domain where Fgf10 induces lung bud formation; Tbx4-Fgf10 appear to regulate the posterior boundary of Nkx2–1-expressing lung progenitors.[22] Genetic studies in mice showed a dose-dependent activity of Tbx4 and Tbx5 in regulating primary bud formation, likely through regulation of Fgf10 and Wnt.[23] Gli 1, 2, 3 are known transcriptional effectors of the sonic hedgehog (Shh) signaling detected early in the foregut mesoderm and subsequently in the lung mesenchyme.[24] Disruption of both Gli2 and Gli3 in mice results in dramatic abnormalities that include abrogation of both tracheal and lung primordium.[25] This intriguing phenotype is more severe than that observed in Shh-null mice and thus may represent a disruption of additional Gli-dependent pathways critical for the primary lung buds.[26]

VENTRAL–DORSAL (V–D) PATTERNING AND TRACHEOESOPHAGEAL SEPARATION

Differences in V–D cell fate are already obvious in the prospective lung region of the foregut (Fig. 4-2B) as the ventral endoderm expresses Nkx2–1 (respiratory progenitors) while the dorsal region (prospective esophagus) expresses Sox2 (SRY-box containing gene 2) and the p63.[3,27,28] Epithelial disruption of Sox2 leads to ectopic dorsal expansion of the Nkx2–1 domain and respiratory fate in the esophagus.[27] The Bmp (Bone Morphogenetic Protein) pathway is also important for V–D patterning. Bmp4 is expressed in the ventral foregut mesenchyme prior to and during the emergence of primary buds while its antagonist Noggin is localized to the dorsal endoderm.[7] Conditional deletion of both Bmpr1a and Bmpr1b

receptors leads to expansion of a dorsal cell population marked by Sox2 at the cost of the ventral population of Nkx2–1 positive cells. Interestingly this results in tracheal agenesis and formation of lung buds ectopically.[7] Noggin has been proposed to protect the dorsal endoderm from the ventralizing effects of Bmp4.[29]

As the lung and tracheal primordia form, a tracheoesophageal septum extends from the posterior to the anterior region of the foregut and ultimately separates the respiratory from the digestive tracts (Fig. 4-2C). Alternative mechanisms initiating this process have been proposed, including the fusion of endodermal ridges in the midline.[8] Failure to separate these compartments results in tracheoesophageal fistula, a condition of high morbidity relatively frequent in neonatal settings. This defect has been observed as part of the phenotype of several mouse mutants, including the $Shh^{-/-}$, $Nkx2\text{–}1^{-/-}$, Sox2 conditional mutant, $Gli2^{-/-}$; $Gli3^{+/-}$, and the $RAR\alpha^{-/-}$; $RAR\beta^{-/-}$ null-mice.[3,25–27,30]

BRANCHING MORPHOGENESIS: FORMATION OF THE BRONCHIAL TREE AND PATTERNING

The bronchial tree forms through a reiterative process of growth and budding of the epithelial tubules collectively termed as branching morphogenesis. This process initiates right after secondary buds form from the lung primordium, in mice at E10.5. Interestingly, at this time the pattern of lobation of the right and left lungs is also established. The lungs are asymmetric in respect to their right and left axis and their number of lobes varies according to the species. For example, mouse lungs have one left lobe and four right lobes. It is thought that this asymmetry is regulated by left–right (L–R) determinants as part of an early global program of axis specification. Among the signals involved in this process are several Tgfβ-related molecules, such as activin receptor II, Lefty1 and 2, growth differentiation factor 1 (Gdf1), and paired-like homeodomain transcription factor 2 (Pitx2).[31–35] Loss of left–right asymmetry resulting in equal number of lobes in both sides is called pulmonary isomerism and is found in several human conditions.[36,37]

Analysis of the three-dimensional branching pattern of embryonic mouse lungs suggests that the bronchial tree is generated by three geometric branching modes: Domain branching, planar bifurcation, and orthogonal bifurcation, following three sequential orders (Fig. 4-3).[38] All modes are used concurrently during development of the bronchial tree. More than one mode is often used in the individual founder branches to generate the next generation of buds. Domain branching is first used to form founder or parent (secondary) branches. This is followed by permanently switching to an orthogonal bifurcation mode or by a combination of the three modes in a defined sequential order. Results from these analyses

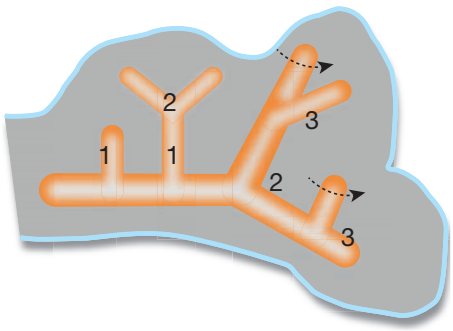

Figure 4-3 Diagram representing the three branching modes: Domain branching (1), planar bifurcation (2), and orthogonal bifurcation (3) (for details see Ref. 38).

strongly suggested that distinct genetically encoded pathways control each branching model. It is likely that these subroutines are also used in the developing human lungs, but this has not been yet demonstrated.

The mechanism generating new buds during branching morphogenesis is similar to that of primary bud morphogenesis and relies on local epithelial activation of Fgfr2b signaling by mesenchymal Fgf10 at the sites of budding.[12,13] Perturbations in levels or distribution of Fgf10 have a major impact in airway morphogenesis and result in smaller than normal hypoplastic lungs. Reduced number of branches among other abnormalities of patterning is found in Fgf10 hypomorphic mice ($Fgf10^{lacZ/-}$).[39] Interestingly, during branching morphogenesis Fgf9 expressed from the pleura and transiently from the distal epithelium serves to expand a population of distal mesenchymal progenitors that expresses Fgf10 (Fig. 4-4A). Mice deficient in Fgf9, have reduced mesenchymal cell population and Fgf10 expression; this leads to disruption of branching morphogenesis and hypoplastic lungs.[40]

How is bud formation controlled during branching morphogenesis? The size and shape of the growing buds is controlled dynamically by exchange of signals between the tip bud epithelium and the immediately adjacent mesenchyme. Shh is a member of the hedgehog family of proteins (sonic, desert, and Indian hedgehog) expressed in the lung predominantly at the tip bud epithelium. Shh signaling is activated in a paracrine fashion in the lung mesenchyme via patched (Ptc)/smoothened (Smo) and its transcriptional effectors Gli (1, 2, 3) proteins where it acts as a critical survival factor for mesenchymal cells.[41–43]

There is accumulated evidence both in vitro and in vivo that Shh has a key role in the developing airways as negative regulator of Fgf10 expression.[41,44] The idea is that during branching, Shh at the tip of growing buds progressively downregulates Fgf10 in distal mesenchymal cells, inhibiting bud outgrowth (Fig. 4-4A). In Shh-null mice there is widespread expression of Fgf10 transcripts and generalized activation of Fgfr2b in lung endoderm that results in severely disrupted branching morphogenesis and cyst-like lungs.[26] A mechanism proposed to maintain the proper balance of Fgf10 levels and prevent excessive Shh signaling is through the Hedgehog interacting protein, Hhip1. Hhip1 is induced by Shh in the mesenchyme adjacent to the distal bud, where it binds to and sequesters Shh ligand preventing it from activating signaling and repressing Fgf10 locally. Indeed Shh activity is aberrantly increased in Hhip-null mice leading to a repression of Fgf10 expression and branching in the developing lung.[45]

The balance of Fgf10 activity in the emerging bud can be regulated by the Sprouty **(Spry)**, a highly conserved family of cysteine-rich proteins (Fig. 4-4A). Spry2 and Spry4 are expressed in the distal lung in the epithelium and mesenchyme, respectively.[46,47] Spry2 negatively regulates the Fgf-mediated activation of receptor tyrosine kinase signaling in the epithelial bud and thus, inhibits bud growth, as demonstrated by functional studies in Drosophila and mice.[48–51] Moreover, Fgf10 protein distribution and receptor binding can be modulated by interactions with heparan sulfate (HS) proteoglycans at sites of budding. Disrupting endogenous gradients of HS or altering HS sulfation in lung culture systems prevents Fgf10 from inducing local responses and can markedly alter lung pattern formation.[52,53]

Another mechanism contributing to airway branching is cleft formation. Here extracellular matrix (ECM) is deposited at branch points, accumulating in the epithelial–mesenchymal interface and preventing local expansion of the epithelium. Clefting has been classically associated with local activity of Tgfβ signaling in the mesenchyme, which suppresses Fgf10 expression and induces synthesis of ECM components (Fig. 4-4B,C). Members of the Tgfβ subfamily Tgfβ1, 2, and 3, their receptors (Tgfβr1 and Tgfβr2)

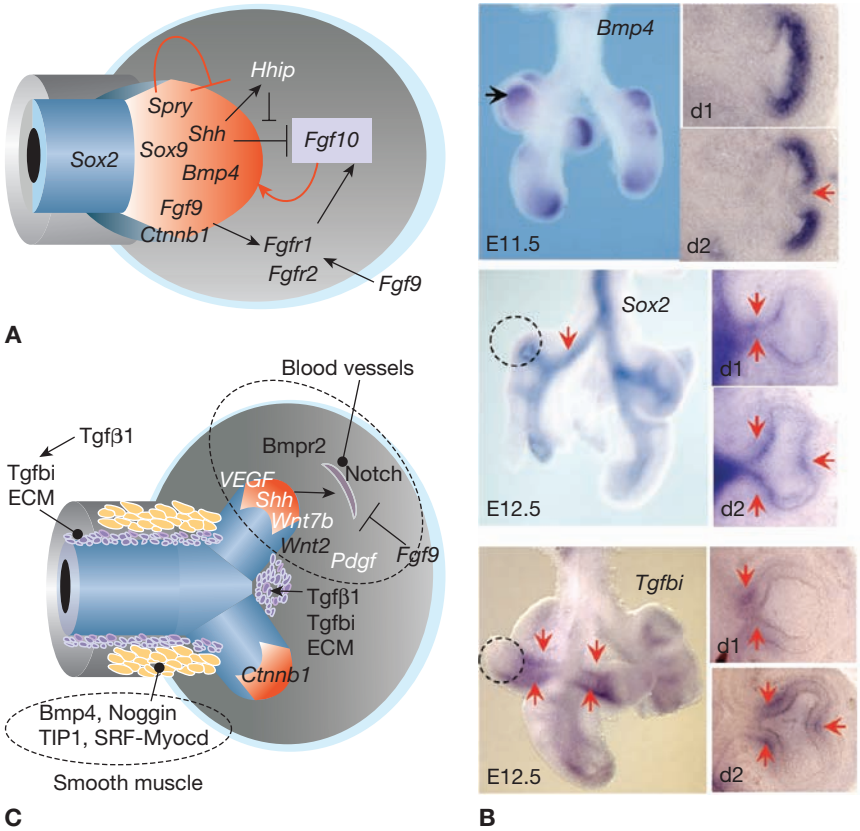

Figure 4-4 Regulation of lung branching morphogenesis, proximal–distal (P–D) patterning and differentiation. **A.** Gene network regulating lung bud elongation. Bud outgrowth is restricted by Fgf10 induction of Bmp4 and Spry2; Spry2 inhibits epithelial Fgf signaling; Bmp4 inhibits epithelial proliferation; Shh inhibits Fgf10 expression through activation of Ptc/Smo signaling. Shh signaling is inhibited by Hhip through a feedback loop. Fgf9 expressed by both mesothelial or distal epithelial cells activate Fgfr1/2 signaling in mesenchyme promoting Fgf10 expression. **B.** ISH of Bmp4, Sox2, and Tgfbi during branching (E11.5–12 in vivo and in E11.5 lungs cultured for 1 and 2 days). Bmp4 labels distal epithelial buds while Sox2 marks the epithelium in stalk and nonbranching proximal regions; Tgfbi labels newly-formed stalks and proximal mesenchyme. **C.** Airway branching and differentiation of mesenchymal components. Localized Tgfβ activity promotes local ECM deposition and cleft formation. Airway and vascular SM requires the input of Shh, Wnt, VEGF, Pdgf notch, and Fgf.

and transducing proteins, Smad 2 and 3 are expressed in different compartments and in a complex pattern during branching morphogenesis. Tgfβ1 transcripts are distributed throughout the lung mesenchyme; however Tgfβ1 protein accumulates in regions between buds and along proximal airways, where ECM components collagen I, III, and fibronectin are abundant.[54] The dynamic activity of Tgfβ during branching is best visualized by expression of its target Tgfbi (Tgfβ-induced or BigH3) in the stalk region of growing buds (Fig. 4-4B,C).[55] Treatment of embryonic lungs in culture with recombinant Tgfβ1 dramatically inhibits branching morphogenesis.[44,56,57] This is likely due to the negative effects on growth and differentiation by epithelial activation Tgfβ signaling, but also from the Tgfβ effects in the mesenchyme. Studies in NIH3T3 fibroblasts, lung and prostate organ cultures demonstrate that Tgfβ1 signaling in mesenchymal cells markedly inhibits Fgf10 expression.[44,58,59] Interestingly Tgfβ1-null mice do not show these defects, presumably due to rescue by maternal transfer of Tgfβ1.[60] Tgfβ2 and Tgfβ3 are expressed in lung epithelium; Tgfβ3 is also found in the developing lung mesenchyme and pleura.[61] Both the Tgfβ2- and Tgfβ3-deficient mice do not have major morphological defects in the lungs at E18.5 but show collapsed lungs postnatally.[62,63]

There is increasing evidence that small noncoding regulatory RNAs are part of the regulatory networks controlling lung development. MicroRNAs (miRNA) are endogenous small noncoding RNAs that regulate target gene expression posttranscriptionally and play important roles in diverse biological processes.[64–67] Individual miRNAs may target multiple message RNAs (mRNAs); conversely, individual mRNAs may contain sequences complementary to multiple miRNA family members.[68] The importance of the miRNA pathway in lung development was demonstrated by the epithelial deletion of Dicer, the key enzyme that processes microRNA precursors into mature miRNAs. Loss of Dicer in the mouse lung epithelium results in drastic arrest of branching morphogenesis and increased epithelial cell death.[69] The increased levels of Fgf10, Bmp4, and Spry-2 in these mutant lungs suggested that the miRNA pathway represses expression of these genes during epithelial–mesenchymal interactions.[69] Interestingly, in humans, DICER mutation has been linked to pleuropulmonary blastoma, a rare pediatric tumor that arises during fetal lung development.[70] It is speculated that loss of DICER in developing lung epithelium alters miRNA-dependent regulation of diffusible growth factors that promote proliferation of both epithelial and mesenchymal cells.

ESTABLISHMENT OF PROXIMAL–DISTAL (P–D) CELL FATE

During lung development, the appearance of distinct fates in epithelial progenitors along the P–D axis is tightly coupled with the branching process. Morphological changes that occur in the epithelial tubules during branching are accompanied by highly dynamic changes in P–D differentiation. For example, the high levels of Bmp4 and Sox9 typically found in the newly formed distal buds are markedly downregulated in the stalks and more proximal regions of the epithelial tubules, which then express Sox2 (Fig. 4-4A,C). Canonical Wnt and Bmp signaling have been implicated as major regulators of P–D cell fate in the lung epithelium.

Wnt ligands, receptors (frizzled), and β-catenin are widely expressed in the developing lung but show distinctive pattern in both epithelium and mesenchyme.[71–73] High activity of Wnt signaling reporter (TOPGAL), nuclear-localized β-catenin, TCF/LEF transcripts, are found in the distal lung buds undergoing branching.[74,75] Targeted disruption of β-catenin, or overexpression of Wnt inhibitor D (Dkk1) in the distal lung epithelium prevents distal bud formation and proximalizes the lung, a phenotype characterized by proximal epithelial phenotypes extending to distal sites. Conversely, activation of canonical Wnt signaling throughout the lung epithelium inhibits Sox2 expression and leads to the appearance of distal fates in proximal airways.[76,77] Thus canonical Wnt plays a key role in the establishment and or maintenance of distal cell fates.

Bmp4 is expressed in lung epithelial progenitors at the tip of growing buds and has been implicated in distal cell fate, potentially through an autocrine activation of Bmpr-Smad signaling.[78] In the lung Bmp4-mediated responses are regulated at

multiple levels, for example by Fgf10-Fgfr2b activation in distal buds, which induces Bmp4 expression, or by known Bmp antagonists present in the lung, such as Noggin, Chordin, Gremlin, and the Cerberus-related factor, Cer1.[42,79–82] Bmp4 protein levels in distal epithelium are potentially under the control of the cysteine protease Cathepsin H, which is significantly induced by Fgfr2b signaling.[83] Transgenic mice expressing Bmpr antagonists in lung epithelial progenitors fail to properly form a distal lung and show proximalization.[84] Using a similar genetic approach Bmp4 overexpression results in small lungs containing distal flat cells that are reminiscent of the distal alveolar type I cells.[78] In lung organ cultures Bmp4 antagonizes the proliferative effects of Fgf10 in the distal epithelium; this could presumably foster distal differentiation.[85] Histone deacetylases 1 and 2 (Hdac1/2), enzymes involved in epigenetic modifications, have been recently shown to regulate P–D patterning through controlling expression of Bmp4 and the tumor suppressor Rb1.[86]

miRNAs also play a significant role in lung P–D patterning. For example, the miR-17-92 cluster is expressed during early lung development; gain of function selectively in the developing lung epithelium of transgenic mice results in increased cell proliferation.[87] Conversely, miR-17-92 cluster knockout mice have hypoplastic lungs.[88] In an independent study, miR-17 family members were shown to modulate Fgf10-Fgfr2b downstream signaling by targeting Stat3 and Mapk14.[89] miR-302/367, a direct target of Gata6 transcription factor, coordinates the balance between proliferation and differentiation of lung epithelium and also regulates apical–basal polarity.[90]

FORMATION OF THE VASCULAR AND OTHER MESENCHYMAL COMPONENTS OF THE LUNG

Besides playing a crucial role in epithelial development, the lung mesenchyme gives rise to the vascular, cartilage, and other stromal components of the lung. In turn, expansion and differentiation of mesenchymal progenitors into these different components require diffusible signals from the epithelial and mesothelial (pleural) layers.

The vasculature develops through sprouting angiogenesis from arterial vessels of the aortic arches migrating to the developing lung and formation of a capillary plexus around the distal bud.[91–93] Pulmonary veins arise from the neighbor atrium. Vascular endothelial growth factor (VEGF) signaling plays a major role in vascular development by promoting endothelial cell differentiation (Fig. 4-4B).[94] VEGF-A is found predominantly in the distal lung epithelium but also in the mesenchyme at early stages and signals through VEGFR2 (Flk1) and VEGFR1 (Flt1) in the mesenchyme.[95–97] Among the several VEGF isoforms, VEGF164 is the most active in the lung.[98] Development of lymphatic vessels is still poorly understood. Studies in mice show that VEGF-C and -D acting through their receptor VEGFR-3 promote lymphoangiogenesis.[99,100] VEGFR-3–null mice fail to develop proper lymphatic vessels.[101]

Smooth muscle (SM) is an integral component of vascular and airway epithelium of the lung (Fig. 4-4B). Vascular SM develops by contribution from mesenchymal precursors through signals derived from the epithelium but also from pleural cells migrating to the vascular structures during blood vessel assembly.[102] Significantly reduced mesenchymal cell proliferation and SM differentiation were observed in Shh-null lungs.[43] Interestingly, a signaling cascade involving Shh, miR-206, and Bdnf (brain-derived nerve growth factor) coordinates innervation and formation of the airway SM layer.[103] Wnt7b, acting through Fzd1, Fzd10, and LRP5, is an important epithelial signal required for vascular SM development and the integrity of blood vessels.[104] Wnt7b-null mice show hemorrhagic lungs resulting from rupture of the blood vessels due to SM structural defects.[105] Assembly of the pulmonary arterial wall occurs through controlled migration of SM cells from the inner to the outer layers in a process mediated mostly by PDGFβ.[106] In addition, vascular SM formation depends on Bmp and Notch signaling.[107,108] Bmp4 and Bmpr2 are expressed in SM precursors and disruption of Bmp signaling is associated with increased SM cell proliferation. This phenotype is reminiscent of the excessive SM growth reported in pulmonary hypertension patients with mutations in the Bmpr2 gene.[109–111] Disruption of canonical Notch signaling interferes with specification of arterial SM cells.[107] Notch3 dysregulation is associated with structural changes in the pulmonary artery postnatally and has been implicated in the pathogenesis of adult pulmonary hypertension.[112] The importance of having a precisely matched airway–vascular development is well illustrated by the role of Foxm1, a transcription factor present in the lung mesenchyme. Foxm1-null mice show pulmonary hemorrhage and perinatal death due to misalignment of epithelial and vascular structures.[113] This phenotype closely reminds the abnormalities seen in human congenital alveolar dysplasia.

Airway SM originates from mesenchymal cells of the developing lung when the initial airway start to branch, preceding the appearance of the lung vascular SM. Evidence from a Fgf10-lacZ reporter mouse, which labels Fgf10-derived lineage cells,[114] suggests that a myogenic program of cell fate in developing airways initiates in the distal lung mesenchyme and progresses as these cells are relocated to the bud stalks and more proximal regions.[114,115] This myogenic program is likely to be triggered by high levels of Bmp4 and Shh present at the bud tips (Fig. 4-4C).[41,78] Canonical Wnt signaling is required for the expansion of the SM progenitors in developing airways.[116] Proper differentiation of the airway SM requires input from pathways, including Fgf, TGFβ, as well as physical stretch transduced by tension-induced proteins, such as Tip1.[117–120] Fgf9-Fgfr1/2 signaling suppresses airway SM differentiation through inhibition of myocardin expression.[42,121,122]

During development, SM is responsible for phasic contractility of airways and growth factor production, contributing to maintain normal lung growth. Airway peristalsis influences branching and epithelial differentiation.[123,124] Interfering with process can result in lung hypoplasia.

Cartilage rings present in trachea and proximal airways develop from the precursors in ventral mesenchyme. Proper formation and patterning of cartilage primordia requires signaling by RA (particularly RAR gamma mediated), Foxf1, Shh, Nkx2–1, among others.[125,126]

AIRWAY DIFFERENTIATION

As the epithelial tubules form and branch, they initiate a program of cell fate choice and differentiation that ultimately gives rise to the various airway epithelial cell types. The initial stage is marked by expression of Sox2 throughout the P–D axis of these tubules from trachea to the most distal airways (Fig. 4-4B).[127]

By the middle of the pseudoglandular period, epithelial cells in proximal airways start to express markers of cell commitment to secretory Clara (the secretoglobin Scgb3a2) ciliated (Foxj1) and neuroendocrine (the bltb transcription factor Ascl1) lineages (Fig. 4-5).[128–133] These committed epithelial progenitors then initiate specific programs of differentiation. Foxj1-expressing cells undergo a dramatic organization of their apical compartment and by the end of the canalicular period form multiciliated cells marked by β-tubulin staining.[134] Concomitantly Scgb3a2-expressing cells acquire expression of the Clara cell marker CC10 (Scgb1a1).[135,136] While in humans mucin-secreting goblet cells are seen throughout the respiratory tract epithelium, in mice, they are relatively rare occurring mostly postnatally in trachea and proximal airways. Their presence is largely increased in exposure to environmental agent or infection.[137]

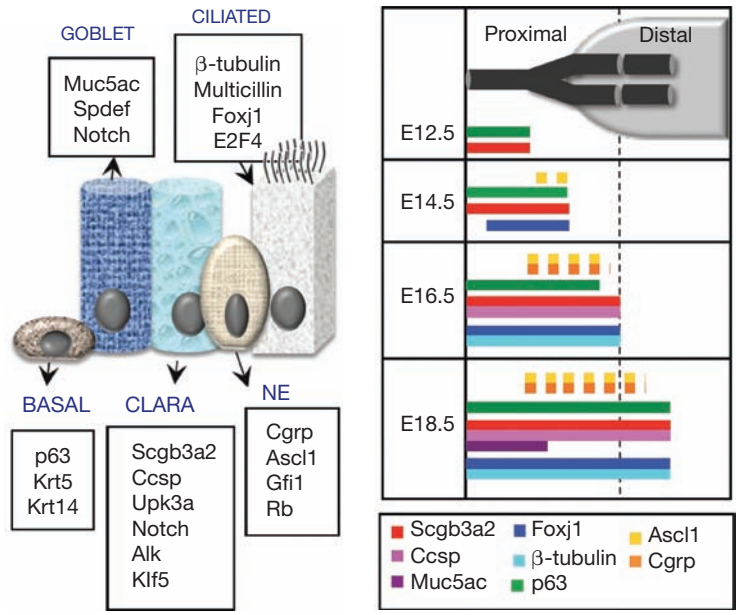

Figure 4-5 Epithelial differentiation in conducting airways. **A.** Cell types and markers associated with or required for the differentiation of specific cells. **B.** Time course of appearance of gene markers associated with different cell lineages in proximal and distal airways of the developing mouse lung.

Ascl1-expressing cells are found in clusters initially in proximal regions and generate neuroendocrine bodies (NEB) and isolated neuroendocrine (NE) cells; they express neural markers such as Cgrp and Pgp9.5. Mice deficient in Ascl1 do not form NE cells or NEB.[130]

Both Clara and basal cells are considered to be progenitor cells of the lung for their ability to self-renew and generate Clara and ciliated cells. Basal cells are recognized by the expression of the transcription factor p63, and also keratins 5 and 14. p63 mutant mice do not form basal cells in the lung or in other regions, such as skin.[138,139] Although p63/Keratin 5-labeled cells can be identified in the embryonic lung, there is no evidence that prenatally they function as lung progenitor cells.

Notch signaling is critical to generate Clara cells and to maintain the balance of the different cell types in the airways.[132] Disruption of Notch signaling in mice results in loss of Clara cells and airways overpopulated by ciliated and NE cells.[107,132,140–141] Conversely, constitutive activation of Notch in the embryonic lung epithelium leads to a decrease in number of ciliated cells and increase in secretory goblet cells.[142] During postnatal life Notch is required to maintain the Clara cell phenotype and prevent them from undergoing goblet cell (mucus) metaplasia.[143] Downregulation of Notch pathway components has been identified in patients with chronic pulmonary obstructive disease (COPD), a condition in which one of the hallmark features is mucus metaplasia.[144] Goblet cell differentiation is also controlled by transcription factors, such as SAM pointed domain-containing ETS transcription factor (Spdef) and Foxa2.[145–147]

Formation of multiciliated cells in the airways depends on expression of the E2F family member E2F4, as well as Foxj1 and multicilin.[148,149] Loss or gain of function of Foxj1 in genetically altered mice leads to absence or ectopic formation of multiciliated cells, respectively.[150,151] miR-449 has been shown to promote the differentiation of ciliated cells by targeting NOTCH1 and the ligand DLL1 in human airway epithelial cells.[152]

FORMATION OF THE GAS EXCHANGE REGION OF THE LUNG

Once branching morphogenesis is completed, distal epithelial buds undergo sacculation. During this morphogenetic process, the lumen of epithelial tubules enlarges at their distal ends to form primitive saccules. Some of the epithelial cells become flattened and very thin, differentiating into type I cells, while the others remain cuboidal and differentiate into surfactant-producing type II cells (Fig. 4-6). Type I cells cover a large area of these saccules and, as the mesenchyme becomes thinner, they come into intimate contact with the capillary network of the primitive saccules to form the primitive alveolar–capillary barrier.[153] Multiple gene knockout mice show defects in sacculation. Among these are T1 alpha,[154] Nfib (nuclear factor I/B),[155] Erk3 (extracellular signal-regulated kinase 3), and Foxm1.[156]

Finally, by late gestation in humans or postnatally in mice the primitive saccules subdivide into smaller units to form the mature alveoli. Alveolization involves formation of secondary septa, which greatly increases the surface area for gas exchange (Fig. 4-6). Alveolar formation is dependent on interstitial myofibroblasts and appear to require tight control of elastin levels. Signaling by Pdgf is necessary to form lung myofibroblasts[157]; Fgfr3 and 4 are required to control proper levels of elastin gene expression.[158] VEGF signaling has also been implicated in maintaining the alveolar structure.[159] Flt1 inhibition leads to immature lungs with decreased alveolar septation. Although there is evidence from some animal models that RA fosters alveolization, some controversies exist and further studies are required to clarify this issue.[160,161] Transcription factors, such as Foxn4 also influence alveolization.[162] Unilateral pneumonectomy (PNX) in mouse stimulates pulmonary capillary endothelial cells (PCECs) to produce angiocrine growth factors that induce

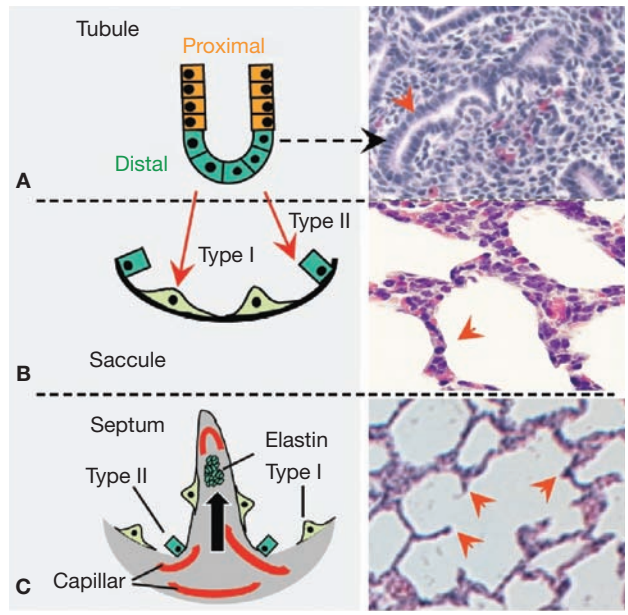

Figure 4-6 Sacculation and alveolar formation, H&E. **A, B.** Distal epithelial tubules expand their lumens and form primitive saccules lined by type I and type II cells. **C.** Septation subdivides saccules into smaller units to form the definitive alveoli.

proliferation of epithelial progenitor cells promoting regenerative alveolization.[163]

FINAL REMARKS

A wealth of information has been generated over the past decades on how growth factors, transcription factors, and matrix components influence lung development. Many of these studies suggest that alterations in developmental pathways reported in animal models are relevant to understand the pathogenesis of human lung conditions. There is also increasing evidence that developmental regulators are recruited in different contexts to mediate normal and aberrant injury–repair responses in the adult lung. Further understanding of these issues will be invaluable in discovery of different therapeutic targets and for the new field of lung regenerative medicine.

CHAPTER 5

Pulmonary Surfactant and Disorders of Surfactant Homeostasis

Jeffrey A. Whitsett
Timothy E. Weaver

INTRODUCTION

Pulmonary surfactant is a complex mixture of phospholipids and proteins that creates a unique interface separating alveolar gas and liquids at the alveolar cell surface, reducing surface tension, and maintaining lung volumes at end expiration. Reduction of the surface tension at the air–liquid interface is a requirement for respiratory function following birth. Deficiency of pulmonary surfactant causes respiratory failure in premature infants, or infantile respiratory distress syndrome (IRDS). The adequacy of pulmonary surfactant is maintained by unique and highly regulated systems mediating the synthesis, secretion, reutilization, and catabolism of surfactant. Loss or inactivation of pulmonary surfactant later in life occurs in the adult respiratory distress syndrome (ARDS), a significant cause of morbidity and mortality following infection, shock, or trauma. Mutations in genes regulating surfactant homeostasis, including SFTPA, SFTPB, SFTPC, ABCA3, TITF1, and CSF2RA cause acute and/or chronic lung disease in newborn infants, children, and adults. Disorders of GM-CSF signaling inhibit surfactant lipid and protein catabolism by alveolar macrophage causing pulmonary alveolar proteinosis (PAP). This chapter reviews the biology of the surfactant system and its implications for the pathogenesis, diagnosis, and treatment of respiratory disease in premature infants and adults. Suggested reviews of these topics are provided in the References section.[1–5]

PHYSICAL FORCES AT THE AIR–LIQUID INTERFACE

In 1929, Van Neergard recognized the critical role of surface tension as a "retractile force" in the lung, observing the marked difference in inflation pressures required to inflate the air- versus water-filled lung. Avery and Mead associated the lack of a lipid-rich material in the lungs of infants dying from idiopathic respiratory distress syndrome with alveolar collapse and respiratory failure.[6] In the absence of pulmonary surfactant, molecular forces at the air–liquid interface create a region of high surface tension because intermolecular forces between water molecules are unopposed at the air–liquid interface, and an area of high retractile force at the surface is created. Forces of 70 dynes/cm^2 are generated at the air–water interface; if unopposed in the alveolus, such forces lead to alveolar collapse and respiratory failure. A surface film composed of multilayered sheets of phospholipids creates a distinct phase separating air and liquid, reducing surface tension to nearly zero and maintaining residual lung volume at end expiration. Complex interactions between surfactant phospholipids and proteins are required to maintain surfactant film throughout life. Pulmonary surfactant lipids and proteins are synthesized and secreted by alveolar type II epithelial cells into the alveoli, where they form multilayered lipid-rich films that reduce surface tension to maintain ventilation (Figs. 5-1 and 5-2).

COMPOSITION OF PULMONARY SURFACTANT

Pulmonary surfactant isolated by lung lavage consists of highly heterogeneous forms of phospholipid–protein aggregates of distinct sizes, structural characteristics, and composition. Tubular myelin is the most abundant form of alveolar phospholipid and consists of large, relatively dense aggregates (termed large aggregate surfactant) composed of phospholipids and surfactant proteins (SPs). Tubular myelin is a highly organized form of surfactant phospholipid, forming square tubular arrays. Tubular myelin represents an extracellular pool of surfactant lipids that rapidly moves to the air–liquid interface and reorganizes to form multilayered sheets that reduce surface tension in the alveolus (Fig. 5-2). Large lamellated structures, with lipid composition similar to that of tubular myelin, are seen within the alveolus and likely represent newly secreted lamellar bodies that unravel to form tubular myelin in the alveoli. The phospholipid composition of lamellar bodies, the intracellular storage form of surfactant, tubular myelin, and lamellated forms present in the alveolus are virtually identical. Smaller, less dense particles (small aggregate surfactant) are also present within the alveolar space, representing remnants or catabolic forms of surfactant that have relatively poor surface activity. Small aggregate surfactant is destined for uptake, reutilization, or catabolism by type II epithelial cells and catabolism by alveolar macrophages.[2,3]

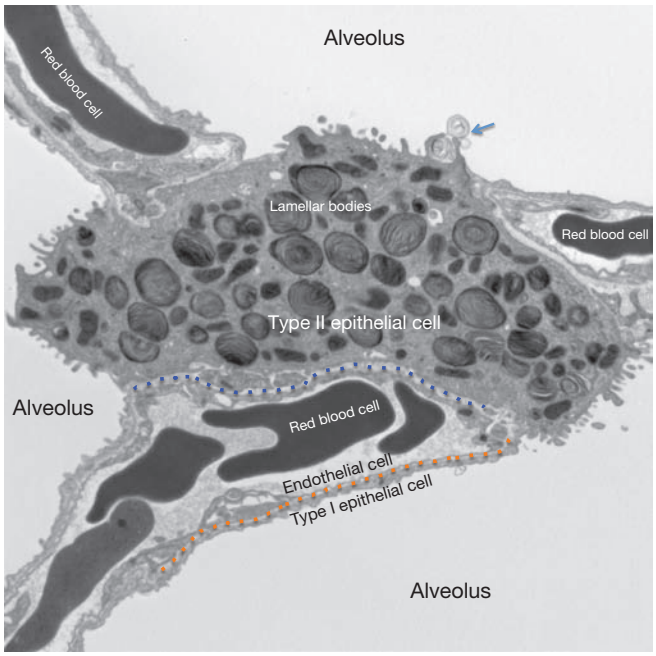

Figure 5-1 Pulmonary alveolar ultrastructure. The air–blood barrier is comprised of the capillary endothelium (above *the dotted orange line*) and the closely apposed type I epithelial cell (below *the dotted orange line*). The dotted blue line delineates the interstitial space between endothelial cells and type II epithelial cells with their specialized secretory lipid organelles (lamellar bodies). Type II cells form tight junctions with type I cells and serve as alveolar progenitor cells. Surfactant lipids and proteins are secreted as lamellar membranes *(arrow)* into the alveolar space forming tubular myelin and lipid membrane multilayers that reduce surface tension, preventing alveolar collapse.

SURFACTANT PHOSPHOLIPIDS AND PROTEINS

The composition of surfactant lipids is similar in all of the structural forms of surfactant isolated from mammalian lungs, with phospholipids generally representing 80% to 90% of the mass of pulmonary surfactant.[3] In the adult lung, phosphatidylcholine (PC) and phosphatidylglycerol (PG) are the most abundant phospholipids, representing approximately 70% to 80% and 5% to 10%, respectively, of the lipid mass. Dipalmitoyl phosphatidylcholine (DPPC) is the most abundant species of PC. Lesser amounts of phosphatidylserine, phosphatidylethanolamine, sphingomyelin, neutral lipids (mostly cholesterol), and glycolipids are also present in surfactant. The lung content of surfactant phospholipids increases markedly with advancing gestation, regulated by a complex signaling and transcriptional network that controls type II alveolar cell differentiation, lipid synthesis, and SP gene expression. Lamellar bodies are secreted into the fetal amniotic fluid. PC, lamellar body counts, DPPC content, and increased lecithin (PC) to sphingomyelin (L/S) ratio, correlate with postnatal respiratory function. These tests are used to predict pulmonary maturity prior to the birth of preterm infants. Lung maturation and synthesis of surfactant components are induced by maternal administration of glucocorticoids, used clinically to prevent respiratory distress prior to premature birth.[7] Proteins represent approximately 5% to 15% of the mass of pulmonary surfactant and include serum proteins and proteins that are synthesized and secreted by type II alveolar epithelial cells. In addition to its specific interaction with SP-B, the anionic phospholipid PG may also play an important role in innate defense. PG constitutes 10 mole% of surfactant lipid, with palmitoyl-oleoyl-PG (PoPG) being the most common species in human surfactant. PoPG specifically suppresses LPS-induced inflammatory responses and prevents infection of epithelial cells by binding RSV or influenza A virus.[8] Thus the unique enrichment of PoPG in the distal airspaces may be an important component of host defense against inhaled pathogens. Four surfactant proteins (SPs), SP-A, SP-B, SP-C, and SP-D, are produced by respiratory epithelial cells, each playing specific roles in surfactant homeostasis and innate host defense.[2,3,9,10]

Surfactant is uniquely enriched in disaturated DPPC. The saturated C16 acyl chains pack densely at an air–liquid interface, reducing tension at the surface. However, dense and stable packing of DPPC occurs at a phase transition of 41°C, far above physiologic temperatures. Thus, at 37°C, pure DPPC maintains a semicrystalline or gel phase that is incapable of moving rapidly with the expansion and compression of the alveoli during the respiratory cycle. The capability of DPPC pulmonary surfactant to move rapidly to the alveolar interface at 37°C and to maintain low surface tension during dynamic compression is conferred by the surfactant-associated

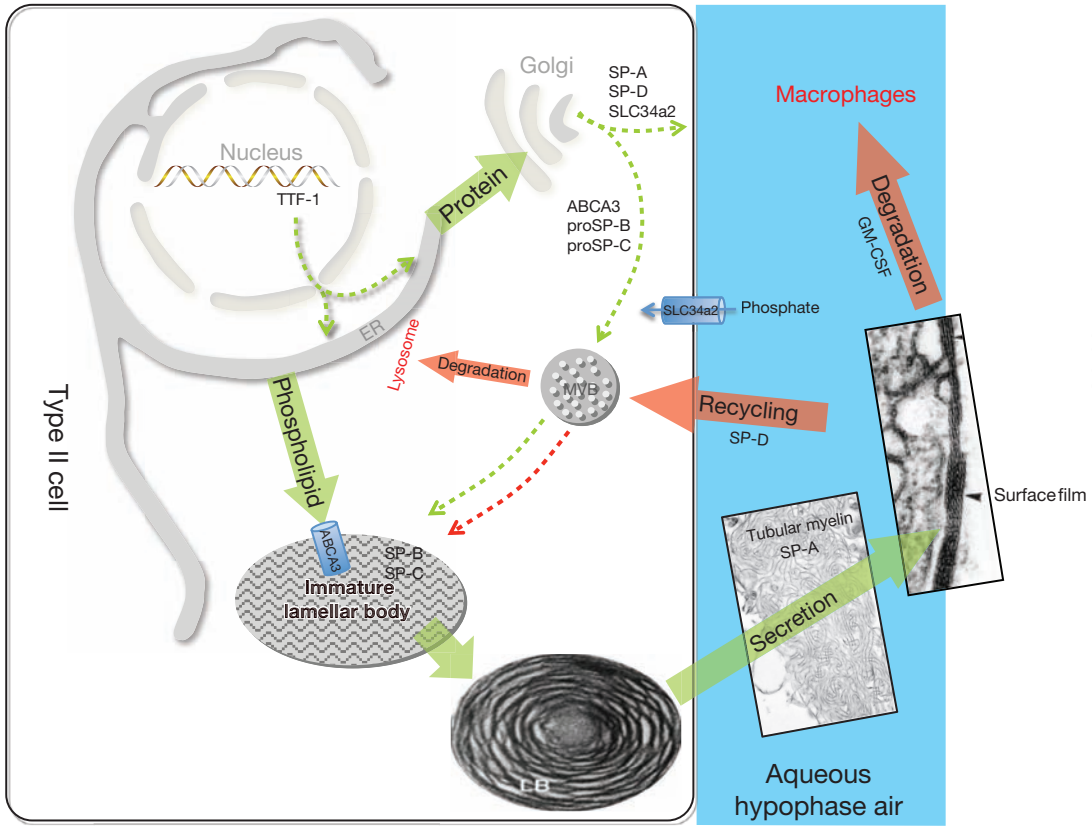

Figure 5-2 Surfactant metabolism. Newly translated surfactant proteins (proSP-B and proSP-C) and lamellar body (ABCA3) proteins traffic from the endoplasmic reticulum (ER) to the Golgi and subsequently to the multivesicular body (MVB). Fusion of the MVB with the lamellar body (LB) is accompanied by proteolytic processing of SP-B and SP-C proproteins to their mature peptides. Surfactant phospholipids (DPPC, PG) are likely transported directly from the ER to the LB by lipid transfer proteins. The contents of the LB are secreted into the alveolar space where they interact with SP-A to form tubular myelin and, ultimately, a phospholipid-rich film (surfactant) at the air–liquid interface. Alveolar surfactant lipids and proteins are cleared through a GM-CSF dependent pathway that regulates alveolar macrophage differentiation and function. Surfactant remnants are also taken up by the type II epithelial cell and recycled to the LB, via the MVB, for resecretion, while a portion is degraded in lysosomes. SP-D plays an important role in regulating alveolar surfactant pool size likely by enhancing its reuptake by type II epithelial cells. The MVB serves to integrate surfactant synthesis, secretion, recycling, and degradation pathways in the type II cell. TTF-1 is a transcription factor critical for differentiation of type II epithelial cells and regulation of expression of Abca3, Slc34a2, and the surfactant proteins. Synthetic pathways are shown in green and catabolic pathways are shown in red.

proteins SP-B and SP-C. PC synthesis in the lung is controlled by genes encoding choline phosphate cytidylyltransferase (PCYTLA) and choline kinase (CHKA), which are required for surfactant lipid synthesis and lung function at birth. DPPC is synthesized in type II alveolar cells via both a de novo pathway and remodeling of lysoPC. The enzyme lysoPC acetyltransferase (LPCAT1) mediates reacylation during surfactant lipid biosynthesis. Surfactant lipids, synthesized in the endoplasmic reticulum (ER) are transferred via a Golgi-independent pathway to lamellar bodies, the major intracellular storage site of surfactant (Fig. 5-2). Transfer of lipids occurs via nonvesicular transport and uptake into lamellar bodies requires the ABCA3 transporter, which selectively transports PC and PG. In contrast, surfactant proteins SP-B and SP-C traffic from the ER to the Golgi and subsequently to multivesicular bodies where proteolytic processing is initiated. Ultimately, multivesicular bodies are incorporated into lamellar bodies with surfactant lipids prior to secretion from type II alveolar cells.[3]

■ STRUCTURE AND FUNCTION OF SURFACTANT PROTEINS

Four distinct surfactant-associated proteins have been isolated from surfactant obtained by lung lavage. Their cDNAs, genes, and structures have been identified and are well characterized (Table 5-1).[9,10] The SPs are expressed in a relatively lung epithelial cell–selective manner and are secreted into the airspaces, where they influence the structure, metabolism, and function of surfactant. Two classes of proteins have been distinguished on the basis of their structures. SP-A and SP-D are relatively abundant, hydrophilic, structurally related proteins and are members of the calcium-dependent lectin family of proteins that have similar amino-terminal collagenous and C-terminal lectin domains.[11] SP-A and SP-D have little "surfactant"-like qualities but are able to bind complex carbohydrates, lipids, and glycolipids, including those on the surface of cells, bacteria, viruses, fungi, and other lung pathogens. SP-A and SP-D influence the structural forms and metabolism of surfactant lipids in the alveolus. They act as opsonins, activate alveolar macrophages, and play important roles in innate host defense in the lung. In contrast, SP-B and SP-C are small, hydrophobic proteins that play critical roles in enhancing the rate of spreading and stability of surfactant phospholipids needed to optimally reduce surface tension.[10] SP-B and SP-C are the sole protein components of the animal-derived surfactant replacement preparations used for the treatment of IRDS at present.[10]

TABLE 5-1 Regulation of Surfactant Homeostasis

Genes/locus	Functions	Inheritance	Presentation	Age at Presentation
ABCA3 16p13.3	Lipid transport Surfactant packaging/function	AR	RDS ILD	Newborns Children
SFTPB 2p12	Surfactant packaging/function	AR	RDS	Newborns
SFTPC 8p21	Surfactant function	AD	ILD > RDS	Infants, children, adults
SFTPA 10q22.2	Tubular myelin, host defense	AD	ILD/lung cancer	Adults
TITF1 14q13	Lung, thyroid, CN morphogenesis, surfactant regulation	AR haploinsufficiency	Thyroid/lung/CNS malformations ILD	Newborns Infants
GM-CSFRα 22.32	Alveolar macrophage function	AR	PAP	Children
GM-CSF 15q31	Alveolar macrophage function	Autoimmune	PAP	Adults

AR, autosomal recessive; RDS, respiratory distress syndrome; ILD, interstitial lung disease; AD, autosomal dominant; PAP, pulmonary alveolar proteinosis.

Surfactant Protein B (SP-B)

SP-B is a hydrophobic, amphipathic 8.8-kDa protein produced from a single gene (SFTPB, OMIM 178640) located on human chromosome 2. The SP-B mRNA is expressed in nonciliated bronchiolar cells and type II alveolar cells and is translated to produce a 40- to 42-kDa precursor that is proteolytically processed in the secretory pathway of type II epithelial cells to form the active 79-amino acid peptide found in alveolar surfactant. In combination with lipids, SP-B can reconstitute most of the surface activity of natural lung surfactant. SP-B contains two regions, (Trp_9-Pro_{23}) and (Ile_{56}-Pro_{67}), predicted to form amphipathic α-helices that interact with the surface of lipid films. Almost 50% of the protein is in an α-helical conformation; the amphipathic domains of SP-B interact with surfactant lipids, and PG in particular, to promote lipid incorporation into and stabilization of the surface film. SP-B contains three intramolecular disulfide bonds that confine the amphipathic helices of SP-B in an antiparallel configuration. Intermolecular disulfide bonds stabilize SP-B dimers. Dimers and higher multimers of SP-B, which are probably stabilized by noncovalent interactions, are readily identified in pulmonary surfactant.

ProSP-B is synthesized in the ER and proteolytically processed in multivesicular and lamellar bodies by cathepsins and other intracellular proteases. The active SP-B peptide is packaged with SP-C and surfactant lipids in lamellar bodies prior to secretion into the alveolus. In the alveoli, the positively charged amino acid residues of SP-B selectively interact with the negatively charged phospholipid DPPG. In a mixed DPPC/DPPG monolayer, SP-B is believed to purify the DPPC monolayer by removal of DPPG. SP-B increases order in the lipid head groups with little effect on order on acyl chains in the lipid membrane interior. The ability to order the lipid head group region is located in the amino- and carboxy-terminal regions of SP-B (1–20) and (53–78), which contain the predicted amphipathic helices. Synthetic peptides that contain these two regions have surface-tension–lowering activity similar to that of native SP-B and peptide mimics have been developed for therapy of respiratory distress in infants. SP-B enhances the insertion (fusion) of phospholipid vesicles into a preformed DPPC/DPPG monolayer, particularly in the presence of divalent cations. SP-B causes lipids in solution to form discoid particles often appearing as stacks or sheets. Together with SP-A, lipids, and Ca^{2+}, SP-B reconstitutes the characteristic ultrastructural features of tubular myelin, producing multilamellar aggregates and square lattice configurations.

SP-B is Required for Survival After Birth Mutations in the gene encoding SP-B (SFTPB, OMIM 265120) cause acute respiratory failure at birth related to surfactant dysfunction.[12,13] Similarly, deletion of Sftpb in the developing lung or its conditional deletion in adult mice causes acute respiratory distress associated with alveolar capillary leak and surfactant deficiency.[14] Pathologic findings of patients with lung disease related to SFTPB mutations are similar to those in mice in which the Sftpb gene is deleted.[14,15] SP-B deficiency is associated with failure to form lamellar bodies, accumulation of abnormal multivesicular bodies within the type II cells, and failure to form tubular myelin or functional surfactant films after secretion into the alveoli.

Hereditary SP-B Deficiency Causes Respiratory Failure at Birth SP-B deficiency is inherited in an autosomal recessive pattern, affected infants developing respiratory failure shortly after birth. While lung morphogenesis proceeds normally in utero, the lack of SP-B results in acute atelectasis and respiratory distress, usually presenting as full-term infants with signs and symptoms of diffuse alveolar collapse after birth. More than 40 distinct SFTPB mutations in patients with SP-B deficiency have been identified.[13,15] The disorder is refractory to surfactant replacement therapy and most patients die from respiratory failure within several months after birth, requiring oxygen and ventilatory support throughout their clinical course. Lung transplantation has been offered to some patients. SP-B deficiency disrupts the formation of lamellar bodies and tubular myelin, and interferes with the processing of proSP-C to the active peptide. Thus, most SP-B–deficient patients lack both SP-B and SP-C peptides in the alveolus. In patients with SFTPB-related disease, proSP-C accumulates in the airspaces, contributing to an alveolar proteinosis–like syndrome. Pathologic diagnoses include desquamative interstitial pneumonitis (DIP), chronic pneumonitis of infancy (CPI) or infantile alveolar proteinosis, histologic changes being influenced by age, and supportive therapies (Fig. 5-3).[16] The definitive diagnosis is made by identification of SFTPB gene mutations, enabling prenatal diagnosis and genetic counseling. While various missense, nonsense, frameshift, and splice variants have been identified, 121ins2 mutation in exon 4 is the most common

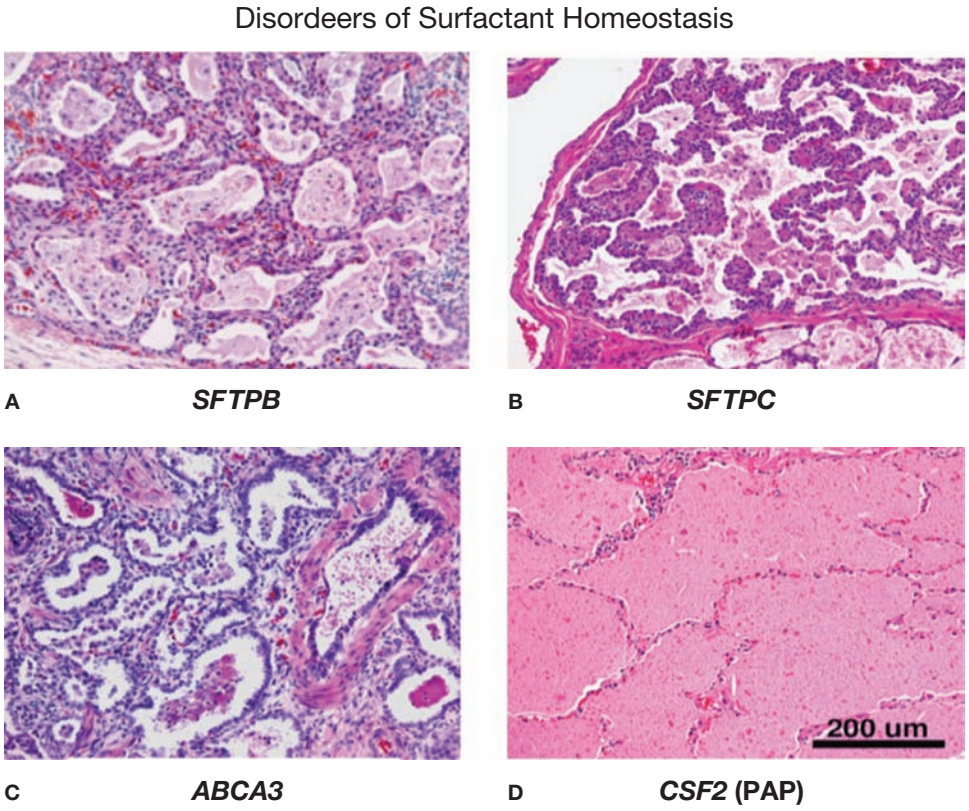

Figure 5-3 Pulmonary histopathology associated with disorders of surfactant homeostasis. Pathologic findings in eonates with mutations in SFTPB (**A**), SFTPC (**B**), and ABCA3 (**C**) are consistent with varying pathologic diagnoses, for example, childhood interstitial pneumonitis (CIP), nonspecific interstitial pneumonitis (NSIP), desquamating interstitial pneumonitis (DIP) or pulmonary alveolar proteinosis (PAP) (**D**). Severe alveolar remodeling, alveolar loss, macrophage infiltration, varying degrees of alveolar proteinosis, and stromal thickening are observed. In contrast, auto-antibodies against GM-CSF or mutations in the GM-CSF receptor (CSFR2A) are associated with pulmonary alveolar proteinosis in which surfactant lipids and proteins accumulate in the alveolus. Alveolar structure is generally well maintained in PAP. *(Reproduced with permission from Whitsett JA, Wert SE, Trapnell BC: Genetic disorders influencing lung formation and function at birth. Hum. Mol. Genet. 2004;13:R207–R215.)*

mutation.[12] In most affected infants, SP-B is lacking in bronchoalveolar lavage fluid and the abnormal proSP-C peptide accumulates in the alveoli, findings that can be verified by immunohistochemistry. Patients with SP-B deficiency do not respond to surfactant replacement and generally succumb from chronic respiratory failure early in infancy in spite of intensive care.

Surfactant Protein C (SP-C) In humans, SP-C is encoded by a single gene (SFTPC, OMIM 178620), located on human chromosome 8.[2,10] SP-C mRNA is expressed exclusively in type II epithelial cells in the lung and is translated to produce a 22-kDa precursor that is palmitoylated and proteolytically processed during intracellular transport to form the active, hydrophobic peptide of 35 amino acids stored in lamellar bodies.[2,3] After secretion, SP-C enhances the surface-active properties of lipid mixtures, lowering surface tension during compression, and enhancing adsorption rate of lipid films at the air–water interface. Both SP-C and SP-B enhance the speed of formation and stability of lipid films. A mixture of surfactant lipids and proteins SP-B and SP-C improves lung inflation and compliance and is useful for treatment of respiratory distress syndrome (RDS) in newborn infants. SP-C is palmitoylated on cysteine residues near the NH_2 terminus. The surface activity of depalmitoylated SP-C is somewhat less than that of palmitoylated SP-C, likely related to reduced stability of the α-helical domain that anchors the peptide within the lipid bilayer. Although the orientation of the palmitoyl groups in a lipid environment is not currently known with certainty, the lipid moiety on SP-C enhances the hydrophobicity of the amino-terminal region enabling its close contact with multilayered lipid films and likely serves to stabilize the α-helical, hydrophobic domain of SP-C. SP-C enhances the uptake of lipids by type II alveolar cells and plays an important role in lipid homeostasis in the alveoli.

In a lipid bilayer, the orientation of the α-helical segment of SP-C is closely parallel with the lipid acyl chains, implying a transbilayer orientation. In a surface monolayer, SP-C has a preferential orientation parallel to the interface, as observed by circular dichroism of monolayer films. The positive charges near the NH_2 terminus of SP-C may promote binding of phospholipid vesicles to the monolayer, a step required for insertion of phospholipids into the monolayer. SP-C forms well-defined domains within DPPC/DPPG films below the phase transition temperature of the bulk lipid. SP-C alters the size and shape of lipid vesicles, disrupting vesicular structures, causing the formation of larger vesicles and discoid particles.

Surfactant lipid films fold as a consequence of dynamic compression during the respiratory cycle in a process enhanced by SP-C and SP-B, each interacting with lipids in distinct ways. SP-B serves to stabilize the membrane-to-membrane interactions between the folded lipid layers to create multilayers.[3]

Role of SP-C in the Pathogenesis of Pulmonary Disease Deletion of Sftpc in transgenic mice perturbed surfactant function and caused severe interstitial lung disease (ILD) with advancing age.[17] While $Sftpc^{-/-}$ mice survive after birth, the mice develop emphysema, pulmonary inflammation, and abnormal lipid accumulations in alveolar macrophages, epithelial, vascular, and stromal cells. Surfactant lipid spreading and stability are only modestly perturbed in the absence of SP-C in vivo. The severity of pulmonary disorder related to SP-C deficiency in mice is strongly influenced by genetic strain, age, and other injuries, indicating that both genetic and environmental factors influence lung structure and function in the absence of SP-C. SP-C binds bacterial endotoxin, supporting a role in innate host defense in the lung. SP-C–deficient mice are susceptible to viral and bacterial pathogens and develop severe pulmonary injury in mouse models of pulmonary fibrosis. The finding that $Sftpc^{-/-}$ mice develop an interstitial pulmonary disorder is consistent with findings in humans, wherein SFTPC mutations cause both acute and chronic lung disease.

Mutations in SFTPC Cause Severe Interstitial Lung Disease in Humans Mutations in SFTPC represent a rare cause of acute and

chronic lung disease in humans.[18,19] SFTPC mutations are generally inherited as an autosomal dominant gene that has been causally linked to acute respiratory disease in newborn infants and more commonly, to chronic ILD in infants, children, and adults. De novo mutations in the SFTPC gene have been reported. The diagnosis of SFTPC-related lung disease (OMIM 610913) is usually made during infancy, but can present later in life, the severity of disease varying in a single extended family.[19] Most mutations occur in the C-terminal BRICHOS domain of proSP-C that serves as an intramolecular chaperone for the metastable membrane-spanning helical domain.[20] The mutant proSP-C protein is misfolded and/or misrouted resulting in intracellular accumulation. Most mutations result in the lack of synthesis of the active SP-C peptide that may influence the pathogenesis of lung disease. Various forms of ILD have been associated with the disease, including acute RDS in newborns, CPI, nonspecific interstitial pneumonitis (NSIP), and other forms of idiopathic pulmonary fibrosis (IPF) (Fig. 5-3).[16] Lung histopathology associated with SFTPC mutations is likely influenced by age, duration and severity of the disease, treatment, and both genetic and environmental factors. Infants with SFTPC mutations often present with severe respiratory signs and symptoms following viral infections. Definitive diagnosis is made by identification of mutations in the SFTPC gene. The onset and severity of pulmonary disease in humans is highly variable, even in the same kindreds, indicating that genetic and environmental factors strongly influence the disorder. At present, there is no effective therapy for SP-C–related disease. Lung transplantation has been offered for treatment of hereditary SFTPC deficiency in patients with respiratory failure. Mutations in SFTPC are a rare cause of acute and chronic ILD. More than 50 distinct mutations in SFTPC have been associated with clinical lung disease and include missense, frameshift, splice, insertions, and deletions that generally disrupt the structure of the C-terminal BRICHOS domain. The most common mutation, I73T, is found in more than one-third of patients.

ABCA3 Mutations Cause Respiratory Failure at Birth ABCA3 is a large, membrane-spanning transport protein that is present in the limiting membrane of lamellar bodies in type II epithelial cells (Fig. 5-2). More than 140 different mutations associated with severe lung disease in newborn infants have been identified, ABCA3 mutations (OMIM 610921) representing the most common genetic cause of neonatal respiratory failure.[1,4,21,22] While expressed in many tissues, patients with mutations in ABCA3 present with isolated lung disease, and abnormalities in other organ structures or functions have not been observed. Pathologic findings in newborn infants with respiratory failure are similar to those in mice wherein ABCA3 has been genetically deleted. ABCA3-related lung disease is generally inherited as an autosomal recessive disorder (Table 5-1). Affected infants present with severe respiratory failure characteristic of surfactant deficiency within the first days of life. Their lung disease is refractory to conventional therapies, resulting in respiratory failure and death within the first months of life. Pathologic findings are similar to those in SFTPB-related disease, and include alveolar proteinosis, lipoid pneumonia, cuboidal epithelial cell hyperplasia, interstitial thickening, loss of normal alveolar structures, and features of DIP (Fig. 5-3).[16] Older children present with features of NSIP. In newborn infants, respiratory failure is not responsive to surfactant replacement. Lung transplantation has been offered to some patients. ABCA3 is a member of the ATP-dependent, Walker domain–containing proteins that comprise a family of membrane-associated transport proteins that includes the cystic fibrosis transmembrane conductance regulator (CFTR). ABCA3 mediates PC and PG transport into lamellar bodies. The diagnosis of ABCA3-related lung disease is confirmed by nucleotide sequencing of the gene in infants and children with refractory pulmonary disease. While most mutations cause respiratory failure in infancy, the E292V mutation is associated with less severe lung disease, these patients often presenting with ILD later in childhood. Ultrastructural analysis of lung tissue from patients with ABCA3 mutations usually demonstrates the presence of small, atypical lamellar bodies in type II epithelial cells and the absence of tubular myelin in the airways, indicating an abnormality in both intracellular and extracellular lipid homeostasis. The processing of proSP-B is disrupted in some patients with ABCA3-related lung disease.[13]

Role of TITF1 in Surfactant Homeostasis TITF1, encoding the homeodomain-containing nuclear transcription factor, thyroid transcription factor-1 (TTF-1), plays a critical role in lung morphogenesis and the expression of SPs.[23,24] TTF-1 is expressed in the central nervous system, thyroid, and lung and is required for lung formation during embryonic development.[24] TTF-1 regulates the SP genes (SFTPA, B, C, and D), ABCA3, SLC34a2, all expressed in alveolar type II epithelial cells.[23] SLC34a2, is a phosphate transporter associated with the disease pulmonary alveolar microlithiasis.[25] Mutations in TITF1 have been linked to disorders of the central nervous system, thyroid, and lung (OMIM 600635), and more than 150 patients have been reported to date.[26,27] TTF-1–related lung disorders are generally inherited as heterozygous mutations resulting in lung dysfunction of varying severity, ranging from disordered alveolar morphogenesis, surfactant deficiency with respiratory failure in neonates and infants, and ILD in older patients. The majority of patients with TITF1 mutations present with severe lung disease, approximately half of which have a spectrum of brain, thyroid, and lung disease. Histologic findings vary greatly with severe abnormalities in the alveoli, and variable loss of SPs and lipids. Pulmonary disease associated with TITF1 mutations is frequently accompanied by congenital hypothyroidism. The severity of TITF1-related CNS, thyroid, and pulmonary disease varies widely in patients with TITF1 mutations. Diagnosis is made by identification of mutations in the TITF1 gene.

THE PULMONARY COLLECTIONS (SP-A AND SP-D)

SURFACTANT PROTEIN A (SP-A)

SP-A is an abundant hydrophilic 26-kDa (monomer) glycoprotein that functions in the host defense, and regulation of extracellular surfactant lipid structure. SP-A mRNA is expressed in nonciliated bronchiolar and alveolar type II epithelial cells in the lung, being translated from two genes (SFTPA1 and 2) located on chromosome 10 in the human.[2,9,11] SP-A in combination with SP-B and SP-C enhances formation of a surface lipid film in the presence of divalent ions, but is not critical for surfactant activity in the alveoli. The amino-terminal third of SP-A is arranged in a collagen-like triple helix, while a carboxy-terminal region has structural similarity to mammalian lectins including SP-D, serum mannose-binding lectin (MBL), and C1q. Protein–protein interactions among SP-A molecules are mediated by the collagen-like domains via intermolecular disulfide bonds that are necessary for SP-A–mediated aggregation of lipids and formation of tubular myelin. Binding and uptake of SP-A by type II alveolar cells and alveolar macrophages are mediated by specific, saturable cell surface receptors; however, the precise nature of the SP-A receptors and their intracellular functions remain unclear.[28] Both collagenous and noncollagenous domains of SP-A bind to isolated type II alveolar cells and immune cells. SP-A increases the association of lipids with type II cells but does not appear to increase internalization of lipid. Deletion of the SP-A gene (Sftpa) in mice does not alter survival or lung function after birth. While tubular myelin is absent, surfactant function, uptake, and secretion are not strongly influenced by deletion of Sftpa in mice.[29] Nevertheless, $Sftpa^{-/-}$ mice are highly susceptible to lung infections by bacterial, viral, and fungal pathogens, indicating that SP-A plays an important role in innate host defense of the lung.[2,9,11]

Usual Interstitial Pulmonary Disease Caused by Mutations in SFTPA2

Missense mutations in the gene encoding SP-A (SFTPA2) have been linked to pulmonary fibrosis pathologically diagnosed as usual interstitial pneumonitis (UIP) (OMIM 178642), generally presenting as ILD in the 4th and 5th decades of life.[30,31] Increased risk of pulmonary adenocarcinoma was observed at more advanced ages. This rare disorder is inherited as an autosomal dominant mutation in which the oligomerization and intracellular trafficking of SP-A(2) is disturbed, resulting in the unfolded protein response and chronic alveolar cell injury.

■ SURFACTANT PROTEIN D (SP-D)

SP-D is a collagenous Ca^{2+}-dependent carbohydrate-binding protein that is structurally related to SP-A and other C-type lectins.[11] SP-D is encoded by a single gene (SFTPD) located near the SFTPA genes on human chromosome 10.[2,9,11] SP-D is synthesized by alveolar type II epithelial cells and nonciliated bronchiolar cells in the lung, but it is also expressed in many other tissues. SP-D forms large oligomers that bind carbohydrates and glycolipids on the surface of bacteria, fungi, and viruses. The interaction of SP-D with microbial pathogens is Ca^{2+}- and carbohydrate-dependent.[11] In contrast to other SPs (SP-A, SP-B, and SP-C), SP-D is not strongly associated with surfactant lipids in the alveolus but plays an important role in determining surfactant structure and homeostasis.

Functions of SP-D In Vivo

Deletion of Sftpd in mice has provided insight into its important role in surfactant and alveolar homeostasis. $Sftpd^{-/-}$ mice survive after birth, but develop severe pulmonary disease associated with macrophage activation, airspace enlargement, and marked accumulation of surfactant lipids in the alveoli.[32,33] SP-D regulates alveolar pools of large and small aggregate surfactant, influencing surfactant particle size and its uptake by type II epithelial cells. Addition of SP-D to surfactant lipid extracts enhances surfactant stability in vitro and protects the preterm lung from endotoxin-induced injury. Infiltration with lipid-laden macrophages, and the induction of synthesis of metalloproteinases 2, 9, and 12 by alveolar macrophages, may contribute to the spontaneous airspace remodeling seen in the $Sftpd^{-/-}$ mice. $Sftpd^{-/-}$ mice are highly susceptible to pulmonary infections and inflammation associated with viral (respiratory syncytial and influenza virus), bacterial, and endotoxin or fungal exposures, indicating that SP-D plays a critical role in innate host defense of the lung.[2,9,11] SP-D binds bacterial, fungal, and viral pathogens, enhancing their opsonization and their killing by alveolar macrophages. Levels of SP-D are low in preterm infants and in infants and older patients with chronic lung disease. SP-D influences immunologic responses to allergens, interacting with alveolar macrophages and lymphocytes in the innate immune system. Thus, SP-D plays an important role in the regulation of surfactant lipid homeostasis, innate host defense of the lung, and prevention of inflammation and alveolar remodeling. Susceptibility to influenza A viral infections has been linked to specific SFTPD alleles, but to date, mutations in SFTPD have not been directly linked to acute or chronic lung disease.

■ RECYCLING AND CATABOLISM OF SURFACTANT LIPIDS AND PROTEINS

Pulmonary surfactant is taken up rapidly in the lung, and much of the lipid is reutilized (Fig. 5-2). After intratracheal administration, labeled lipid appears in type II cells and alveolar macrophages, but is not found in type I cells, indicating that the type II cells actively take up surfactant lipids from the alveolus for recycling or catabolism. Isolated epithelial type II alveolar cells internalize[3] H-PC and resecrete the internalized material or degrade it with reincorporation into other lipids. Isolated type II cells endocytose SP-C and SP-B. SP-A also binds to type II epithelial cells and is endocytosed by a receptor-mediated mechanism. While a number of candidate SP-A and SP-D receptors and binding proteins have been identified, whether the proteins are efficiently recycled and mechanisms by which they signal to influence surfactant homeostasis remain unclear.

Pulmonary surfactant as isolated from lavage fluid exists in several forms that can be fractionated based on density. In vivo labeling indicates that phospholipid is initially secreted in the heaviest forms, followed by conversion into distinct heavy and light forms. The most dense or ultraheavy form contains lamellar bodies and tubular myelin. Small aggregate forms are comprised of small unilamellar vesicles. While their lipid composition is similar to that of large aggregates, small aggregates are depleted of SP-A, SP-B, and SP-C, and lack surfactant function. SP-A and SP-D play important roles in the maintenance of the large aggregate surfactant structures. Cycling surfactant by expansion and contraction of a surface film in vitro converts lipids from large to small aggregates that are likely remnants destined for catabolism or recycling. See Perez-Gil and Weaver[3] for review.

REGULATION OF SURFACTANT PRODUCTION

The synthesis of pulmonary surfactant is subject to precise regulatory controls both during development and postnatally.[34] Surfactant phospholipid synthesis increases markedly in late gestation and is enhanced by a variety of hormones, including glucocorticoids in the fetal lung. Lung phospholipid content increases in the latter two-thirds of gestation in preparation for respiratory adaptation at birth. Prenatal glucocorticoids are routinely used to induce lung maturation and surfactant synthesis in infants at risk for preterm delivery.[7] Glucocorticoids reduce the risk of IRDS and enhance the efficacy of surfactant replacement therapy after birth. Like surfactant phospholipids, the SPs are highly regulated, increasing in the latter two-thirds of gestation in the mammalian species studied. Expression of SPs is regulated in complex ways by a variety of hormonal agents. The levels of SP mRNA increase in the perinatal period in association with increased surfactant synthesis and secretion required for postnatal respiratory adaptation. Expression of the SPs is regulated at both transcriptional and posttranscriptional levels, maintaining steady-state protein concentrations within tight constraints in the adult lung. Surfactant production is, in general, enhanced by glucocorticoids, epidermal growth factor (EGF), and cyclic adenosine monophosphate (cAMP) but inhibited by tumor necrosis factor-α (TNF-α), transforming growth factor-β(TGF-β), and insulin, depending on experimental conditions. Transcriptional control of the surfactant genes is modulated by a number of nuclear transcription factors, for example, TTF-1, cyclic AMP-responsive binding protein (CREBPα), members of the forkhead family transcription factors (FOXA2), retinoic acid receptors (RARs), sterol-responsive element-binding protein (SREBP), GATA-binding proteins, Krüppel-like factor 5 (KLF-5), NFATC3, and coactivators associated with these transcription factors.[35] In the lung, surfactant proteins A, B, and D are expressed in nonciliated bronchiolar and type II alveolar cells, while SP-C is expressed exclusively in type II alveolar cells. Transcriptional, epigenetic, and posttranscriptional mechanisms influence the synthesis of SPs and lipids, regulating surfactant concentrations in the airspace during development and repair.

■ SURFACTANT SECRETION

Lamellar bodies containing SPs SP-B and SP-C and lipids are secreted into the alveoli in a process mediated by activation of β-adrenergic receptors and P2×7R purinergic receptors that regulate intracellular cAMP and calcium homeostasis to influence cytoskeletal organization and secretion.[36] Recent studies support a role

for the orphan receptor (GPRC116) in the regulation of surfactant secretion, loss of GPRC116 resulting in increased purinoreceptor activity, increased surfactant secretion, and increased alveolar surfactant pool sizes.[37] While secretion of surfactant lipids SP-B and SP-C occurs via lamellar bodies, secretion of surfactant-associated proteins SP-A and SP-D occurs via a distinct, vesicular secretory pathway (Fig. 5-2). Interactions of SP-A and SP-D with lipids occur after their secretion into the alveoli.

GM-CSF Signaling Regulates Surfactant Clearance

Mutations in the genes encoding the GM-CSF receptor (CSFR2A, OMIM 13899) and autoantibodies against CSF2 (GM-CSF) have been associated with early-onset PAP in children and in adults, respectively.[5,38] While less than 10% to 15% of surfactant lipids is cleared by catabolism in alveolar macrophages, this pathway is critical in controlling steady-state surfactant concentrations in vivo. Granulocyte macrophage colony–stimulating factor (GM-CSF or CSF2) and GM-CSF receptors are required for normal surfactant catabolism. See Suzuki et al.[5] and Trapnell et al.[39] for review. SP and lipid clearance are decreased in Csf2 and Csfr2a gene–deleted mice causing PAP in which SPs and phospholipids accumulate in the lung. Findings in the mouse models led to the discovery that GM-CSF signaling abnormalities cause idiopathic PAP.[5,40] Clinical studies demonstrate that idiopathic PAP in adults is usually caused by autoantibodies against GM-CSF.[38] Similar abnormalities in surfactant homeostasis, alveolar macrophage morphology, and function are observed in patients with PAP, whether caused by mutations in GM-CSF receptors or by neutralization of GM-CSF by autoantibodies. Lung lavage and GM-CSF, given systemically or by aerosol, have been successfully used to treat adults with PAP (see Chapter 70).

SURFACTANT HOMEOSTASIS AND REPLACEMENT IN INFANTILE RESPIRATORY DISTRESS SYNDROME

IRDS is associated with prematurity, the risk increasing as gestational age decreases. In addition to the morphologic immaturity of the respiratory tract, lung phospholipid content and surfactant secretion are decreased in preterm infants. While functional surfactant can be isolated from infants with IRDS, surfactant pool sizes are markedly decreased in the preterm compared to the term infant and the surface activity of surfactant from infants with IRDS is decreased. Alveolar–capillary leak of blood or serum proteins inactivate surfactant function. Decreased alveolar surfactant activity associated with pulmonary immaturity causes atelectasis, alveolar collapse, pulmonary hemorrhage, and hypoxemia in preterm infants. A schematic representing factors influencing the pathogenesis of IRDS is provided by Figure 5-4.[41]

Supplemental oxygen and mechanical or assisted ventilation is routinely used to treat IRDS. During the last two decades, widespread use of exogenous surfactant has markedly ameliorated the morbidity and mortality associated with IRDS in preterm infants. Exogenous surfactants – in the form of synthetic mixtures of phospholipids and extracts of lung or surfactant containing bovine or porcine SPs B, C, and phospholipids – have been used extensively for prevention and therapy of RDS in newborn infants.[42] Surfactant replacements with preparations containing SPs B and C act rapidly, increasing lung volumes, and compliance and decreasing the requirements for positive-pressure ventilation and oxygen. Morbidity and mortality from IRDS have been markedly reduced since the application of surfactant replacement for preterm neonates, decreasing barotrauma, pneumothorax, and mortality. Surfactant replacement is given intratracheally resulting in improved lung function and oxygenation. Synthetic surfactants lacking SPs improve lung function in a delayed manner, and treatment with both synthetic and protein-containing surfactants were effective in decreasing morbidity and mortality from IRDS in clinical studies. Animal-based surfactant preparations containing SP-B and SP-C are now standard treatment for IRDS. The effectiveness of surfactant therapy is likely related to the immediate surface tension–reducing properties and to the reuptake and reutilization of the exogenous surfactant lipids by the respiratory epithelium. Following preterm birth, production of endogenous surfactant lipids and proteins by the respiratory epithelium is rapidly induced; therefore, surfactant replacement is primarily utilized in the first few days following birth. Surfactant replacement has been used successfully in the treatment of meconium aspiration and pneumonia in neonates.

SURFACTANT HOMEOSTASIS IN ADULT RESPIRATORY DISTRESS SYNDROME

ARDS occurs in association with trauma, sepsis, long bone fractures, thermal burns, and injury to the lung from aspiration of gastric contents, pneumonia, inhalation of toxic gases, and infection (see Chapter 141). In ARDS, increased permeability of the microvasculature permits leakage of protein and fluid into the lung, inactivating surfactant. Epithelial cell injury may also contribute to surfactant deficiency in ARDS. Various non-SPs and lipids present in elevated concentrations in the lung in ARDS have been implicated in reducing surface activity of pulmonary surfactant; these include immunoglobulins, albumin, fibrinogen, fatty acids, lysophosphatidylcholine, and C-reactive protein. The mechanisms causing the decrease in surfactant activity in ARDS include competition of the proteins for the air–liquid interface, sequestration and dilution of surfactant in non–surface-active particles, and inhibition of SP and lipid synthesis and secretion. Alterations in surfactant composition occur during ARDS and may precede the development of respiratory failure.[43] Phospholipid, SP-A, and SP-B concentrations are decreased, and the minimum surface tension of surfactant tested in vitro is increased

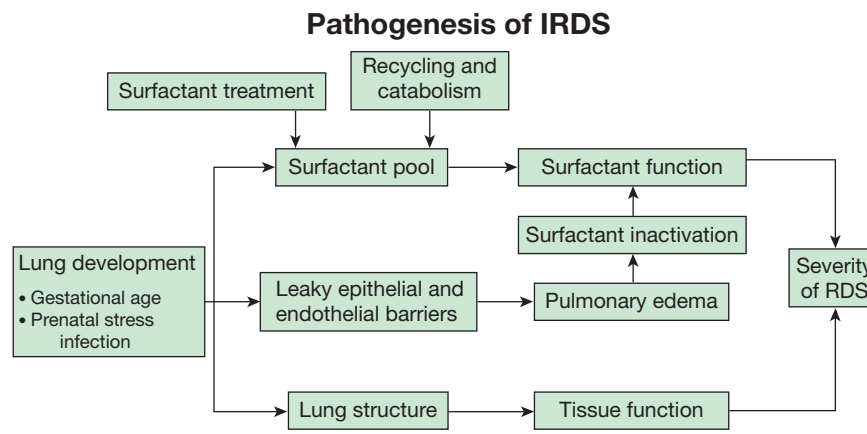

Figure 5-4 Factors influencing the pathogenesis of idiopathic respiratory distress syndrome. The pathogenesis of idiopathic RDS is multifactorial. Immaturity of the alveolar type II cells results in decreased surfactant pools. Lung collapse and injury are caused by surfactant deficiency. Alveolar damage causes leakage of serum proteins and edema that inactivate surfactant, increasing the severity of respiratory distress. Surfactant treatment reduces surface tension, restores phospholipid pool sizes, and improves alveolar–capillary leak to maintain surfactant function. *(Used with permission of Dr. Alan Jobe.)*

in patients at risk for ARDS. In ARDS, total phospholipid, PC, PG, and surfactant proteins SP-A and SP-B are decreased and the ratio of small to large aggregates is significantly increased compared to that in non-ARDS patients. Thus, ARDS leads to both a deficiency in pulmonary surfactant constituents and inhibition of the activity of the remaining surfactant. While surfactant has been effective in ARDS syndromes in laboratory experiments, to date, clinical studies have not supported the routine use of surfactant replacement for RDS in adult patients. In contrast, application of careful ventilatory support has improved outcomes in ARDS.

INHIBITION OF SURFACTANT ACTIVITY DURING LUNG INJURY

Phospholipases A_2 and C and their products, fatty acids, lysoPC, and dipalmitin inhibit surface activity in vitro. These molecules may be released or produced during lung injury. Inhibitory effects of oleic acid may be related to its miscibility with phospholipids, disrupting the interfacial surfactant film, rather than by competition for the interface. The inhibition by PAF, lysoPC, and oleic acid is not reversible, suggesting that their direct interaction with surfactant lipids disrupts lipid organization needed to form stable films. In contrast, palmitic acid improves surfactant function of preparations used for therapy of IRDS. The surface activity of pulmonary surfactant is readily destroyed by phospholipase A_2 or phospholipase C. Oxygen therapy, used routinely for ARDS and IRDS, may influence surfactant homeostasis and function in the alveolus. The rate of synthesis of surfactant lipids and clearance of radiolabeled surfactant extracts decreased in rabbits exposed to 100% O_2 for 64 h. In contrast, exposure of adult rats to 85% O_2 increased expression of surfactant proteins SP-A, SP-B, and SP-C and phospholipids. Oxidants are also released locally in the lung by activated immune cells. Activated alveolar macrophages secrete NO and superoxide, which can then react to form peroxynitrite that can oxidize and inactivate proteins and lipids.[44] Peroxynitrite inhibited the surface activity of surfactant, damaging both lipids and SPs.[42]

PLASMA PROTEINS INACTIVATE PULMONARY SURFACTANT

Edema fluid leaks into the airspace in both ARDS and IRDS. Edema fluid obtained from hyperoxia-exposed rabbits contains serum proteins capable of inhibiting surface activity of surfactant extracts, as evaluated in the pulsating bubble apparatus. Thus edema fluid may interfere with surfactant therapy, although the concentration dependence of the inhibition suggests that increased doses of surfactant may aid in overcoming the inhibitory effects of edema fluid. Serum albumin, globulin, and fibrinogen reduce the rate of adsorption, increase the minimum surface tension of the surfactant film, and reduce the hysteresis area between compression and expansion curves in vitro. The mechanism by which plasma proteins inhibit the activity of pulmonary surfactant is likely to be one of competition for the interface, because higher surfactant lipid concentrations overcome albumin inhibition even at high albumin concentrations. Inhibition by C-reactive protein, fibrinogen, and other plasma proteins is reversible. Addition of SP-A and organic surfactant extracts reverses inhibition caused by soluble proteins but not by lysoPC. Both SP-C and SP-B increase the ability of a phospholipid mixture to resist inhibition of surface activity by plasma proteins. SP-B is more effective than SP-C at resisting inhibition by fibrinogen. Optimal resistance to surfactant inhibition by serum protein was observed when both SP-C and SP-B were present.

REDUCTION OF SURFACTANT SYNTHESIS IN ARDS

In addition to the inactivation of pulmonary surfactant by proteins and lipids in edema fluid, a reduction of synthesis of surfactant may contribute to the decreased surfactant activity in ARDS. *Escherichia coli* endotoxin inhibited surfactant synthesis in lung organ cultures. Synthesis of SPs is also influenced by inflammatory responses following lung injury or infection. TNF-α decreased de novo synthesis of SP-A, SP-B, and SP-C mRNA and caused respiratory distress when administered intratracheally to the mouse. TGF-β1, produced during lung injury, decreased the expression of SP-A and SP-C in vitro. Thus, sepsis or lung injury may reduce both the synthesis and functions of surfactant lipids and proteins.

SUMMARY

Pulmonary surfactant is required for airbreathing after birth and for protection of the lung from microbial pathogens and toxicants. Surfactant homeostasis requires the integrated functions of SPs and lipids to reduce surface tension in the alveolus. Decreased production or inactivation of pulmonary surfactant has been associated with both IRDS and ARDS. Mutations in genes mediating surfactant synthesis (ABCA3, SFTPA, SFTPB, SFTPC, TITF1, and CSFR2A receptors) are rare genetic causes of acute or chronic lung diseases.[1–5,15,45] Identification of the genes and proteins mediating alveolar homeostasis provides the knowledge and tools to diagnose and treat rare lung diseases caused by disorders of surfactant homeostasis.

CHAPTER 6

Mucociliary Clearance

Burton F. Dickey
Michael R. Knowles
Richard C. Boucher

Mucus forms an essential barrier that protects the lungs from inhaled particles, pathogens, and toxicants. However, excessive mucus accumulation contributes to the pathogenesis of all the common diseases of the airways. Therefore, understanding airway mucus function and dysfunction is important for pulmonary medicine. The airway mucus barrier is mobile, continually propelled in a proximal direction by ciliary beating. Ciliary dysfunction causes disease both because of the failure to clear xenobiotics from the lungs and because it results in mucus accumulation. Mucus and ciliary biology will be considered together in this chapter as they interact to achieve, or fail to achieve, airway clearance.

MUCOCILIARY CLEARANCE IN HEALTH

AIRWAY SURFACE LIQUID

Liquid in the airway lumen is distributed between two distinct layers—a mobile mucus layer and a stationary periciliary layer (Fig. 6-1). Secreted polymeric mucins are the principal macromolecular components of the mucus layer, whereas membrane-tethered mucins and nonmucin glycoconjugates are the principal macromolecular components of the periciliary layer.

Mucus Layer

Normal mucus has physical characteristics on the border between a viscous fluid and a soft and elastic solid. Its physical state can vary with the extent of hydration and other conditions as described below in Mucociliary Dysfunction in Disease. Mucus is formed by a network of mucin polymers in water, with water accounting for ~98% of the mass, mucins 0.7%, and salts and nonmucin macromolecules the remainder. Mucins are exceedingly large glycoproteins (monomeric masses up to 3×10^6 Da) that link up to form long chains and branched networks. MUC5AC and MUC5B are the major secreted mucins in the airways.[1–3] They exhibit similar molecular weights and primary structure (Fig. 6-2A), but differ in function (see Secretory Cells) and polymer structure. Whereas MUC5B forms end-to-end polymers (Fig. 6-2B), emerging data suggest that MUC5AC forms branched covalent networks. They have characteristic regions rich in serine and threonine residues linked by their hydroxyl side groups to sugar chains (*O*-glycosylation) that account for 50% to 90% of the mass of mucins.

Mucins are packaged dehydrated in secretory granules. After secretion, they rapidly adsorb several hundred fold their mass of water, so it is critical there be sufficient airway surface liquid.[4] Insufficient liquid results in formation of a gel that is too viscoelastic to be readily cleared by ciliary motion or cough. Once immobile mucus plaques are formed, they swell only very slowly if subsequently exposed to additional liquid because of the high degree of entanglement of the mucin polymers. Besides the need for sufficient surface liquid, adequate bicarbonate must be present in the liquid to allow proper mucus maturation by chelating calcium. In secretory granules, calcium organizes the folding of mucin polymers, and must dissociate to allow mucus expansion.[5–7] Chloride and bicarbonate are both secreted into

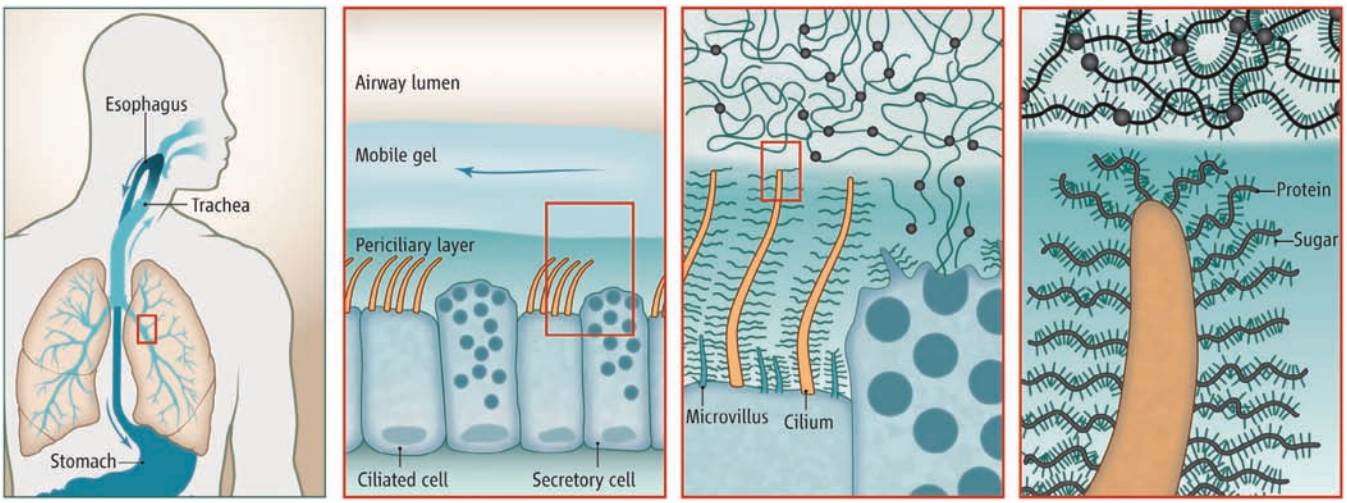

Figure 6-1 Airway surface liquid layers. **A.** Mucus is continuously produced in the conducting airways of the lungs, and swept by ciliary action from distal to proximal airways. After passing through the larynx, mucus is swallowed. **B.** The mobile mucus layer *(light blue)* glides over a periciliary layer of higher osmotic modulus *(dark blue)*. **C.** Airway secretory cells synthesize and secrete mucin polymers that interact with water to form the mobile mucus layer. Ciliated cells are covered by a dense glycocalyx containing glycosaminoglycans, membrane-tethered mucins, and other glycoconjugates that give the periciliary layer its high osmotic modulus. **D.** Mucin polymers are illustrated in the mucus layer with the protein core shown in *black*, sugar side chains in *blue*, and sites of end-to-end polymerization as *black circles*. Membrane-tethered mucins are shown densely coating cilia, while other glycoconjugates are not illustrated. *(Reproduced with permission from Dickey BF: Biochemistry. Walking on solid ground, Science. 2012;337(6097):924–925.)*

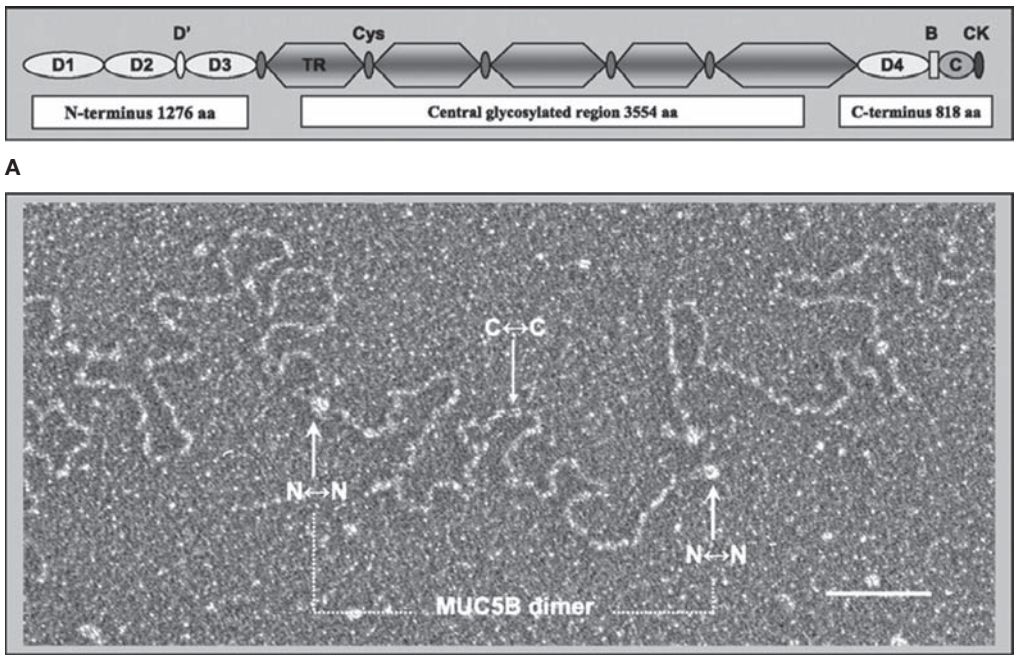

Figure 6-2 The structure of MUC5B. **A.** Structural domain representation of the MUC5B monomer. MUC5B has Von Willebrand factor (VWF)-like domains at NH_2- and COOH-terminal regions (D, B, C, and CK domains). The central region contains five heavily glycosylated, tandem repeat (TR), mucin domains and five small cysteine-rich (cys) regions. **B.** Electron microscopy image of a conformationally relaxed, linear MUC5B molecule. The MUC5B intact molecule in mucus is assembled from disulfide bond-mediated interactions between COOH-terminal domains of monomers to form dimers, and subsequent interactions between NH_2-terminal domains to form higher polymer oligomers. The assignment of the structure as a dimer (dotted bar) is made on the basis of the length (850 nm), which is greater than that obtainable by a single MUC5B monomer. The N↔N terminal region and C↔C terminal region can be identified by their size. Scale bar, 100 nm. *(Reproduced with permission from Kesimer M1, Makhov AM, Griffith JD, et al. Unpacking a gel-forming mucin: a view of MUC5B organization after granular release. Am J Physiol Lung Cell Mol Physiol. 2010;298(1):L15-L22.)*

the airway lumen by the cystic fibrosis transmembrane regulator (CFTR). Since the airway epithelium is quite water-permeable, water follows chloride and bicarbonate into the airway lumen.[8] Additional hydration can be provided by other chloride channels as described below in "Mucociliary Dysfunction Disease the sections "Secretory Cells" and "Asthma."

Mucus is produced throughout the conducting airways down to the level of the smallest bronchi and the larger bronchioles, but not in terminal or respiratory bronchioles (Fig. 6-3A). Bronchioles lack submucosal glands, and overall it is estimated that two-thirds of airway mucus is produced by surface epithelial cells and one-third by submucosal glands in primates (Fig. 6-3B).[9] In the most distal airways, the mucus layer is vanishingly thin, but it becomes increasingly thick as it travels proximally, both because additional production adds to its bulk and because the total cross-sectional area of the airways progressively narrows. In the trachea, the mucus gel layer is ~50 μm thick. Besides mucus acting as a simple physical barrier, the mucin sugar side chains act as a combinatorial library to bind particles and pathogens, and a thicker mucus layer has been shown to protect against infection.[10]

Periciliary Layer

It was widely believed until recently that cilia beat in a watery layer of lower density than the overlying mucus layer. However, recent data indicate that the periciliary layer has a higher density than the mucus layer due to a high concentration of membrane-tethered mucins (MUC 1, 4, and 16) and mucopolysaccharides (also called glycosaminoglycans).[11–13] This finding has several important implications for airway function.[14] First, it helps to explain how distinct layers form because dense packing of the grafted glycoconjugates of the periciliary layer tends to exclude the unattached polymeric mucins of the mucus layer (Fig. 6-1C). Second, charged polymers are highly effective lubricants in an aqueous environment, allowing low friction ciliary beating despite the high density of grafted glycoconjugates, and low friction between the periciliary and gel layers. Third, spatial impingement by grafted glycoconjugates may physically couple neighboring cilia to coordinate their beating (Fig. 6-1C). Fourth, glycoconjugates are grafted with increasing density from the top of the periciliary layer to the bottom, which should propel exogenous particles and pathogens out of the periciliary layer for removal by the mobile mucus layer. Fifth, the higher density of water-avid glycoconjugates in the periciliary layer and their grafting to the cell surface results in a nearly constant amount of liquid in this layer except under conditions of severe underhydration. In conditions of overhydration, liquid is transferred to the mucus layer, which is generally well tolerated.

■ AIRWAY EPITHELIAL CELLS

The surface airway epithelium forms a mosaic of two major cell types—secretory and ciliated (Figs. 6-1, 6-4, and 6-5). In addition, basal cells that do not contact the airway lumen serve as progenitors in the proximal airways, and neuroendocrine cells that secrete basolaterally toward sensory neurons are scattered throughout the airways. Secretory and ciliated cells are multilayered and have a tall columnar shape in proximal airways but become single layered and progressively shorter in distal airways until they have a cuboidal shape in bronchioles. Ciliated cells are more abundant than secretory cells in proximal airways, whereas secretory cells are more abundant in distal airways.

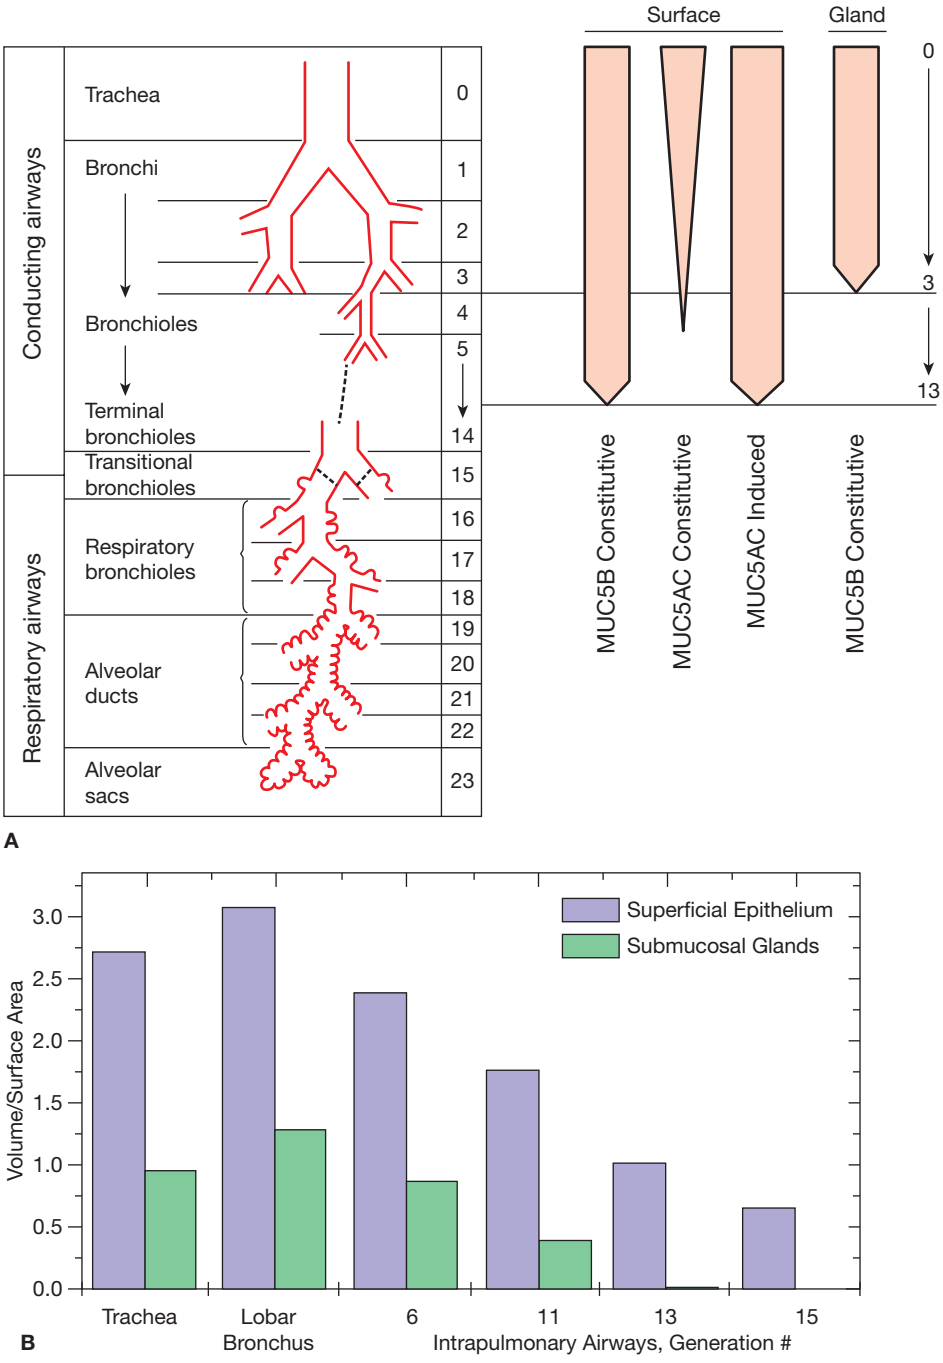

Figure 6-3 Mucin production in conducting airways. **A.** MUC5B is produced constitutively by surface epithelium down to the level of bronchioles proximal to terminal bronchioles, and by submucosal glands present in the trachea and bronchi but not bronchioles. MUC5AC is produced constitutively by surface epithelial cells with a goblet morphology in more proximal airways, and its production can be induced in nongoblet secretory cells that produce MUC5B down to the level of terminal bronchioles. Airway generation is listed numerically in the third column. **B.** The relative amount of mucin produced by surface epithelium and submucosal glands has been estimated by morphometric analysis of the airways of rhesus monkeys stained with Alcian blue/PAS, expressed as the ratio of volume of stained material ($mm^3 \times 10^{-3}$) per unit area of basal lamina (mm^2). *(A: Modified with permission from Weibel ER: Morphometry of the Human Lung. Heidelberg: Springer-Verlag; 1963; B: Reproduced with permission from Plopper CG1, Heidsiek JG, Weir AJ, et al. Tracheobronchial epithelium in the adult rhesus monkey: a quantitative histochemical and ultrastructural study, Am J Anat. 1989;184(1):31–40.)*

Secretory Cells

Subsets of airway secretory cells have been given different names based upon differences in their microscopic appearances, including goblet and club (Clara) cells. However, molecular techniques reveal overlap between these subsets, such as the presence of CCSP (SCGB1A1) in cells with a goblet morphology that express mucin, and the presence of MUC5B in cells with a club morphology.[15–17] Secretory cells are unified by the stable expression of an apical-regulated exocytic machinery,[18,19] whereas the presence of secretory products such as mucins and secretoglobins varies with exposure to extracellular signals that acutely regulate their expression and secretion (Fig. 6-5). Therefore, it is simplest to refer to these cells generically as airway secretory cells, while further specifying their appearance, airway level, and gene expression as appropriate.

Secretory cells in bronchi and proximal bronchioles constitutively express MUC5B (Figs. 6-3 and 6-5), whereas secretory cells in terminal and distal bronchioles do not express MUC5B either constitutively or inducibly.[1,15,20] The same bronchial and proximal bronchiolar secretory cells that express MUC5B can also express MUC5AC, with MUC5AC expressed constitutively in proximal airways but only inducibly in distal airways (Figs. 6-3 and 6-5). Mice with deletion of Muc5b die postnatally from upper and lower respiratory tract inflammation and infection.[21] In contrast, mice with deletion of Muc5ac are healthy at baseline but fail to clear parasitic worms from their guts,[22] and induced expression of Muc5ac in rat lungs prevents worms from transiting the lungs.[23] Thus, Muc5b/MUC5B appears to be the principal mucin functioning in baseline clearance of the airways, while Muc5ac/MUC5AC appears to function principally in parasite defense.

The effector function of Muc5ac in parasite defense dovetails well with the central role of IL-13 in parasite defense and the ability of IL-13 to strongly induce expression of Muc5ac/MUC5AC (>100-fold

in cultured human airway cells and 40-fold in mice in vivo).[24–26] Other cytokines that promote mucin gene expression include IL-1β, 4, 6, 9, 23, and 25, but whether they do this directly or by amplifying the intensity of IL-13 signaling is not yet clear.[1] Complement protein C3a, epinephrine, and γ-aminobutyric acid signaling interact with IL-13 signaling to augment Muc5ac expression.[1] ClCa1 is a secreted protein that signals in an autocrine and paracrine fashion in response to IL-13 to increase Muc5ac/MUC5AC expression.[24] A network of transcription factors has been identified that regulates Muc5ac/MUC5AC expression, including STAT6, SPDEF, Foxa2, Foxa3, Notch, β-catenin and XBP-1. While some components of the signaling pathways connecting extracellular ligands with transcriptional regulation are known, such as the key roles of STAT6 downstream of IL-13 and MAPK13 downstream of ClCa1,[24,27] many details remain to be elucidated. The pathways and transcription factors regulating Muc5b/MUC5B expression have been less studied, probably reflecting the fact that expression of this mucin is relatively stable compared to Muc5ac/MUC5AC.[28] However knowledge of the regulation of MUC5B expression during development is likely to give important insight into cell fate specification in the airway, and the recent discovery of aberrant MUC5B expression in interstitial lung diseases highlights its clinical importance (see the section "Interstitial Lung Diseases"). Along with production of the polymeric mucins themselves, specialized enzymes required for glycosylation (e.g., GalNAc-T),[29] folding and polymerization (e.g., AGR2),[30] and other aspects of mucin processing are produced by airway secretory cells.

Mucins are secreted into the airway lumen at a low basal rate and a high stimulated rate. A regulated exocytic mechanism mediates both rates as indicated by abnormal phenotypes in both basal and stimulated secretion when Munc13-2, a sensor of second messengers, is deleted in mice.[16] Additional molecular components of the exocytic mechanism have been identified and their function studied (Fig. 6-6).[18,19,31,32] The rate of mucin secretion is regulated by the second messengers calcium and diacylglycerol, which are generated by a signaling cascade downstream of G-protein–coupled receptors that include the $P2Y_2$ purinergic and A3 adenosine receptors.[18,33,34] ATP is released in autocrine and paracrine fashion and activates $P2Y_2$ receptors and is metabolized to adenosine. It is possible that additional ligands such as histamine and acetylcholine may serve as secretagogues in inflammation, though they may act indirectly by causing smooth muscle contraction and nucleotide release.

As secreted mucins must adsorb large volumes of water to yield mucus of normal viscoelasticity, it is important that adequate airway lumenal water be available. The autocrine/paracrine ligands ATP, adenosine, and ClCa1 regulate the expression and/or activity of CFTR, the calcium-activated chloride channel (CaCC) TMEM16 A, and solute carrier family 26, member 9 (SLC26A9) to control chloride secretion.[24,33,35] As these same ligands regulate mucin production and/or secretion as described earlier, mucin release is thus coordinately regulated with water translocation.

Besides their role in mucin production and secretion, airway secretory cells serve as progenitors of both secretory and ciliated cells.[36] They also express components of the cytochrome P450 system that inactivates toxic inhaled organic compounds by oxidation.[37] They secrete antimicrobial peptides and reactive oxygen species constitutively, and they are capable of sensing pathogens and responding by augmenting their antimicrobial defenses and signaling to leukocytes.[38]

Ciliated Cells

Motile cilia are the defining structural and functional feature of airway ciliated cells (Fig. 6-4) (Video 6-1 Normal). They are evolutionary conserved and share homologous features with flagella of unicellular eukaryotes and mammalian sperm tails. Respiratory cilia have the "9+2" microtubular axonemal structure, which comprises nine peripheral doublets plus a central pair.[39,40] The outer doublets are linked together by proteins that form the dynein regulatory

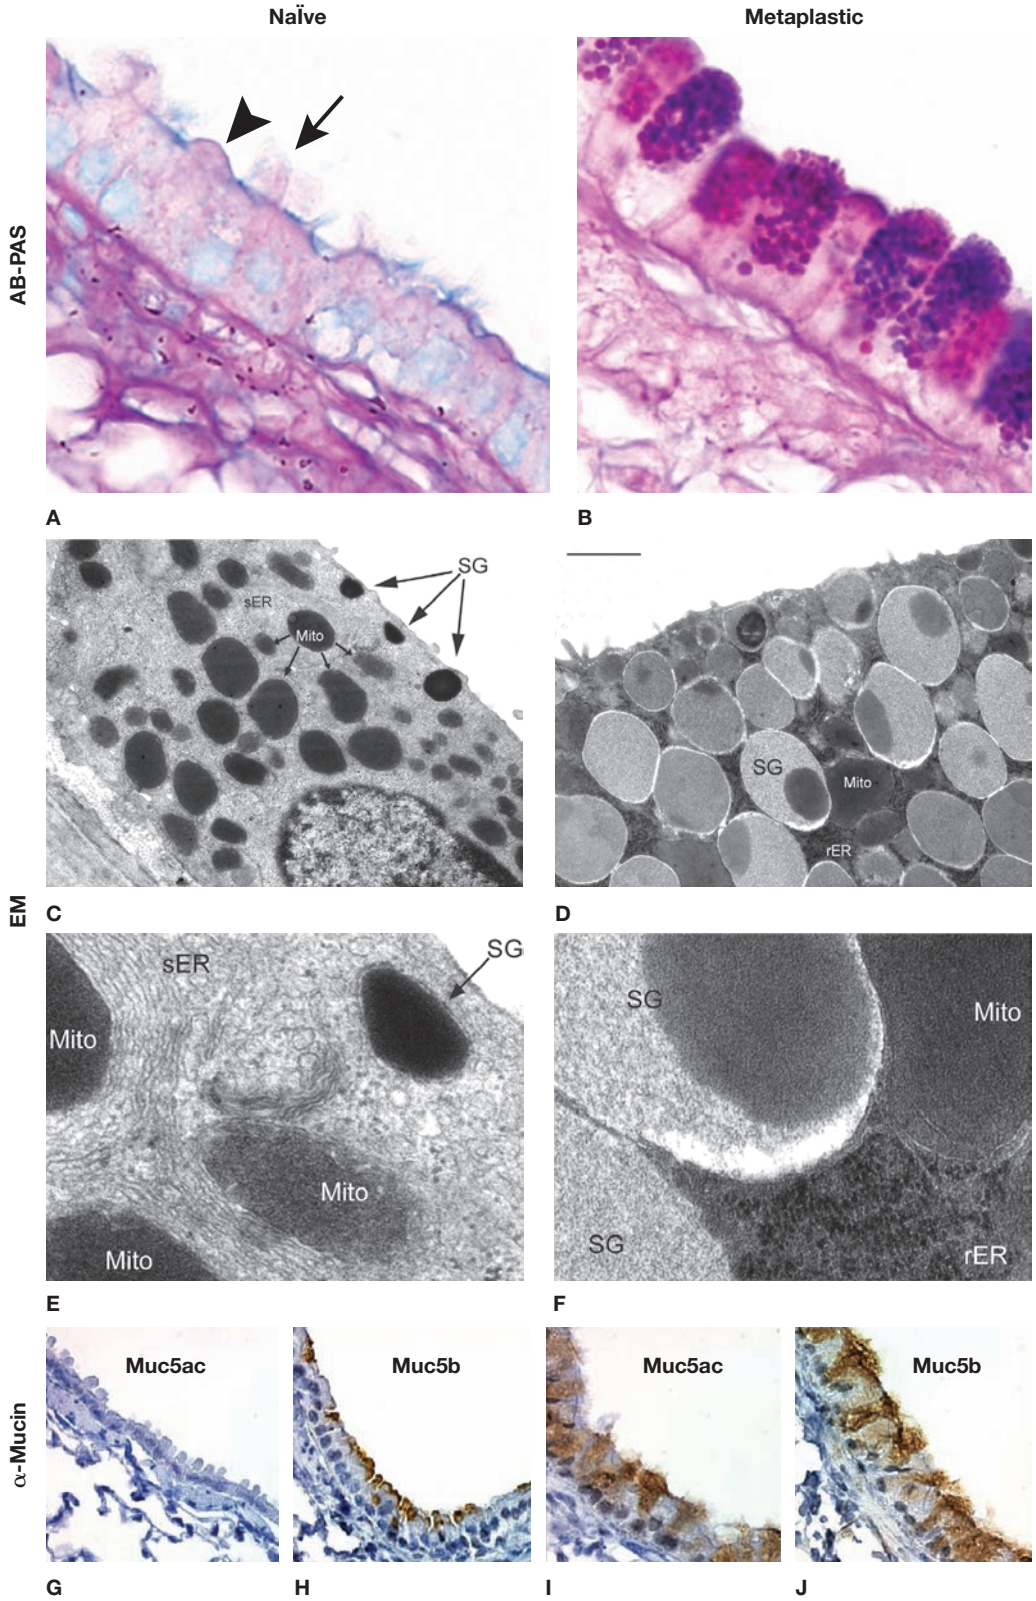

Figure 6-5 Airway epithelial mucus metaplasia. Light micrographs with AB-PAS staining (**A, B**), electron micrographs (EM) (**C–F**; low and high magnification), and immunohistochemical images using mucin-specific antibodies (**G–J**). On the left are images from the airway of a healthy mouse without airway inflammation (naïve), and on the right are images from the airway of a mouse with mucus metaplasia 3 days after the onset of allergic inflammation, as described by Evans et al.[15] Cells in the top row on the left show alternating ciliated *(arrow)* and domed secretory *(arrowhead)* cells, and on the right show prominent mucin granules in secretory cells. Cells in the EM images on the left show small numbers of electron-dense secretory granules (SG) near the apical membrane, numerous mitochondria (Mito), and abundant smooth endoplasmic reticulum (sER). Cells in the EM images on the right show numerous electron-lucent SG containing mucins and an electron-dense core, and abundant rough ER (rER). Images in the bottom row show that Muc5b is present in naïve airways even though it is not apparent by insensitive AB-PAS staining, and that both Muc5ac and Muc5b are present in the thickened metaplastic epithelium. Scale bar in the right middle panel is 10 μm for top row, 1 μm for second row, 150 nm for third row, and 30 μm for bottom row.

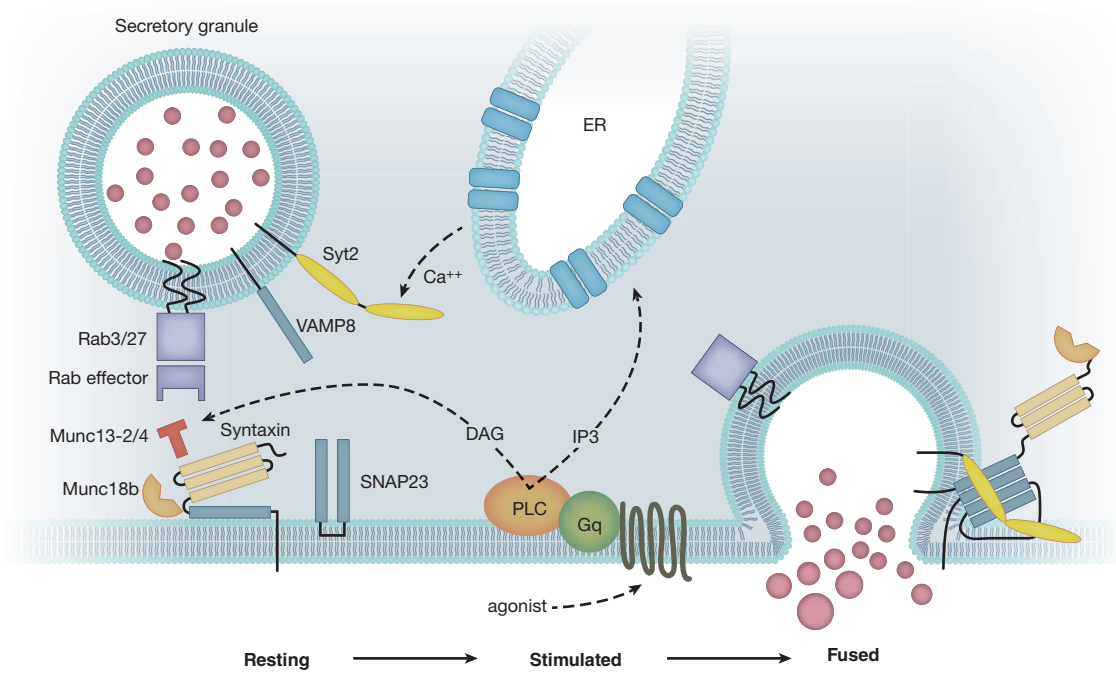

Figure 6-6 Airway mucin secretion. Initially, mucin granules become tethered to the plasma membrane by Rab proteins and their effectors in the vicinity of the exocytic SNARE proteins (VAMP8, SNAP23, and an unknown Syntaxin, shown as black bars) *(Left)*. Activation of heptahelical receptors such as those for ATP ($P2Y_2$) and adenosine (A3R) leads to activation of the trimeric G-protein, Gq, and phospholipase C (PLC), resulting in generation of the second messengers diacylglycerol (DAG) and inositol trisphosphate (IP_3). Diacylglycerol activates the priming protein Munc13-2, and IP_3 induces the release of calcium from apical ER to activate Synaptotagmin-2 (Syt2) *(Center)*. Activation of the regulatory Munc13 and Syt proteins leads to full coiling of the SNARE proteins to induce fusion of the granule and plasma membranes. The interactions of the SNARE proteins take place on a scaffold provided by Munc18b *(Right)*. *(Adapted with permission from Davis CW1, Dickey BF: Regulated airway goblet cell mucin secretion, Annu Rev Physiol. 2008;70:487–512.)*

complex (previously known as "nexin link"), and radial spokes extend from the doublets to the central pair. Taken together, these axonemal components provide the framework for generation of a complex ciliary waveform. The key components for driving ciliary movement are the inner and outer dynein arms, which are present at repetitive multiple units of 96 nm along the length of the peripheral microtubules (doublets) and contain enzymes for ATP hydrolysis to generate force for dynein arm movement. Each cilium contains >300 different proteins and is rooted in the airway epithelial plasma membrane by a basal body, which is a modified centriole. Mutations in genes encoding any part of the axonemal structure or functional components of motile cilia, or components necessary for the biogenesis of cilia, including cytoplasmic proteins, can result in primary ciliary dyskinesia (PCD), as described below in Mucociliary Dysfunction in Disease.

The function of normal motile cilia is to provide mucociliary clearance in the conducting airways, an important innate defense mechanism of the lungs.[41] Cilia provide the coordinated motive force for mechanically clearing mucus containing infectious agents, particles, and toxic substances from the conducting airways. ATP hydrolysis in the dynein arms produces sliding of adjacent axonemal structures and generates the complex ciliary waveform that occurs in human airways.[39,40] Approximately 200 cilia per cell beat in a coordinated fashion on and across cells (Video 6-1). This coordinated vectorial synchrony results from the planar orientation that occurs during ciliogenesis, as well as refinement by cilia-driven fluid flow and the tight packing of cilia due to the negatively charged glycoproteins that coat the ciliary shaft.[11,42] The ciliary forward (power) stroke is more rapid and extends a bit more into the mucus layer than the recovery stroke.[42] Cilia beat at ~6 to 12 Hz, and propel mucus proximally at ~1 mm/min. The regulation of ciliary beat frequency involves a variety of signaling molecules and multiple feedback mechanisms.[39,43] In brief, ciliary beat frequency and mucociliary clearance do not operate at full capacity under basal conditions, but can be stimulated by several intracellular signaling mechanisms including cyclic adenosine monophosphate (cAMP)– and cyclic guanosine monophosphate (cGMP)–dependent phosphorylation of axonemal components, as well as changes in intracellular calcium and pH. In contrast, protein kinase C downregulates ciliary beat frequency.

Besides their role in moving the mucus layer, ciliated cells play additional crucial roles in airway homeostasis. They have a major function in ion transport across the airway luminal surface since both the epithelial Na^+ channel (ENaC) and CFTR are expressed predominantly in ciliated cells. Ciliated cells autoregulate airway surface hydration by sensing both macroscopic (e.g., airflow) and microscopic stresses (e.g., interaction of cilia with the mucus layer) and transmitting these signals into extracellular ATP release. Extracellular ATP regulates the balance between ENaC (inhibits) and CFTR (activates) to constantly adjust airway surface hydration.[44] In addition, ciliated cells are capable of flattening to cover epithelial gaps when secretory cells are injured.[45]

SUBMUCOSAL GLANDS

In bronchial airways, submucosal glands contribute to the secretion of mucins and liquid. Each gland is connected to the airway lumen

by a superficial ciliated duct that propels secretions outward and a deeper nonciliated collecting duct.[46] The body of the gland is located between the spiral bands of smooth muscle and the cartilage plates in the airway wall. Mucus cells constitute ~60% of the gland volume, and serous cells, located distal to the mucus cells, make up the remaining ~40%. Glandular mucus cells express MUC5B almost exclusively with very little expression of MUC5AC.[1] The serous cells secrete anions, proteoglycans, and numerous antimicrobial proteins. The rate of submucosal gland secretion can be greatly increased by cholinergic, adrenergic, and peptidergic stimulation. In pathologic states such as COPD and cystic fibrosis (CF), the volume of submucosal glands can increase several fold while maintaining a normal ratio of mucus and serous cells.[47,48]

MUCOCILIARY CLEARANCE

Mucus rises up the trachea by ciliary beating, then leaves the lungs by passing through the vocal cords to enter the pharynx to be swallowed (Fig. 6-1A). The vocal cords are covered by squamous epithelium that cannot provide a propulsive surface, but the posterior commissure is covered by mucociliary epithelium and is ideally situated adjacent to the esophagus. Approximately 30 mL of respiratory mucus is propelled out of the lungs daily, carrying inhaled particles and pathogens that are excreted in the gastrointestinal tract.[49]

The rate of mucociliary clearance can be measured in human subjects by a variety of techniques, including direct bronchoscopic observation of the movement of instilled particles and external imaging of the movement of radiolabeled particles. From a practical standpoint, the only commonly used technique is the inhalation of small radiolabeled particles, such as sulfur colloid labeled with technicium-99m, followed by serial imaging with a planar gamma camera.[49,50] The movement of labeled particles from peripheral to central lung regions over the course of several hours is then measured. This technique is used for the evaluation of both disease pathophysiology and the efficacy of therapeutic interventions.[50] Mucus velocity is highest in the trachea and decreases in successive airway generations.[49] Different techniques yield different velocities, but these center around a mucus velocity of 10 mm/min in the trachea of a healthy young adult. Cough clearance provides an important backup mechanism when mucociliary clearance is impaired, and its rate can also be measured using standardized protocols of controlled coughs with imaging of the clearance of inhaled radiolabeled particles.[50]

Mucociliary clearance depends upon a mucus layer of appropriate viscoelasticity, a periciliary layer of appropriate depth, and effective ciliary beating. When these components are interacting optimally, particles and pathogens suspended in the 10,000 L of air that are inspired daily are cleared from the lungs with minimal impact on the underlying epithelium. However failure of any of these components can lead to cascading dysfunction that causes symptoms and contributes to disease pathogenesis.

MUCOCILIARY DYSFUNCTION IN DISEASE

The principal symptoms of mucociliary dysfunction are dyspnea and cough. Dyspnea is caused by reduction of the total cross-sectional area of the conducting airways from mucus occlusion. This occurs most commonly from diffuse plugging of small airways, but may also occur when a central airway becomes plugged by mucus due to an underlying anatomical abnormality. Cough is caused by the stimulation of vagal afferents in the intrapulmonary airways or larynx and pharynx. Patients often infer that laryngopharyngeal stimulation, described as "a tickle in the throat," results from postnasal drip because they recognize that mucus descends from the nasopharynx by gravity but are unaware it also ascends from the lungs by ciliary action. Physical signs of impaired mucus clearance include cough, bronchial breath sounds, rhonchi, and wheezes. Radiographically, retained mucus may appear as localized atelectasis or linear and branched opacities. It is important to recognize the role of retained mucus in disease presentation so that symptoms can be relieved and its contribution to disease progression addressed.

Asthma

The central role of diffuse airway obstruction by lumenal mucus in fatal asthma (Fig. 6-7) has been recognized by pathologists for more than 100 years and confirmed in multiple subsequent autopsy case series.[51,52] Mucus occlusion is particularly dangerous

A B C

Figure 6-7 Airway obstruction by mucus in asthma. **A.** Lungs removed at autopsy from a patient who died from asthma. The lungs did not spontaneously collapse as they normally do because the airways were obstructed by lumenal mucus and bronchoconstriction. **B.** Cut surface of the lungs from the same patient showing mucus plugs *(arrows)* filling the large airways. **C.** Light microscopic image of a small airway from another patient who died from asthma showing infiltration of the airway wall and the lumenal mucus by inflammatory cells. *(**A, B:** Used with permission of James C. Hogg, University of British Columbia; (**C**) Used with permission of Martha L. Warnock, University of California, San Francisco.)*

in asthma because smooth muscle contraction around the lumenal plugs further constricts airflow. The principal underlying cause of mucus dysfunction in asthma is mucin overproduction. This is usually driven by allergic inflammation mediated by IL-13,[53] though IL-17 can also cause mucin overproduction and airway hyperresponsiveness.[54–56] IL-13 can increase the production of MUC5AC in human airway epithelial cells in vitro more than 100-fold,[24,25] and the production of Muc5ac in the lungs of mice in vivo more than 40-fold.[26] In contrast, the production of Muc5b/MUC5B increases minimally or may even decrease at the level of transcripts.[26,57] Mucus plugs in asthma often have a rubbery quality, suggesting that the large quantities of mucins that are produced overwhelm the available airway surface liquid when they are suddenly secreted in response to inflammatory stimuli. This abnormality can occur despite the additional hydration provided by SLC26A9 and ClCa1-dependent CaCC activity that are coordinately upregulated with MUC5AC production by IL-13.[24,35] Additional contributors to abnormal rheologic properties of asthmatic mucus are a high concentration of plasma proteins resulting from increased microvessel density and permeability in the airway wall,[58,59] and the presence of granule and cytoplasmic macromolecules from eosinophils and other leukocytes. The therapeutic focus in addressing mucus dysfunction in asthma should be reducing mucin overproduction and plasma extravasation through the use of anti-inflammatory drugs. Corticosteroids have been the mainstay of treatment, but immunotherapies directed at IgE, IL-13, and IL-5 play increasing roles, and deeper understanding of pathways that control MUC5AC expression may lead to targeted therapies.

Cystic Fibrosis

Complications from the impaired clearance of airway mucus dominate the clinical course of patients with CF. Mutation of the anion channel CFTR causes an imbalance between salt and water absorption mediated by ENaC and secretion mediated by CFTR that results in insufficient airway surface liquid.[60] Defective CFTR function also produces deficient bicarbonate transport that results in impaired mucin unfolding.[5,7] Together these deficiencies lead to the formation of mucus with an abnormally high mucin concentration and viscoelasticity that is poorly cleared by ciliary motion. This problem is compounded when the insufficiency of airway surface liquid becomes so severe that the periciliary layer loses height such that cilia cannot beat and the dehydrated mucus layer adheres to periciliary glycoconjugates.[11,14] Retained lumenal mucus is apparent pathologically in small airways and glandular ducts early in life.[61] Eventually, the failure of mucociliary clearance results in airway colonization with bacteria and fungi, and paradoxically, the mucus gel layer that evolved to protect the lungs from infection instead provides a protected environment for microbial growth. Besides the mechanical problems of mucus clearance in CF, there are likely additional defects in host defenses. For example, the deficiency of bicarbonate secretion results in acidification of airway surface liquid which impairs antimicrobial protein function,[62] and CFTR normally transports thiocyanate that is oxidized by lactoperoxidase to form isothiocyanate, an antimicrobial effector of the innate immune system that is variably reduced in CF.[63] Microbial infection leads to inflammation, and cellular debris such as DNA and actin from necrotic leukocytes further impairs the biophysical properties of mucus. Hydration therapy with aerosolized hypertonic saline solution has become a mainstay of the therapy of CF, together with aerosolized DNase and aerosolized antibiotics. Further discussion of the pathogenesis and therapy of CF is found in Chapter 50.

Video 6-2 Lateral view of defective ciliary function in Primary Ciliary Dyskinesia (PCD) associated with defective outer dynein arms (ODAs). Note the very limited range of motion, which gives the appearance of the cilia being "stiff." *Access at www.fishmansonline.com*

Primary Ciliary Dyskinesia

PCD is a genetically heterogeneous recessive disorder of motile cilia with an estimated incidence of 1 per 10 to 20,000 births.[64] However, due to the inadequacies of diagnostic methods that involve studies of ciliary ultrastructure and/or function, there are only ~1000 patients in the United States with a well-established diagnosis of PCD. Clinical disease reflects defective function of motile cilia in the conducting airways, paranasal sinuses, middle ear (eustachian tube), and the reproductive tract (Video 6-2, ODA defect). Respiratory distress occurs in >80% of full-term neonates with PCD, and infants and children have daily nasal congestion and year-round wet cough occurring soon after birth.[65] Chronic otitis media and recurrent sinus infections are also common. Cough clearance is preserved in PCD compared to CF, which may partially compensate for defective mucociliary clearance; however, recurrent bacterial infections occur in the lower airways, and ~65% of older pediatric patients and all adults have bronchiectasis with predilection for the middle lobe, lingula, and basal segments. Abnormal lung function develops early in life in PCD infants and young children, and spirometry worsens with increasing age.[65] Respiratory microbiology is similar to CF, though chronic *Pseudomonas aeruginosa* infection occurs at an older age in PCD. The prevalence of nontuberculous mycobacterial infection also parallels that seen in CF, with ~15% of adults and a lower percentage of children infected.

The diagnosis of PCD is challenging, because current diagnostic techniques are not standardized or readily available. Identification of PCD requires recognition of key phenotypic features, which include neonatal respiratory distress and situs inversus or ambiguous.[64,65] Identification of ciliary ultrastructural defects by electron microscopy can no longer be the sole "gold standard" for diagnosis because of technical limitations in its routine performance and the fact that at least 30% of PCD patients have normal ultrastructure.[66] The majority of electron microscopic abnormalities involve defective outer dynein arms or combined defects in outer and inner arms. Isolated inner dynein arm defects account for <5% of electron microscopic defects, and false-positive diagnoses commonly occur. Assessment of ciliary motility has been used to confirm a diagnosis of PCD, but technical limitations also preclude this as the sole diagnostic method. Mutations have been described in 21 genes that cover ~65% of PCD patients, and there is strong correlation between mutations in specific genes and defects in ciliary ultrastructure and function. Diagnostic capabilities have recently benefited greatly from measurement of nasal nitric oxide (nNO), which is low in PCD (10%–20% of normal, or <77 nL/min) regardless of the mutated gene.

There are no validated PCD-specific therapies, and treatment for PCD lung disease is extrapolated from other diseases with abnormal mucociliary clearance, particularly CF. Airway clearance therapies, inhaled antibiotics, oral macrolides, and inhaled hypertonic saline solution are useful in CF; thus, these therapies are being used in PCD. Otolaryngologic complications of middle ear disease and sinusitis are managed by standard approaches.

COPD

A role for mucus dysfunction in COPD has long been recognized in the syndrome of chronic bronchitis, defined as a persistent cough

that produces sputum for at least 3 months per year in 2 consecutive years. The productive cough probably results from mucus overproduction in proximal airways due to surface epithelial mucus metaplasia and submucosal gland expansion, combined with ciliary dysfunction.[1,67] More recently a second role for mucus dysfunction in COPD has been recognized in the widespread obstruction of small airways identified in pathologic analysis of resected surgical specimens.[68,69] The extent of small airway mucus occlusion correlates with the degree of airflow obstruction, occurs even in patients with an emphysematous phenotype, and predicts longevity. These two mucus phenotypes in COPD – productive cough and airflow obstruction – correlate only weakly.[67] These findings suggest that individuals have differential susceptibility to the effects of cigarette smoke on different aspects of mucociliary clearance, as well as reflecting the independent roles of emphysema and small airway fibrosis in airflow obstruction in COPD.

Mucus overproduction and ciliary dysfunction both result from exposure to toxic products in cigarette smoke and environmental pollutants. Among these products, acrolein is a particularly potent inducer of MUC5AC production.[70] In ciliated cells, cigarette smoke causes both structural and functional changes.[71] Besides these effects, cigarette smoke also decreases airway surface liquid by reducing CFTR function and increasing ENaC function.[72] As is the case in CF, impaired mucociliary clearance results in persistent airway infection, particularly with unencapsulated *Haemophilus influenzae*. Further discussion of the pathogenesis and therapy of COPD is found in Chapters 40 and 42.

Interstitial Lung Diseases

A link between mucus dysfunction and interstitial lung disease was not suspected until a genome-wide association study in 2011 found genetic linkage between a polymorphism in the MUC5B promoter and both familial interstitial pneumonia (FIP) and idiopathic pulmonary fibrosis (IPF). The promoter variant is present in 50% to 60% of individuals with FIP or IPF compared to 19% of unaffected individuals, and increases the risk of disease 7-fold in heterozygotes and 21-fold in homozygotes.[73] Subsequent studies have extended the association to other idiopathic interstitial pneumonitides[74] and subclinical radiographic interstitial abnormalities.[75] The presence of the promoter variant is associated with improved survival in patients with IPF.[76] The promoter variant causes overexpression of MUC5B, but whether disease ensues because of mucus dysfunction in the airway lumen, an epithelial stress response induced the demands of synthesizing such a large and complex molecule, or some other mechanism is not yet known. Further discussion of the pathogenesis and therapy of IPF is found in Chapters 28 and 56.

Other Diseases

Acquired bronchiectasis may be due to a variety of causes including an unrecognized genetic disorder, a respiratory infection early in life, or immunodeficiency. Similar to CF, retained mucus and airway infection dominate the clinical course. Aerosolized 7% hypertonic saline solution treatment has been shown to improve lung function and quality of life.[77]

Viral respiratory infections commonly lead to mucociliary dysfunction, both because of increased mucin production and injury to ciliated cells. In subjects with underlying asthma, viral respiratory infections are a common cause of exacerbation.[78]

Allergic bronchopulmonary aspergillosis (ABPA) can present with symptoms and clinical findings that range from mild to severe. Florid overproduction of MUC5AC resulting from allergic inflammation induced by the persistent fungal infection can lead to atelectasis and mucus impaction of small or large airways. ABPA is addressed in greater detail in Chapter 48

Panbronchiolitis is a syndrome of small airway inflammation and mucus obstruction that occurs predominantly in Asian subjects, and was reported to be associated with a polymorphism in the MUC5B promoter.[79] A molecular mechanism of mucin gene dysfunction has not been identified, nor is it yet known whether there is a relationship between promoter dysfunction in panbronchiolitis and in the interstitial lung diseases.

Localized anatomic abnormalities of the airways, such as the presence of a stricture, a surgical anastomosis, or a therapeutic stent, can result in localized mucus accumulation that can lead to infection or airway closure. It may be possible to remove the localized mucus accumulation by flexible or rigid bronchoscopy, and instillation of sodium bicarbonate solution may partially dissolve the mucus.

Retained mucus is a common problem in intubated patients and those in whom lung mechanics are disrupted as a result of paralysis, immobilization, or surgery; atelectasis and pneumonia are frequent complications in such patients.[1]

Treatment

Therapies for mucus dysfunction can be divided into those that treat mucin production, mucin secretion, mucus clearance, or airway infection.[1] Mucin overproduction has been effectively treated in asthma with the use of corticosteroids and newer drugs that target allergic inflammation, though these agents have not been very effective in neutrophilic airway inflammation as occurs in COPD and CF. Despite evidence of a general role of the EGF receptor in mucin production, an inhibitor did not show benefit in COPD patients.[80] In view of the generally pathologic role of MUC5AC and generally homeostatic role of MUC5B, strategies that selectively target MUC5AC production are attractive. Inhibiting mucin secretion may seem to be an obvious strategy to treat combined overproduction and secretion (mucus hypersecretion), and is being pursued using modified botulinum toxins and MARCKS inhibitors.[1] However it may be difficult to precisely titrate mucin secretion to preserve baseline homeostatic function while inhibiting pathologic secretion, and clinical trials have not so far shown evidence of benefit.

Treatments that promote mucus clearance include physical measures to remove retained secretions and pharmacologic agents to improve mucus rheology.[1] Among physical measures, mechanical insufflation–exsufflation has been shown to effectively clear mucus in patients with weak cough, there is evidence of moderate benefit from multiple measures to increase expectoration in CF, and there is anecdotal evidence of benefit in non-CF bronchiectasis.[81,82] Drugs that effectively improve mucus rheology in specific settings include inhaled dornase alfa, inhaled hypertonic saline solution, and ivacaftor in CF. Inhaled hypertonic saline solution has also shown benefit in non-CF bronchiectasis,[77] and is under investigation in COPD. In contrast, dornase alfa did not show benefit in non-CF bronchiectasis, asthma, or COPD. For the treatment of infected airway mucus, a variety of inhaled, oral and intravenous antibiotic regimens have been shown to have utility in specific situations, particularly in CF and COPD.[1]

CHAPTER 7

The Genetic Basis of Respiratory Disorders

Micheala A. Aldred

The field of genetics and genomics is advancing at an incredible pace. The completion of the Human Genome Project was just the beginning. Now, thanks to rapid advances in sequencing technology and bioinformatics, we have made significant progress toward sequencing 1000 genomes from around the world, uncovering great genetic diversity and challenging us to understand the biologic relevance. Sequencing the exome (the protein-coding parts of the genome) of a patient with an undiagnosed condition is already a reality. Even beyond human genetics, genomic technologies are making an impact on pulmonary disease, enabling characterization of new respiratory pathogen genomes, such as the SARS virus and pandemic H1N1 influenza, with unprecedented speed. Against this backdrop, a chapter on the genetics of lung diseases could easily be out of date before it is even in print. Thus it does not seek to be encyclopedic, but to give the reader a grounding in the principles of human genetics, an overview of current knowledge in Mendelian lung diseases and a summary of recent progress in understanding genetic factors contributing to common lung conditions. It outlines some of the emerging roles of epigenetic modifications and aims to give a vision of where the field is moving, concluding with current and future prospects for genetically targeted therapies.

PRINCIPLES OF HUMAN GENETICS

GENOME ORGANIZATION

The term "genome" refers to the genetic make-up of an organism (Table 7-1). Mammalian genomes are composed of deoxyribonucleic acid (DNA) and can be subdivided into a nuclear genome – DNA within the nucleus of each cell – and a separate circular genome housed within each mitochondrion. DNA has a double-helix structure, each strand comprises four constituent bases – adenine (A), cytosine (C), guanine (G), and thymine (T) – that pair together, A with T and G with C. DNA needs to be replicated each time a cell divides. This strict base pairing ensures accurate copying of the DNA code.

The human genome is approximately 3.3 billion base pairs in size. This large amount of DNA is wound around proteins known as histones, then packaged into higher-order structures called chromosomes that can be visualized under a light microscope. Most cells of the body contain two copies of each chromosome; one inherited from each parent, and are termed "diploid." Diploid cells contain 23 pairs of chromosomes. During meiosis, these pairs of chromosomes are separated, giving rise to oocytes and sperm that contain a single copy of each chromosome (termed "haploid"). Thus fusion of two haploid gametes gives rise to a new diploid organism, preserving the correct copy number of DNA through the generations. Gender is determined by a pair of sex chromosomes, X and Y; females have two copies of the X-chromosome, whereas males have one each of X and Y. The other 22 pairs of chromosomes are known as the autosomes. Genetic diseases are mainly caused by mutations in autosomal or X-chromosome genes; the Y-chromosome harbors only a few genes and these are mainly involved in determining male characteristics.

GENE STRUCTURE

Only about 1% to 2% of the human genome actually encodes for proteins. The noncoding portion was originally considered to be junk DNA, but it is now increasingly clear that some of it has important regulatory functions. The protein-coding units are called genes. The DNA within a gene is first transcribed into ribonucleic acid (RNA). RNA has a similar base structure to DNA, but is single stranded, has a slightly different sugar backbone and thymine (T) is replaced by uracil (U). Genes are typically divided into coding exons and intervening noncoding introns. The intronic sequences are spliced out of the initial RNA transcript to produce the mature messenger RNA (mRNA) molecule. Some genes have alternative splicing patterns that can give rise to slightly different variants ("isoforms") of the protein. The mRNA is then translated into protein by ribosomes. Ribosomes read the RNA code as a triplet of bases or "codon" and add the corresponding amino acid to the growing protein chain. There is some redundancy in the genetic code and amino acids may be encoded by several different codons. Four codons have a special function: AUG encodes methionine and always marks the initiation site for protein translation, while UGA, UAG, and UAA are stop signals that lead to termination of translation. The DNA flanking the coding region of a gene is not translated but contains important regulatory elements, including the promoter region that regulates transcriptional activity.

CLASSES OF MUTATION

Alterations in the DNA sequence occur when there is an error in DNA replication prior to cell division or DNA damage occurs through environmental exposures such as UV radiation or tobacco smoke. Such mutations may affect a single base (known as a point mutation) or may involve the insertion or deletion of multiple bases. Cells have an extensive DNA repair mechanism that will correct most of these mutations, but any that escape may lead to a permanent change in the sequence that is propagated to daughter cells. Mutations in noncoding regions of the genome often have no detrimental effect and over time, they may become quite common in the population. Variants that are present at a frequency of greater than 1% are known as polymorphisms and have been widely used in genetic mapping studies. Thus the two copies of a gene in any individual are subtly different at the DNA sequence level. These variant forms are known as "alleles." However, mutations that occur in the introns of genes may lead to disease, especially if they disrupt the highly conserved splicing signals immediately flanking an exon. Within the coding region of a gene, the consequence of a point mutation depends on whether it alters the genetic code (Fig. 7-1). Most redundancy lies in the third base of the codon, so for example, a change from GGG to any of GGA, GGC, or GGU still encodes glycine and would not change the sequence of the protein. Such changes are usually silent and may become common polymorphisms. Mutations that lead to an amino acid substitution, for example UGU (cysteine) to UAU (tyrosine), are known as missense mutations. Their effect on protein function depends much on the specific structure and function of that protein. In general, missense mutations in regions that are functionally critical, such as the catalytic domain of an enzyme, will be highly deleterious. These regions are often highly conserved across species, indicating that mutations have not been tolerated during evolution. Missense mutations that affect residues important in secondary structure and protein folding are also likely to have adverse effects, whereas mutations in linker regions may be less critical. Thus interpreting the consequences of genetic changes requires an in-depth knowledge of the protein concerned.

TABLE 7-1 Glossary of Genetic Terms

Genome	The complete genetic makeup of an organism, including all coding and noncoding DNA
Gene	A discrete protein-coding unit within the genome. Genes are typically subdivided into exons (blocks of protein-coding DNA), introns (intervening noncoding DNA), and flanking regulatory regions
Exome	The entire sequence of all exons within the genome
Somatic	Relating to any cell of the body other than the germ cells. Mutations in somatic cells cannot be passed on to the next generation
Chromosome	A higher order structure into which DNA is packaged. Humans have 23 pairs of chromosomes, 22 autosomes, and a pair of sex chromosome, X and Y, that determine gender
Telomere	The cap at the ends of each chromosome, composed of hundreds of copies of the repeat sequence TTAGGG
Diploid	Containing a full complement of 23 chromosome pairs. All normal somatic cells are diploid
Haploid	Having only a single copy of each chromosome. Mature gametes are haploid, ensuring that a new zygote has the correct chromosome complement
Aneuploid	Cells that have a nondiploid number of chromosomes due to gain or loss of one or more chromosomes during cell division. Aneuploidy commonly occurs in cancer cells, which may become highly abnormal as the tumor progresses
Mutation	Strictly, any change that occurs in the DNA sequence, however in relation to genetic diseases, the term is mainly used to refer to changes that have a deleterious clinical effect
Polymorphism	A genetic variant present at a frequency of at least 1% in a given population, often used synonymously with mutations that have no adverse effect
SNP	Single nucleotide polymorphism: a polymorphism resulting from a single DNA base substitution
Allele	Referring to a specific version of a gene, often used to distinguish between the copies inherited from each parent, or between wild-type and mutant copies
Heterozygote	An individual with one wild-type allele and one variant
Homozygous	An individual with two copies of the same variant allele. In autosomal recessive diseases where an individual inherits two different mutations, one from each parent, the term "compound heterozygote" is used
Genotype	The genetic sequence of the two alleles at a particular gene location
Phenotype	The clinical manifestation of genetic change
Dominant	A mutation that exerts a phenotypic effect in heterozygous form
Recessive	A mutation that is masked by the wild-type allele in a heterozygote and only results in a phenotype when wild-type function is lost
Penetrance	The likelihood that an individual with a mutation will develop clinical disease
Heterogeneity, allelic	The presence of different pathogenic mutations in same gene across different individuals. Most genetic diseases show allelic heterogeneity, unless they are caused by gain of an abnormal function that is only conferred by one specific mutation (e.g., sickle cell disease)
Heterogeneity, genetic	Diseases for which a mutation in one of several different genes can lead to the same clinical phenotype
Heritability	The proportion of trait variance that can be attributed to genetic factors versus the environment
Haplotype/ Haplogroup	A specific combination of SNPs on a contiguous piece of DNA. Haplotype is used when defining the arrangement of SNPs on an individual chromosome; haplogroup refers to groups of ancestrally related variants in mitochondrial genome
Genetic anticipation	A phenomenon in which the age of onset of an autosomal dominant disease becomes earlier with each successive generation. It is most often observed in a group of neuromuscular diseases caused by a unique class of DNA-repeat mutations, but also occurs in familial pulmonary fibrosis associated with telomerase mutations
Imprinting	Epigenetic silencing of an allele based on its parental origin. Relatively few genes are imprinted, but those that are give rise to unusual patterns of inheritance, as the mutation is masked when present on the silenced allele

Mutations that lead to premature truncation of a protein are highly likely to be pathogenic and are a major cause of inherited diseases. Several different types of mutation can lead to premature protein truncation. Nonsense mutations result from a single base change that introduces a stop codon earlier than the natural translation end-point, for example, AGA (arginine) to UGA (stop). Small insertions and deletions can also introduce premature stop codons because if the number of bases added or lost is not a multiple of three, the reading frame for the triplet codon is offset and it is read incorrectly. This is known as a frameshift mutation (Fig. 7-1). Splice-site mutations can lead to retention of an intron, which does not normally code for a protein and, therefore, often contains a stop codon. Alternatively splice-site mutations can lead to exon skipping and again, if the size of the missing exon is not a multiple of three bases, this leads to a downstream frameshift, in addition to losing a whole exon of sequence. The presence of a premature stop codon often triggers a process known as nonsense-mediated mRNA decay (NMD), which leads to degradation of the nonsense-containing mRNA transcript, preventing translation of a truncated protein. This protects the cell from potentially adverse effects of an abnormal protein product. The mechanisms underlying NMD are not fully understood and some transcripts are degraded more efficiently than others. Nonsense mutations in the last exon of a gene do not trigger NMD, due to their proximity

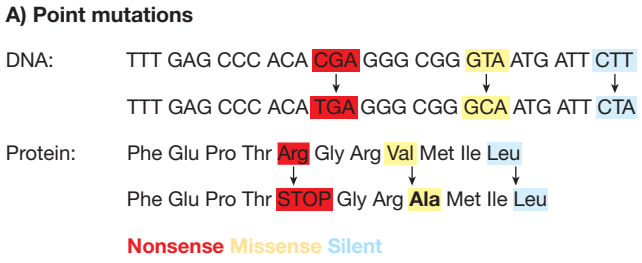

Figure 7-1 Classes of genetic mutations. **A.** Single base changes within an exon may lead to premature protein truncation (nonsense mutation, shaded in red), an amino acid substitution (missense mutation, yellow), or there may be no change due to redundancy in the genetic code (silent, blue); **B.** Insertions or deletions lead to frameshift mutations if the number of bases involved is not divisible by three. This almost invariably leads to premature protein truncation downstream of the mutation site.

to the natural stop codon, whereas mutations in first exon, close to the translation initiation codon, may lead to reinitiation at a downstream ATG site.

The last major class of mutation is gene rearrangements, large deletions, or duplications that affect one or more exons. These mutations can be missed by sequence-based methods of DNA analysis and require specialized methods that measure the copy number of DNA across the gene. They typically lead to major disruption of the gene structure and any protein that may be produced is likely to be nonfunctional.

MODES OF INHERITANCE

The pattern of inheritance of a genetic disease within a family is determined by the location of the mutation – on an autosome, the X-chromosome, or in the mitochondrial genome – and whether or not a clinical effect (phenotype) is evident when only one copy of the gene is mutated. When mutation of a single allele is sufficient to cause disease, it is known as dominant because the mutation is sufficient to overcome the positive effect of the remaining wild-type allele. Genes that are affected by dominant mutations are typically very sensitive to the 50% reduction in gene dosage that results from inactivating one allele. Alternatively the mutation may cause an abnormal gain of function, or create an abnormal protein that in turn interferes with the function of the wild-type protein, an effect known as dominant negative. In contrast, recessive mutations have no detrimental effect when only one allele is mutated. The remaining wild-type allele is sufficient to maintain normal gene function and a clinical phenotype is only apparent when both alleles are inactivated and the gene function is completely lost. Individuals with a personal or family history of genetic disease should be offered genetic counseling to help them understand their risks and options, and to facilitate appropriate genetic testing.

AUTOSOMAL DOMINANT

Autosomal dominant mutations result in a strong pattern of disease in each generation of a family (Fig. 7-2A). An individual with such a mutation has a 50% chance of passing the disease on to each of their children. The hallmarks of autosomal dominant inheritance are approximately equal proportions of males and females affected by the disease and the presence of male-to-male transmission. However, several factors can complicate this model. Some dominant diseases may skip a generation, due to reduced penetrance (Fig. 7-2B). The penetrance of a mutation is defined as the likelihood that someone with the mutation actually develops the disease. If the penetrance is less than 100%, then an individual who inherits the mutation may escape the disease themselves, while still being at 50% risk of passing it on to their children. Independently, the gender ratio may skewed by environmental and/or genetic modifying factors. The most extreme example is inherited diseases affecting sex-specific organs. For example, ovarian cancer can be inherited in an autosomal dominant manner but only females with the mutation actually develop the disease.

AUTOSOMAL RECESSIVE

The pattern of inheritance of autosomal recessive diseases is quite different. Individuals with a single copy of the mutation are known as carriers or heterozygotes. Since there is no clinical effect, such individuals are usually unaware of their status. However, when both parents are carriers, each has a 50% chance of passing on the mutation, meaning there is a 25% chance that a child will inherit two copies of the mutation and be affected by the disease. Consequently, autosomal recessive diseases often appear "out of the blue" in a family with no previous history of the condition (Fig. 7-2C). The incidence of recessive diseases largely depends on the heterozygote frequency in the population, but the risk increases in consanguineous families.

X-LINKED INHERITANCE

X-linked diseases are caused by mutations in genes on the X-chromosome. Most are recessive, but the different sex-chromosome constitution between females and males, XX versus XY, leads to a unique pattern of inheritance. Males who inherit an X-linked mutation have no wild-type allele on the Y-chromosome to mask its effect, and consequently they develop the disease. Female carriers are generally unaffected, as for autosomal recessive diseases. Thus X-linked diseases are passed through the female line and typically affect only males (Fig. 7-2D). A female carrier has a 50% chance of an affected son. Importantly, males cannot pass the mutation to their sons, so an evidence of male-to-male transmission rules out X-linked inheritance, but all of their daughters will be carriers. In reality, females only have a single X-chromosome active in any given cell, due to a process of X-inactivation in early embryonic development that adjusts the dosage of X-linked genes to be the same as in males. If X-inactivation is random, approximately half of cells in a carrier will express the wild-type allele and half express the mutation, meaning that female carriers usually have no phenotype or are only mildly affected. However, if X-inactivation is highly skewed toward expression of the mutant allele, then female carriers may be as severely affected as males. Rarely, X-linked mutations may be dominant, meaning that all females who inherit the mutation will be affected. Such mutations are often lethal in males. Examples of X-linked recessive conditions that affect the lung include X-linked agammaglobulinemia, an immunodeficiency that can lead to chronic lung disease, and X-linked severe combined immunodeficiency caused by mutations in the *IL2RG* gene that encodes a subunit of the receptor for multiple interleukins.

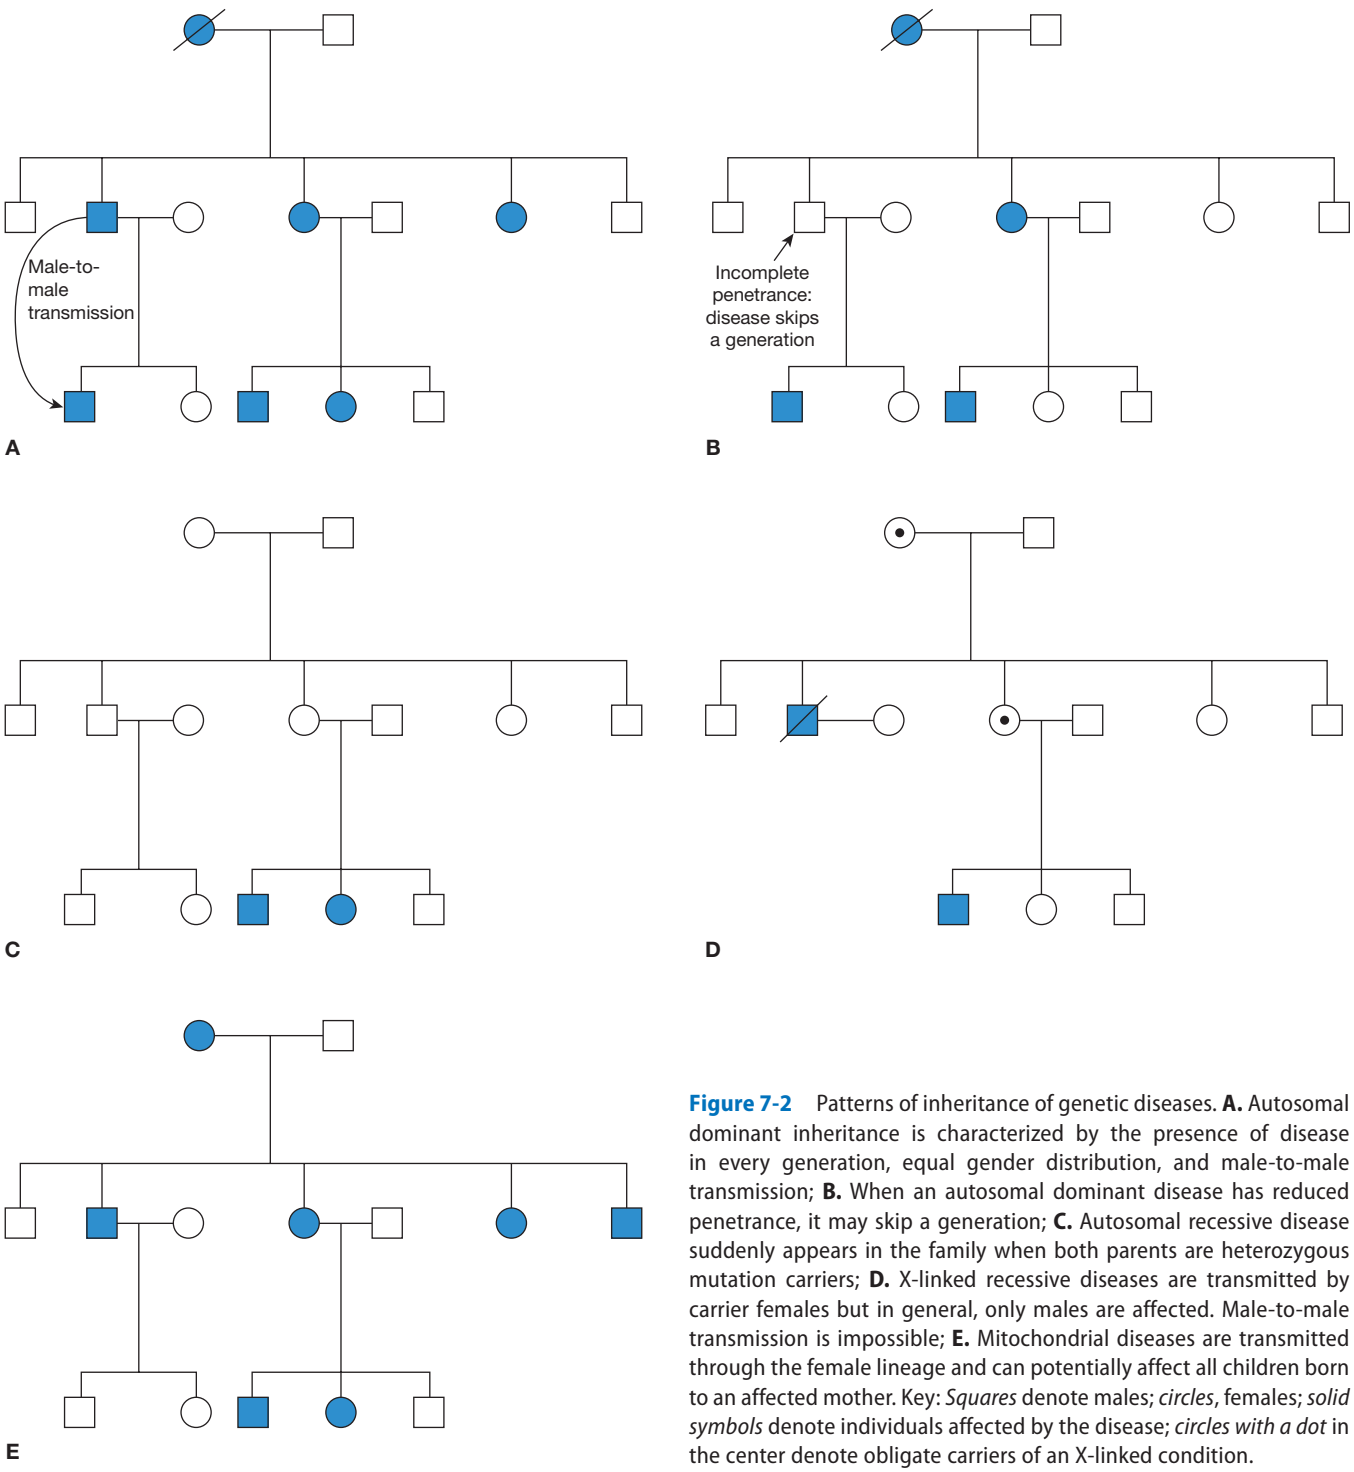

Figure 7-2 Patterns of inheritance of genetic diseases. **A.** Autosomal dominant inheritance is characterized by the presence of disease in every generation, equal gender distribution, and male-to-male transmission; **B.** When an autosomal dominant disease has reduced penetrance, it may skip a generation; **C.** Autosomal recessive disease suddenly appears in the family when both parents are heterozygous mutation carriers; **D.** X-linked recessive diseases are transmitted by carrier females but in general, only males are affected. Male-to-male transmission is impossible; **E.** Mitochondrial diseases are transmitted through the female lineage and can potentially affect all children born to an affected mother. Key: *Squares* denote males; *circles*, females; *solid symbols* denote individuals affected by the disease; *circles with a dot* in the center denote obligate carriers of an X-linked condition.

■ MITOCHONDRIAL MUTATIONS

The mitochondrial genome is a small circular molecule, approximately 16,500 bases long. It encodes some of the proteins required for oxidative phosphorylation and electron transport, together with multiple transfer RNAs and ribosomal RNAs. Mutations in mitochondrial genes adversely affect energy production and thus the clinical consequences are greatest in tissues with high-energy requirements, such as heart, brain, and skeletal muscle. Two characteristics make the inheritance of mitochondrial gene mutations unique. First, mitochondria are almost exclusively transmitted through the maternal lineage; sperm only have mitochondria in the tail for motility and do not enter the oocyte at fertilization. Thus, the pattern of inheritance within a family is similar to X-linked inheritance, with no male-to-male transmission, but differs in that females and males are equally likely to be affected (Fig. 7-2E). In theory, all children born to an affected mother would inherit the mutation and develop the disease. In reality, however, there are many copies of the mitochondrial genome per cell and each cell has a mixture of wild-type and mutant mitochondria (heteroplasmy). The segregation of these mitochondria during cell division is random, so by chance, an oocyte may have a

high or low number of mitochondria carrying the mutation. This random drift continues throughout embryonic development and beyond, generating considerable variability in the severity of disease and the tissues that are affected, even among individuals in the same family. Pulmonary involvement is not a major feature of most mitochondrial diseases, but several case reports link pulmonary hypertension with mutation in mitochondrial genes or a nuclear-encoded mitochondrial protein.[1–8] Pulmonary complications of mitochondrial disease are most likely to present as part of a multiorgan syndrome that may also include cardiac and/or skeletal myopathy, neuropathy, retinopathy, renal problems, or metabolic abnormalities.

Another fascinating property of the mitochondrial genome is its high degree of polymorphic variation. Clusters of variants, or "haplogroups," have been used to plot early human migration patterns across the globe. As new variants arose, they were propagated to offspring in the immediate geographic area, but were not present in other populations that had already migrated to different regions. Some of these variants confer subtle functional differences and may have been selectively enriched by helping adaptation to a new environment. They may also modulate risk of disease, particularly for conditions where there is oxidative stress. Data concerning lung diseases are currently limited, but associations with different haplogroups have been reported for atopy and asthma, chronic obstructive pulmonary disease (COPD), high-altitude pulmonary edema, and lung cancer risk.[9–13]

SOMATIC MUTATIONS AND CANCER

Not all of the genetic changes that contribute to disease are inherited. This is particularly true in cancer where, although there may be an inherited predisposition, most genetic changes are somatic and confined to the tumor itself. A later chapter is devoted to the molecular basis of lung cancer, so here we will briefly review the types of somatic changes observed in cancer cells and their relevance to benign lung conditions.

Two major classes of genes may be mutated in cancer: oncogenes and tumor suppressor genes. Oncogenes promote tumorigenesis when they are expressed at an abnormally high level or are inappropriately expressed in tissues where the gene should normally be silent. This may occur due to amplification (extra copies) of the gene, overactivation by upstream transcription factors, a chromosome rearrangement that brings the gene under the control of a strong promoter, or loss of DNA methylation as described in the following section on epigenetics. Alternatively the gene may be mutated in a way that gives the protein a novel gain of function. For example, mutation of a ligand-dependent receptor such that, once activated, it cannot be switched off and continues to signal in the absence of the ligand. These types of oncogenic mutations are usually dominant missense mutations at specific amino acid sites within the protein.

Tumor suppressor genes (TSGs) are like the brakes on the cell; they control cell growth, differentiation, and apoptosis. When their function is lost, the cell proliferates uncontrollably or evades programmed cell death. TSGs are predominantly inactivated by nonsense and frameshift mutations, large gene deletions, or loss of an entire chromosome. They may also be silenced by hypermethylation of their promoter, as described in the next section. In contrast to oncogenes, TSG mutations are often recessive at the cellular level and both copies of the gene must be inactivated before the full cancer-promoting effect is seen. Both mutations may occur as somatic changes in the cell that initiates the cancer, or the first mutation may be inherited, predisposing the individual to the risk of cancer, a model that was first proposed by Alfred Knudson.[14]

As tumors proliferate, their genome may become highly disorganized. Abnormal segregation of the chromosomes during mitosis can lead to aneuploidy, with gains and/or losses of entire chromosomes. There may also be translocations, where segments of different chromosomes are inappropriately joined together, and localized deletions or duplications of large segments of DNA. Such large rearrangements will clearly affect many different genes and can contribute to the activation of oncogenes and/or loss of TSG function.

The study of somatic mutations requires tissue from the affected area, ideally with a comparison to normal tissue from the same patient and also normal tissue from unrelated controls. Due to the difficulty of obtaining such tissues for benign lung diseases, somatic changes have mainly been studied in the context of cancer, but the same approach has recently been applied to pulmonary arterial hypertension (PAH). In addition, somatic epigenetic changes described below are common both in cancer and in several chronic lung diseases, emphasizing the importance of acquiring tissue from the site of disease when this is ethically possible.

EPIGENETICS

DNA AND HISTONE MODIFICATIONS

The term epigenetics refers to factors that influence gene expression without altering the underlying base sequence. Both DNA and histones, the proteins around which DNA is wound, may be epigenetically modified. These changes are usually reversible and play important roles in regulating gene expression and genome stability. The most common DNA modification is methylation of cytosine residues. The promoters of many genes contain a CpG island, a region with a high density of CG dinucleotides. Methylation of CpG sites in these islands leads to a closed chromatin conformation that makes the DNA inaccessible to transcription factors, turning off expression of the gene. Conversely, when most of the cytosines are unmethylated, the DNA is open and actively transcribed. DNA methylation, therefore, plays a critical role in regulating tissue-specific patterns of gene expression. Patterns of DNA methylation are controlled by DNA methyltransferases (DNMTs). DNMT3A and 3B are responsible for de novo methylation of residues that were previously unmethylated. Established patterns of methylation are then maintained by DNMT1. Further fine tuning of gene regulation comes through methylation and acetylation of histones. Acetylation mainly occurs on lysine residues and relaxes the interaction between histone and DNA, leading to increased gene transcription. Deacetylation reverses this and leads to a more tightly closed chromatin conformation. Histone acetylation patterns are controlled by histone acetyltransferases (HATs) and deacetylases (HDACs).

Within noncoding regions of the genome, DNA methylation and chromatin condensation act to suppress repetitive elements that could otherwise recombine and cause structural alterations. In cancer, there is often a global loss of methylation, which can lead to activation of mobile and repetitive elements, predisposing to the genomic instability that is the hallmark of many cancers. Loss of methylation at gene promoters can also activate oncogenes that in turn accelerate the growth of the tumor. At the same time, there may be hypermethylation of specific gene promoters, causing loss of expression of TSGs. It is increasingly clear that more subtle epigenetic changes likely contribute many other diseases, including lung conditions such as idiopathic pulmonary fibrosis (IPF) and COPD.[15,16] Unlike the DNA sequence, epigenetic modifications can change dynamically with age and are influenced by dietary factors such as folate intake. There is also mounting evidence that airborne pollutants such as small diesel particulates and tobacco smoke can directly mediate epigenetic changes.[17,18] Thus the lung may be particularly susceptible to epigenetic changes caused by repeated exposure to these environmental modulators. Importantly, though, some adverse epigenetic changes are reversible with time, for example, smoking-induced changes in DNA methylation gradually revert after quitting.[19] Also, the anti-inflammatory action of

corticosteroids is in part epigenetic, recruiting HDAC2 to the site of acetylated (activated) inflammatory genes.[20] Characterizing the role of epigenetics in lung disease is challenging because it requires access to affected and control lung tissues. It may also be difficult to distinguish which changes are causative of disease and not just a reaction to the disease state. However, considerable progress has already been made under the auspices of the NIH Roadmap Epigenomics Consortium and other focused research initiatives.

NONCODING RNAs

Noncoding RNAs can directly regulate gene expression at the RNA level without being translated into a protein product. The best characterized family is the microRNAs (miRs), first studied in plants but now also recognized to be important throughout the animal kingdom. Primary miR transcripts are transcribed in the same manner as regular protein-coding genes. In some cases the miR gene may be within an intron of a protein-coding gene and is controlled by the promoter of the "parent" gene. In other cases, miRs may be encoded as separate genes, individually or in a cluster, with their own promoter. The primary miR transcript is then processed into a pre-miR, about 70 to 80 nucleotides in length (Fig. 7-3). The ends of the pre-miR are highly homologous, causing the molecule to loop back on itself in a hairpin-like conformation. This double-stranded RNA structure is then exported from the nucleus into the cytosol, where it is cleaved by the enzyme Dicer into a mature single-stranded miR, approximately 18 to 22 nucleotides long (Fig. 7-3). The mature miR negatively regulates gene expression by binding to the 3′-untranslated region of its target mRNA, which either leads to degradation of the mRNA or inhibits protein synthesis. The seed sequence that initiates binding between the miR and its mRNA target is very short, typically around seven nucleotides, and does not require perfect base pairing. As a consequence, a single miR can potentially target tens or even hundreds of genes.

miRs have been widely studied in cancer and several, such as miR-21, have been dubbed "oncomiRs" because their overexpression promotes tumorigenesis by downregulating tumor suppressor pathways.[21–24] In comparison, relatively little is known about the role of miRs in benign lung diseases. However, it is now an intense area of research and recent data highlight important roles in IPF and PAH, as detailed in the disease-specific sections that follow. The miR pathway is often considered to be an epigenetic mechanism, yet it can be influenced by changes in DNA sequence, either through mutation affecting the miR gene itself, or mutations and polymorphisms that alter the seed sequence in the mRNA target.

Another major class of noncoding RNAs is the long noncoding (lnc) RNAs, greater than 200 bases long. lncRNA transcripts can be thousands of bases in length and, unlike miRs, they may be encoded by large multiexon genes that undergo splicing in the same manner as most protein-coding genes. Well-known examples of lncRNAs are *XIST*, which coats the inactive X-chromosome in female cells, and *TERC*, part of the telomerase complex that maintains the ends of the chromosomes (telomeres). As yet, very little is known about the role of lncRNAs in human disease, the notable exception being *TERC* mutations, one of several causes of IPF described below.

INHERITED LUNG DISEASES

This section provides an overview of the genetic basis of inherited conditions that include lung disease as a major component (Table 7-2). These brief summaries cannot provide exhaustive

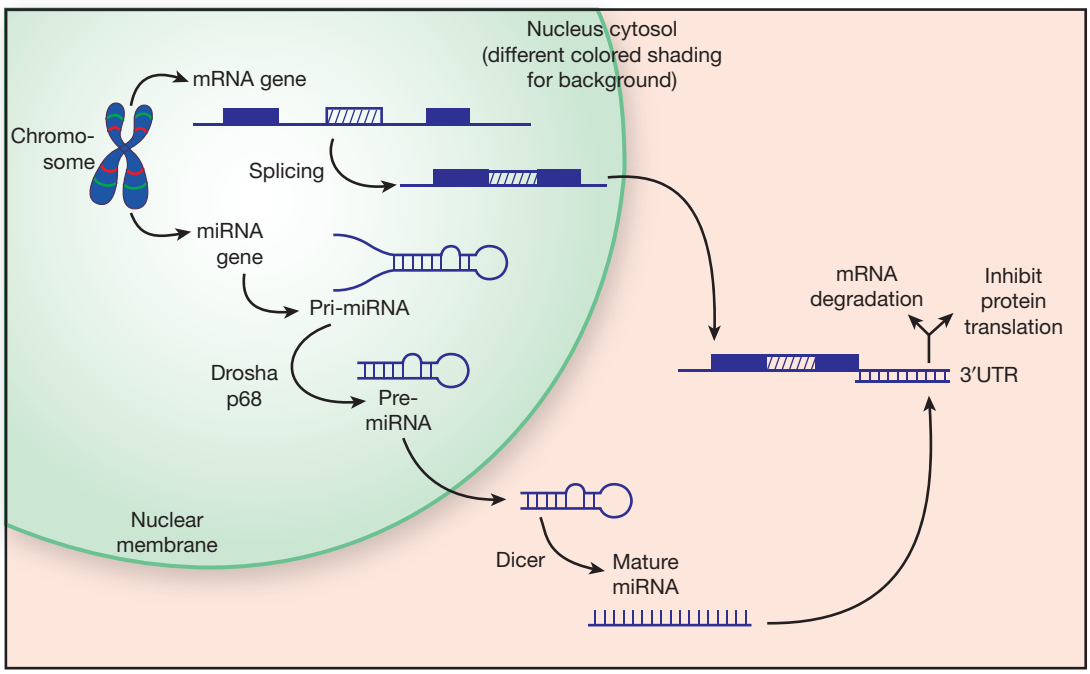

Figure 7-3 microRNA biogenesis. microRNAs that are encoded by independent genes are transcribed by RNA polymerases (mainly RNA pol II) into a primary miRNA transcript with a 5′-cap and 3′-polyadenylation. The primary miRNA molecule is cleaved by a protein complex, including Drosha and p68, into a double-strand hairpin RNA known as the pre-miRNA. For a subset of microRNAs, recruitment to the p68-Drosha complex is stimulated by activation of the bone morphogenetic protein and transforming growth factor-beta pathways,[67,68] a process that is disrupted by some mutations that cause pulmonary arterial hypertension.[58] Alternatively, some miRNA genes are embedded within the introns of mRNA genes, in which case they are transcribed along with the host gene and the pre-miRNA is generated during mRNA splicing. The pre-miRNA is then exported to the cytosol, where the Dicer complex converts it to the mature single-stranded miRNA molecule. Mature microRNAs negatively regulate expression of their target genes by binding to the 3′-untranslated region of the mRNAs, which either leads to degradation of the mRNA or blocks protein translation.

TABLE 7-2 Mendelian Inherited Lung Diseases

Disease	OMIM	Mode of Inheritance	Gene(s)	Chromosome	Comments
Cystic fibrosis	219700	Autosomal recessive	*CFTR*	7	ΔF508 accounts for ~75% of mutations; many other mutations described at a frequency of 5% or less
Alpha-1 antitrypsin deficiency	613490	Autosomal recessive	*SERPINA1*	14	Z allele (E342K) associated with severe disease, S allele (E264V) is intermediate
Sickle cell disease	603903	Autosomal recessive	*HBB*	11	Predominantly caused by a single mutation, E6V, which leads to an abnormal hemoglobin molecule (HbS)
Pulmonary arterial hypertension	178600	Autosomal dominant, reduced penetrance	*BMPR2* *SMAD9* *ACVRL1* *ENG* *CAV1*	2 13 12 9 7	6–10% of patients have a family history and an additional 15–20% of patients with sporadic idiopathic disease carry a mutation in one of these genes. *BMPR2* mutations account for about 80% of all families and over 200 different mutations have been described
Idiopathic/Familial Pulmonary fibrosis	614742 614743 178500 610913	Autosomal dominant, variable penetrance	*TERT* *TERC* *SFTPA2* *SFTPC*	5 3 10 8	Mutations in *TERT* or *TERC* lead to shortened telomeres. The severity of disease is inversely correlated with telomere length and the age of onset decreases with each succeeding generation (genetic anticipation)
Surfactant metabolism dysfunction	265120 610921 614370 300770	Autosomal recessive X-linked	*SFTPB* *ABCA3* *CSF2RB* *CSF2RA*	2 16 22 X	Disease presentation can range from severe respiratory distress in neonates, through childhood or adult-onset interstitial lung disease. *SFTPC* mutations, listed above under IPF, can also lead to neonatal or childhood surfactant metabolism dysfunction
Alveolar capillary dysplasia	265380	Usually de novo	*FOXF1*	16	Caused by de novo heterozygous mutations or deletions of maternal origin; gene is imprinted; occasionally transmitted as a dominant trait by an unaffected mother
Primary ciliary dyskinesia	Multiple	Autosomal recessive	Multiple	Multiple	Highly heterogeneous disorder with at least 15 different genetic loci
Agammaglobulinemia	300300	X-linked	*BTK*	X	Rare B-cell disorder; recurrent respiratory tract infections
Severe combined immunodeficiency	300400	X-linked	*IL2RG*	X	Rare, affects at least two immune cell types; more severe than agammaglobulinemia; also several autosomal recessive forms

reviews of current knowledge, but we refer the reader to entries in Online Mendelian Inheritance in Man (OMIM) and other web resources listed at the end of this chapter, for in-depth information.

CYSTIC FIBROSIS

Cystic fibrosis (CF; OMIM 219700) is the most common autosomal recessive disorder in Northern European Caucasians, with a carrier frequency of 1 in 20 to 1 in 25. It is caused by mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene on chromosome 7, which encodes a transmembrane channel protein important for chloride transport.[25] The most common mutation in Northern Europeans, accounting for about 75% of all CFTR mutations, is a deletion of three base pairs of DNA encoding phenylalanine at codon 508, denoted ΔF508. The frequencies of other mutations are all much lower, each accounting for less than 5% of the total. Thus approximately 56% of individuals with CF will be homozygous for ΔF508 and the majority of others will be compound heterozygotes for two different mutations. In Southern Europeans, ΔF508 is somewhat less common and the mutation spectrum is markedly different in the Ashkenazi Jewish population. Many countries now perform newborn screening for the most common CF mutations, enabling early diagnosis and treatment.

CF mutations can be subdivided into several categories, based on their molecular consequences.[26] Class I mutations, including most nonsense, frameshift, and splice-site mutations and large gene deletions, result in loss of CFTR protein. Class II mutations encode stable proteins that are abnormally processed, leading to retention of the mutant protein in the endoplasmic reticulum. ΔF508 is an example of a Class II mutation. Class III and IV mutations localize correctly to the membrane but they either fail to activate or are inefficient at transporting chloride ions. Class V mutations reduce the rate of CFTR synthesis. Some of these mutations retain a degree of residual function and can mitigate the severity of clinical phenotype.[26,27] Understanding the molecular consequences of these different mutations has been instrumental to developing new therapeutic approaches that seek to correct these defects, as described in the concluding section of this chapter.

Most genetic diseases show variability in the extent and severity of clinical disease, even for individuals with identical mutations. Just as common SNPs may confer risk or protection for common disease, they may also act as genetic modifiers in Mendelian traits. CF is a multisystem disease and with a large enough cohort of patients, it has been possible to identify polymorphisms that modify different aspect of the disease, including pulmonary function (FEV1), bacterial colonization, meconium ileus, and diabetes.[28,29] One particularly interesting polymorphism involves a run of thymine residues in intron 8 of CFTR, commonly present as 9T, 7T, or 5T alleles. These bases are just upstream of exon 9 of the genes and are part of an important signal to regulate mRNA splicing. The shorter alleles splice less efficiently and, in particular, the 5T allele can lead to abnormal splicing that excludes exon 9 from a proportion of the transcripts. Since some full-length CFTR is still made, this is not a severe CF mutation. However, it can lead to a partial phenotype in combination with other mutations and is, therefore, an intragenic modifier. Embryonic development of the vas deferens in males is especially sensitive to the amount of CFTR protein and the 5T allele

can contribute to congenital bilateral absence of the vas deferens, even in individuals with little or no lung disease.[30]

ALPHA-1 ANTITRYPSIN DEFICIENCY

Alpha-1 antitrypsin deficiency (AATD; OMIM 613490) is an autosomal recessive disease caused by mutations in the *SERPINA1* gene on chromosome 14, which encodes the protease inhibitor alpha-1 antitrypsin (AAT). AATD was one of the earliest genetic diseases to be understood at the molecular level, since the variant alleles could be identified by protein gel electrophoresis (isoelectric focusing) before the advent of DNA-based genetic testing. Consequently, the alleles are denoted by letters assigned for their relative position on the gel. The wild-type allele is designated M. The most common deficiency allele is Z, a missense mutation that changes glutamic acid to lysine at codon 342 (E342K). Its frequency is highest in Northern European populations. AATD is likely underdiagnosed and the true prevalence may be higher than CF in some countries.[31–33] ZZ homozygotes have low plasma AAT concentrations and are at highest risk for developing lung disease. Accumulation of the mutant protein in the liver can also lead to liver damage. The other most common allele, denoted S (amino acid change E264V), is intermediate in respect to both the level of AAT and disease risk. It is highly prevalent in Southern European populations, with frequencies of 15% to 20% in Spain and Portugal.[33] Clinically, the S allele is of greatest concern in SZ compound heterozygotes, but the severity of lung disease is generally less than for ZZ homozygotes. Individuals with the MZ, MS, or SS genotypes may have slightly impaired lung or liver function. Thus, while overt AATD is considered a recessive condition, the alleles are codominant in their influence on AAT levels and associated risk of disease. There is also a strong gene–environment interaction with tobacco smoking, which can inactivate AAT, further decreasing the level of active protein and greatly increases the risk of lung disease in susceptible genotypes.

Testing for the S and Z alleles may be performed by isoelectric focusing or DNA-based testing. Isoelectric focusing has the advantage that it will pick up other rare alleles that lead to altered protein mobility, whereas the DNA-based tests target only the two known mutations. However, both methods fail to detect rare null mutations that lead to complete loss of protein and, therefore, it is also important to measure the level of AAT in the plasma. This may be followed up with sequencing of the entire *SERPINA1* gene if rare alleles are suspected. Recommendations for genetic testing have been developed by a joint task force of the American Thoracic Society and European Respiratory Society.[34]

PULMONARY ARTERIAL HYPERTENSION

PAH (OMIM 178600) may be idiopathic (IPAH) or associated with an underlying condition such as connective tissue disease, congenital heart defect, or HIV infection (APAH). About 6% of IPAH patients have a family history. PAH is inherited as an autosomal dominant trait with reduced penetrance; on average, only about 27% of mutation carriers will actually develop symptomatic disease. It is more common in females than males and the gender-specific penetrances were recently estimated to be 42% and 14%, respectively.[35] Initial suggestions of genetic anticipation have now been disproved.[35]

Mutations in the bone morphogenetic protein receptor type-II (*BMPR2*) gene account for approximately 80% of familial PAH.[36,37] These are predominantly nonsense, frameshift, or splice-site mutations that lead to premature protein truncation or NMD.[38] Larger gene rearrangements are also frequent.[39,40] Mutations triggering NMD may cause less severe disease than missense mutations resulting in a stable dominant-negative protein, but data from different centers are conflicting.[41,42] *BMPR2* mutations are also found in 11% to 40% of IPAH patients without a family history.[43–45] The revised classification of PAH agreed at the fourth World Symposium created a new category – heritable PAH (HPAH) – that encompasses all patients with a detectable mutation, irrespective of family history.[46,47] *BMPR2* mutations have also been identified in patients with pulmonary veno-occlusive disease[48,39] and in PAH associated with anorexigen exposure,[49,50] congenital heart disease[51] but not in connective tissue disease.

Other genes within the bone morphogenetic protein pathway can also predispose to PAH. Mutations in the type-I receptor ALK1 and its accessory protein endoglin (*ENG*) predominantly cause hereditary hemorrhagic telangiectasia (HHT). However, PAH has been reported in a number of families and may precede the onset of signs or symptoms of HHT.[52–56] Patients with HHT may also develop pulmonary arteriovenous malformations. Several mutations have also recently been identified in the *SMAD9* gene, which encodes Smad8, a downstream mediator of bone morphogenetic protein signaling.[57–59] About 20% of PAH families remain without an identified genetic mutation. Exome sequencing is now being used to determine the cause of PAH in these families and has already led to the identification of two new loci, caveolin-1 (*CAV1*)[60] and a potassium channel gene, *KCNK3*.[61] Whereas *CAV1* mutations were only found in one family and one sporadic case,[60] *KCNK3* mutations were found in three families and 3 of 230 patients with idiopathic PAH.[61] One exciting aspect of this gene discovery is that some mutations could be corrected in vitro by the phospholipase inhibitor ONO-RS-082, raising the possibility of targeted therapeutic intervention for patients carrying a *KCNK3* mutation.[61]

The low penetrance of PAH mutations suggests that additional genetic and/or environmental factors also play a role. The proliferative vascular changes share many features with cancer[62–64] and analysis of affected lung tissues provides molecular support for this hypothesis, with evidence of somatic mutations, microsatellite instability, and aneuploidy.[65,66] miRs likely play an important role in PAH pathogenesis. The bone morphogenetic protein pathway regulates expression of a subset of miRs by promoting processing of the primary miR transcripts.[67,68] This pathway is lost in patients with *BMPR2* or *SMAD9* mutations,[59] whereas several other miRs have also been implicated in PAH, independent of mutation status.[69–74] Overall, despite the progress in understanding HPAH, relatively little is known about the genetic factors that may influence other forms of PAH, particularly APAH, and the heterogeneous nature of the disease remains a challenge.

IDIOPATHIC PULMONARY FIBROSIS

The genetics of IPF (OMIM 178500, 614742, 614743) parallels that of PAH in many respects. A small proportion of cases are familial and the only significant difference in clinical presentation is an earlier age of onset. The pattern of inheritance is autosomal dominant with variable penetrance. Familial pulmonary fibrosis (FPF) is genetically heterogeneous, but unlike PAH, the genes involved do not all fall in a common pathway. Around 3% of families have mutations in either surfactant protein A2 (*SFTPA2*) or surfactant protein C (*SFTPC*) genes, but a much larger proportion of families have mutations affecting telomerase.[75–77] Telomeres are like protective caps on the ends of chromosomes, important in maintaining genome stability. Their DNA sequence comprises many hundreds of copies of the repeat TTAGGG. Due to its position at the end of the chromosome, this sequence cannot be fully replicated and over time the number of repeats gets progressively shorter. Indeed, telomere shortening is believed to be one of the major molecular factors underlying aging. To counteract this, proliferative cells express telomerase, which catalyzes the addition of telomeric DNA. It is especially important in stem cells and germ cells, but is turned off in most differentiated cells. Cancer cells frequently reactivate telomerase. Telomerase is a heteromeric complex composed of a protein with reverse transcriptase activity, encoded by the gene *TERT*, and

an lncRNA (*TERC*) that provides the template for synthesizing new telomeric DNA.

The link between IPF and telomerase first came from the identification of genes causing dyskeratosis congenita, a rare multisystem genetic disorder. Patients with dyskeratosis congenita have shortened telomeres and a high incidence of pulmonary fibrosis, prompting analysis of telomere-related genes in FPF.[78] About 18% of families have now been identified with heterozygous mutations in *TERT* and about 1% with *TERC* mutations.[76,77] The average length of the telomeres modifies disease severity and, since the telomeres become progressively shorter with each generation, families with these mutations demonstrate increasingly earlier onset of disease in successive generations, a phenomenon known as "genetic anticipation." Patients with very short telomeres are also at risk for developing aplastic anemia or dyskeratosis congenita.[77] An additional 20% of FPF families have evidence of shortened telomeres but the genetic mutation has not yet been identified. In the remaining 60% of families, the cause of their disease remains unknown.[76]

For patients with IPF (i.e., without a family history), approximately 3% have a *TERT* mutation and less than 1% surfactant protein mutations. However, 25% have a telomere length below the 10th percentile in the general population, suggesting that shortened telomere length is a major risk factor for pulmonary fibrosis, even in the absence of an identifiable mutation.[79] Genomic studies of IPF lung tissue have already yielded considerable insight into the genetic changes contributing to lung fibrosis,[80] including distinct changes in gene expression,[81–83] DNA methylation patterns,[84–86] and miR expression,[87–90] though these have not as yet been translated in new therapeutic approaches.

SURFACTANT METABOLISM DYSFUNCTION

Genetic disorders of surfactant metabolism (OMIM 265120, 300770, 610913, 610921, 614370) range from severe neonatal respiratory distress and congenital pulmonary alveolar proteinosis to interstitial lung disease presenting in childhood or adulthood. It is important to note that acquired pulmonary alveolar proteinosis is a distinct autoimmune disorder. Autosomal recessive forms of surfactant metabolism dysfunction are caused by mutations in surfactant protein B gene (*SFTPB*)[91] or the transporter gene *ABCA3*.[92–94] Both lead to severe neonatal respiratory distress. Recessive forms of pulmonary alveolar proteinosis can also be caused by mutations in the granulocyte-macrophage colony-stimulating factor receptor subunits *CSF2RA,* which is X-linked recessive, or *CSF2RB,* autosomal recessive. *SFTPC* mutations are inherited as an autosomal dominant trait with variable penetrance. The phenotype may range from severe neonatal or childhood-onset interstitial lung disease to adult-onset pulmonary fibrosis.[95,96]

ALVEOLAR CAPILLARY DYSPLASIA

Alveolar capillary dysplasia (ACD; OMIM 265380) with misalignment of the pulmonary veins is a rare condition caused by heterozygous mutation or deletion of the *FOXF1* gene on chromosome 16.[97] It is usually lethal in infancy and, therefore, mutations are not inherited from an affected parent, rather they occur de novo in the oocyte or sperm, or in the very early embryo. However, one family has been described very recently in which the mother had five affected children and was found to carry a missense mutation in *FOXF1,* despite being unaffected herself.[98] The mutation had arisen de novo on her paternally derived chromosome 16. The authors proposed that *FOXF1* is imprinted on the paternal allele, meaning that it is only expressed from the maternal allele. Thus when the mutation first arose on the paternal allele, its effect was masked because only the normal maternally derived allele was expressed. However, when the mother passed the mutation on to her children, it was now on a maternally derived chromosome and was expressed, leading to ACD and multiple congenital anomalies.

PRIMARY CILIARY DYSKINESIA

Primary ciliary dyskinesia (PCD; numerous OMIM numbers) is an autosomal recessive disorder in which abnormalities of the cilia lead to frequent respiratory infections and chronic lung disease. Other manifestations of the condition may include situs inversus and infertility. PCD is genetically very heterogeneous; mutations in at least 15 different genes have so far been identified. Several of these encode components of axonemal dynein, a critical structural component of cilia. Approximately 40% of cases have no identifiable mutation and thus it is expected that many more genes may be identified. This very high level of genetic heterogeneity represents a significant challenge, but the ability to sequence the entire exome of affected individuals holds promise for identifying additional genes.[99–101]

SICKLE CELL DISEASE

Sickle cell disease (OMIM 603903) is the most common autosomal recessive disease in Africans and African Americans. Although primarily a blood disorder, it can give rise to significant pulmonary complications, including acute chest syndrome, emboli, and pulmonary hypertension. It is caused by a single A>T mutation in the beta-globin gene that leads to substitution of valine in place of glutamic acid at codon 6. The resulting hemoglobin molecule has reduced solubility compared to the wild-type protein, an example of a mutation that causes gain of an abnormal function. Heterozygous carriers of the mutation have increased resistance to malaria, which is believed to account for the high frequency of the mutation in regions where malaria is or was previously endemic.

GENETIC BASIS OF COMMON LUNG DISEASES

Common lung diseases such as asthma and COPD are not inherited as strong Mendelian traits. However, they may show evidence of familial clustering, suggesting that there is a genetic component to their etiology. The proportion of variation that is estimated to come from genetic factors is termed the "heritability" of the trait, high heritability indicating a strong genetic component. Since common complex diseases do not show clear segregation patterns within families, traditional model-based (parametric) mapping studies cannot be used. Instead, nonparametric methods have been employed across large collections of small family groupings, such as affected sib pairs. Early studies used a candidate gene approach. More recently genome-wide association studies (GWAS) have been used in very large case–control cohorts. Both types of study utilize some of the millions of polymorphic genetic variants throughout the genome and look for a statistically significant association between these genetic markers and the trait of interest. Single nucleotide polymorphisms (SNPs) are now the most commonly used genetic variants, as microarray technology enables simultaneous analysis of more than one million SNPs on a single array. Correlations can also be tested with clinical parameters and biomarkers such as exhaled nitric oxide, serum IgE, and FEV1. Analyzing so many variants across thousands of samples raises the problem of multiple testing, whereby the large number of comparisons between cases and controls greatly increases the likelihood that differences will be identified just by chance. To reduce the number of false-positive results, stringent correction for multiple testing is required. Also, cases and controls must be carefully matched to ensure there is no hidden population stratification that might distort allele frequencies. It is important to note that many of these SNPs are in noncoding regions of the genome and do not directly affect gene regulation or protein function. Rather, they are markers that tag a nearby sequence that may modulate disease risk. In comparison to Mendelian diseases, where mutations confer a high risk of developing the condition, the relative risks for loci identified in GWAS are generally quite small. They have little or no predictive value and so in this respect their

clinical utility is limited; the value of these studies is in identifying new pathways and targets for therapeutic intervention.[102] Large amounts of money have been invested in GWAS in a wide range of diseases and the challenge now is to identify the functional variants and fully realize the translational potential of this research. A new and powerful approach is systems biology, which aims to integrate multiple types of "omics" data, such as GWAS, genome-wide expression data, miRs, and epigenomics into networks that identify new pathways and biologic connections.

The literature on GWAS in common lung diseases is large and continues to expand rapidly. In this brief space, it is not possible to discuss these studies in any detail, especially given the complexities of racial and ethnic differences in SNP frequencies and the many subphenotypes that have been studied. We will, therefore, briefly overview some of the major candidate loci and refer the reader to reviews that can be used as a starting point for in-depth reading.

■ ASTHMA

Asthma has a high heritability and has, therefore, been a good candidate for GWAS. Some of the strongest loci identified thus far include HLA-DQ, Orosomucoid-like 3 (*ORMDL3*), and several interleukins and interleukin receptors.[103,104] *ORMDL3* is inducible in the bronchial epithelium and in mice, has been shown to regulate metallloproteinases and several cytokines.[105] SNPs in the same region also modulate expression of a neighboring gene, gasdermin-B (*GSDMB*), part of a family of genes implicated in regulating epithelial cell apoptosis. Through increasingly large studies and meta-analyses, it has been possible to start dissecting the genetic factors associated with specific subgroups, such as childhood asthma, severe asthma, and atopy.[106] Several genes are also associated with response to bronchodilators.[107] Hispanic and African American populations have a higher incidence of severe asthma but are understudied in comparison to Caucasians and represent an important research priority.

Environmental factors such as air pollution and smoking are known to be important modulators of asthma risk. This may be mediated, at least in part, through epigenetic changes affecting DNA methylation, histone acetylation, and miR expression.[16] Changes in DNA methylation directly regulate the arginase–nitric oxide pathway[18,107] and distinct methylation profiles have been identified in asthmatic children compared to controls.[108]

■ CHRONIC OBSTRUCTIVE PULMONARY DISEASE

As described previously, the strongest genetic risk factor for COPD is a mutation in the *SERPINA1* gene that encodes AAT, a risk that is further heightened by tobacco smoke exposure. More common variants with smaller effect size include the nicotine receptors *CHRNA3* and *CHRNA5*, hedgehog-interacting protein (*HHIP*), and *FAM13A*.[109] Smoking is a major risk factor for COPD and as mentioned previously, induces many epigenetic changes in the lung. Altered DNA methylation patterns have been identified in COPD patients in comparison with controls[110] and histone deactylase activity is decreased.[111] Importantly, methylation changes associated with cigarette smoking are reversible with time after quitting[19] and epigenetic changes offer promising targets for drug therapy.[20]

■ SARCOIDOSIS

Relatively little is known about genetic susceptibility to sarcoidosis and despite its prevalence in African Americans, early studies were mainly conducted in cohorts of European ancestry.[112,113] Surprisingly, emerging data suggest common risk loci across multiple different ethnic groups,[114–116] a marked contrast from the heterogeneity in GWAS data for some other diseases. Key loci identified from these studies include the *ANXA11* gene and several HLA subtypes.

TARGETED THERAPIES FOR GENETIC DISEASE

The completion of the human genome project led to high expectations (and in some cases, hype) of a new era of personalized medicine. The first arena in which this has been realized is in the treatment of cancer. Drugs such as imatinib (for chronic myeloid leukemia) and Herceptin (in breast cancer) target specific gene rearrangements or amplifications occurring in these cancers. Several drugs are approved to target epidermal growth factor receptor (EGFR) in non–small-cell lung cancer. Targeted lung cancer therapies are discussed in detail in a later chapter. Progress in other fields has been slower, but some recent advances show great promise, especially for CF.

Initial hopes for gene replacement therapy in CF failed to live up to expectations, but detailed characterization of the types of mutations and their functional consequences are now translating into new therapies. One approach is to promote read-through of nonsense mutations with a small molecule called Ataluren (PTC124).[117] This reduces the recognition of a premature stop codon and allows the ribosome to translate a full-length protein. The same approach has been tried previously with aminoglycoside antibiotics, but Ataluren is more potent and has fewer adverse effects.[118] In theory it should work for any nonsense mutation, but in practice some mutant transcripts are rapidly degraded by nonsense-mediated decay. Logically, therefore, the approach has proven to be most effective for mutations that are relatively stable and not subject to NMD.[119] After positive results in mouse models of CF and Duchenne muscular dystrophy, Ataluren was given orphan drug designation by the FDA and has shown very promising results in phase-II CF clinical trials.[120]

Where a full-length protein is made but it either mislocalizes (class II) or is an inefficient chloride transporter (classes III and IV), drugs are being tested that could improve trafficking to the membrane and improve transporter function. Ivacaftor (VX-770) was found to be effective in rescuing function of the G551D mutation,[121] a class III mutation with a frequency of 3% to 5%. A randomized placebo-controlled trial of Ivacaftor produced exciting results, with highly significant improvements in FEV1, sweat chloride levels, weight, and quality of life scores.[122] Therapies to help the majority of CF patients who are homozygous for ΔF508 are still awaited, but these successes build hope that the vision of personalized medicine, therapies tailored to an individual's personal genetic profile, may become a reality.

Other lung diseases are lagging behind compared with CF, although many do not have the benefit of more than two decades of research on a single gene. However, new therapeutic targets are starting to emerge from some of the research summarized earlier, particularly at the epigenetic level. Several approaches to improving BMPR2 signaling in HPAH are being studied.[123–125] At the epigenetic level, histone deacetylase inhibitors have been proposed as a possible therapy in PAH,[126] whereas corticosteroid-resistant COPD may benefit from increasing HDAC2 activity.[20] As our understanding of the effect of specific genetic mutations and epigenetic modifications increases, the future for targeted therapeutic intervention is bright.

CHAPTER 8

Stem Cells and Respiratory Disease: Prospects for the Future

Darrell N. Kotton*

INTRODUCTION

Advances in stem cell research offer unprecedented opportunities to develop new treatments, disease models, and drug screens for previously untreatable conditions. These discoveries have captivated the imagination of the lay press and have inspired hope in patients, clinicians, and scientists. Inevitably, in an emerging new field, there are false starts that accompany promising discoveries. If rigorous researchers in the field have difficulty discerning hype from hope, what is a busy clinician to do when confronted with basic questions, such as: "Is stem cell therapy available for my lung disease?" or "Shall I bank my baby's cord blood in case he/she develops cystic fibrosis or emphysema?". This chapter is designed to describe the quickening pace of stem cell and regenerative medicine research related to lung disease and to place the latest discoveries in a historical context, before discussing future prospects.

Stem cells have been found in an increasing number of tissues whose biology is characterized by rapid turnover of differentiated cells. In these tissues, for example, blood, skin, and intestine, a stem cell hierarchy has been described where rare stem cells proliferate occasionally, giving rise to stem cell daughters or to progenitors that can proliferate rapidly, and differentiate into mature cells required for the function of that tissue. These properties of self-renewal and differentiation are the classic hallmarks of stem cells, and their importance in homeostatic maintenance of the blood, skin, and intestine, are well accepted.[1–3] These features also make stem cells attractive vehicles for clinical applications such as the reconstitution of injured or diseased tissues. Several decades of research focused on animals and humans, including the seminal bone marrow transplantation work of Till and McCullough[4] has rigorously proven, for example, that the hematopoietic stem cell, a cell that comprises 1 in 10,000 bone marrow cells, can be delivered to a recipient by simple intravenous infusion, reconstituting all cells of the bone marrow and circulating blood for the life-time of the recipient.[1]

Given the virtually unlimited self-renewing capacity and blood differentiation repertoire of hematopoietic stem cells, most pulmonologists are surprised to learn that cells of similar capacity have not been reproducibly proven to exist in the lung and may not be necessary for the homeostasis of an organ with a quiescent epithelium that contrasts with the rapidly self-renewing epithelia of intestine and skin.

LUNG EPITHELIAL RESPONSES TO INJURY

Because the unperturbed adult lung epithelium displays remarkably slow cell turnover, the post-injury or disease responses of human or animal lung have been studied to elucidate both the proliferation potential and differentiation repertoire of various lung cell types. These injury models have been used to search for potential specialized lung cells that might exhibit stem cell properties, such as self-renewal and multipotent differentiation (reviewed by Rawlins and Hogan).[5] Beginning in the 1970s, morphologic studies of human and animal lungs defined subsets of lung epithelia with proliferative capacity, revealing basal, secretory, and club cells (previously called Clara cells) of the proximal airway, and type 2 alveolar cells of the distal lung parenchyma all had the capacity to enter cell

*The author has no financial conflicts of interest to disclose.

cycle in response to lung injury.[6–14] More recently, thymidine-labeling techniques have been replaced by newer methods of identifying proliferating cells or tracking their progeny. These studies have emphasized that most lung epithelial cells, except for airway ciliated cells or type 1 alveolar cells, can proliferate after injury in a remarkably resilient organ where many differentiated epithelial subtypes contribute to tissue repair.[5,15–18]

Beyond assessing the proliferation of cells in the adult lung, the classic developmental biologist's method of "lineage tagging" cells has allowed investigators to follow the origin of lung epithelial cells during development, and to assess where they go upon ageing or after injury.[15,19–21] It is now well established that the many types of epithelial cells in the adult lung arise during development from a few progenitor cells in the embryonic foregut endoderm.[22] The concept has become generally accepted that a limited number of lung epithelial cell types are specified during embryonic development and sustain their committed differentiated state throughout life.[21] In the nascent field of stem cell research, most investigators agree that multipotent, bona fide lung epithelial progenitors exist, if only fleetingly early in embryonic development.[22,23] It remains unclear, however, whether any specialized progenitors or stem cells similar to these embryonic endodermal precursors remain in the lung postnatally or are rederived after injury.

EVOLVING STUDIES IN THE SEARCH FOR LUNG STEM CELLS

With so many proliferation-competent epithelial cells in the adult lung able to participate in post-injury repair, perhaps equally, some investigators have begun to wonder whether some cells are "more equal" than others. The search for specialized reparative lung cells in recent years has been propelled by the emergence of specific and sensitive molecular biology tools and laboratory instruments that can refine our previous understanding of lung biology (Fig. 8-1). New studies suggest that a much greater diversity exists within the previously identified broad classifications of lung airway and alveolar epithelial cells.[24] For example, the response of mouse lung to recover from naphthalene exposure, an injury that depletes the lung of most club cells (identified by the marker club cell secretory protein [CCSP; also known as Scgb1a1 or CC10]), revealed a small subset of airway progenitors, called "variant club cells" (previously variant Clara cells).[25,26] These cells expressed CCSP, but were resistant to naphthalene injury and rapidly reconstituted both secretory and ciliated populations of the injured airway. Most intriguing was the observation that, this rare subset of CCSP+ cells appeared to reside in two specialized microanatomical locations or niches: adjacent to neuroepithelial bodies of the airways and at bronchoalveolar duct junctions. This observation remains one of the most convincing examples to date, suggesting the lung contains progenitor niches, or microanatomical cell compartments with specialized stem or progenitor cells.

One remarkable and controversial study by Kim et al. has proposed that some of these rare CCSP+ progenitors located at the bronchoalveolar duct junction may possess the capacity to reconstitute both airway and alveolar epithelia, suggesting the lung contains rare, multipotent, "bronchoalveolar stem cells" (BASCs).[27] However, the existence of BASCs has been contested in later work by Hogan et al.[19] who employed lineage tagging to trace the progeny of club or variant club cells expressing the CCSP marker which would presumably include the putative BASC population. These investigators found that these cells, either following an injury or during normal fetal lung development, gave rise only to conducting airway but not alveolar epithelia. In later work, Hogan et al. found that under some circumstances, such as following bleomycin-induced lung injury in mice, CCSP+ lineage tagged cells could give rise to alveolar epithelial cells. This confusing literature continues to cause controversy and uncertainty in the field and has dampened enthusiasm for the concept of a lung stem cell

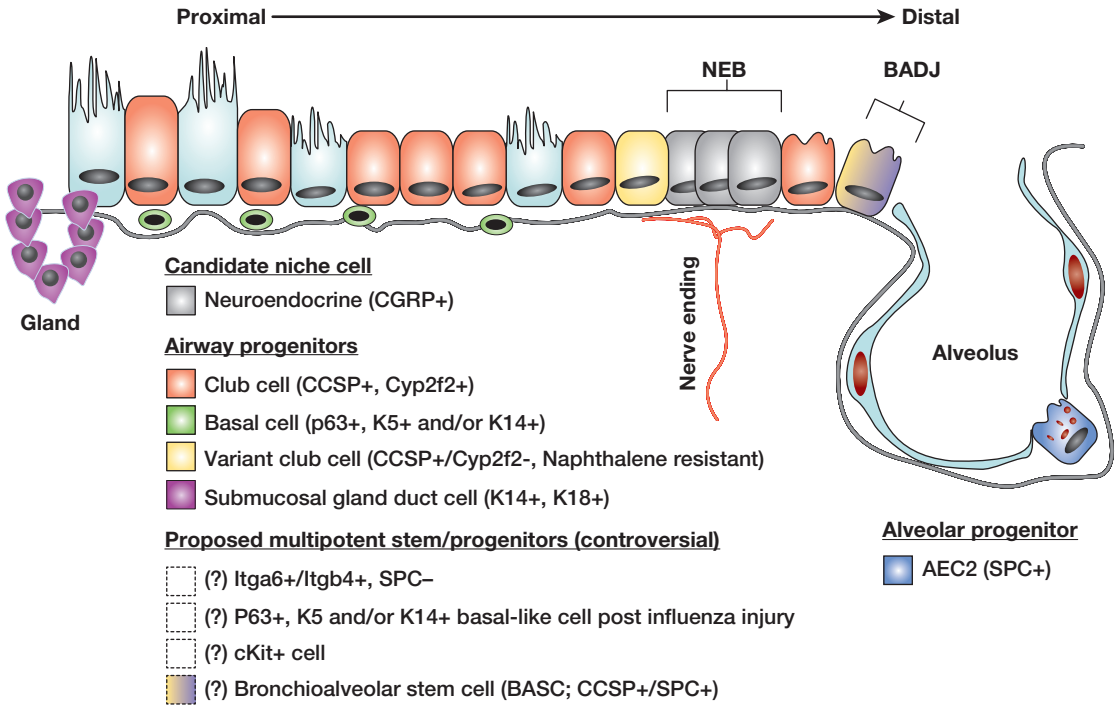

Figure 8-1 Lung epithelial stem and progenitor cell candidates. Schematic of proposed lung epithelial candidate stem or progenitor cells and their niches in the proximal conducting airways and distal alveoli. Cells whose localization or existence is not yet clear or accepted are indicated with dashed boxes and/or question marks. NEB, neuroepithelial body; BADJ, bronchoalveolar duct junction; Gland, submucosal gland duct; AEC2, type 2 alveolar epithelial cell; Marker abbreviations used for each cell subtype include the following: Itg, integrin; K, cytokeratin; CCSP, club cell secretory protein; SPC, surfactant protein-C. *(Modified with permission from Kotton DN: Next-generation regeneration: the hope and hype of lung stem cell research. Am J Respir Crit Care Med. 2012;185(12):1255–1260.)*

hierarchy that might follow the classical paradigm of hematopoietic stem cells of the blood-forming bone marrow.

In the more proximal airways, such as the mouse trachea or human bronchi, investigators have also found remarkable subsets of basal cells that contain extensive proliferative potential and a multipotent differentiation repertoire consisting of the capacity to give rise to basal, secretory, and ciliated lung epithelial cells.[28,29] With the advent of modern flow cytometry, these cells can now be sorted to purity, allowing the cataloging of protein markers (such as p63, NGFR, CK5, or CK14) that identify these cells as well as the delineation of their global transcriptome by microarray analysis.[28,30] The capacity to purify, expand in culture, and differentiate basal cells has resulted in a number of publications in recent years with important implications for those searching for lung cells with stem or progenitor potential.[28,30,31] First, these studies have confirmed that heterogeneity and diversity within the previously limited subsets of lung epithelial cells is indeed much greater than that appreciated a decade ago.[24,32] Second, the studies have revealed the impressive proliferative potential and differentiation repertoire of some subtypes of single lung epithelial cells (such as basal cells), which can expand almost indefinitely in vitro, similar to classically studied stem cells of the skin.[28,31] Taken together, this body of work supports the concept that basal cells can function as tissue-specific stem cells of the proximal conducting airway epithelium.

While there is a quickly growing list of stem/progenitor candidate cells able to reconstitute the conducting airway epithelium, the type 2 alveolar epithelial cell to date remains the best accepted progenitor of the lung alveolus.[33] Basic scientists are on the trail of new candidate alveolar progenitors, however, as evidenced by a notable new study demonstrating the clonal expansion in culture of cells from human or mouse lungs that express basal cell markers yet possess both airway and alveolar differentiation potential in vitro.[31] The authors who described these cells have proposed them as candidate alveolar stem cells, and other labs are working on reproducing these findings before their differentiation repertoire or nomenclature can be established. Most importantly, the p63+ or CK5/14+ lung stem cells described in this exciting study appeared to emerge during recovery from influenza-induced injury in regions of distal lung alveoli, an area of the lung that does not normally harbor cells expressing the basal cell markers p63 or CK5. Other recent studies have utilized flow cytometry to isolate new candidate lung progenitors, identified by coexpression of alpha6 and beta4 integrins.[34] This population appeared to proliferate in response to lung injury, and after purification from mouse lungs displayed remarkable potential for multipotent airway and alveolar differentiation.

While the therapeutic application of these progenitor populations remains years away, it is already clear that the lessons learned from studying the biology of progenitor cells in both mouse models and humans with lung disease can be applied to clinical settings. For example, many publications now demonstrate that communications between some of the best studied lung epithelial progenitors and their neighbors, either in the epithelium or surrounding lung mesenchyme, helps to regulate the fine balance between progenitor self-renewal and differentiation.[17,32,35] Perturbations in these communications, controlled by familiar developmental signaling molecules (such as Wnt, Notch, FGF, retinoic acid, and TGFβ) disturb the balance of lung epithelial homeostasis[36] and contributes to the disordered histopathology and physiology of many lung diseases, including cystic fibrosis, emphysema, idiopathic pulmonary fibrosis, and asthma.[32,37,38] The increased understanding provided by studying the basic biology of lung progenitors and epithelial–mesenchymal interactions has thus allowed a more complete understanding of clinical disease.[37,39] and already is being applied for the development of new pharmaceuticals designed to modulate the above signaling pathways. The long-term goal of achieving sophisticated drug therapies for a variety of lung diseases is likely to ultimately involve activation of endogenous lung progenitors or mature epithelia to accomplish reparative reepithelialization to avoid pathologic lung remodeling.[40]

Common to most of the aforementioned studies evaluating the differentiation repertoire of purified lung progenitor candidates is the suggestion that if an effective technique for grafting these cells into injured lungs were available, these progenitors might be used to regenerate injured epithelia in patients. The prospect of engineering entirely new bioartificial lungs from these cells has also been proposed to meet the needs of growing numbers of patients with end-stage lung diseases who require lung transplantation. Pioneering studies in tissue engineering[41,42] have attempted to develop methods for preparing lung scaffolds or bioartificial lungs that might surmount this highest hurdle in our field: a method for delivering candidate progenitors or lung reparative cells in vivo for engineered lung regeneration. For example, the laboratories of Harald Ott and Laura Niklasson in 2010, both published a technique of engineering bioartificial lungs through the method of detergent-based decellularization of rodent lungs. This method leaves the 3D architecture of the lung matrix intact while stripping away rodent cells. This matrix then served as a scaffold upon which rodent or human cells were adhered to generate "recellularized" lung tissue able to carry out gas exchange in vitro or even in vivo after transplantation.[41,42]

CONTROVERSIAL CLAIMS OF PARADIGM SHIFTING STEM CELL RESEARCH DISCOVERIES

This aforementioned studies of lung epithelial injury, proliferation, and regeneration are slowly defining and refining our understanding of candidate lung epithelial progenitors, but there are occasional studies that challenge earlier paradigms of lung development and repair after injury. For example, the laboratory of Anversa et al. in 2011 reported the discovery of a rare cKit+ lung stem cell that they claim can be purified from human lung tissue, can be expanded indefinitely in simple culture media supplemented with serum alone, can be differentiated into multiple lung epithelia by adding dexamethasone, and most importantly, can be injected into injured mouse lungs giving rise to essentially all lung tissues, including mesodermally derived vasculature and endodermally derived airway and alveolar epithelia.[43] This property of naturally occurring pluripotency, defined as the capacity to give rise to multiple cell types across multiple germ layers, is without proven precedent in any adult tissue outside the germline and contradicts many decades of developmental biology research, according to some leaders in this field.[44]

Perhaps it is easiest to understand this new work when placed in the historical context of other prior studies that also initially proposed to shift paradigms in lung biology, including the work of this writer[45] who found that advances in techniques and methods often reveal established paradigms to be correct, and data suggesting paradigm shifts often have simple, alternative explanations that are not obvious at first glance.[46] In the 1990s and early 2000s, for example, a wave of publications claimed that, cells within the bone marrow, such as marrow stromal cells (also known as mesenchymal stem cells [MSCs]) or hematopoietic stem cells, could circulate to the lung and give rise to almost any type of differentiated lung epithelial or vascular endothelial cell. Similar findings were reported when examining injured hearts, brains, livers, and other organs, creating understandable excitement (reviewed by Weiss et al. and Wagers and Weissman[32,47]). Clinical trials were rapidly planned to expose patients to injections of bone marrow–derived cells in the hope of reconstituting degenerative or injured tissues. The opportunity for financial profit inspired companies to promote the banking of cord blood from babies, with glossy pamphlets suggesting to expectant parents that umbilical cord blood containing "stem cells" (now more appropriately called HSCs and MSCs) had the potential to treat diabetes, cystic fibrosis, Parkinson's disease, strokes, or a myriad of

other diseases. These diseases might be treated with banked cord blood, if indeed, circulating blood or bone marrow–derived cells could form reconstituting cells for each relevant organ. In hindsight, the launch of some clinical trials and the promotion of cord blood as a panacea was premature as it was based on a first wave of controversially published literature. Advances in laboratory instruments and follow-up laboratory studies begun in 2000, slowly revealed that artifacts, such as autofluorescence, nonspecific antibody labeling, and the fusion of marrow-derived myeloid cells with recipient tissues were actually responsible for the bulk of initial observations and misinterpretations of bone marrow–stem cell engraftment.[46,47]

Clinicians understand that results from an initial, controversial clinical trial require repeating and reproduction of findings before treatment approaches, or established conventions should be radically altered. Likewise, the 2011 published work by Anversa et al. will need to be repeated and reproduced by other scientists before a paradigm shift is warranted. The historical context and false starts of our "lung stem cell field" should make this requirement for reproducibility particularly apparent.

ONE CELL TO RULE THEM ALL: PLURIPOTENT STEM CELLS

Because it remains controversial as to whether an endogenous lung cell possesses broad multipotency or the capacity to produce any type of lung cell, some investigators have chosen to focus their research on the de novo derivation of lung lineages in vitro from pluripotent stem cells, such as embryonic stem (ES) cells, which have well-established potential to generate all cell types in the body,[48] including all lung cells (at least after injection into mouse embryos). The controversy over human ES cell research, unlike other stem cell fields, is not focused on the differentiation potential of the cells, but rather on the ethical debate over whether it is permissible to utilize cells for research that are derived from a pre-implantation human blastocyst embryo (typically those unused from fertility clinics). Despite this ethical controversy, rapid progress is being made in recent years, and ES cells can now be grown indefinitely in culture and then differentiated into lung epithelial lineages upon exposure to defined growth factors.[49–51]

The key advance that has enabled the derivation of lung progenitors from ES cells came with the discovery by Keller et al. that the soluble growth factor, Activin A (hereafter Activin) induced the differentiation of these pluripotent stem cells into the germ layer, definitive endoderm.[52] Since the lung develops from this germ layer, emerging from the anterior foregut endoderm by budding and then branching, the derivation of definitive endoderm from ES cells is a key milestone on the way to generating lung epithelial cells from ES cells.[54] Keller's discovery was based on a careful study of how the embryo develops in vivo. Secreted nodal protein from the node of the embryo is known to differentiate embryonic cells of the epiblast into primitive streak and then into definitive endodermal progenitors within the anterior region of this primitive streak. Since Activin binds similar receptors to nodal protein, Keller et al. found that ES cell cultures exposed to Activin differentiated efficiently into definitive endoderm. Subsequently, investigators in the laboratories of Snoeck,[49] and later Kotton,[50] and Rajagopal[51] found that ES cell–derived endoderm could be patterned into anterior foregut-like precursors that were competent to respond to activated BMP, FGF, and Wnt signaling, differentiating further into primordial lung epithelial progenitors, identified by expression of the transcription factor Nkx2–1 (also known as thyroid transcription factor-1 [TTF1 or Titf1]). Again, these discoveries of how to differentiate stem cells into lung progenitors through activating a sequence of developmental milestones was made possible by mimicking the published inductive signals known to be active during in vivo embryonic endoderm and lung development.[53,54] Once primordial Nkx2–1-expressing primordial lung progenitors have been derived from ES cells (or from induced pluripotent stem [iPS] cells) the cells can be further differentiated into cells expressing a variety of markers of airway and alveolar lineages, including markers of basal cells (p63), ciliated cells (Foxj1 and Cftr), secretory cells (CCSP or mucins), and type 2 or type 1 alveolar epithelia (SPC, SPB, or T1 a), respectively.[50,51] Most intriguing is the finding that ES cell–derived lung epithelia can be used to reconstitute 3D lung tissue scaffolds with cells reminiscent of the morphologic and molecular phenotypes of primary alveolar epithelia.[50]

REPROGRAMMING APPROACHES FOR THE DERIVATION OF LUNG DISEASE-SPECIFIC OR PATIENT-SPECIFIC "INDUCED PLURIPOTENT STEM (iPS) CELLS"

Despite the accepted scientific promise of ES cell research discoveries, there has been a continuing public debate and uncertainty regarding whether it is ethically acceptable to allow public funding of research that uses cells derived through a process that previously involved the destruction of human embryos. The political and ethical concerns that have limited funding or progress in the ES cell research fortunately have found one potential solution in the remarkable discovery of reprogramming technology by Dr. Shinya Yamanaka in 2006. Yamanaka's work revealed that four transcription factors (Oct4, Klf4, Sox2, and cMyc) transferred into cells could reset the epigenetic state of somatic cells, such as skin fibroblasts, into an embryonic like state virtually indistinguishable from ES cells.[55] Reproduction and refinement of this discovery established reprogramming as an accepted technique to engineer iPS cells from dermal fibroblasts or from peripheral blood cells, such as those obtained from simple skin punch biopsies, or banked blood (reviewed by Stadtfeld and Hochedlinger[56]). Like ES cells, the broad differentiation repertoire of iPS cells suggests their potential to form any desired somatic cell type, including lung epithelium.[49] In contrast to ES cells, iPS cells are genetically identical to the individual from whom they are derived, raising the prospect of utilizing iPS cells for autologous cell-based therapies without risk of rejection. Yamanaka, together with his predecessor, Sir Jon Gurdon, who discovered reprogramming approaches in tadpoles 50 years earlier, were awarded the 2012 Nobel Prize in Physiology or Medicine for their paradigm shifting discoveries.[57]

To establish clinically relevant pluripotent stem cell platforms for lung disease research, some investigators have developed new reprogramming technologies able to derive "clinical grade" iPS cells from human skin or blood.[56] and have successfully applied these technologies to generate banks of "lung-disease specific" iPS cell lines from patients with a variety of end-stage lung diseases.[58] In one example of how these cells are being applied to model disease, Rossant et al. generated iPS cells from patients with cystic fibrosis and differentiated these cells in air–liquid interface cultures into cells expressing the Cftr gene responsible for cystic fibrosis, thus modeling Cftr dysfunction using cells of the patients' own genetic background and studying the effects of a pharmaceutical product designed to correct Cftr chloride ion flux.[59] Many other groups are now focused on utilizing patient-specific iPS cell lines (and ES cells) to model lung diseases in vitro, to screen drugs and gene therapy approaches, and to derive de novo replacement lung epithelia and endothelial cells that may one day be transplanted back into the patients from whom they have been derived (Fig. 8-2). The lessons learned from the failed attempts to deliver bone marrow–derived cells to the injured lung epithelium have taught us that delivery of iPS cell–derived lung cells (or any other lung cell) in vivo will not be easy or straightforward. Still, precedent has already been set in rat models of Parkinson's disease and mouse models of sickle cell disease, for example, where iPS-derived replacement neurons and hematopoietic stem cells, respectively, can result in clinical improvementwhen technology for effective differentiation and transplantation of these cells is carefully developed (reviewed in Stadtfeld and Hochedlinger[56]).

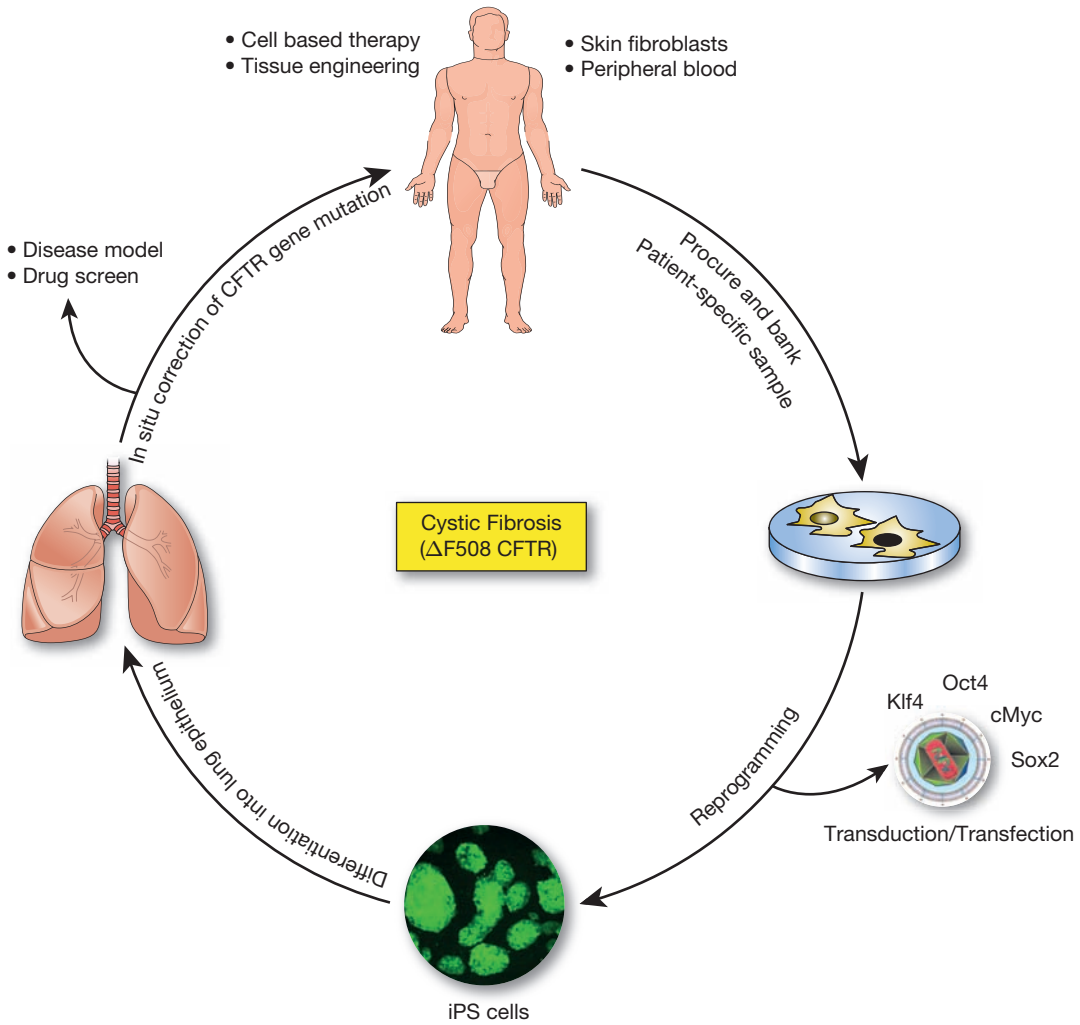

Figure 8-2 Schematic indicating approach for generating patient-specific or disease-specific induced pluripotent stem (iPS) cells from humans with lung disease. Peripheral blood cells or skin fibroblast cells harvested from a patient with lung disease, exemplified by cystic fibrosis, are reprogrammed into iPS cells using defined transcription factors. The resulting iPS cells undergo in vitro "directed differentiation" into lung epithelial or other lung lineages. These lineages can be employed for in vitro studies of disease pathogenesis modeling or high-throughput screening of drugs to predict efficacy. The cells may also undergo correction of any disease-causing gene mutations (such as ΔF508 CFTR) *via* zinc finger nuclease–mediated gene repair. Correction may be performed in the undifferentiated state, or (as shown) following directed differentiation into lung lineages. For future studies, corrected cells may be employed to tissue engineering bioartificial lungs or to develop cell-based therapy by transplantation back into the patient from whom they have been derived. Alternatively, drugs passing in vitro screening can be administered to the patient as personalized medicine.

In almost any field of research where cells reminiscent of the early embryo are employed, such as iPS cells or ES cells, recapitulating the milestones of early development of that tissue lineage has proven to be the most effective and most efficient way to derive desired differentiated lineages in vitro.[48] Unfortunately, little is known about many stages of embryonic lung development, a deficit that limits progress in deriving de novo mature lung epithelia from pluripotent stem cells (be they ES or iPS cells) in vitro and hampers our ability to properly understand and modulate repair after lung injury.

FUTURE PROSPECTS FOCUSED ON THE CLINICAL APPLICATIONS OF STEM CELLS

Given that safe clinical applications of most of the aforementioned exciting stem cell advances remain years away, how is a pulmonologist able to answer questions and respond to the pleas of patients desperate for stem cell therapies? One resource designed to help both physicians and patients access reliable information is the International Society for Stem Cell Research (ISSCR) webpage, which features a downloadable free "Patient Handbook" designed to educate the public about the promise and perils of stem cell research (www.closerlookatstemcells.org). The American Thoracic Society webpage equivalent also helps to objectively caution patients that most stem cell trials charging fees for claimed "treatments" have not been reviewed or substantiated by experts (http://patients.thoracic.org/materials/stem-cells.php).

At the time of publication of this chapter, a number of clinical trials are listed at clinicaltrials.gov for evaluating various cell-based therapies for several lung diseases (reviewed by Weiss et al.[32]). Infusions of MSCs to treat patients suffering from COPD, bronchopulmonary dysplasia, bronchiolitis obliterans, asthma, or acute lung injury, are either planned or underway. Additional trials are listed to test treatments for pulmonary hypertension (employing infusions of endothelial progenitor cells (EPCs) or bone marrow progenitors) and to assess treating pulmonary silicosis utilizing intrabronchial instillations of bone marrow cells.[32] Clinical

investigations in Europe, not listed on this website, have also targeted idiopathic pulmonary fibrosis with cell-based therapy.

It is still too early to determine whether any of these trials will prove efficacious, but accumulating data from >100 MSC clinical trials (mostly phase I or II) registered on clinicaltrials.gov for treating diseases affecting other organs suggests that, at least for MSCs, there appears to be little safety risk to participants. That said, there is also little reason to believe that these trials will result in regeneration of lung tissue for participants, as the bulk of basic mechanistic studies in animals suggest the infused cells work mostly via paracrine or immunomodulatory effects on recipient lung tissue.[32] Thus, these trials might be viewed as evaluations of cell-based immunomodulatory drug delivery rather than attempts to regenerate lung tissue.[60] Infused EPCs also appear to have paracrine and perhaps angiogenic effects on recipient tissue,[32] but their capacity to directly form replacement endothelial cells in the lung remains in doubt. When viewed with these results in mind, the term "stem or progenitor cell" – used to refer to the cells being infused in the trials to date – risks misleading clinicians and participants attracted by the promise that these terms imply. The dream of delivering truly regenerative or reconstituting cells to the lung, such as endogenous lung progenitors, ES cells, or iPS cells, will need to be appropriately delayed while these cell populations are fully evaluated in laboratory animals. The impressive differentiation and proliferation potential of the newly described pluripotent stem cell populations also makes them potentially risky and teratogenic in human trials, if deployed before their biology is more fully understood.

All indicators suggest that we are at the onset of realizing the promise of lung regenerative medicine propelled by the quickening pace of stem cell research. Endogenous lung stem or progenitor cell populations, such as basal cells, are just beginning to reveal the mechanisms that control their biology in careful studies at the lab bench.[30,35] New bioartificial lungs generated in the laboratory have already been successfully transplanted into rat recipients,[41,42] and human iPS cells generated from patients with alpha-1 antitrypsin (AAT) deficiency have undergone successful gene correction in vitro followed by hepatic transplantation into rodents.[61] This latter study by Vallier et al. is a conceptual advance for research related to preventing the progression of emphysema caused by AAT deficiency. These researchers demonstrated the full proof of concept of how gene edited iPS cells might be used as a clinical therapy since the research team derived iPS cells from a patient with AAT deficiency, performed gene editing with zinc finger nuclease technology to change the iPS cells from mutant (PiZZ) genotyped cells into gene-corrected (PiMZ or PiMM) cells. The gene-corrected cells were then differentiated into hepatocytes in vitro and then were engrafted in a rodent liver in vivo and secreted human AAT protein. If this approach were applied successfully to humans with AAT deficiency, it would be expected to replace current weekly augmentation therapy treatments and might potentially prevent the progression of emphysema through modulating protease–antiprotease imbalance.

How will the emerging studies focused on lung stem cells impact future clinical care of patients with lung disease? Treatment approaches are likely to involve one or more of several approaches based on the growing literature on endogenous lung progenitors and the newly described lung lineages just now being developed from exogenous pluripotent stem cell sources, such as iPS cells. First, an improved understanding of the pathways that regulate endogenous lung progenitors and control their cell fate decisions to self-renew or differentiate is likely to result in pharmaceutical approaches designed to regulate the behavior of these cell populations during disease pathogenesis. For example, if syndromes such as bronchiolitis obliterans result from an inability to maintain bronchiolar epithelial homeostasis, then an improved understanding of the biology of progenitors of the airways should with time lead to drug approaches for regulating the behavior of these cells toward improved maintenance of homeostasis, epithelial–mesenchymal cross talk, or epithelial barrier integrity. Second, gene therapies aimed at correcting monogenic lung diseases, such as cystic fibrosis or alpha-1 antitrypsin deficiency, likely will involve gene editing[61] or gene correction of lung progenitors or stem cells. A key hurdle limiting progress in lung gene therapy has been the inability to accomplish gene transfer into enough cell numbers. Stem cells provide a potential solution to this problem, since correction of just one stem cell may be sufficient if that cell can self-renew (either in vitro or after engraftment in vivo) extensively enough to reconstitute large numbers of lung epithelial cells via their progeny. Hence, methods for the delivery or engraftment of stem cells into human lung tissue remain a key hurdle still to be solved in order for this hope to come to fruition.

iPS cells are likely to impact lung disease treatments in several ways in the future. First, personalized therapeutic drug regimens can be screened in vitro using lung lineages derived from each patient's iPS cells, potentially predicting effective individualized drug regimens for each individual, rather than the globalized approach currently used to treat disease, where treatments for disease targets are chosen based on trial data from heterogeneous cohorts of patients. If approaches for engrafting or reconstituting lung tissue with exogenously delivered cells are ever successfully developed, iPS-derived cells are one potential source of autologous cell derivatives for potential reconstituting therapies. A particularly attractive, yet far-off goal of some stem cell researchers is the engineering of tissues from stem cells, including the tissue engineering of a whole, functioning, transplantable lung.[41,42] Several groups are working to optimize this approach using iPS cells to derive lung lineages for recellularizing these grafts to optimize tissue engineering of bioartificial lungs for transplantation in future.

While some prospects for employing stem cell–based therapies will take many years to come to fruition, this exciting field of research raises many potential avenues for achieving the long sought-after goal of lung regenerative therapies. Perhaps at this, the most optimistic time in a century of basic science research, we would be most wise to re-emphasize that many of the miraculous advances being made in this field are based on basic science research discoveries realized by investigators who originally had no practical clinical translation in mind. Those who simply wondered what made the Drosophila fly's wing notched, or made the jellyfish glow green, for example, paved the way for today's stem cell discoveries. In 1976, Comroe and Dripps found that the top 10 clinical advances in cardiac and pulmonary medicine derived from 529 key articles, 61.7% of which were classified as "basic science research" and 42% were not clinically oriented at the time the work was done, leading the authors to conclude that "basic science research" pays off in terms of key discoveries.[62] Their report from 38 years ago potentially provides a guide for realizing the full promise of lung-related stem cell research in the years ahead.

SUMMARY

Research discoveries in the fields of stem cell biology and regenerative medicine are beginning to advance and refine an understanding of lung injury and repair. While these emerging studies offer unprecedented opportunities to develop novel therapies for a variety of lung diseases, realization of these therapies will take time and clinical application remains predominantly a future prospect rather than a clinical trial-ready treatment. Given the increasing number of questions from patients about how stem cell research will impact their care, this chapter provides an overview for the clinician or clinician-researcher of the latest advances in lung-related stem cell research and places the new discoveries in a historical context. Established, lineage-restricted, epithelial progenitors of the conducting airways and gas-exchanging alveoli are briefly reviewed,

and controversial, newly proposed, tissue-specific candidate lung stem/progenitor cells with broader differentiation repertoire are introduced. Exogenous derivation of lung epithelia from ES cells or iPS cells is also presented as an alternative method for engineering lung tissue de novo in culture.

CHAPTER 9

Personalized Pulmonary Medicine

Benjamin A. Raby
Kelan G. Tantisira

INTRODUCTION

Since the first draft sequences of the human genome were completed in 2001,[1,2] medical research has increasingly focused on the utilization of genetic and genomic profiling in the prediction of disease susceptibility and natural history, as well as drug response and drug development. Personalized medicine can be defined as an approach to medicine in which medical decisions are tailored to the individual patient. In theory, personalized medicine will avoid costly and prolonged trial and error approaches resulting in unwanted therapeutic side effects or diminished treatment efficacy. Diagnostically, personalized medicine uses molecular tracking to signal risk of disease on a genetic level, which may identify disease presence before clinical indications and symptoms appear. Thus, personalized medicine enhances the focus on preventive medicine at the primary, secondary, and tertiary levels. Fully realized, personalized medicine has the potential to facilitate early diagnosis and/or prevention of disease and selection of optimal therapeutic choices with minimal attendant side effects for established disease states. The potential savings, from both a financial and quality-of-life perspective, are enormous.

Much of the efforts to adopt personalized medicine into clinical practice have centered on genetic approaches, as sequence changes in deoxyribonucleic acid (DNA) have been closely associated with a wide range of disease susceptibilities and therapeutic responses. However, the "omics" era includes enhanced focus on cellular and metabolic changes downstream of DNA sequence variation including genomics or transcriptomics (the analysis of gene expression), proteomics (the analysis of protein changes), and metabolomics (the analysis of end products of cellular metabolism). Adding to genomic complexity are the so-called epigenetic changes, the study of changes in gene expression or cellular phenotype caused by mechanisms other than changes in DNA sequence, such as DNA methylation, post-translational modification of gene expression, and microRNA (see further in Chapter 7). Each of these genomic study types has the potential to serve as a biomarker in a personalized medicine context.

In this chapter, the foundations of personalized pulmonary medicine will be reviewed and current approaches designed to facilitate a personalized approach to the diagnosis and treatment of pulmonary disorders will be discussed, including specific examples of personalized approaches currently being implemented in clinical practice. We provide overviews of human genetics, personalized pulmonary diagnostic testing, pharmacogenomics, biomarkers, and future implementation as they relate to personalized respiratory medicine.

DETERMINANTS OF THE CLINICAL UTILITY OF A GENETIC TEST

The predictive power of a genetic test is a function of four interdependent estimable parameters: (1) the *heritability* of the trait; (2) the *penetrance* of the tested genetic variant; (3) *allelic heterogeneity*; and (4) the variant *allele frequency*.

Heritability can be defined as the proportion of disease risk that is explained by genetic determinants. Heritability is highest (~100%) among monogenic diseases like cystic fibrosis (CF), while common diseases such as asthma or obstructive sleep apnea have more modest estimates (30%–60%), with a substantial proportion of disease risk is due to environmental factors. The heritability for many of the commonly measured pulmonary traits is modest (Table 9-1).

Penetrance is defined as the likelihood of the disease among individuals who carry the risk genotype (Fig. 9-1). Penetrance is highest for variants implicated in rare monogenic disorders, approaching 100% for the ΔF508 mutation in CF, and is lowest for more frequent genetic variants associated with common diseases. Wide ranges of intermediate penetrance have also been reported in pulmonary disease, from 90% for FLCN mutations in Birt–Hogg–Dubé syndrome (BHD)[3] to 20% to 50% for *BMPR2* mutations in familial pulmonary hypertension[4] and the *MUC5B* promoter polymorphism in familial pulmonary fibrosis.[5] Penetrance is phenotype-dependent. For example, in BHD, although ~90% of patients with *FLCN* mutations have radiographic evidence of cystic lung disease, dermatologic findings are seen in only ~60%, and spontaneous pneumothorax is observed in only 38% of patients.[3] Similarly, though virtually all PiZ homozygotes have markedly reduced circulating levels of alpha 1-antitrypsin levels, only a subset of these individuals manifests symptomatic emphysema.[6]

TABLE 9-1 Heritability Estimates in Pulmonary Medicine

Trait	Heritability Estimates
Pulmonary diseases	
Cystic fibrosis	1.0
Asthma	0.36–0.72
COPD	0.40–0.77
Sarcoidosis	0.60–0.70
Obstructive sleep apnea	0.33–0.52
Quantitative traits	
FEV_1	0.38–0.77
FVC	0.54–0.91
FEV_1/FVC	0.44–0.46
Airways responsiveness	0.30–0.66
D_{LCO}	0.39–0.46
IgE levels	0.40–0.60

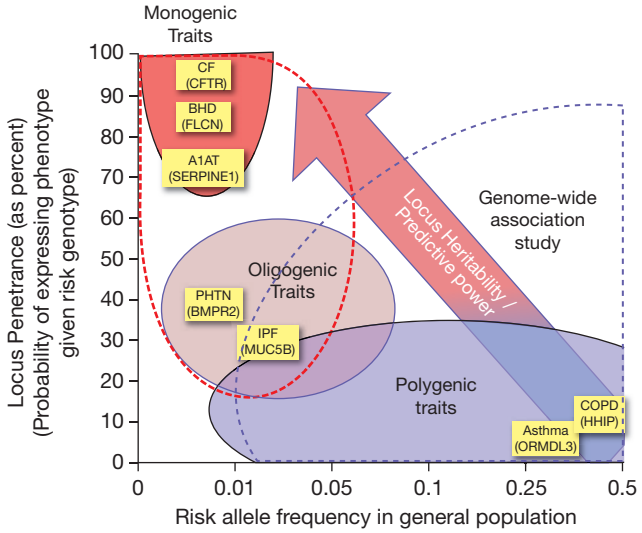

Figure 9-1 The relationship between allele frequency, locus heritability, predictive power, and genetic mapping strategies: Monogenic diseases, such as cystic fibrosis (CF), Birt–Hogg–Dubé syndrome (BHD), and alpha 1-antitrypsin deficiency (A1AT) are caused by highly penetrant, deleterious causal mutations that can be detected by parametric linkage analysis. Polygenic, complex traits, such as asthma and COPD, are caused by numerous genes (dozens to hundreds) harboring variants of much weaker genetic effect. Genome-wide association studies can identify the subset of these variants, but their individual predictive value is low. Oligogenic traits, like familial forms of pulmonary hypertension (PHTN) and idiopathic pulmonary fibrosis (IPF), are caused by variants in a handful of genes with both intermediate frequencies and intermediate penetrance functions.

Allelic heterogeneity refers to the existence of more than one causal allele present in the reference population. Though one variant often predominates as the most prevalent disease allele (e.g., the Z allele in 85% in alpha 1-antitrypsin deficiency), numerous pathogenic variants are typically described, including more than 20 *SERPINE1* mutations in alpha 1-antitrypsin, 50 *FLCN* mutations in BHD, and more than 1800 pathogenic *CFTR* variants in CF. *Locus heterogeneity* is a situation where the same phenotype can manifest through mutations in different genes. For example, familial bronchiectasis resulting from primary ciliary dysfunction has been mapped to no fewer than 18 genes that code for distinct proteins of the ciliary apparatus. There are numerous reports of confirmed primary ciliary dyskinesia where only one of two pathogenic mutations is identified in any one gene,[7,8] suggesting the potential for digenic inheritance, where the combination of two mutations in different genes is sufficient to cause disease.

The influence of variant *allele frequency* on the predictive power of a genetic test is complex, and depends largely on the strength of the genetic effect conferred (the locus heritability) and the disease prevalence. Rare monogenic lung diseases typically result from highly penetrant, low frequency (<1%) variants situated in highly conserved protein-coding sequences. Most common disease susceptibility variants reported are of high frequency (>5% in the general population) but individually are of weak effect. In many instances, the population risk allele frequency exceeds the population disease prevalence (such as the asthma-associated *ORMDL3/GSDMB* risk haplotype, frequency of 62% in asthmatics). In these cases, the specificity of the variant is quite weak. In contrast, rare variants of high penetrance implicated in common disease will have high specificity, yet their low population prevalence diminishes their clinical predictive value, as sensitivity and negative predictive values will be poor.

GENETIC TESTING

All of the major classes of genetic variation – including single nucleotide substitutions, insertions and deletions, copy number variants, and larger, more complex structural variants – have been described in pulmonary disease (Table 9-2), and no single technology has been developed that can reliably survey all these forms simultaneously, though next-generation sequencing (NGS) technologies are emerging as one possible solution. The rapid pace of technological advancement and the vast number of technologies in current use preclude comprehensive survey of all aspects of DNA technologies here. Instead, we emphasize NGS technology as a current and future direction for use in clinical practice.

Whole-genome sequencing. NGS platforms enable DNA sequencing in a highly paralleled fashion, without the need for predefined sequence-dependent hybridization. These methods generate short sequence reads (30–135 bases in length), sampled randomly from the target sample. With these methods, whole-genome sequencing of nearly all genomic regions is now feasible, and is being widely implemented for both research and clinical purposes. The massive parallel nature of these techniques, and their lack of reliance on Sanger chemistries, have resulted in dramatic reductions in cost (now $1500–$2000) for whole-genome sequence, favorably raising the prospects for comprehensive genomic testing and personalized medicine.

The major technical challenge, and primary determinant of cost, is achieving sufficient base-calling accuracy. Given the very large numbers of both the bases being called (billions) and polymorphisms per genome (~3–4 million), accuracies of >99.9% are needed to limit the number of spurious findings (both false positive and false negative). Such accuracy can be achieved by ensuring high read depth—the number of times a given base is sequenced. For clinical purposes, minimum average read depths of 30 to 40 times provide reasonable accuracies. For whole genomes, such coverage can only be achieved by performing multiple sequencing runs, increasing costs considerably. More expensive are the downstream costs related to the involved analytical processes of quality assessment, sequence annotation, and variant classification (see below). Additional costs are incurred from the current clinical guidelines that mandate independent technical validation of all actionable (clinically relevant, reportable) variants by Sanger sequencing. Thus, while the technical cost continues to fall, current total charges (often exceeding $10,000 per clinical genome) preclude widespread adoption of whole genome sequencing at present.

TABLE 9-2 Types of Genetic Variation and their Relative Contribution to Disease Phenotype

Genetic Variation	Definition	Phenotypic Variation %[a]	Example	Pulmonary Manifestation
Chromosomal abnormalities				
Numerical abnormalities	Variations in chromosome number			
Polyploidy	Additional genome copies		69 XXY	Fetal loss
Aneuploidy	Variable number of single chromosome	<1%	Trisomy 21: Down syndrome	Obstructive sleep apnea and pulmonary hypertension
		<1%	Monosomy XO: Turner syndrome	No common pulmonary phenotype
Structural abnormalities	Variations in chromosome structure			
Gross rearrangements	Visible by karyotype/FISH	1%	del(4)(q12): FIP1L1-PDGFRA gene fusion	
Translocations	Aberrant exchange of DNA sequence between two different chromosomes		T(9;22) – Philadelphia chromosome of chronic myelogenous leukemia	Somatic translocations commonly seen in lung cancer tumors
Inversions	Altered sequence orientation		900-kb inversion on 17q21	Glucocorticoid pharmacogenetic response
Copy number variants	Gains or losses of DNA sequence spanning 500 bp or more	9%	GSTM1 null variant	Smoking-related lung function decline
Sequence variants				
Single nucleotide polymorphism	Single base pair substitutions			
Nonsense/Missense	Variant introduces stop codon/ amino acid substitution	55%	FLCN R4496X: Birt–Hogg–Dubé	Spontaneous pneumothorax
			SERPINE1 Glu366Lys (Z) allele	alpha 1-antitrypsin deficiency, emphysema
Splicing	Variant alters normal intron splicing pattern	9.20%	DNAI1 IVS1+3insT: Primary ciliary dyskinesia	Bronchiectasis
Regulatory	Variant alters mRNA transcription or protein translation	2%	17q21 rs12936231 variant alters ORMDL3/GSDMB expression	Asthma
Insertion/Deletion (Indel)	Gain or loss of one or more nucleotides	23%	CFTR ΔF508	Cystic fibrosis
Short tandem repeat	Repetitive element that varies in copy number	0.30%	PHOX2B exon 3 polyalanine repeat expansion	Primary central hypoventilation syndrome

[a]*Percent of total variation listed in Human Gene Mutation Database (http://www.hgmd.cf.ac.uk/ac/index.php, accessed May 30, 2013).*

Targeted sequencing panels. While use of whole-genome sequencing in clinical practice remains modest, there is increasing utility in highly focused, targeted NGS of selected genes or gene regions, which is achieved by "pulling-down" DNA segments of interest using oligonucleotide filters (i.e., probe sets that bind complementary sequence). These filters can be customized to target specific sequences, ranging from a handful of genes to all gene-coding regions (i.e., whole exome filters). This approach markedly reduces the size of targeted sequence length (e.g., an exome sequence is only 3% of the total genome sequence), with numerous advantages for clinical implementation. The marked reduction in target size accommodates clinically reliable read depths in one sequence run, reduces analytic costs (as there is less sequence to annotate), and reduces follow-up validation costs.

Pulmonary-specific sequencing panels. Targeted sequencing of selected genes implicated in pulmonary disease is available commercially through several companies and clinical laboratories. The services provided differ from each other primarily in the gene content of the tests, which are frequently organized in discrete gene panels. Most panels are designed to assess selected gene sets implicated in disorders typified by a particular clinical or radiographic manifestation (i.e., a pulmonary fibrosis panel) or a shared molecular defect (i.e., ciliopathy panel). The largest panels available are those for workup of pulmonary fibrosis and bronchiectasis. Due to technical limitations and the constant pace of novel disease-gene discovery, few panels can be considered fully comprehensive. Yet, most offer coverage of the most commonly implicated genes being considered clinically. Panels of 5 to 20 genes typically cost $2500 to $6000, in comparison to the cost of clinical resequencing of individual genes (on average $1500–$2000). Thus, when more than one gene is clinically suspected, or for diseases with known locus heterogeneity, diagnostic panels offer greater cost efficiency over single gene resequencing.

More broad sequencing panels may have particular value in the evaluation of patients with more complex presentations (e.g., patients presenting with a combination of bronchiectatic and fibrotic features, or with parenchymal lung disease disproportionate to the degree of concomitant pulmonary hypertension). When a genetic basis is suspected, massively paralleled sequencing across panels of genes may help narrow the differential diagnosis to one or two disorders. Currently, only one laboratory – the Laboratory for Molecular Medicine at the Partners HealthCare Center for Personalized Genetic Medicine – offers combination panel testing, at incremental cost over one panel. Though possibly more cost-effective over current diagnostic strategies, the value of such an approach to the workup of patients with complex presentations remains unclear.

We emphasized that, before ordering more expansive tests, patients must be made aware that surveys of larger panels of genes increase the likelihood of identifying variants of unknown clinical significance (so-called VUS). Patients must be counseled pretest regarding the uncertainty these findings may impart. Genetic test results classify variants according to their likelihood as disease-causing variants. Variants classified as "pathogenic" are those firmly implicated as disease causing due to their demonstrated functional impact, their localization to a highly conserved functional genomic sequence, their presence in affected individuals only, and their strong segregation with disease. So-called "likely pathogenic" variants have many, but not all, of these features. "Benign" variants are those that are common among healthy controls, have no demonstrable function, and do not segregate with disease in families. Counseling of patients regarding these three classes of variants is often unambiguous. In contrast, VUS variants fall into a grey zone, in that they do have features that suggest functional impact but are either observed in unaffected subjects or segregate imperfectly in affected pedigrees (features that suggest incomplete penetrance). Patients must understand the possibility of such findings, and their implications on subsequent workup and management.

Clinical indications for genetic testing. Table 9-3 lists the most common uses of genetic information in clinical practice, both for the patient and at-risk family members. Diagnostic genetic testing is of greatest value when knowledge of the specific gene or mutation will directly impact clinical management. In these cases, genetic testing should be offered to patients in whom the possibility of defining an actionable variant is high, including those with specific disease presentations compatible with the diagnosis of interest, at-risk family members of patients with confirmed molecular diagnoses, and subjects with strong family histories. Some examples are as follows:

- Confirmation of alpha 1-antitrypsin deficiency in patients with emphysema and lung function decline identifies a small subset of COPD patients who may benefit from replacement therapy.
- Identification of Class III CFTR genotypes (particularly the G551R variant) in patients with CF. These patients are candidates for mutation-specific CFTR potentiating therapy with ivacaftor.[9]

TABLE 9-3 Utility of Genetic Information in Clinical Practice

Activity	Paradigmatic Example	Current/*Potential* Utility in Pulmonary Medicine
Preimplantation screening	Tay–Sachs disease	*Primary ciliary dyskinesia*
In utero diagnosis	Trisomy 21	*Congenital diaphragmatic hernia*
Newborn screening	Phenylketonuria	Cystic fibrosis
Diagnostics		LAM vs. Birt–Hogg–Dubé syndrome
Prognostics	Expansion length and age of onset in Huntington's disease	*MUC5B as positive prognostic in IPF*
Presymptomatic interventions	BRCA1 and prophylactic mastectomy/oophorectomy	*BMPR2 and vasodilator therapy*
Surveillance strategies	APC mutations and familial adenomatous polyposis	FLCN mutations and renal cancer screening in Birt–Hogg–Dubé syndrome
Replacement therapies	Gaucher's disease	Alpha 1-antitrypsin deficiency
Mutation-directed therapies	Tyrosine-kinase inhibition in EGFR+ tumors	Ivacaftor in G551R positive cystic fibrosis
Pharmacogenetics	Warfarin dosing	*Polygenic model of inhaled corticosteroid response in asthma*
Gene replacement therapy	X-linked severe combined immunodeficiency	*Surfactant gene replacement in infantile pulmonary fibrosis*

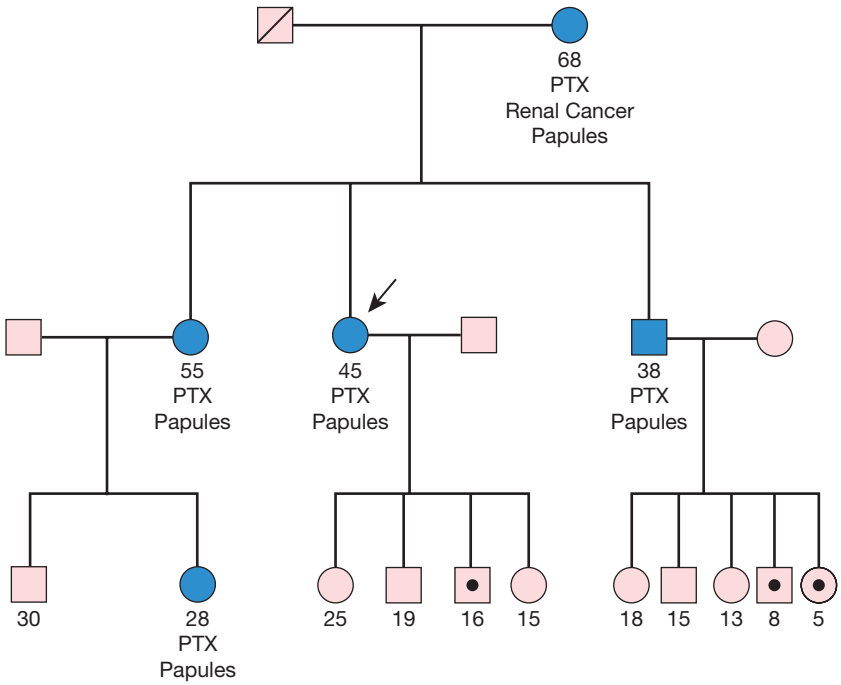

Figure 9-2 Birt–Hogg–Dubé (BHD) syndrome: Index patient *(arrow)* confirmed to harbor a pathogenic FLCN gene mutation. The maternal history of renal cancer places other mutation carriers in this family at risk of both renal and other malignancies. In this pedigree, the large number of reportedly unaffected offspring of two carriers is unusual, given a 50% probability of transmission from carrier to offspring. More likely, the mutation was passed on (hypothetically denoted by *dot*), but these carriers have not yet developed clinical manifestations, possibly due to their younger age. Such individuals would be at risk of eventually developing BHD, including malignancy. Therefore, confirmation of carrier status among at-risk, but seemingly unaffected, family members is warranted.

- Differentiating molecular forms of familial idiopathic pulmonary fibrosis: (1) Patients with *SFTPC* mutations may benefit from hydroxychloroquine treatment[10]; (2) TERC and TERT mutations help identify patients with short telomere syndrome (STS) at risk of marrow and liver failure, including during the post-lung transplant period; (3) Hermansky–Pudlak syndrome (HPS) can often be overlooked clinically due to subtle neurologic (nystagmus) and dermatologic (albinism) features, though these patients are at risk for a potentially severe, but treatable (with DDAVP), bleeding diathesis.

For highly penetrant monogenic diseases, the implications of a positive test result are often profound, even in instances where gene- or mutation-specific therapies are not yet available. Examples include preclinical identification of patients at risk for malignancy (e.g., in BHD or LAM), accelerated lung function decline (in LAM, familial fibrosis), or pulmonary hypertension, who can be more closely followed enabling earlier intervention, and who can be more vigorously counseled regarding the benefits of tobacco smoke avoidance. An illustrative example is provided in Figure 9-2, depicting the value of testing in a family pedigree with BHD. For autosomal dominant diseases of variable penetrance, and for recessive disease, genetic testing offers the ability to identify at-risk carriers prior to the onset of symptoms, providing opportunities for early diagnosis. Negative test results are also of value, providing reassurance to relatives that they are not at risk of developing an illness they may have witnessed afflicting their relatives.

Genetic counseling in pulmonary medicine. The inherently predictive, personal, and irreversible nature of an individual's genetic code distinguishes genetic from other forms of clinical testing. The psychological impact of genetic test results, whether positive or negative, cannot be underestimated. Feelings of inadequacy or imperfection, a sense of inevitable doom and therapeutic nihilism due to a genetic "fate" are not uncommon with a confirmed genetic diagnosis. Conversely, negative results can lead to a false sense of invincibility, leading to unhealthy behaviors (e.g., continuing to smoke). Inherently, the potential impact of genetic testing extends beyond the patient, implicating all blood relatives. Moreover, test results can impact family dynamics and the way in which individual family members react to their test results. For example, though most at-risk family members will be relieved by a negative test result, some experience a deep sense of guilt (so-called "survivors guilt") in relation to their affected family members. Finally, despite legislation at state and federal levels protecting patients from genetic discrimination in the workplace and in access to health care insurance, patients must be informed regarding this risk in other contexts (e.g., the impact on eligibility for life insurance policies).

For all these reasons, it is advised that genetic testing be offered only by, or in consultation with, experienced providers familiar with these issues, including certified genetic counselors, who can adequately address the medical, psychological, and familial implications of test results. We recommend initiating these discussions before testing, so that patients are empowered to provide truly informed consent. Patients should be made aware of the medical implications of both positive and negative results, and should be advised regarding the impact these results may have on them and their family members. Genetic pretest counseling should also address the potential identification of variants of unclear significance.

MUTATION-SPECIFIC THERAPIES IN MONOGENIC LUNG DISEASE

One of the primary goals of genetic classification of disease is the development of mutation-specific therapies. Such activities have traditionally focused on the development of replacement therapies for loss-of-function recessive diseases (i.e., recombinant human alpha 1-proteinase inhibitor replacement therapies). Newer pharmacologic approaches, including small molecule screens and others informed by the functional impact of specific mutations are emerging.

TYROSINE-KINASE INHIBITION FOR HYPEREOSINOPHILIC SYNDROME

Imatinib was identified as a therapy for chronic myelogenous leukemia (CML). However, once the functional mechanisms underlying its therapeutic effects were elucidated, other therapeutic uses were identified. The treatment of hypereosinophilic syndrome (HES) is one such example. Subsets of HES patients harbor a chromosome 4q interstitial deletion that results in the creation of a fusion of the *FIP1L1* and *PDGFRA* genes. The resultant fusion protein has tyrosine-kinase activity similar to that of BCR-ABL, the target site in CML and HES patients positive for the *FIP1L1-PDGFRA* rearrangement respond positively to imatinib therapy.[11,12] *FIP1L1-PDGFRA*-negative HES patients do not. Similar to CML,

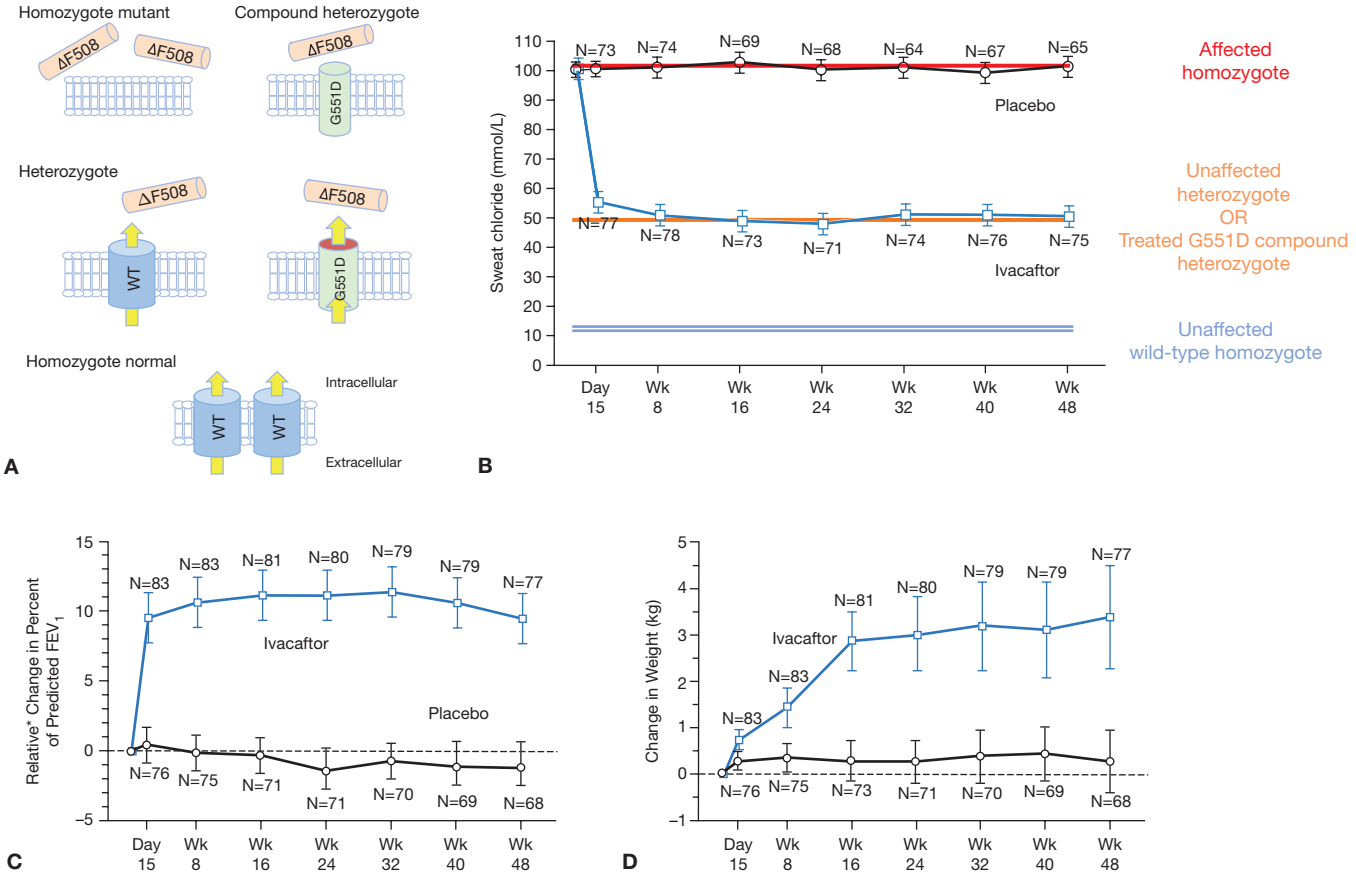

Figure 9-3 Mutation-specific therapeutic action of ivacaftor in cystic fibrosis: **A, B.** The additive effect of CFTR mutations on epithelial chloride efflux and sweat chloride levels, and the effect of ivacaftor. Individuals with two normal alleles have normal chloride efflux *(yellow arrows)*, and a corresponding normal sweat chloride test *(blue double line)*. Individuals with two mutated alleles demonstrate markedly reduced chloride efflux and elevated sweat chloride *(red line)*. Heterozygotes with ~50% normal functional chloride channels on epithelial cell surfaces manifest intermediate reductions in both chloride efflux and sweat chloride responses *(orange line)*. G551D compound heterozygotes treated with ivacaftor *(red disc)* demonstrate sweat chloride levels similar to heterozygote carriers. **C, D.** Therapeutic efficacy of ivacaftor: Patients randomized to ivacaftor demonstrated improvements in relative change in percent of predicted FEV_1 (**C**) and weight (**D**) over 48 weeks, in addition to improvements in symptoms and in quality of life scores (not shown). *Original report erroneously labeled figure as Absolute (not relative) change in percent of predicted FEV_1. (***B–D.*** *Reproduced with permission from Ramsey BW, Davies J, McElvaney NG, et al. A CFTR potentiator in patients with cystic fibrosis and the G551D mutation. N Engl J Med. 2011;365(18):1663–1672.)*

mutations of the tyrosine-kinase binding site have been reported upon HES relapse.

■ MUTATION-SPECIFIC THERAPIES FOR CYSTIC FIBROSIS

In 2011, positive results of a randomized clinical trial of a novel therapy for G551D-positive CF were reported (Fig. 9-3).[9] In a 48-week, randomized, double-blind, placebo-controlled trial, 167 patients received either placebo or ivacaftor—an oral agent that "potentiates" CFTR activity by prolonging channel opening times and augmenting transmembrane chloride transportation. Compared to patients receiving placebo, patients treated with ivacaftor demonstrated significant improvements in FEV_1, fewer respiratory exacerbations, improved quality of life, and a positive weight gain. The ~50% reduction in sweat chloride levels to those approaching those observed in asymptomatic *CFTR* mutation carriers (i.e., heterozygotes) serves as an elegant molecular–clinical correlate, suggesting selective effect on the G551D+ channel, but not ΔF508+ channels. While G551D and other variants likely to benefit via ivacaftor are observed in only ~6% of patients, their identification opens new therapeutic options for this subset of CF patients. The advent of this novel treatment strategy provides motivation for the development of additional agents that target other *CFTR* mutation classes (including the most common *CFTR* mutation—ΔF508), and the application of similar strategies for the treatment of other genetic diseases.

BIOMARKERS IN PULMONARY MEDICINE

Biomarkers have been defined as "biological characteristics that can be objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacological responses to a therapeutic intervention".[13] Ideal biomarker characteristics have been espoused (Table 9-4).[14] There are two major types of biomarkers applicable to clinical medicine: (1) biomarkers of exposure, which are used in risk prediction; and (2) biomarkers of disease, which are used in the screening, diagnosis, and monitoring of disease progression, as well as response to therapy. Thus, biomarkers have the potential to support clinical decisions, from diagnosis to treatment planning; to improve tailored treatment strategies; to avoid over- or undertreatment and adverse side effects; and to enhance prognosis and cost-effectiveness.

While a number of biomarkers have been evaluated in a wide range of pulmonary conditions, including MMP-7, ICAM-1, and IL-8 for interstitial lung disease,[15] procalcitonin for community acquired pneumonia,[16,17] exhaled nitric oxide for asthma and other inflammatory lung disease,[18,19] and RAGE, ICAM-1, and SP-D for ARDS,[20] few are

TABLE 9-4 Ideal Biomarker Characteristics

Easy to measure
Safe to measure
Low cost to measure
Consistent across gender, age, race
Cost of follow-up tests is reasonable
Proven therapy to modify biomarker
Modification of biomarker is proven to protect against disease or outcome

recommended for routine clinical use. This stems largely from their relatively weak predictive power. For instance, at a 5% false-positive rate (specificity 95%), a relative odds of 3.0 between the first and fifth quartiles of a biomarker gives only a 20% detection rate.[21] As such, most current biomarkers cannot substitute other clinical parameters in clinical evaluation, but are used as adjuncts to support clinical judgment.

An example of a biomarker in prominent routine use in pulmonary medicine is the D-dimer and its role in the diagnosis of acute pulmonary embolism (Fig. 9-4). The quantitative rapid enzyme-linked immunosorbent assay (ELISA) has a sensitivity of 95%. In patients with low pretest clinical probability (i.e., 4%–15%), a normal D-dimer rapid ELISA substantially reduces the posttest probability of pulmonary embolism to 0.7% to 2%.[22] Therefore, these patients can safely be excluded from further evaluation.[22–25] Notably, the D-dimer is still used adjunctively to clinical judgment, as both the predictive ability falls in patients with intermediate to high pretest clinical likelihood of pulmonary embolism and the relatively poor specificity (of about 27%)[26] of the D-dimer limit its usefulness outside of low probability cases. There is, however, evolving evidence that may support the use of the D-dimer in the exclusion of pulmonary embolism, even with intermediate levels of clinical probability.[27–29]

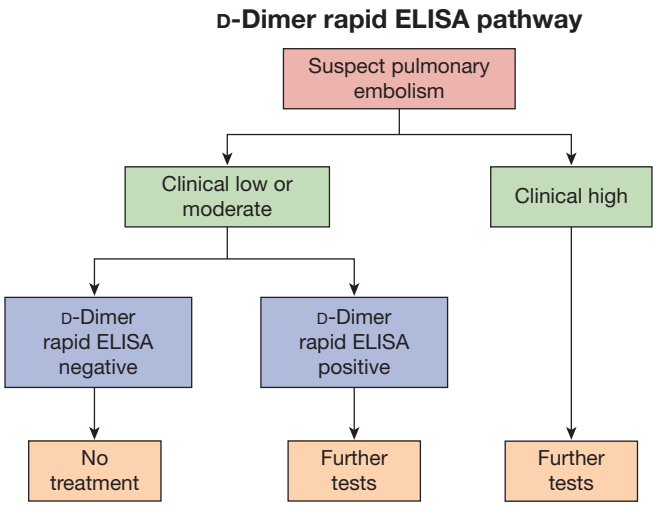

Figure 9-4 Use of D-dimer as a biomarker in the exclusion of pulmonary embolism. The quantitative rapid enzyme-linked immunosorbent assay (ELISA), with a sensitivity of 95%, showed the most clinically useful values among the various D-dimer assays. When used in combination with a low probability objective clinical assessment, which ranges from 4% to 15%, the post-test probability of pulmonary embolism ranges from 0.7% to 2% with a normal D-dimer rapid ELISA. No further testing is required if D-dimer is normal in a patient with a low probability clinical assessment. *(Reproduced with permission from Stein PD, Woodard PK, Weg JG, et al. Diagnostic pathways in acute pulmonary embolism: recommendations of the PIOPED II investigators. Am J Med. 2006;119(12):1048–1055.)*

The integration of biomarkers in drug development and their use as a companion diagnostic in clinical practice has been encouraged by regulatory authorities.[30,31] One example of this in clinical practice has been the development of periostin as a biomarker for treatment with lebrikizumab (anti-IL-13). In a study of 42 asthmatic patients and 28 healthy controls, conducted by Woodruff et al.,[32] a three-gene airway epithelial cell expression signature composed of periostin (*POSTN*), chloride-channel regulator 1 (*CLCA1*), and serpin peptidase inhibitor clade B, member 2 (*SERPINB2*), was used as a surrogate marker of T_H2 inflammation. Multivariate cluster analysis defined groups of patients: a T_H2-high cluster (asthmatic patients with high expression of T_H2 cytokine-induced gene expression) and a T_H2-low cluster (asthmatic subjects whose expression analysis was the same as healthy controls). The T_H2-high cluster phenotype was characterized by increased serum IgE levels, allergic inflammation, airways hyperresponsiveness, and increased responsiveness to inhaled corticosteroids.[32]

In a study of lebrikizumab, an IL-13 monoclonal antibody, in 219 adults who had poorly controlled asthma despite inhaled glucocorticoid therapy,[33] high serum periostin levels at baseline predicted a positive treatment response (improvement in FEV_1). Nevertheless, the performance of periostin expression as a clinical predictor has yet to be independently confirmed. Indeed, in a clinical trial of asthmatic subjects not taking inhaled corticosteroids, lebrikizumab did not show any significant improvement in lung function regardless of baseline periostin status.[34]

PHARMACOGENETICS

The response to pharmacologic agents varies tremendously between individuals. For instance, the plasma level of a given medication can vary more than 1000-fold between two individuals having the same weight when treated with the same drug dosage.[35] On average for a given drug, 30% of patients show beneficial effects, 30% fail to improve, 10% only experience side effects, and 30% are noncompliant (which may be related to either lack of efficacy or side effects).[36] Therefore, as many as 70% of all patients are unnecessarily exposed to the potential to develop adverse drug reactions (ADRs).[37–39] In the United States, over 2 million hospitalizations due to serious ADRs and over 100,000 fatal ADRs were noted in 1994, ranking ADRs between the fourth and the sixth leading cause of death.[40] Worldwide, the prevalence of hospitalizations due to ADRs was recently estimated at a median of 5.3% (interquartile range [IQR] 2.7%–9.0%), as based on prospective cohort studies of over 100,000 admissions.[41] Overall, the cost of drug-related morbidity and mortality in the United States exceeded $177.4 billion in 2000,[42] a figure more than double the estimate from 1995.[43] As enormous as these figures are, the burden due to lack of therapeutic response to drug therapy is likely to be much greater.[44]

Pharmacogenetics is the study of variability in drug response due to heredity. Pharmacogenetic variability in drug absorption, drug metabolism, and drug action at the receptor level is well-known. Overall, it is estimated that genetics can account for 20% to 95% of variability in drug disposition and effects.[45] Ideally, pharmacogenetics will allow for "individualized therapy" based upon an individual's genetic makeup that will maximize the potential for therapeutic benefit, while minimizing the risk of adverse effects. The potential for cost savings and for decreasing morbidity and mortality is immense.

PHARMACOGENETIC RESPONSE CATEGORIES

The heritability of many therapeutic agents has been formally established via genetic studies, including the twin studies of Vessel and Page.[46–50] Barring formal genetic studies, the response distribution can also strongly suggest a heritable response. The interindividual response

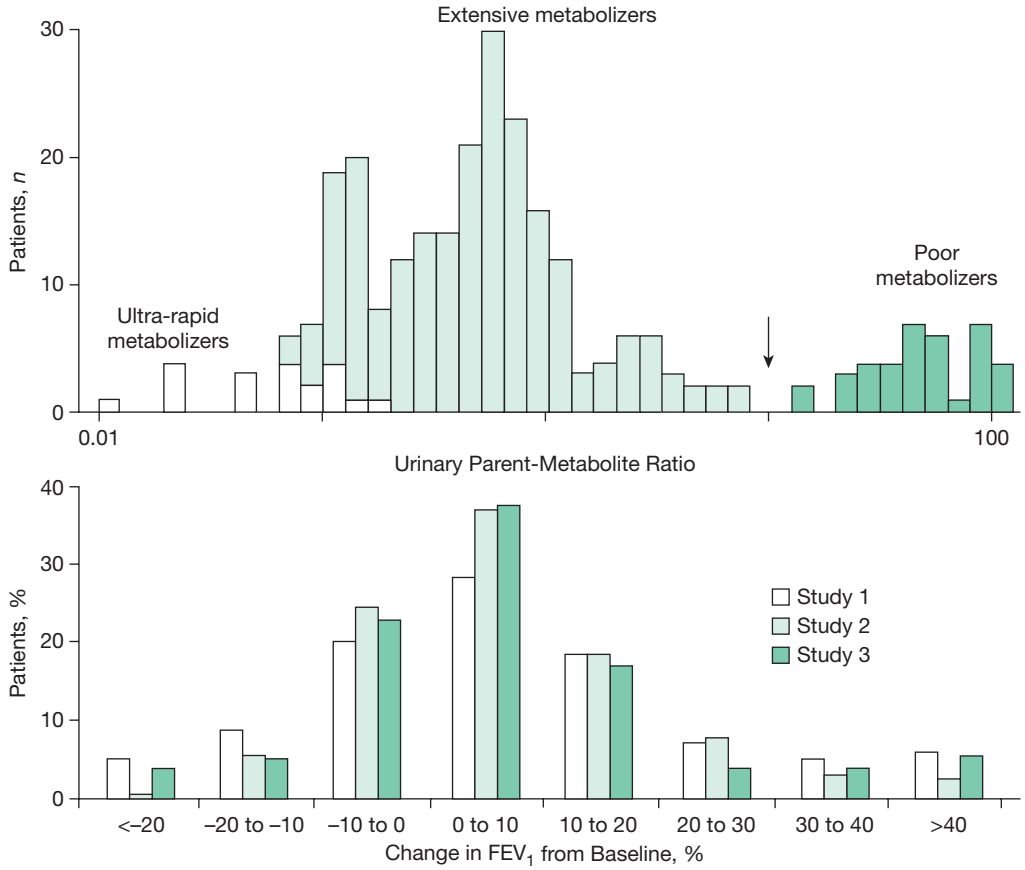

Figure 9-5 Patterns of variation in drug response. *Top.* Multimodal response common to many drug metabolizing enzymes. *Bottom.* Unimodal, yet highly variable, response noted in complex trait drug response. In this case, Studies 1 to 3 refer to three independent clinical trials that measured inhaled corticosteroid response over time. *(Reproduced with permission from Roden DM, Altman RB, Benowitz NL, et al. Pharmacogenomics: challenges and opportunities. Ann Int Med. 2006;145(10):749–757.)*

distribution may be either multimodal or unimodal (Fig. 9-5). A multimodal distribution suggests distinct population subgroups of response, thereby directly supporting a pharmacogenetic basis for response. A unimodal drug response distribution still supports the concept of interindividual variation, with subjects demonstrating both "good" and "poor" responses. The combination of wide interindividual response with high repeatability (the likelihood of a subsequent beneficial/poor response to a drug given a prior response) supports the plausibility of a pharmacogenetic effect.[51]

Pharmacogenetics has traditionally been divided into four categories based upon the effects of genetic variability on the pharmacologic properties of a drug. For instance, one genetic variant can alter the rapidity of drug metabolism (thereby altering bioavailability), whereas another genetic variant can affect binding to a drug receptor (thereby decreasing therapeutic efficacy). The four categories include variation related to pharmacokinetics, pharmacodynamics, idiosyncratic reactions, and disease pathogenesis (Fig. 9-6).[52] Each of these categories will be discussed below, followed by a known example or examples pertinent to pulmonary medicine. Clinical implementation guidelines for several of these examples have been developed.[53–57] Additional examples likely to be encountered by the respiratory practitioner and labeled by the US Food and Drug Administration (FDA) are listed in Table 9-5.

Pharmacokinetics studies the effect of the body upon an administered drug, including the absorption, distribution, tissue localization, biotransformation, and excretion of drugs.[58] Common drug metabolizing enzymes implicated in pharmacogenetics and their estimated effect on drug dosing are shown in Figure 9-7. The cytochrome p450 enzymes (*CYP*s) encode for ~60% to 70% of all phase I (i.e., structural transformation) dependent metabolism and have been the classic examples of drug metabolizing enzymes. The clinically most important *CYP*s are *CYP2C9, CYP2D6,* and *CYP3A4*, with *CYP2C9* discussed in the context of warfarin administration later in this chapter. *CYP* genotypes generally result in three metabolic phenotypes, ultra-rapid metabolizers, extensive (normal) metabolizers, and poor metabolizers (Fig. 9-5).

An example of polymorphic phase II (i.e., drug conjugation) drug metabolizing enzymes is the metabolism of azathioprine by thiopurine-*S*-methyltransferase (*TPMT*).[59] Azathioprine, which is commonly used in the therapy of interstitial lung disease and pulmonary vasculitides, is converted to the active 6-mercaptopurine, which is then metabolized by *TPMT* or converted into 6-thioguanine nucleotides. Decreased *TPMT* activity, as mediated through genetic variation, occurs in about 10% of individuals at intermediate levels, while ~0.3% (1 in 300) have low to absent activity. Clinically, this results in drug-related myelosuppression in 5%, severe leukopenia in 1.2%, and is fatal in 0.3% of subjects taking azathioprine.[60] Both clinical phenotyping (predrug assessment of *TPMT* activity) and genotyping assays are available. Such testing has been noted to be cost-effective

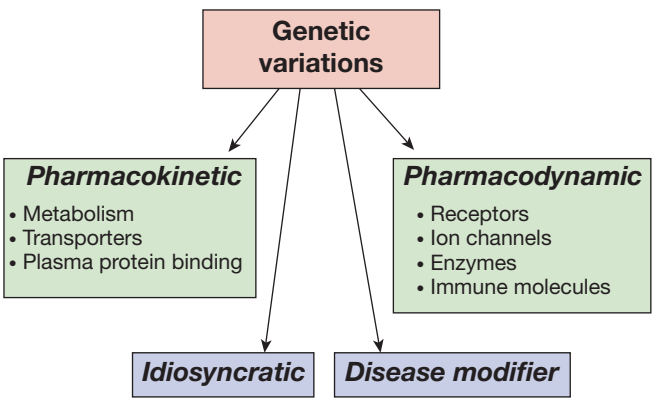

Figure 9-6 Categories of pharmacogenetic response, based upon site of activity of the genetic variant of interest.

TABLE 9-5 Common Pulmonary Medications FDA Labeled for Pharmacogenomic Effects

Drug	Therapeutic Area	Genotype	Variant Genotype Effect
Azathioprine	Interstitial lung disease	*TPMT*	Increased potential for bone marrow suppression
Cisplatin	Oncology	*TPMT*	Children with variants may have an increased risk of ototoxicity
Codeine	Analgesics, cough suppression	*CYP2D6*	Decreased pain relief in poor metabolizers
Dapsone	Anti-infective	*G6PD*	Hemolytic anemia
Erlotinib	Oncology	*EGFR*	EGFR-TK mutation is biomarker of erlotinib efficacy in lung cancer
Gefitinib	Oncology	*EGFR*	EGFR-TK mutation is biomarker of gefitinib efficacy in lung cancer
Imatinib	Pulmonary hypertension	*CYP3A4*	Decreased efficacy in rapid metabolizers, increased toxicity in poor metabolizers
Irinotecan	Oncology	*UGT1A1*	Increased potential for severe diarrhea and fatal neutropenia
Ivacaftor	Pulmonary	*CFTR (G551D)*	G551D genotype is one benefitting from actions of ivacaftor
Lansoprazole	Gastroenterology	*CYP2C19*	Increased efficacy (higher intragastric pH) vs. extensive (normal) metabolizers
Mercaptopurine	Oncology	*TPMT*	Increased potential for bone marrow suppression
Mycophenolic acid	Transplantation	*HGPRT*	Should be avoided in patients with hereditary deficiency of hypoxanthine-guanine phosphoribosyltransferase (HGPRT) such as Lesch–Nyhan or Kelley–Seegmiller syndrome
Omeprazole	Gastroenterology	*CYP2C19*	Increased efficacy (higher intragastric pH) vs. extensive (normal) metabolizers
Isoniazid	Anti-infective	*NAT1; NAT2*	Increased risk of peripheral neuropathy with *NAT1* variation; attenuated with pyridoxine administration; *NAT2* influences drug level
Voriconazole	Antifungals	*CYP2C19*	Possible risk of subtherapeutic voriconazole concentrations, and subsequently of treatment failure
Warfarin	Hematology	*CYP2C9; VKORC1*	Higher warfarin levels and increased potential for adverse effects

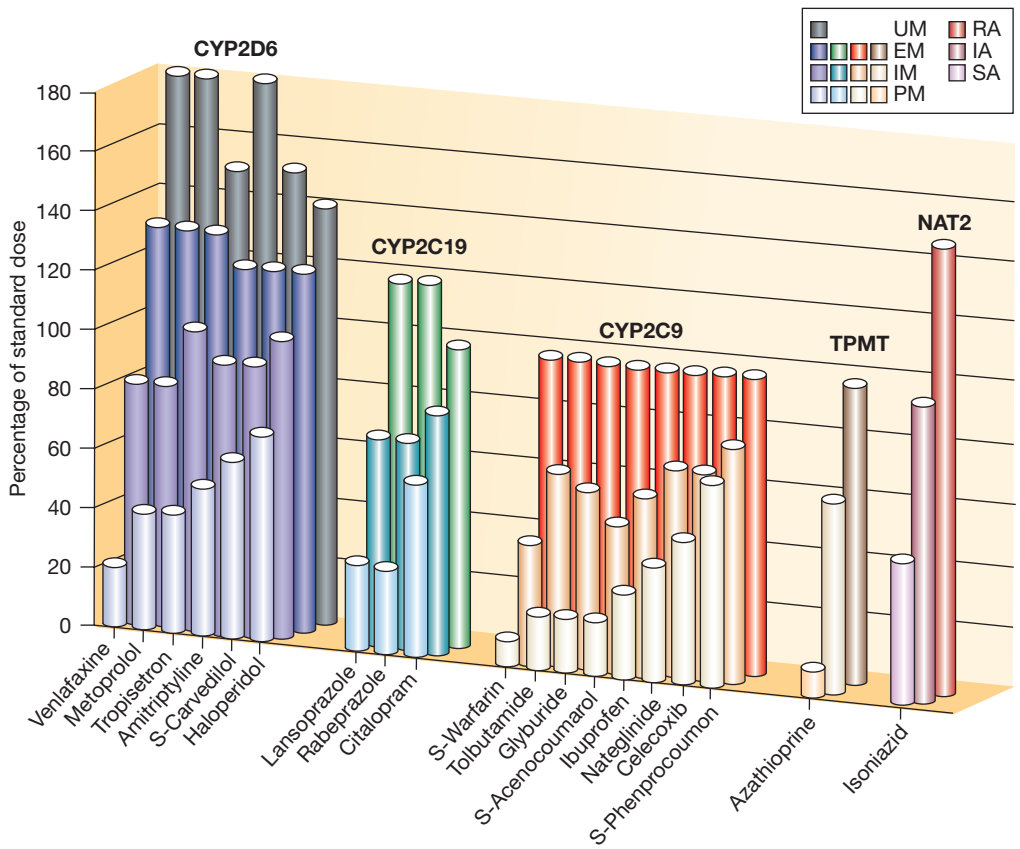

Figure 9-7 Common drug metabolizing enzymes and their standardized effect on drug dosing, according to the difference in pharmacokinetic parameters from clinical studies. Substantial adjustments need to be made to drug dose to achieve the same level of drug exposure in individuals with different genotypes. EM, extensive metabolizer; IA, intermediate acetylator; IM, intermediate metabolizer; PM, poor metabolizer; RA, rapid acetylator; SA, slow acetylator; UM, ultra-rapid metabolizer. *(Reproduced with permission from Kirchheiner J, Fuhr U, Brockmoller J. Pharmacogenetics-based therapeutic recommendations–ready for clinical practice? Nat Rev Drug Discov. 2005;4(8):639–647.)*

in a variety of diseases,[61–63] including recent modeling of azathioprine use in interstitial pulmonary fibrosis.[64] Clinical pharmacogenomic implementation guidelines have been published.[53,56]

Genetics can also influence drug transporters affecting drug absorption, distribution, and excretion. As an example, the solute carrier organic anion transporter family member 2B1 (*SLCO2B1)* mediates the Na(+)-independent transport of organic anions such as leukotriene C4. A nonsynonymous *SLCO2B1* polymorphism (rs12422149) has been associated with significantly reduced plasma concentration of differential response to therapy with montelukast as assessed by change in baseline Asthma Symptom Utility Index scores.[65]

Pharmacodynamics is the study of the biochemical and physiological consequences of the administration of a drug and its mechanism of action,[58] that is, the effect of a drug at its therapeutic target. Genetic variation may lead to response differences despite appropriate concentrations of a drug at its intended target. This category is especially pertinent to pulmonary medicine, since many conditions are treated with inhaled medications which bypass first-pass metabolism by the liver, thereby limiting the effect of pharmacokinetic variants.

Warfarin is the most commonly prescribed anticoagulant medication worldwide and in respiratory medicine is commonly used for the treatment of pulmonary embolism. For warfarin, cytochrome p450 2C9 (*CYP2C9*) is the primary enzyme involved in its metabolism, while vitamin K epoxide reductase complex, subunit 1 (*VKORC1*) is its primary therapeutic target, responsible for the conversion of vitamin K-epoxide to vitamin K. FDA labeling of warfarin includes consideration for testing of variants involved in both pharmacokinetics and pharmacodynamics. "High" and "low" dose risk variants of the *VKORC1* gene, as well as variants of the *CYP2C9* gene have been identified.[66] Overall, *VKORC1* variants account for ~25% of variability in warfarin dosing, with *CYP2C9* adding an additional 6% to 10%.

Multiple early studies supported the ability to predict initial warfarin dosing using a genotype stratified approach.[66–70] Initial guidelines for the clinical implementation of warfarin pharmacogenetics have been detailed.[55,71] However, in two[72,73] of three recently published clinical trials comparing use of a pharmacogenetic algorithm to a clinical dosing strategy, no significant benefit was noted in terms of percentage of time spent within the therapeutic international normalized ratio (INR) range, with the third[74] demonstrating only a modest (67.4%–60.3%) benefit to pharmacogenetics. While disappointing from a pharmacogenetic dosing standpoint, these studies were not powered to address the more important issue of bleeding and thrombotic complications. One study comparing a current genotyped cohort with historical controls demonstrated 31% fewer hospitalizations overall (adjusted hazard ratio [HR]: 0.69, 95% confidence interval [CI]: 0.58–0.82) and 28% fewer hospitalizations for bleeding or thromboembolism (HR: 0.72, 95% CI: 0.53–0.97) based upon pharmacogenetic dosing.[75] Further study in this area is warranted.

Pharmacogenetic tests aimed at combining multiple genetic predictors will likely continue to be a focus going forward. For instance, variants in *CRHR1* and *GLCCI1* have been associated with lung function response to inhaled corticosteroids in multiple asthmatic populations.[76,77] However, these account for just a small proportion of the variability in response to these medications. Nonetheless, combining two variants in the *CRHR1* and *GLCCI1* genes significantly improves the ability to predict response in a replicable fashion.[78]

The **idiosyncratic** category of pharmacogenetic response to drugs includes the individuals that experience an ADR to a therapeutic agent that could not be anticipated based upon the known drug target. Examples of the idiosyncratic category include some compounds that are metabolized by arylamine-*N*-acetyltransferase 2 (*NAT2*). Genetic differences in *NAT2* have been associated with predisposition to the development of peripheral neuropathy in certain individuals taking isoniazid[79] and hypersensitivity reactions to trimethoprim/sulfamethoxazole (including rash, granulocytopenia, and abnormal liver function tests).[79,80] Interestingly, the *NAT2* acetylator phenotype (based upon metabolized level of drugs) may correlate poorly with *NAT2* genotype,[81,82] suggesting that factors other than drug level may explain these idiosyncratic reactions associated with genetic variation.

The final pharmacogenetic category is that of genetic factors influencing **disease pathogenesis**. By modifying the underlying biology/severity of the disease, these genetic factors can also influence which therapies will work or how effective a given medication might be. As a brief example, in CF, the *CFTR* ΔF508 variant has been associated with earlier colonization with *Pseudomonas aeruginosa*,[83] whereas the G551D mutation has a milder clinical phenotype with later *P. aeruginosa* colonization.[84] Therefore, *CFTR* genotype would affect both severity of disease and frequency of antibiotic dosing.

PERSONALIZED PULMONARY MEDICINE: THE CHALLENGE

Despite the availability of personalized diagnostic panels, labeling changes implemented by regulatory agencies (e.g., FDA), and an ever-increasing compilation of genetic, biomarker, and pharmacogenetic studies in the literature, actual translation of personalized pulmonary testing to the bedside has been slower than expected. There are several of reasons for this delay. In the preceding sections, we have outlined how low heritability, variable penetrance, and the need for large effect sizes may affect test performance. Other implementation issues include (1) limitations in the design of published studies, (2) regulatory and ethical concerns, (3) lack of cost-effectiveness analyses, and (4) need to educate both patients and providers.

Study design limitations. Despite the availability of numerous reported genetic and pharmacogenetic associations in the literature, many have not been reproduced in subsequent studies.[85,86] False-positive initial associations may be due to the fact that many pharmacogenetic studies are "spin-offs" from clinical trials or for improperly designed case-control studies and, thus, are underpowered for genetic association. The nature of clinical trials (for pharmacogenetics) and of individualized cohorts (for genetic association) may also result in multiple distinct clinical phenotypes, which vary from study to study. This "phenotypic heterogeneity" combined with "genotypic heterogeneity" (interrogating disparate markers within the same gene) may also contribute to failure to replicate initial findings. These issues were detailed in an evaluation of the pharmacogenetic associations of the β_2-adrenergic receptor (*ADRB2*) gene[87] with β_2-agonist response in asthma. Overall, in 21 studies that focused on the two most common *ADRB2* coding variants (Arg16Gly and Gln27Glu), there were large differences in study design for both genotype definition (e.g., single variant vs. haplotype) and phenotypic outcome. Of a total of 487 interrogated associations, only 2 associations were probed in at least 5 of the studies, for the same endpoint, time of assessment, type of intervention, and genetic group. Not surprisingly, no definitive conclusions have been made regarding the utility of *ADRB2* variants to guide asthma therapy. Clearly, a continued focus on appropriate phenotypes and more precise replication of existing data are needed.

While beyond the scope of this chapter, two additional topics related to study design should be mentioned. The first relates to systems biology and personalized medicine. Given that multiple genetic and environmental factors impact the majority of respiratory disease susceptibility and treatment response, systems approaches seek to integrate data both at the level of data type (e.g., epistasis or gene–gene interactions) and across data types (e.g., integration of biomarker, gene expression, and SNP data) to formulate predictive models.[88–92] While young, this approach is promising with regard to complex trait test development. The second additional point is the ongoing controversy regarding study design and whether prospective, genotype-stratified trials are necessary prior to implementation of pharmacogenetic testing. One perspective is that dosing and administration of drug changes warrant such trials, while the other

perspective argues that genotypes are invariant (since people are born with them) and therefore precede even retrospective studies. A potential compromise might be in the use of adaptive clinical trials, with pharmacogenomics included as part of the main trial adaptations.[93]

Regulatory and ethical concerns. As noted earlier the FDA has been proactive in terms of pharmacogenetics, with pharmacogenetic information included on about 10% of labels for drugs approved by the FDA. Nevertheless, questions regarding the regulation of genotyping tests and the extent to which pharmacogenetic analyses should be incorporated into new drug development before or after large clinical trials, remain.[94] While beyond our current scope, one detailed perspective on how pharmacogenetic testing might be included in each phase of clinical drug development has been recently published.[95] Another potential boon to genetic test development is the recent ruling by the US Supreme Court that genes cannot be patented.[96,97]

From an ethics perspective, the longstanding concern has been whether genetic variants could result in stigmatization (e.g., denied insurance).[94] A major step in the protection of individuals' rights came with the passage of H.R. 493, the Genetic Information Nondiscrimination Act of 2008. This law protects Americans against discrimination based on their genetic information in matters related to health insurance and employment and should translate into increased acceptance of personalized testing by the public in the future.

Lack of cost-effectiveness analyses. Despite the multitude of pharmacogenetic association studies in the literature, relatively few cost-effective analyses have been performed. These studies will be crucial prior to the availability of widespread reimbursement for routine personalized pulmonary testing. Circumstances that favor cost-effectiveness of a genetic test include the following: a high prevalence of the genetic variant of interest in the target population, good correlation between phenotype and genotype, satisfactory diagnostic test criteria, disease associated with significant morbidity or mortality if left untreated or undiagnosed, and, for pharmacogenetic variants, significant reduction in ADRs resulting from testing.[98]

Need to educate both patients and providers. Pharmacogenetics and the promise of personalized medicine have been frequently mentioned in the popular lay press. It is therefore incumbent upon both the developers of a given test, as well as healthcare professionals responsible for ordering the test, to be cognizant of the test characteristics and interpretation and to be able to effectively disseminate that information to patients. In turn, in the era of personalized medicine, the need for educating health care providers in both the broad array of potential predictive tools (in addition to genetic variants, genomic, proteomic, and other molecular biomarkers will be increasingly available), as well as the strengths and weakness of each of these approaches, will be needed. The context for these educational efforts is not yet clear. Given available tests, providers will potentially need a diagnostic step to determine which drug is best suited to each patient. Of paramount importance, providers will need to be reassured and cognizant that these tests will not and cannot replace sound clinical judgment.

CONCLUSION

Variation in the susceptibility to disease and response to drugs within pulmonary medicine has a significant heritable component. Although many challenges remain, testing of personalized pulmonary medicine, biomarkers, and pharmacogenetics has begun in earnest. Given the rapidity of new genetic knowledge, we are making progress toward the goal of individualized medicine.

CHAPTER 10 Pulmonary Mechanics

Murray D. Altose

For venous blood to be properly arterialized, the distribution of air and blood within the lung is automatically matched to ensure effective gas exchange across alveolar–capillary membranes. Arterialization comprises a series of interrelated processes that begin with the mechanical performance of the ventilatory apparatus—that is, the lungs and the chest wall, including the rib cage, diaphragm, and abdominal wall. The ventilatory apparatus is critical for replenishing fresh air to the lungs for gas exchange. Although the function of each component of the lung and of the chest bellows can be deranged by injury or disease, the design of the ventilatory apparatus provides for considerable reserve. As a result, mechanical derangements are usually quite severe by the time clinical symptoms appear or arterial blood-gas levels become abnormal.

Depending on the nature of the underlying disorder, assessment of the mechanical properties of the ventilatory apparatus provides several different types of information. In some instances, characterization of the mechanical abnormality provides insight into pathogenesis and affords a quantitative measure of severity. In others, once the nature of the mechanical disorder is understood, the mystery surrounding a life-threatening disorder in gas exchange may be dispelled. Finally, certain breathing patterns make sense only if the mechanical performance of the chest bellows is taken into account.

During breathing, the lungs and chest wall operate in unison. The lungs fill the chest cavity so that the visceral pleura are in contact with the parietal pleura of the chest wall. The two pleural surfaces are separated by only a thin liquid film, which provides the bond holding the lungs and chest wall together.

At the end of a normal exhalation when the respiratory muscles are at rest, the ventilatory apparatus is in a state of mechanical equilibrium. The pressure along the entire tracheobronchial tree from the airway opening to the alveoli is equal to atmospheric pressure. The tendency of the lung is to deflate, however, and lung elastic recoil is directed centripetally. This is counterbalanced by the elastic recoil of the chest wall, which is directed centrifugally to favor an increase in volume. These opposing forces generate a subatmospheric pleural pressure of about −5 cmH_2O (Fig. 10-1A). The tendency for the lung to recoil inward and for the chest wall to recoil outward is illustrated by the observation that when the chest is opened at autopsy, the lungs collapse to a nearly airless state and the thorax expands.

Although it is conventional to consider pleural pressure as a single, mean value that reflects mechanical events within the entire ventilatory apparatus, this is clearly an oversimplification on several accounts: (1) pleural pressure is not directly determinable because normally there is only a potential space between the visceral and parietal pleura; (2) on conceptual grounds, distinctions exist between surface and liquid pleural pressures; (3) pleural pressures are not uniform over the surface of the lungs, being strongly affected by gravity; and (4) transmission of pleural pressures at the surface to alveoli located at different depths and loci with the lungs depends on the structural interplay among supporting structures in the alveolar walls (interdependence), which resists any inclination of individual alveoli or even a lobule to collapse.[1] Nonetheless, the concept of mean pleural pressure, as generally used in considerations of respiratory system mechanics, has proved to be of great practical value.[2]

The contraction of the muscles of inspiration produces the forces that permit the flow of gas along the tracheobronchial tree and the expansion of the lungs and chest. The movement of air into the lungs requires a pressure difference between the airway opening and the alveoli sufficient to overcome the resistance to airflow of the tracheobronchial tree. Also, a pressure difference across the alveolar walls (between the alveoli and pleural space) must be generated to overcome elastic recoil and inflate the lungs. During spontaneous breathing, the action of the inspiratory muscles causes an increased outward pull on the chest wall.[3] As a result, the pleural pressure becomes more subatmospheric. This pressure change is transmitted to the interior of the lungs, so alveolar pressure also becomes subatmospheric (Fig. 10-1B). In contrast, during artificial ventilation with a positive-pressure ventilator, a supra-atmospheric pressure applied at the inlet to the airways creates the proper pressure gradient between the airway opening and alveoli for airflow.

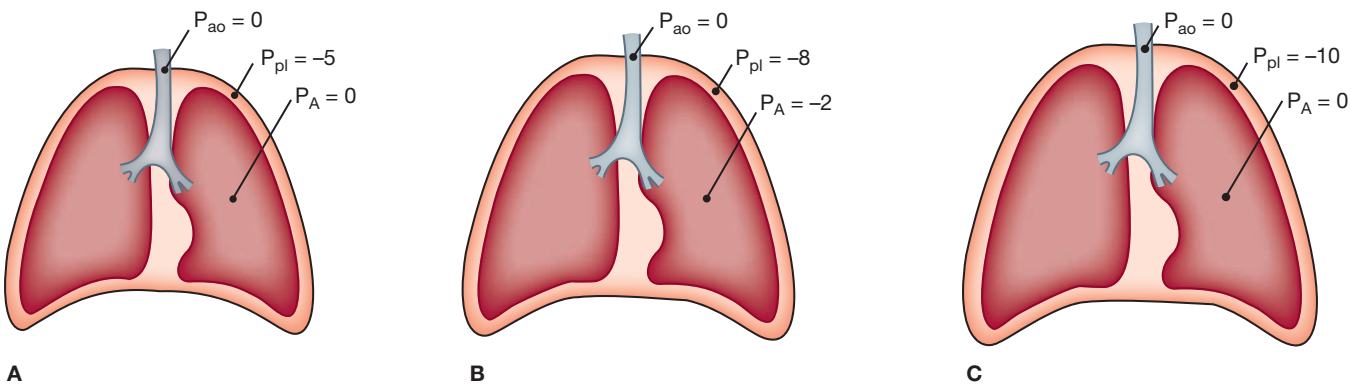

Figure 10-1 Respiratory pressures during a breathing cycle. **A.** End expiration. **B.** During inspiration. **C.** End inspiration. P_{pl}, pleural pressure; P_A, pressure in the alveoli; P_{ao}, pressure at the airway opening.

TABLE 10-1 Lung Volumes and Subdivisions

The *functional residual capacity* (FRC) is the volume of air that remains in the lungs at the end of a normal expiration.
The *tidal volume* (TV) is the volume of air that is drawn into the lungs during inspiration from the end-expiratory position (and also leaves the lungs passively during expiration) in the course of quiet breathing.
The *expiratory reserve volume* (ERV) is the maximum volume of air that can be forcibly exhaled after a quiet expiration has been completed (i.e., from the end-expiratory position).
The *residual volume* (RV) is the volume of air that remains in the lungs after a maximal expiratory effort.
The *inspiratory capacity* (IC) is the maximum volume of air that can be inhaled from the end-expiratory position. It consists of two subdivisions: tidal volume and the *inspiratory reserve volume* (IRV).
The *total lung capacity* (TLC) is the total volume of air contained in the lungs at the end of a maximum inspiration.
The *vital capacity* (VC) is the volume of air that is exhaled by a maximum expiration after a maximum inspiration.

Expansion of alveoli depends on the achievement of an appropriate distending pressure across alveolar walls. This distending pressure or transpulmonary pressure is the difference between alveolar (P_A) and pleural (P_{pl}) pressures. As shown in Figure 10-1A, the transpulmonary pressure at end expiration ($P_A - P_{pl}$) is 5 cmH_2O. At the end of inspiration (Fig. 10-1C), the lungs contain more air and the distending pressure which also represents the recoil pressure is greater.

The energy used during inspiration to overcome the elastic resistance of the lungs is stored. Expiration occurs when these forces are released. When the inspiratory muscles relax, the recoil of the lungs causes the alveolar pressure to exceed the pressure at the mouth, and air flows out of the lungs. Although expiration during quiet breathing is passive, the expiratory muscles are engaged at high levels of ventilation to assist the movement of air out of the lungs.

LUNG VOLUMES

The lung volumes and capacities (Table 10-1) are also considered elsewhere in this book (see Appendix B). The end-expiratory position of the lungs, functional residual capacity (FRC), is the major reference point for the subdivisions of lung volume. This position is set by the opposing recoil forces of the lung and chest wall when the respiratory muscles are at rest.

Total lung capacity (TLC), the total volume of air contained in the lungs after a maximal inhalation, is determined by the balance between the force-generating capacity of the inspiratory muscles and the opposing elastic recoil forces of the lung and chest wall.[4] Weakness of the muscles of inspiration or increased stiffness of the lung reduces TLC. Loss of retractive forces exerted by the lung, as in emphysema, enlarges TLC.

Residual volume (RV), the volume of air remaining in the lungs after a complete exhalation, is set by the balance between the actions of the expiratory muscle and the recoil forces of the lung, which act to decrease lung volume, and the outward recoil forces of the chest wall, which favor lung expansion. In middle-aged and older individuals, closure of airways at low lung volumes, with air trapping in the lung, is an important determinant of RV.[5]

STATIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

To assess the elastic properties of the ventilatory apparatus, it is expedient to evaluate the elastic properties of the lungs and chest separately. Elastic properties are conventionally assessed over a fixed range of volumes during periods of arrested airflow.

ELASTIC PROPERTIES OF THE LUNGS (PULMONARY COMPLIANCE)

The change in transpulmonary pressure required to effect a given change in the volume of air in the lungs is a measure of the distensibility, or compliance, of the lungs. Pulmonary compliance is calculated as the ratio of the change in lung volume to the change in transpulmonary pressure—that is,

$$C = \frac{\Delta V_L}{\Delta(P_A - P_{pl})}$$

where

C = lung compliance
$\Delta(P_A - P_{pl})$ = change in transpulmonary pressure
P_A = alveolar pressure and P_{pl} = pleural pressure
ΔV_L = change in lung volume

Compliance denotes distensibility, the ease of stretch or inflation. The inverse of compliance (i.e., elastance) refers to the stiffness or the tendency to resist distortion and to return to the original configuration when the distorting force is removed.

In practice, pulmonary compliance is determined by relating the changes in transpulmonary pressures to the changes in lung volume during interruptions in the course of an expiration after a maximal inspiration (i.e., starting from TLC).

The pressure–volume characteristics of the lung are nonlinear. As lung volume increases, the elastic elements approach their limits of distensibility, and a given change in transpulmonary pressure produces smaller and smaller increases in lung volume.[6,7] Thus, the compliance of the lung is least at high lung volumes and greatest as RV is approached (Fig. 10-2). Elastic recoil forces favoring collapse of the lung can be demonstrated throughout the range of the vital capacity, even at low lung volumes approaching the RV. If the

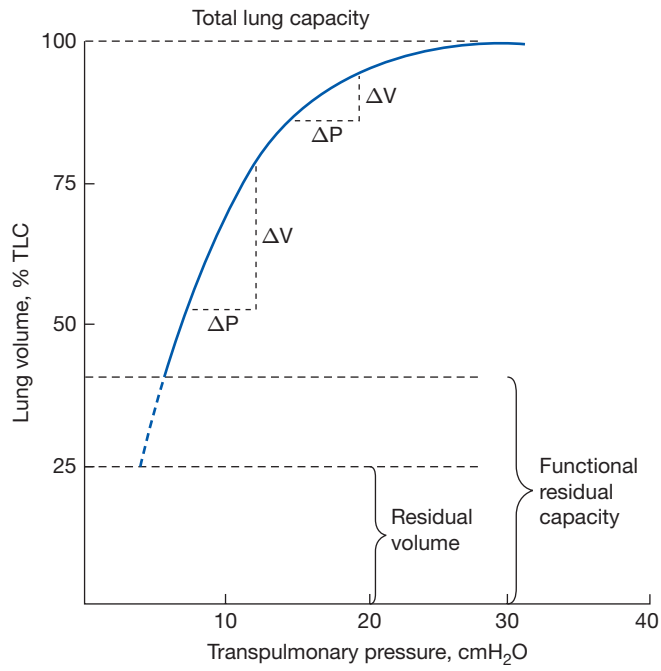

Figure 10-2 Pressure–volume curve of the lung. The static elastic recoil pressure of the lung is approximately 5 cmH_2O at FRC and 30 cmH_2O at TLC. The compliance of the lung ($\Delta V/\Delta P$) is greater at low lung volumes than at high lung volumes.

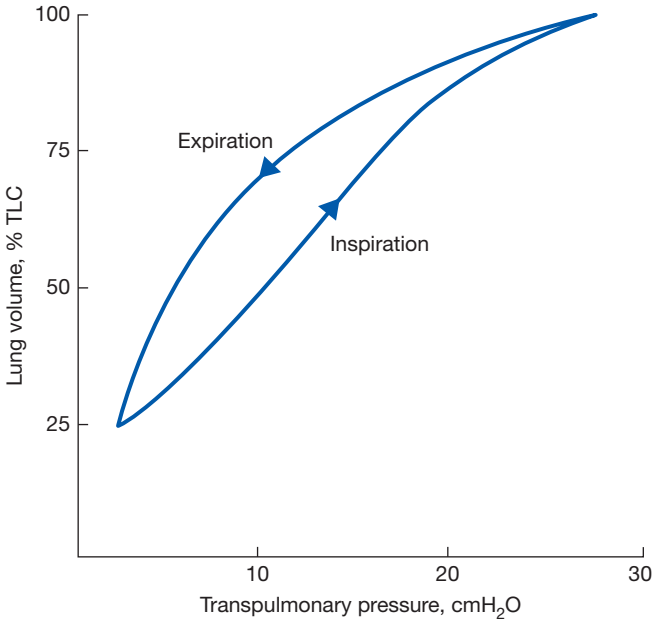

Figure 10-3 Pressure–volume curves of the lung during inspiration and expiration.

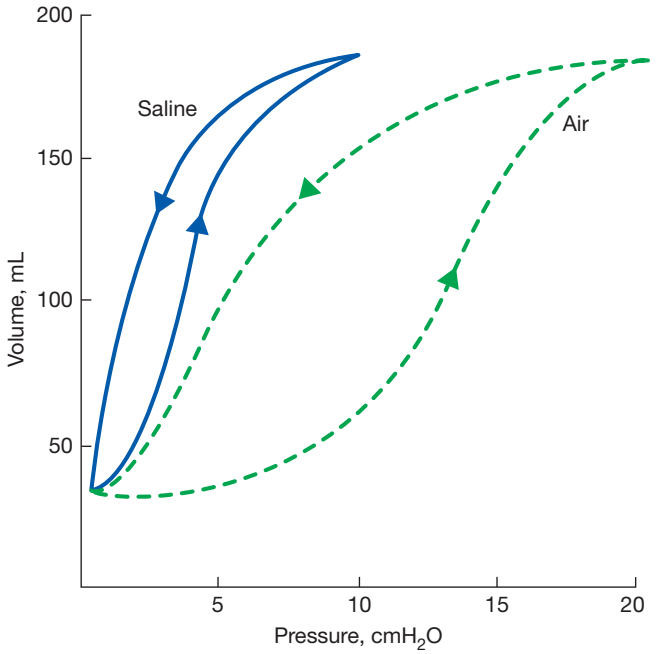

Figure 10-4 Comparison of pressure–volume relationships of air- and saline-filled excised lungs. *Arrows* directed upward indicate inflation; those directed downward indicate deflation. Since saline eliminates surface forces at the liquid–air interface without affecting tissue elasticity, the difference in pressure between the two curves, at any lung volume, is that required to overcome surface forces. To maintain a small lung volume, a large proportion of the pressure is used to overcome surface forces. In contrast, at high lung volumes a greater fraction of the pressure is used to overcome tissue elasticity.

opposing forces of the chest wall on the lungs are eliminated – for instance, by removing the lungs from the thorax or by opening the chest – the lung collapses to a near-airless state. A minimal volume of air does remain in the lungs because of closure of small airways resulting in the trapping of air in more distal airspaces.

If static measurements of transpulmonary pressure are made during lung inflation rather than deflation, the pressure–volume curve has a different configuration (Fig. 10-3). This indicates that the elastic recoil of the lung depends not only on the lung volume at which the determination is made but also on the "volume history" of the lung.[8]

■ HYSTERESIS

Differences in the pathways of the static pressure–volume curve during inspiration (when force is applied) and expiration (when force is withdrawn) are designated as hysteresis, which is a property of all elastic structures. In the lungs, it is due to the surface forces and the properties of the surface material lining the alveolar walls and also to the elastic properties of the tissues. The tissues of the lung are also subject to stress adaptation whereby over time, the pressure required to maintain a given lung volume will decline.[9] An additional factor relates to the closure of small airways at low lung volumes. Once these airways close, the lung units that they serve will not expand during inspiration until a critical opening pressure has been exceeded; only then will the closed units inflate. Recruitment of additional lung units as increasing transpulmonary pressure expands the lungs from low lung volume contributes to the hysteresis of the pressure–volume curve.

The elastic behavior of the lung depends on two factors: the physical properties of the lung tissue, per se, and the surface tension of the film lining of the alveolar walls.

■ SURFACE FORCES

The interior surfaces of the alveoli are lined by a thin liquid layer of osmophilic material. The surface tension at the air–liquid interface of the alveoli, in addition to the elastic properties of the parenchyma, contributes importantly to the elastic recoil of the lungs and acts to decrease lung compliance.[10] The cohesive forces between the molecules of the liquid lining of the alveoli are stronger than those between the film and alveolar gas, thereby causing the film to shrink to its smallest surface area. The behavior of this surface film has been examined in experimental animals by comparison of pressure–volume relationships of air-filled lungs with those of saline-filled lungs; saline eliminates the liquid–air interface without affecting elastic properties of the tissue. A lung distended with saline requires a lower transpulmonary pressure to maintain a given lung volume than a lung that is inflated with air.[11] Also, hysteresis is less in the saline-filled lung. The greater hysteresis in the air-filled lung is explained by the surface tension of the film lining the alveoli, which is higher during inflation as the film expands than it is during deflation as the film is compressed (Fig. 10-4).

By considering the alveolus to be a sphere, Laplace's law can be applied. Laplace's law states that the pressure inside a spherical structure—for example, the alveolus—is directly proportional to the tension in the wall and inversely proportional to the radius of curvature:

$$\text{Alveolar pressure} = \frac{2T}{r}$$

where

T = tension (dyn/cm)
r = radius

Abolition of the liquid–air interface by the instillation of saline into the alveolar spaces eliminates surface forces, thereby reducing the transpulmonary pressure required to maintain a given lung volume.

The surface film lining the alveoli of the lung is termed surfactant.[12] The superficial layer of the film facing the alveolar air is made up of surface-active phospholipids, notably dipalmitoyl lecithin. The deeper layer termed the hypophase consists of surface-active phospholipids linked to protein. Surfactant is generated by type

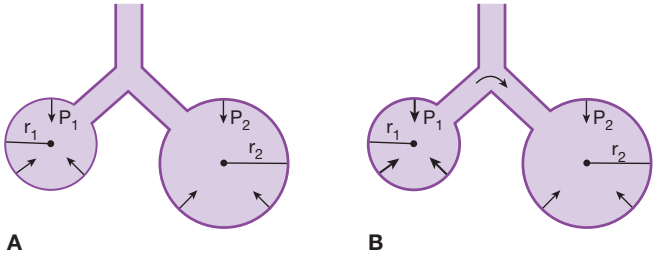

Figure 10-5 The effects of surfactant in maintaining alveolar stability. **A.** Surfactant lowers the tension of the alveolar walls at low lung volumes. Consequently, the transpulmonary pressure (P) of large and small communicating airspaces is the same. $r_1 < r_2, T_1 < T_2, P_1 \leftarrow P_2$. **B.** Without surfactant, the surface tension remains constant as lung volume changes, and the recoil pressure of small airspaces exceeds that of larger ones. As a result, small alveoli tend to empty into larger ones. $r_1 < r_2, T_1 = T_2, P_1 > P_2$.

II alveolar cells and undergoes a continuous cycle of formation, removal, and replenishment.[13]

Surfactant serves several important functions. The surface tension of surfactant is inherently low and decreases even further at low lung volumes when the surface area of the film is reduced. The minimization of surface forces, particularly at low lung volumes, minimizes the adherence of the walls of distal airways that tend to close at low lung volumes and increases the compliance of the lung and decreases the work required to inflate the lungs during the next breath. The automatic adjustment of surface tension as lung volume changes also promotes stability of alveoli at low lung volumes; if the surface tension were to remain constant instead of changing with lung volume, the transpulmonary pressure required to keep an alveolus open would increase as the radius of curvature diminished with decreasing lung volume. Therefore, small alveoli would empty into the larger ones with which they communicate, and atelectasis would be a regular occurrence (Fig. 10-5). Surfactant dysfunction as occurs with acute lung injury results in marked increases in surface tension causing stiffening and instability of alveoli and leads to alveolar collapse.

INTERDEPENDENCE AND COLLATERAL VENTILATION

The low surface tension of surfactant is not the most important determinant of alveolar stability. In reality, the alveoli form a froth rather than individual bubbles.[14] The walls of each alveolus are shared in common with those of adjacent alveoli so that contiguous airspaces attached by their connective tissue framework are tethered to one another and are not free to move independently. The tendency of any one alveolus to collapse is opposed by the traction exerted by the surrounding alveoli. This mechanical interdependence of adjacent airspaces resists the collapse of individual alveoli and serves as a stabilizing influence and ensures uniform inflation.[15] Even when a distal airway is completely obstructed, the alveoli served by the airway can still be ventilated through collateral channels between alveoli (pores of Kohn) and from bronchioles to alveoli (canals of Lambert). This collateral ventilation also prevents alveolar collapse and enhances the uniformity of ventilation, particularly in patients with lung disease.[16]

PHYSICAL PROPERTIES OF LUNG TISSUE

A number of different tissue components contribute to lung elasticity. The pleura, the intralobular septa, peripheral airway smooth muscle tone, and pulmonary vasomotor tone, as well as the tissues of the alveolar walls, play a role in shaping lung elastic recoil.

The major connective-tissue elements of the alveolar walls are the collagen and elastin fibers.[17] Elastin fibers in the alveolar walls and surrounding the bronchioles and pulmonary capillaries have a low tensile strength but can be stretched to over twice their resting length. Elastin fibers are thought to bear most of the stress in the lung at low volumes. Collagen fibers have high tensile strength but are poorly extensible and probably act to limit expansion at high lung volumes.[18] Like a stretched nylon stocking, expansion of the lungs appears to entail an unfolding and geometric rearrangement of the fibers and only slight elongation of individual fibers.

As a result of alterations in the elastin and collagen fibers in the lung, the distensibility of the lungs (measured as compliance) increases with age.[7] This is part of the normal aging process. Pulmonary compliance is also increased by the destruction of alveolar walls and the enlargement of alveolar spaces that characterize pulmonary emphysema. In contrast, the distensibility of the lungs is reduced by pulmonary fibrosis, which stiffens its interstitial tissues.[6]

ELASTIC PROPERTIES OF THE THORAX

The elastic recoil of the chest wall is such that if it were unopposed by the lungs, the chest would enlarge to approximately 70% of TLC. This position represents its equilibrium or resting position.[19] In this position (when the respiratory muscles are completely relaxed), the pressure difference across the chest wall – that is, the difference between pleural pressure and the pressure at the surface of the chest – is zero. If the chest were forced to enlarge beyond its equilibrium position by an increasingly positive pleural pressure or by the application of subatmospheric pressure at the body surface, it would, like the lung, recoil inward, resisting expansion and favoring return to its equilibrium position. Conversely, at volumes less than 70% of TLC, the recoil of the chest is opposite that of the lung and is directed outward (Fig. 10-6).[20] The chest wall can also be

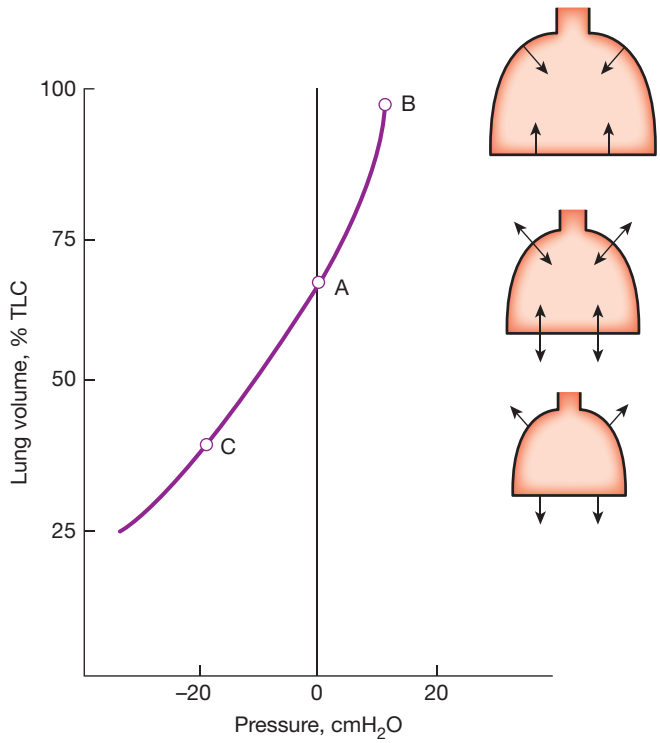

Figure 10-6 Pressure–volume relationships of the isolated chest wall. The direction of the recoil forces across the chest wall is represented by the *arrows*. The equilibrium position of the chest wall at point A, unopposed by the lungs, is approximately 70% of the total lung capacity. In this position, the pressure difference across the chest wall is zero. At larger volumes (B), there is inward recoil of the chest wall; at volumes below the equilibrium position (C), the recoil of the chest wall is directed outward, favoring expansion.

represented as a two-compartment system consisting of the rib cage and the abdomen, and volume changes can be partitioned between the two compartments.[21] Changing from the upright to the supine position at a constant overall lung volume produces a shift in volume from the abdominal to the rib cage compartment. The compliance of the rib cage is similar in the supine and upright positions, but the compliance of the abdominal compartment – particularly at high volumes – is greater in the supine position.[22]

The elastic recoil properties of the chest wall play an important role in determining the subdivisions of lung volume. They may be seriously deranged by disorders affecting the chest wall, such as marked obesity, kyphoscoliosis, and ankylosing spondylitis.

■ ELASTIC PROPERTIES OF THE RESPIRATORY SYSTEM AS A WHOLE

During breathing the lung and the chest wall move together and operate mechanically in series. At any given lung volume the elastic recoil pressure of the total respiratory system (P_{rs}) can be calculated as the algebraic sum of the pressures exerted by the elastic recoil of the lung (transpulmonary pressure) and the elastic recoil of the chest wall.[23]

Since the elastic recoil of the lung is determined (under static conditions of arrested airflow) as the difference between alveolar pressure (P_A) and pleural pressure (P_{pl}) – that is, $P_A - P_{pl}$ – and the elastic recoil of the chest wall is determined (while the respiratory muscles are completely at rest) as the difference between pleural pressure and the pressure at the external surface of the chest (P_{bs})—that is, $P_{pl} - P_{bs}$, the elastic recoil of the entire respiratory system can be expressed as the sum of the two:

$$P_{rs} = (P_A - P_{pl}) + (P_{pl} - P_{bs}) = P_A - P_{bs}$$

Thus, a measure of the elastic recoil of the respiratory system is supplied by the alveolar pressure, provided that the respiratory muscles are completely at rest and the pressure of the body surface is at atmospheric levels. In the absence of airflow into or out of the lung and when the glottis is open, alveolar pressure corresponds to the pressure at the mouth.

Relaxation Pressure–Volume Curve

The elastic properties of the entire respiratory system can be determined from the relaxation pressure–volume curve (Fig. 10-7). FRC represents the equilibrium position of the lung–chest wall system while the respiratory muscles are relaxed. At this point, the opposing recoils of the lung and chest wall are of equal magnitude, and the recoil pressure of the entire respiratory system is zero. With increases in lung volume above FRC, the recoil pressure of the entire system becomes positive, owing to the combination of an increase in centripetal elastic recoil of the lungs and a decrease in the centrifugal recoil of the chest wall. The net effect favors a decrease in lung volume, and lung volume can be maintained with the airway open to the atmosphere only by the action of the inspiratory muscles. As lung volume exceeds 75% of TLC, the recoil of the chest wall also becomes centripetal and the recoil pressure of the chest wall adds to the inward forces acting to diminish lung volume. TLC represents the lung volume at which the inward passive elastic recoil pressure of the respiratory system reaches the maximum force that can be generated by the inspiratory muscles.

At lung volumes below FRC, when the centrifugal recoil of the chest wall exceeds the reduced centripetal recoil of the lungs, the relaxation pressure is negative and this net effect favors an increase in lung volume. Lung volumes below FRC are achieved and maintained by the muscles of expiration.

A switch from the sitting to the supine position decreases FRC because of the effects of gravity. In the upright position, gravity pulls the abdominal contents away from the chest wall. In contrast, in the supine position, the push of the abdominal contents against the diaphragm decreases the centrifugal recoil of the chest wall. The chest wall pressure–volume curve – and, consequently, the pressure–volume curve of the entire respiratory system – is displaced to the right.

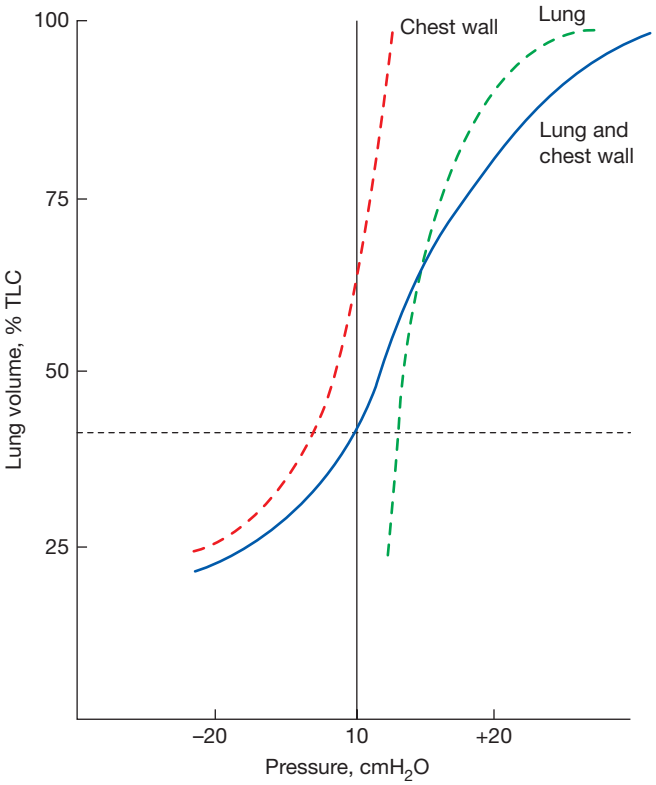

Figure 10-7 Relaxation pressure–volume curves. The lungs and the chest wall function mechanically in series so that the elastic recoil pressures of the total respiratory system, represented by the *solid line*, is the algebraic sum of the separate recoil pressures of the lung and chest wall. At the volume represented by the horizontal *dashed line*, the recoil pressures of the lung and chest wall are equal but in opposite directions. Consequently the net recoil pressure is zero, and the respiratory system is in a position of equilibrium.

DYNAMIC MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

The total nonelastic resistance of the lungs consists of the resistance of the airways to airflow (airway resistance), defined in terms of the driving pressure and the resulting rate of airflow, and the frictional resistance of the lung tissues to displacement during breathing (tissue resistance). Normally, tissue resistance makes up only 10% to 20% of the total pulmonary nonelastic resistance, but in diseases of the pulmonary parenchyma, it may increase considerably.

■ AIRWAY RESISTANCE

A large fraction of the resistance to airflow is in the upper respiratory tract, including the nose, mouth, pharynx, larynx, and trachea. During nasal breathing, the nose constitutes up to 50% of total airway resistance. During quiet mouth breathing, the mouth, pharynx, larynx, and trachea constitute 20% to 30% of the airway resistance; but they account for up to 50% of the total airway resistance when minute ventilation increases—during vigorous exercise, for example. Most of the remainder of airway resistance is in medium-sized lobar, segmental, and subsegmental bronchi up to about the seventh generation of airways.[24,25] Additional branching distally causes a progressive increase in the number of airways in

any generation. While the caliber of individual airways in daughter branches compared to the parent branch is reduced, the total cross-sectional area of all of the airways in a given generation increases tremendously with successive generations along the tracheobronchial tree. Consequently, in the normal lung, the small peripheral airways, particularly those less than 2 mm in diameter, constitute only about 10% to 20% of the total airway resistance.[26]

Airway Caliber

The airways, like the pulmonary parenchyma, exhibit elasticity and can be compressed or distended. Therefore, the diameter of an airway varies with the transmural pressure applied to that airway—that is, the difference between the pressure within the airway and the pressure surrounding the airway. The pressure surrounding intrathoracic airways approximates pleural pressure, since these airways are tethered to the parenchymal tissue and are exposed to the expansive forces that are active in overcoming the elastic recoil of the lung.[1]

Airway resistance varies inversely with lung volume. As the lung volume increases, the elastic recoil forces of the lung increase; the traction applied to the walls of the intrathoracic airways also increases, widening the airways and decreasing their resistance to airflow. Conversely, at low lung volumes, the transmural airway pressure is lower and airway resistance increases.[27,28] If the elastic recoil of the lung is reduced – by destruction of alveolar walls in pulmonary emphysema, for instance – the transmural airway pressure at any given lung volume decreases correspondingly; the airways are narrower and airway resistance is greater even though there is no disease of the airways per se.

The effects of a change in transmural pressure on airway caliber depend on the compliance of the airways—which, in turn, is determined by their structural support. The trachea, for example, is almost completely surrounded by cartilaginous rings, which tend to prevent complete collapse even when the transmural pressure is negative. The bronchi are less well supported by incomplete cartilaginous rings and plates, whereas the bronchioles lack cartilaginous support. All airways can be stiffened, albeit to different degrees, by contraction of smooth muscle in their walls.

In patients with airway disease, mucosal edema, hypertrophy and hyperplasia of mucus glands, increased elaboration of mucus, and hypertrophy of smooth muscle further compromise airway caliber and increase airway resistance.

Neural pathways and humoral mechanisms are also important in controlling airway smooth muscle tone and regulating airway caliber. Cholinergic parasympathomimetic stimulation originating from the vagus nerve and mediated through the release of acetylcholine causes airway smooth muscle contraction and airway narrowing. Noncholinergic parasympathetic activity may play a role in airway smooth muscle relaxation through the release of vasoactive intestinal peptide and the subsequent production of nitric oxide.[29] Beta-adrenergic receptors in bronchial smooth muscle activated by various sympathomimetic agents promote airway smooth muscle relaxation and airway dilatation.[30]

Pressure–Flow Relationships: Theoretical Considerations

In the lungs, pressure–flow relationships are extremely complicated because the airways consist of a system of irregular branching tubes that are neither rigid nor perfectly circular. For purposes of simplification, pressure–flow relationships in rigid tubes are generally regarded as a model for those in the airways.

The driving pressure that produces flow of air into and out of the lung must suffice to overcome friction and to accelerate the air. Acceleration in the lungs is of two types: local (i.e., changes in the rate of airflow with time when flow is initiated) and convective (i.e., acceleration of molecules of air over distance while flow is constant). The driving pressure required for convective acceleration

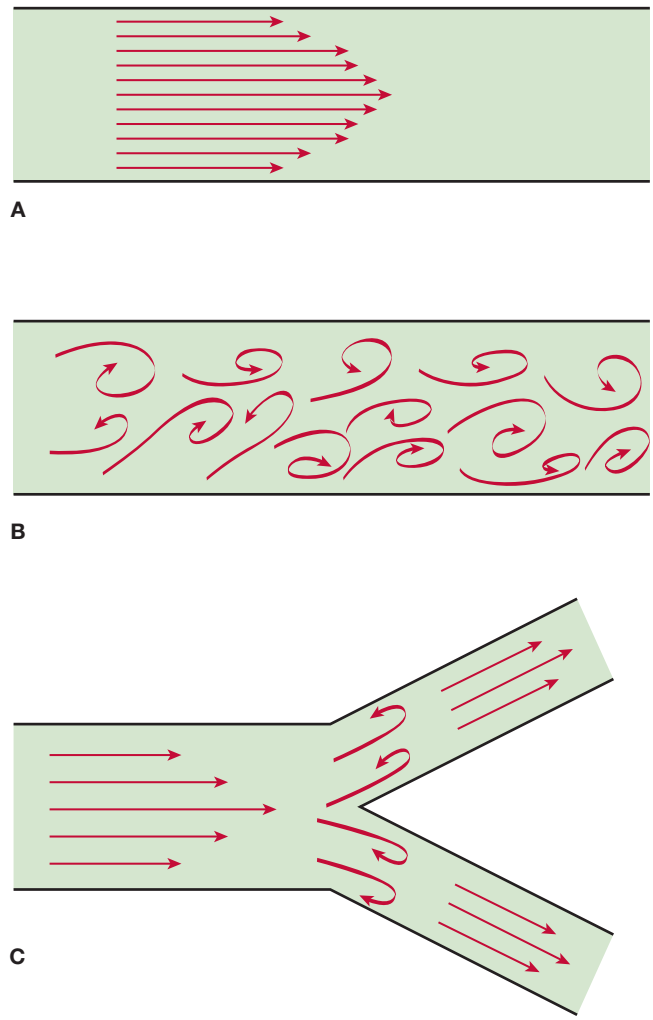

Figure 10-8 Patterns of airflow. **A.** Laminar flow. **B.** Turbulent flow. **C.** Transition flow that occurs at bifurcations.

is proportional to the gas density and to the square of the flow rate. It is important during expiration because, as air moves downstream from the alveoli toward the airway opening, the total cross-sectional airway diameter decreases; therefore, molecules of air must accelerate through the converging channels even though the overall flow rate remains unchanged. Also, the driving pressure that produces high expiratory flow rates at large lung volume serves for convective acceleration rather than for overcoming friction.[31,32]

The driving pressure required to overcome friction depends on the rate and the pattern of airflow. Two major patterns of airflow warrant special consideration: laminar and turbulent. Laminar flow is characterized by streamlines that parallel the sides of the tube and are capable of sliding over one another. Also, because the streamlines at the center of the tube move faster than those closest to the walls, the flow profile is parabolic (Fig. 10-8). The pressure–flow characteristics of laminar flow depend on the length (l) and the radius (r) of the tube and the viscosity of the gas (η) according to Poiseuille's equation:

$$\Delta P = \frac{\dot{V} 8 \eta l}{\pi r^4}$$

where

ΔP = the driving pressure (pressure drop between the beginning and the end of the tube)
$\dot{V}$ = the flow rate that the driving pressure produces
r = the radius of the tube

The critical importance of tube radius in determining the driving pressure for a given flow is apparent in the previously mentioned equation. If the radius of the tube is halved, the pressure that is required to maintain a given flow rate must be increased 16-fold. Laminar flow patterns occur only in small peripheral airways, where, because of the enormous overall cross-sectional area, flow through the individual airways is exceedingly slow.

Turbulent flow occurs at high flow rates and is characterized by a complete disorganization of streamlines, so that the molecules of gas move laterally, collide with each other, and change velocities. Under these circumstances, pressure–flow relationships change. In contrast to laminar flow, the rate of turbulent airflow is no longer proportional to the driving pressure. Instead, the driving pressure to produce a given rate of airflow is proportional to the square of flow and is dependent on gas density. Turbulent flow occurs regularly in the trachea.

At lower flow rates during expiration – particularly at branches in the tracheobronchial tree, where flow in two separate tubes comes together into a single channel – the parabolic profile of laminar flow becomes blunted, the streamlines separate from the walls of the tube, and minor eddy formation develops. This is referred to as a mixed, or transitional, flow pattern. In a mixed pattern of airflow, the driving pressure for a given flow depends on both the viscosity and the density of the gas.

Whether airflow is laminar or turbulent is predictable from the Reynolds number (Re), a dimensionless number that depends on the average velocity ($\overline{v}$), the density of the gas (ρ), the viscosity of the gas (η), and the diameter of the tube (D), so that

$$\mathrm{Re} = \frac{\overline{v} D \rho}{\eta}$$

In straight, smooth, rigid tubes, turbulence occurs when the Reynolds number exceeds 2000. Therefore, turbulence is most apt to occur when the average velocity is high, gas density is high, gas viscosity is low, and the tube diameter is large. Since most of the resistance to airflow in the normal lung is in large airways, where airflow is largely turbulent and where resistance is density dependent, breathing a mixture of 80% helium and 20% oxygen (a mixture that is 64% less dense than air) reduces the Reynolds number favoring a conversion from turbulent to laminar flow. Consequently airflow increases at a given driving pressure and airway resistance falls.[24]

Calculation of Airflow Resistance

The driving pressure along the tracheobronchial tree – that is, the difference between alveolar pressure and the pressure at the airway opening (mouth) that is required to produce a given rate of airflow into the lungs – provides a measure of the flow resistance of the airways, according to the equation

$$R_{aw} = \frac{P_A - P_{ao}}{\dot{V}}$$

where

$\dot{V}$ = airflow (L/s)
P_A = alveolar pressure (cmH_2O)
P_{ao} = airway-opening pressure (cmH_2O)
R_{aw} = airway resistance (cmH_2O/L/s)

Flow–Volume Relationships

Considerable insight into the flow-resistive properties of the airways can be obtained from the relationship between airflow and lung volume during maximal expiratory and inspiratory maneuvers.[33] In practice, a person inhales maximally to TLC; then exhales as forcefully, rapidly, and completely as possible to RV; and then returns to TLC by a rapid, forceful inhalation (Fig. 10-9). During the maximal

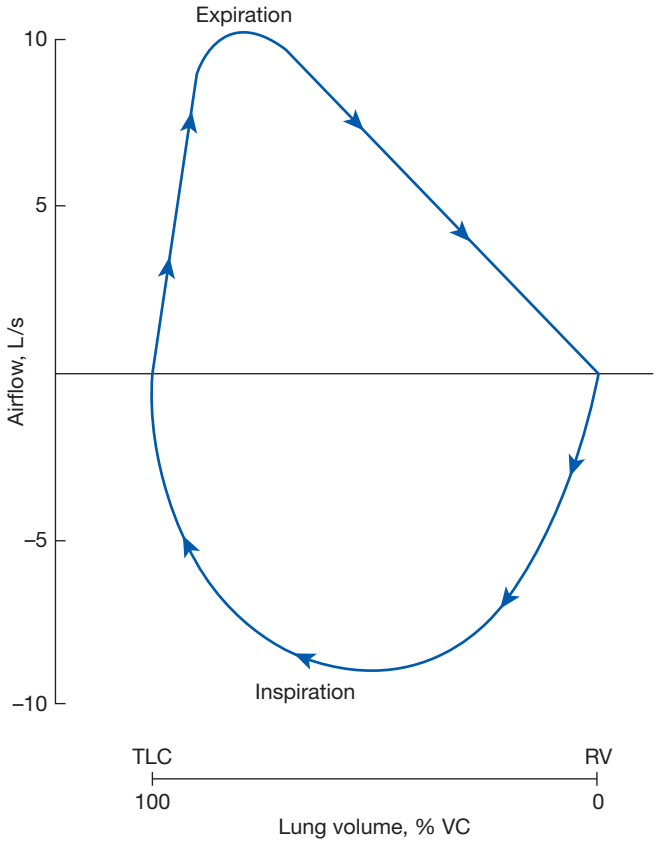

Figure 10-9 Maximal expiratory and inspiratory flow–volume loop.

expiration, the rate of airflow peaks at a lung volume that is close to the TLC; as the lung volume decreases and intrathoracic airways narrow, airway resistance increases, and the rate of airflow decreases progressively.

During maximal inspiration, the pattern of airflow is different. Because of the markedly negative pleural pressure and large transmural airway pressure, the bronchi are wide, and their calibers increase further as lung volume increases. Consequently, inspiratory flow becomes high while the lung volume is still low and remains high over much of the vital capacity, even though the force generated by the inspiratory muscles decreases as they shorten.

A family of flow–volume loops is produced by repeating full expiratory and inspiratory maneuvers over the entire range of the vital capacity using different levels of effort (Fig. 10-10). The greater the effort exerted during inspiration, the greater is the rate of airflow over the entire range—that is, from RV to TLC. Similarly, during expiration, the rate of airflow increases progressively with increasing effort at large lung volumes close to TLC. At intermediate and low lung volumes, the rate of expiratory airflow reaches a maximum while the effort expended is only moderate; thereafter, airflow does not increase further despite increasing expiratory efforts.

■ ISOVOLUME PRESSURE–FLOW CURVES

Separation of the effects of increasing effort from those of changes in lung volume on the rate of airflow during expiration can be accomplished by using isovolume pressure–flow curves (Fig. 10-11). During repeated expiratory maneuvers performed with varying degrees of effort, simultaneous measurements are made of airflow rate, lung volumes, and pleural pressure. For each lung volume the rate of airflow is plotted against the pleural pressure, as an index of the degree of effort.[34]

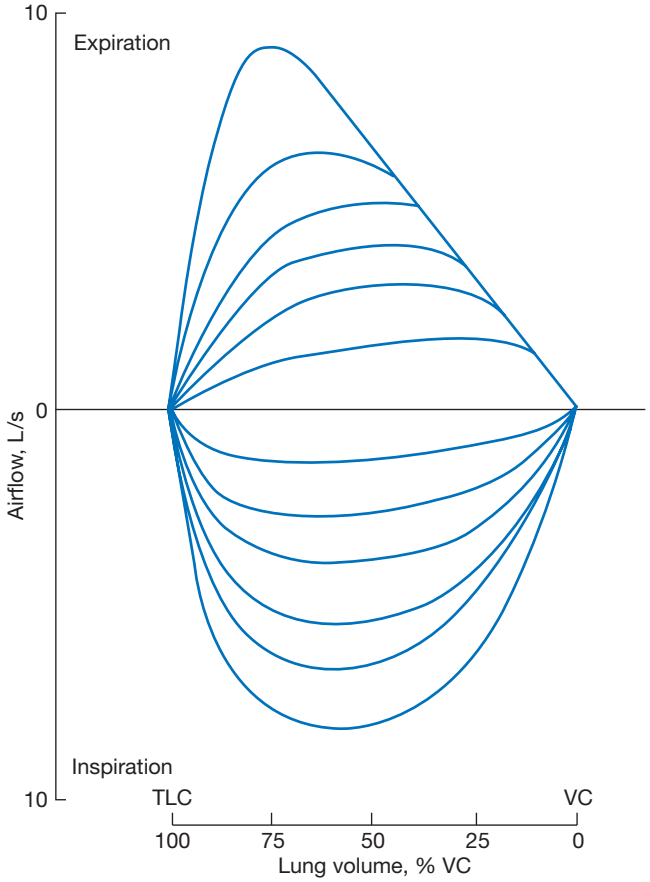

Figure 10-10 Series of flow–volume loops constructed from complete inspiratory and expiratory maneuvers repeated at different levels of effort.

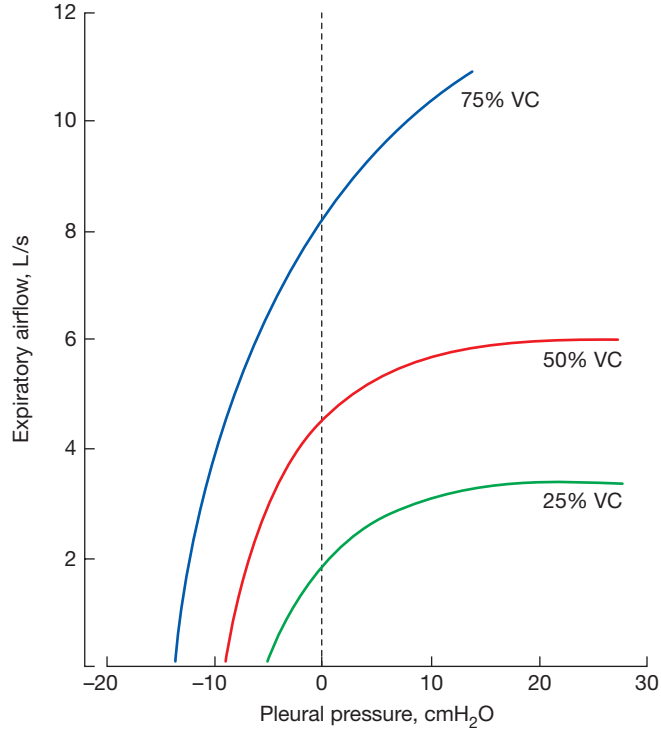

Figure 10-11 Isovolumetric pressure–flow curves. At lung volumes greater than 75% of the vital capacity, airflow is effort dependent; that is, airflow increases progressively with increasing effort. At lower lung volumes, airflow is effort independent; that is, airflow becomes fixed at a maximum level and does not increase despite further increases in effort.

As expiratory effort is increased at any given lung volume, the pleural pressure increases toward, and then exceeds, atmospheric pressure; correspondingly, the rate of airflow increases. At lung volumes above 75% of the vital capacity, airflow increases progressively as pleural pressure increases; it is considered to be effort dependent. In contrast, at lung volumes below 75% of the vital capacity, the rate of airflow levels off as the pleural pressure exceeds atmospheric pressure and becomes fixed at a maximum level. Thereafter, further increases in effort, and in pleural pressure, effect no further increase in the rate of airflow; at these lower lung volumes, airflow is considered to be effort independent. Since the rate of airflow remains constant despite increasing driving pressure, it follows that the resistance to airflow must be increasing in direct proportion to the increase in driving pressure. This increase in resistance is attributed to compression and narrowing of large intrathoracic airways.

EQUAL PRESSURE POINT THEORY: DYNAMIC COMPRESSION OF AIRWAYS

To illustrate the mechanisms that normally limit airflow during a maximal expiratory maneuver, it is useful to consider a model of the lung where the alveoli are represented by an elastic sac and the intrathoracic airways by a compressible tube, both enclosed within a pleural space (Fig. 10-12).[35]

At a given lung volume, when there is no airflow (as during breath holding with the glottis open), pleural pressure is subatmospheric, counterbalancing the elastic recoil pressure of the lung. The alveolar pressure (P_A), which is the sum of the recoil pressure of the lung and pleural pressure (P_{pl}), is zero (Fig. 10-12A). Since airflow has ceased, the pressure along the entire airway is also atmospheric.

At the same lung volume during a quiet expiration, pleural pressure is less subatmospheric. Since lung volume and the elastic recoil pressure of the lung are unchanged, alveolar pressure is now positive with respect to atmospheric pressure; airflow occurs. The alveolar pressure is gradually dissipated along the airway in overcoming resistance so that the pressure at the airway opening (P_{ao}) is zero. All along the airway, however, the airway pressure exceeds pleural pressure and the transmural pressure is positive; the airways remain open, and flow continues (Fig. 10-12B).

A forceful expiration raises pleural pressure above atmospheric pressure and further increases alveolar pressure (Fig. 10-12C). Airway pressure again falls progressively from the alveolus toward the airway opening. But at some point along the airway – the equal pressure point – the drop in airway pressure is equal to the recoil pressure of the lung; intraluminal pressure and the pressure surrounding the airways are equal and the same as pleural pressure. Downstream (i.e., toward the airway opening) the transmural pressure is negative, because the intraluminal airway pressure is less than pleural pressure; the airways are subjected to dynamic compression.

The equal pressure point divides the airways into two components arranged in series: an upstream segment, from the alveoli to the equal pressure point, and a downstream segment, from the equal pressure point to the airway opening. With increasing expiratory effort as the pleural pressure becomes more and more positive with respect to atmospheric pressure, the equal pressure point moves upstream. Once maximum expiratory flow is achieved, the position of the equal pressure point becomes fixed in the region of the lobar or segmental bronchi. Further increase in pleural pressure by increasing expiratory force simply produces more compression of the downstream segment without affecting airflow through the upstream segment.

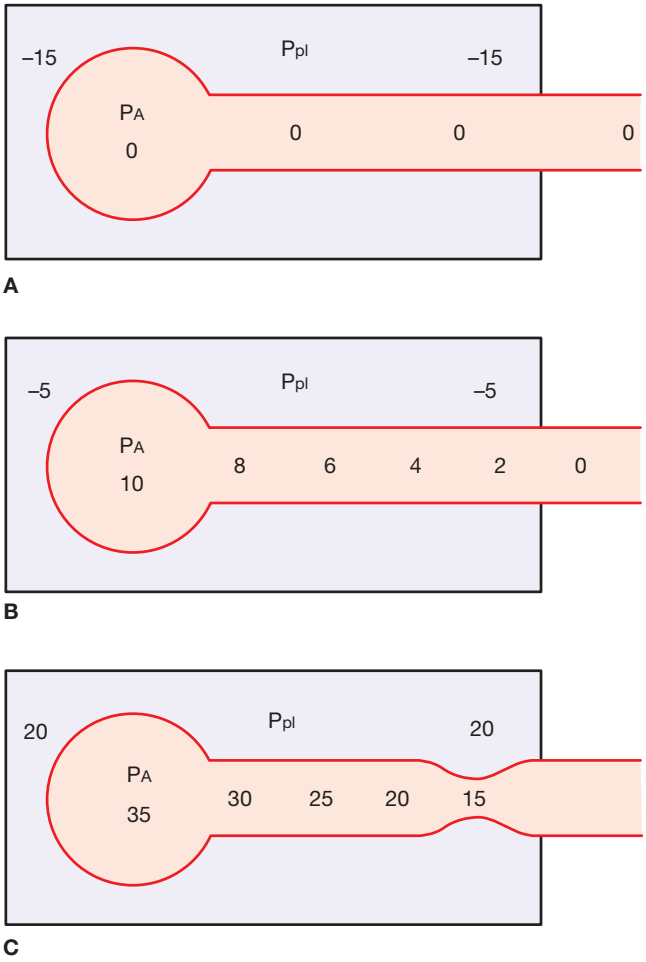

Figure 10-12 Schema of the distribution of pleural, alveolar, and airway pressures at rest and during expiration, illustrating the equal pressure point concept. **A.** End expiration. **B.** Quiet expiration. **C.** Forced expiration.

The driving pressure of the upstream segment – that is, the pressure drop along the airways of that segment – is equal to the elastic recoil of the lung. The maximum rate of airflow during forced expiration ($\dot{V}_{max}$) can be expressed in terms of the elastic recoil pressure of the lung (P_L) and the resistance of the upstream segment (R_{us}), as follows:

$$\dot{V}_{max} = \frac{P_L}{R_{us}}$$

Measurements of the rate of airflow during force expiration form the basis of many tests used to assess the flow-resistive properties of the lung. It is evident, however, that the maximum rate of expiratory airflow depends on many factors: The lung volume at which airflow is determined; the force of expiration (particularly at high lung volumes [i.e., above 75% of vital capacity]); the elastic recoil pressure of the lung; the cross-sectional area of large airways; the collapsibility of large intrathoracic airways; and the resistance of small peripheral airways.

WAVE SPEED LIMITATION THEORY

An alternative explanation for airflow limitation during forced expiration is based on principles of wave speed theory.[36] The wave speed theory proposes that flow is limited by the velocity of propagation of pressure waves along the wall of the tube. The velocity of propagation (v) varies proportionally with the cross-sectional area of the tube (A) and with airway stiffness. At a site where the linear velocity of gas molecules equals the velocity of propagation of pressure waves that is, wave speed, a choke point develops, preventing further increases in flow rate. The flow rate at wave speed is a function of the cross-sectional area of the tube at the choke point (A) and the stiffness of the choke segment (dP/dA), where P is the transmural airway pressure. Where choke points occur in the tracheobronchial tree depends on the lung volume: at large lung volumes, a choke point is situated in the vicinity of the lower trachea; at lower lung volumes, choke points develop more upstream along the bronchial tree. Extension of the neck exerts longitudinal tension and stiffens the trachea, increases wave velocity, and increases maximum expiratory flow rates at large lung volumes.[37]

MECHANICAL DETERMINANTS OF REGIONAL VENTILATION

The lung is not homogeneous, and the mechanical properties of all airways in a given generation and of all alveoli are not the same. This results in important nonuniformities of regional ventilation.

Pleural pressure in the upright person is more subatmospheric at the apex than at the base of the lung, because of the effects of gravity and the weight of the lung.[38] Pleural pressure topography and regional lung expansion are also determined by the shape of the chest wall and by the forces required for the lung to conform to the thoracic cavity shape[9].[39] The rate of increase in pleural pressure from top to bottom is approximately 0.25 cmH_2O per centimeter of vertical distance. Consequently, the transpulmonary pressure – that is, alveolar pressure minus pleural pressure – is greater at the top than at the bottom of the lung. Therefore, at most lung volumes, the alveoli at the lung apexes are larger (more expanded) than those at the lung bases (Fig. 10-13).

Because of regional variations in lung compliance, ventilation is not uniform, even in the normal lung. With the use of external scanners after the inhalation of a radioactive gas, such as ^{133}Xenon, it has been demonstrated that within the range of normal tidal volume, lung units are better ventilated, and ventilation per alveolus is greater, at the bottom than at the top of the lung.[40] This is because alveoli near the top of the lung are positioned on the upper, flatter part of the pressure–volume curve and are less compliant than alveoli at the lung bases positioned on the lower, steeper portion of their pressure–volume curves.

At low lung volumes (i.e., near the RV), pleural pressure at the bottom of the lung actually exceeds airway pressure and leads to closure of peripheral airways (Fig. 10-13). During a breath taken from RV, air that enters the lungs first is preferentially distributed to the lung apexes.

The distribution of ventilation within the lungs and the volume at which airways at the lung bases begin to close can be assessed by the single-breath N_2 washout test.[41] This test requires a maximum expiration into an N_2 meter after a maximal inspiration of pure O_2 from RV; the changing concentration of nitrogen is plotted against expired lung volume (Fig. 10-14). Because the inspiration starts at the RV,

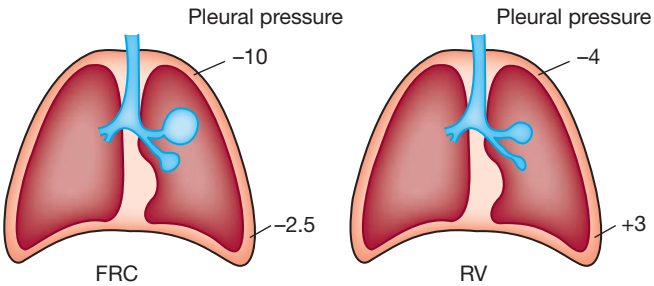

Figure 10-13 Pleural pressure gradients in the upright lung at FRC (left) and at RV (right). The effect of the gradient on alveolar volumes is shown schematically for each case.

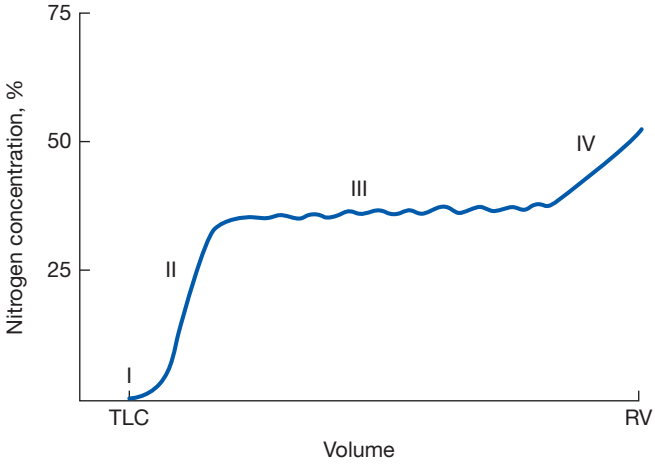

Figure 10-14 Tracing of expired nitrogen concentration during a slow expiration from TLC to RV after a full inspiration of pure O_2. The four phases are indicated. For further details, see text.

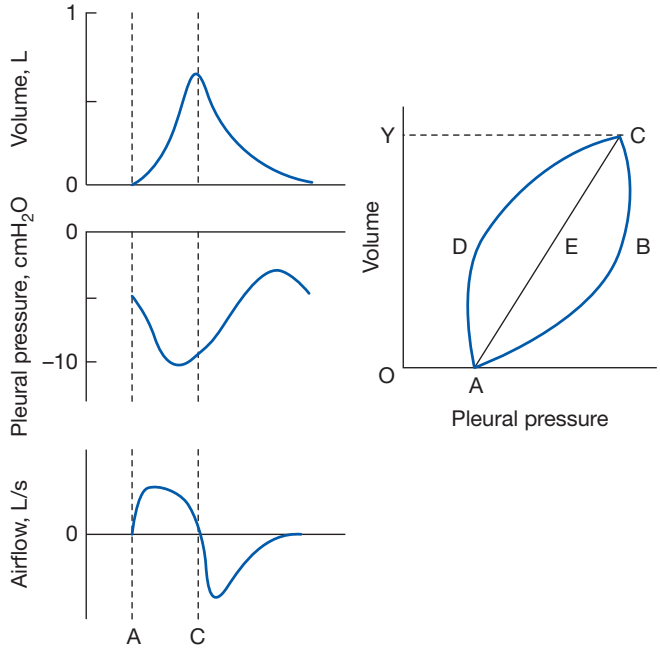

Figure 10-15 Individual tracings of tidal volume, pleural pressure, and airflow, taken simultaneously during a single complete breath, are shown on the left. The relationship between volume and pleural pressure is illustrated by the dynamic pressure–volume loop on the right. Dynamic compliance is determined as the slope of the line AEC. The work of breathing during inspiration to overcome the elastic forces of the lung is represented by the area of the trapezoid OAECY, and the work required to overcome nonelastic forces is represented by the area of the loop ABCEA. The loop AECDE represents the work required to overcome airflow resistance during expiration.

the initial portion of the breath containing dead-space gas, rich in nitrogen, is distributed to alveoli in the upper lung zones. The rest of the breath, which contains only O_2, goes preferentially to lower lung zones. Consequently, the concentration of nitrogen is lower in the alveoli at the lung bases than in the alveoli at the apexes of the lungs.

During expiration, the initial portion of the breath consists of O_2 remaining in the large airways; it contains no N_2 (phase I). As alveolar gas containing N_2 begins to be washed out, the concentration of N_2 in the expired air rises to reach a plateau. The portion of the curve where the concentration of N_2 rises steeply is phase II. The plateau is phase III. Phase III depends on the uniformity of the distribution of ventilation in the lung. If gas enters and leaves alveoli throughout the lung synchronously and equally, phase III is flat. But when the distribution of ventilation is nonuniform, so that gases coming from different alveoli have different N_2 concentration, phase III slopes upward.

At low lung volumes, airways at the lung bases close; only alveoli at the top of the lung continue to empty. Since the concentration of N_2 in the alveoli of upper lung zones is higher than in the alveoli at the lung bases, the slope of the N_2–volume curve increases abruptly, marking the start of phase IV. The volume, above RV, at which phase IV begins is termed the closing volume.[42]

The closing volume increases with advancing age. With diseases of the peripheral airways closing volume may rise to levels above FRC. This results in lung units that are perfused but poorly ventilated leading to reductions in arterial oxygenation.[43,44]

■ DYNAMIC COMPLIANCE OF THE LUNGS

The relationship between changes in volume and changes in pleural pressure during a normal breathing cycle is shown in Figure 10-15. Airflow momentarily ceases at the end of expiration (A) and at the end of inspiration (C); the change in pleural pressure between these two points reflects the increasing elastic recoil of the lung as the volume of air in the lungs increases. The slope of the line connecting the end-expiratory and end-inspiratory points (AEC in the figure) on a pressure–volume loop provides a measure of the dynamic compliance of the lungs.

In normal persons, dynamic compliance closely approximates inspiratory static lung compliance and remains essentially unchanged even when breathing frequency is increased up to 60 breaths per minute. This indicates that lung units that are parallel with each other normally fill and empty uniformly and synchronously, even when airflow is high and the change in lung volume is rapid. The rate of filling and emptying of a lung unit depends on its time constant—that is, the product of its resistance and compliance. Lung units with high resistance and high compliance take longer to fill and empty more slowly compared to units with low resistance and low compliance. In order for the distribution of ventilation in parallel lung units to be independent of the rate of airflow, the resistance and compliance of these units must be matched so that the time constants of individual units throughout the lungs are approximately the same. The time constants of lung units distal to airways 2 mm in diameter are approximately 0.01 second, and fourfold differences in time constants are necessary to cause dynamic compliance to become frequency dependent.[26]

Patchy narrowing of small peripheral airways produces regional differences in time constants. At low breathing frequencies, when the rate of airflow is low, ventilation is fairly evenly distributed. As the breathing frequency increases, however, ventilation tends to be distributed to areas that offer the least resistance to airflow. Therefore, lung units fed by narrowed airways receive proportionally less ventilation than do areas of the lung where the airways remain normal; the change in pleural pressure required to effect the same change in overall lung volume increases. As a result, the dynamic compliance falls.

Measurements of frequency dependence of dynamic compliance are time-consuming and technically difficult, but this test has proved useful in the diagnosis of obstruction in small peripheral airways when results of other conventional tests of lung mechanics are still within normal limits.[45]

WORK OF BREATHING

During breathing, the respiratory muscles work to overcome the elastic, flow-resistive, and inertial forces of the lungs and chest

wall.[46] The elastic work of breathing is done to overcome the elastic recoil of the lungs and chest wall; the resistive work is done in overcoming the resistance of airways and tissues. The mechanical work of breathing can be determined by relating the pressure exerted across the respiratory system to the resulting change in volume, since the product of pressure (P) and volume (V) has the dimension of work, according to the equation

$$\text{work} = \int P \, dV$$

Recordings of pleural pressure and lung volume changes during spontaneous breathing can be used to measure the work of breathing; the work of breathing performed on the lungs can be determined from the area of the dynamic pressure–volume loop (Fig. 10-15) and fractionated into its elastic and resistive components. During inspiration, the work done to overcome the elastic forces of the lung is determined from the area of the trapezoid OAECY (Fig. 10-15). The area of the loop ABCEA is the work in overcoming nonelastic forces during inspiration, and the area of the loop OABCY is the total work of breathing during inspiration.

Expiration during quiet breathing is passive, since the elastic recoil of the lung suffices to overcome the expiratory airflow resistance. Some of the stored elastic energy is also used to overcome inspiratory muscle activity that persists into the expiratory phase of breathing. At high levels of ventilation and when airway resistance is increased, additional mechanical work during expiration is required to overcome nonelastic forces. Under these circumstances, the pleural pressure exceeds atmospheric pressure, and the loop AECDA extends beyond the confines of the trapezoid OAECY (Fig. 10-15).

The work of breathing at any given level of ventilation depends on the pattern of breathing. Large tidal volumes increase the elastic work of breathing, whereas rapid breathing frequencies increase the work against flow-resistive forces. During quiet breathing and during exercise, people tend to adjust tidal volume and breathing frequency to values that minimize the force and the work of breathing.[47] Similar adjustments are also seen in patients with pulmonary disorders. Patients with pulmonary fibrosis, which is characterized by an increased elastic work of breathing, tend to breathe shallowly and rapidly; those with airway obstruction and increased nonelastic work of breathing usually breathe more deeply and slowly.

The work done on the chest wall during breathing is calculated by subtracting the work performed on the lung from the total mechanical work of breathing. The total mechanical work of breathing cannot be readily measured during spontaneous breathing because the respiratory muscles that perform the work also make up part of the resistance offered by the chest wall. But the total mechanical work can be determined during artificial ventilation by using either intermittent positive airway pressure or negative pressure applied to the chest, provided that the respiratory muscles are completely at rest. For this determination, the change in lung volume is related to the pressure difference across the respiratory system—that is, differential pressure between the mouth and the body surface. Disturbances of the chest wall, such as kyphoscoliosis and obesity, increase the work of breathing severalfold.

■ OXYGEN COST OF BREATHING

In order to perform their work, the respiratory muscles require O_2. The O_2 cost of breathing, which reflects the energy requirements of the respiratory muscles, provides an indirect measure of the work of breathing.[48,49] The O_2 cost of breathing is assessed by determining the total O_2 consumption of the body at rest and at an increased level of ventilation produced by voluntary hyperventilation or CO_2 breathing. Provided there are no other factors acting to increase O_2 consumption, the added O_2 uptake is attributed to the increased metabolism of the respiratory muscles.

The O_2 cost of breathing in normal subjects is approximately 1 mL/L of ventilation and constitutes less than 5% of the total O_2 consumption. At high levels of ventilation, however, the O_2 cost of breathing becomes progressively greater. There is a dramatic increase in the O_2 cost of breathing at high levels of ventilation in some diseases of the lung, such as pneumonia, pulmonary fibrosis, and emphysema, and in disorders of the chest wall, such as obesity and kyphoscoliosis. The increase in the energy requirement of the respiratory muscles during increased ventilation, concomitant with a decrease in O_2 supply secondary to arterial hypoxemia, contributes to muscle fatigue, thereby limiting the amount of exertion that these patients can sustain.[3]

CHAPTER 11
Control of Ventilation

Frank J. Jacono
Xavier Soler
Atul Malhotra

INTRODUCTION

Breathing is a rhythmic motor act, which is under both conscious and automatic control. This system maintains numerous controlled variables within their homeostatic ranges, but is also responsible for rapidly changing ventilation in response to often unpredictable stimuli. We will discuss the anatomy and physiology of the ventilatory control system, then address integrated responses and illustrative examples of adaptation and dysfunction in the setting of selected disease states.

ANATOMY AND PHYSIOLOGY

The respiratory control system, broadly speaking, comprises a controller, sensors, and a plant (Fig. 11-1). This hierarchical structure, in which there is central processing of afferent input, is important for coordinating respiratory movements with behaviors such as eating, speaking, and moving.[1] The controller is a neuronal network within the central nervous system (CNS), which is responsible for generating and modulating individual breaths and the overall breathing pattern. Often referred to as the respiratory central pattern generator (rCPG), the controller comprises reciprocally connected neuronal populations in the medulla and pons.[2,3] Neural output from the rCPG drives the activity of various motor neuron pools. Motor

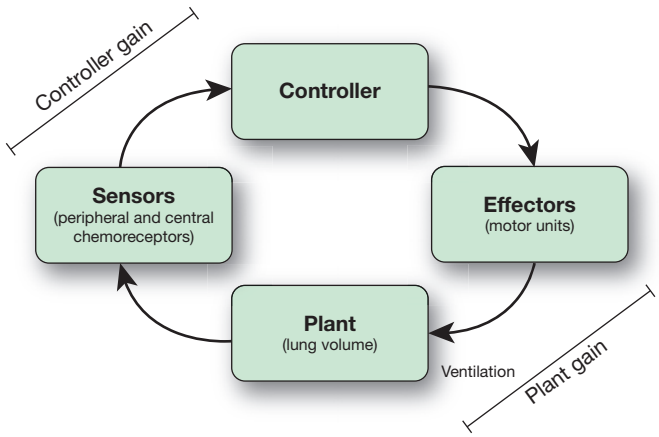

Figure 11-1 Block diagram of the respiratory control system.

neurons in the spinal cord (e.g., phrenic and intercostal) innervate the respiratory pump muscles, while brain stem motor neurons innervate upper airway muscles. The so-called "plant" includes the CO_2 stores, which are made up of lung stores and circulating blood volume including hemoglobin, and is an important component of breathing control. Closed loop feedback to the controller is supplied by chemoreceptors and mechanoreceptors.

The consistent cycling of the ventilatory pattern is generated spontaneously from the spatial and functional architecture of the rCPG. Intrinsic membrane properties of rhythmically active neurons within the rCPG are capable of producing automatic periodicity.[4] In addition, reciprocal (excitatory and inhibitory) synaptic connections between neuronal populations in the medulla and pons are believed to be critical for the automatic generation of the respiratory rhythm.[2,3]

The neural respiratory cycle comprises three phases (Fig. 11-2).[5] Inspiration (T_I) involves ramp-like increases in inspiratory motor neuron firing, which drive phrenic nerve activity throughout this phase. The first phase of expiration (T_{E1}) is often called post-inspiration, because inspiratory motor neurons are still active. Persistent inspiratory motor activity during T_{E1}, which declines throughout this phase, acts to slow the exit of air from the lungs. Finally, during the second phase of expiration (T_{E2}), expiratory muscles are typically electrically silent. During this phase of passive relaxation, gas is expelled as the lungs and chest wall return to their equilibrium state (i.e., functional residual capacity). However, under conditions where respiratory drive is increased, expiratory muscles including the internal intercostal and abdominal muscles become active during T_{E2}. This notion is an example of how the central controller, influenced by sensory feedback, modulates and alters the integrated motor response of the system.

BRAIN STEM

Within the medulla and pons, interconnected neuronal populations constitute a network, which is considered necessary for the generation of the respiratory rhythm (Fig. 11-3).[2,3,6] This bilateral pontomedullary respiratory network, which is also responsible for control of the ventilatory pattern, contains the ventral respiratory column (VRC) and the pontine respiratory group (PRG). Afferent signals from lung mechanoreceptors and peripheral chemoreceptors enter the pontomedullary network via the nucleus of the solitary tract (nTS) in the dorsal respiratory group (DRG). The nTS has projections to both pontine and ventral medullary components of the central respiratory network. Taken together, the VRC, DRG, and PRG comprise the brain stem rCPG. The rhythmic output of the rCPG drives the activity of spinal phrenic, intercostal, and lumbar motor neuron pools that innervate the muscles of respiration. Other brain stem motor neurons exhibit respiratory modulation and control muscles of the upper airway. Finally, the rCPG is influenced by higher CNS structures, which allows for conscious control of the ventilatory pattern.

Several regions of rhythmically active neurons in the VRC represent the core circuitry of the rCPG. The pre-Bötzinger complex (pre-BötC) within the VRC is believed to be the main source of rhythmic excitation driving inspiratory premotor neurons and other brain stem circuits. Furthermore, the pre-BötC has been shown to manifest intrinsic rhythmic activity.[4] However, the mechanisms responsible for rhythmic inspiratory pattern generation are complex given the large number of modulatory inputs that converge on the pre-BötC compartment, and are likely to manifest as the result of

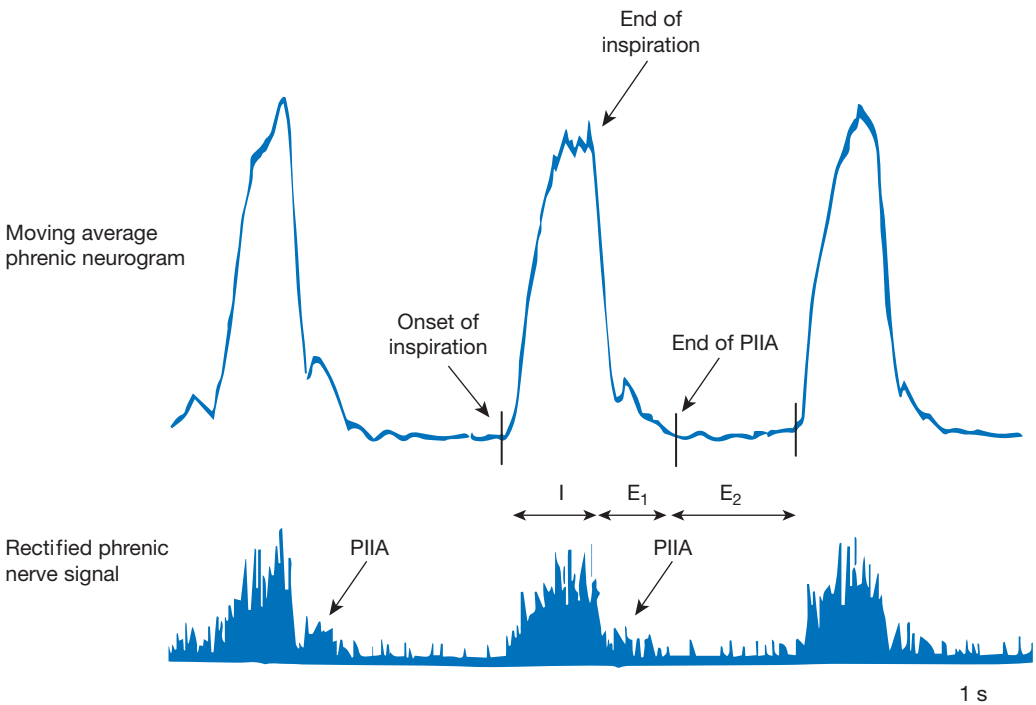

Figure 11-2 Recording of phrenic nerve activity (below) and its moving average (above), which highlights the three phases of the respiratory cycle: (1) Inspiration (I), (2) post-inspiratory activity (expiration, phase 1, E_1), and (3) late expiration (expiration, phase 2, E_2). PIIA, post-inspiratory inspiratory activity.

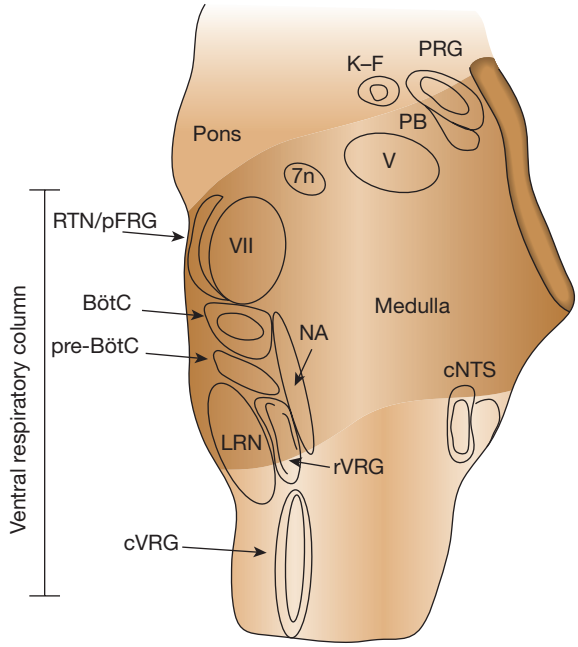

Figure 11-3 Overview of the respiratory central pattern generator (rCPG) within the brainstem. The ventral respiratory column (VRC) is orientated in the rostral-to-caudal direction. The VRC extends from the retrotrapezoid nucleus (RTN) adjacent to the rostral facial nucleus (VII) superiorly, to the caudal ventral respiratory group (cVRG) near the spinomedullary junction inferiorly. The main areas of rhythmically active VRC respiratory neurons are in the Bötzinger complex (BötC), pre-Bötzinger complex (pre-BötC), rostral ventral respiratory group (rVRG), and cVRG. The parafacial respiratory group (pFRG) overlaps anatomically with the RTN, and together these regions include intrinsically bursting neurons which may contribute to rhythm generation. Peripheral chemo- and mechanosensory inputs are transmitted to the nucleus of the solitary tract (nTS) in the dorsal respiratory group (DRG). The pontine respiratory group (PRG) includes the Kölliker–Fuse (K–F) and the parabrachial (PB) nuclei which contain respiratory-modulated neurons. See text for additional details.

network properties. Neuronal populations in the Bötzinger complex (BötC) are the major source of expiratory network activity during normal breathing. Thus, BötC neurons are important for control of the transition between inspiratory and expiratory activities in the rCPG and maintenance of the rhythmicity of normal breathing.

Neurons within the PRG are critical for formation of normal resting breathing patterns. Functional connections between the pons and the rest of the rCPG modulate phase switching (onset and termination of inspiration). For example, the dorsolateral pons (dlPons) is a region within the PRG with respiratory-modulated neurons whose activity varies depending on the presence of vagal afferent feedback. In particular, eupneic breathing patterns are dependent on excitatory drive from pontine neurons to the VRC, emphasizing the importance of the spatial and functional architecture of the brainstem respiratory network. Medullary raphé nuclei likely represent a system of intermediate relays for signaling between the PRG and the VRC. Transmission of an efference copy of ventilatory drive from the VRC is an example of one of these reciprocal connections. These medullary circuits may serve to maintain an overall level of rCPG activity. In addition, certain (particularly rostral) regions within the medullary raphé are chemosensitive, responding to local changes in carbon dioxide or pH, as well as exhibiting altered activity with stimulation of peripheral chemoreceptors.

The rostral ventral respiratory group (rVRG) region within the VRC comprises excitatory neurons that drive spinal phrenic and intercostal inspiratory motor neurons. This group of neurons is inhibited by the BötC during expiration and excited by the pre-BötC during inspiration. These rhythmically alternating influences, along with modulatory inputs from other areas of the pontomedullary network, are responsible for shaping and controlling the pattern of inspiratory rVRG activity. In contrast, the cVRG is thought to be the expiratory counterpart to rVRG activity.

Peripheral chemo- and mechanosensory inputs are transmitted to the nTS, which contains second-order neurons critical for reflex respiratory responses. For example, carotid body chemoreceptor and baroreceptor afferents terminate in the medial and lateral subnuclei of the nTS. Lung mechanoreceptors have projections to "pump cells" in the nTS, resulting in rhythmic activity of these cells which is modulated by lung inflation. The retrotrapezoid nucleus (RTN) is a site of central chemoreception. Chemoresponsive neurons within this region project to other areas of the rCPG and provide excitatory drive to the VRC and PRG. These sensory afferents, and the way in which they modulate breathing, will be discussed in subsequent sections. As part of the respiratory neural network, the nTS modulates breathing via projections to both pontine and ventral medullary components of the central respiratory network. In addition, neurons within the nTS receive inspiratory drive from the VRC and reciprocal pontine projections gate neuronal activity in the nTS.

CHEMORECEPTORS

The carotid and aortic bodies are bilateral sensory organs that detect changes in arterial oxygen. Although very small in size, the reflexes initiated by these tissues (particularly the carotid bodies) are critical for evoking stimulation of breathing during hypoxemia.[7] Stimulation of the carotid body by hypoxia (O_2 sensing) involves stimulus transduction and afferent nerve activation. Carotid bodies are composed of two cell types: type I and type II. Type I cells (also referred to as glomus cells) are of neural crest origin and are considered the putative oxygen-sensing cells. Glomus cells express a variety of neurotransmitters that play critical roles in sensory transmission of hypoxemia. Afferent nerve endings, whose cell bodies lie in the petrosal ganglion, form synaptic contacts with glomus cells and are responsible for afferent signaling to the CNS. The type II cells (also referred to as sustentacular cells) resemble glial cells and they are thought to act primarily as supporting cells.

There are two main pathways by which the carotid body senses hypoxia, although which mechanism is primary remains an area of debate.[8–10] The first main pathway for oxygen sensing involves heme-containing proteins in the glomus cell (metabolic hypothesis). First proposed by Mills and Jobsis, and later supported by studies using exogenous carbon monoxide (CO), there is evidence that mitochondrial cytochrome(s) may act as potential O_2 sensors. Further, several nonmitochondrial heme proteins that are expressed in glomus cells, including NADPH oxidases and heme oxygenase-2 (HO-2), have been proposed as potential oxygen sensors. Finally it has been suggested that hypoxia leads to the formation of iron-containing compounds via chelation as part of the transduction process, although the putative proteins and downstream signaling pathways responsible for afferent nerve activation are not well defined.

The second general mechanism by which hypoxia leads to depolarization of glomus cells is via inhibition of an O_2-sensitive, membrane-bound K^+ channel. This pathway for sensory transduction is based on the neuronal phenotype of the glomus cells and is referred to as the membrane hypothesis. Glomus cells express a variety of O_2-sensitive K^+ channels including outward rectifiers, Ca^{2+}-activated K^+ channels, human-ether-a-go-go (hERG), and twin pore-acid–sensitive K^+ (TASK) channels.[11] There is published evidence supporting and refuting aspects of both the metabolic and

membrane hypotheses. Most likely, both pathways complement each other and work in concert to facilitate oxygen sensing by glomus cells. For example, it has been proposed that with increasing severity of hypoxemia, additional pathways are activated, allowing the carotid body to respond to a wide range of arterial oxygen levels.

Regardless of the mechanism(s) involved, hypoxic sensing ultimately leads to a Ca^{2+}-dependent release of neurotransmitters from glomus cells. These signaling molecules activate nerve endings in the carotid sinus nerve leading to an increase in afferent nerve activity (sensory transmission). The carotid body expresses several classes of neurotransmitters, including (1) biogenic amines (acetylcholine [Ach], dopamine, norepinephrine, and 5-hydroxytryptamine), (2) neuropeptides (enkephalins, substance P, and endothelins), (3) adenosine triphosphate (ATP), (4) amino acids (e.g., GABA), and (5) gas transmitters (CO and nitric oxide, NO). Some of the transmitters (e.g., ACh, substance P, ATP) stimulate whereas others (e.g., dopamine, enkephalins) inhibit carotid sinus nerve activity. Identifying which transmitters are primarily responsible for hypoxia-induced afferent nerve activation under physiological conditions remains an area of active research, and it is possible that corelease of multiple molecules, acting in concert, may ultimately be responsible for sensory excitation by hypoxia. While the carotid body is the primary peripheral chemoreceptor responsible for oxygen sensing, carbon dioxide also stimulates the carotid body, but the mechanisms are not fully understood. Finally, the interaction of the central and peripheral chemoreceptors is still debated, but recent evidence supports a hyperadditive model whereby the gain of one group of chemoreceptors can increase the responsiveness of the other (e.g., carotid body stimulation increases the gain of the central chemoreceptors).[12]

MECHANORECEPTORS

The lung, chest wall, and respiratory muscles all contain mechanoreceptors, which provide closed-loop feedback to the rCPG. This afferent input regulates minute ventilation independent from chemical drive. In addition, mechanoreceptor reflexes modulate the respiratory pattern on a breath-by-breath basis by enhancing or terminating inspiration. Afferent axons from lung mechanoreceptors are contained within the vagus nerve, but the importance of these receptors to control of respiration in awake, adult humans is likely small. Additional mechanoreceptors in the respiratory muscles and chest wall have central projections which travel in spinal nerves and the spinal cord. These receptors are important to coordinating the breathing pattern during trunk twisting and during movement between the upright and supine positions.

Several broad categories of mechanoreceptors have been identified which are relevant to ventilatory control:

1. Lung stretch receptors are present in the airway smooth muscle of the distal airways. These slowly adapting receptors are stimulated by lung inflation. Afferent signaling following activation of these receptors tends to terminate inspiration without altering the slope of the inspiratory ramp, as well as to promote expiratory activity. Slowly adapting receptors in the lung are the afferent fibers responsible for the Hering–Breuer reflex, which describes the termination of inspiration (promotion of inspiratory-to-expiratory phase switching) that occurs as a result of lung inflation. In addition, expiratory prolongation and occasional apneas which occur with large and sustained inflation of the lung are a manifestation of this reflex.
2. Rapidly adapting receptors respond to changes in airway mechanical properties that accompany lung inflation and deflation, and become more active as the rate of airflow increases. These receptors are also activated by stimuli that induce bronchospasm, edema, or mucus secretion. For example, they produce cough and laryngeal narrowing in response to stimulation by dust, ammonia, histamine, and other agents, as well as in response to increases in inspiratory airflow. These lung mechanoreceptors are primarily located in the epithelial and submucosal layers of the larger airways, accounting for their sensitivity to inhaled agents. Finally, rapidly adapting receptors lead to increased respiratory frequencies at low lung volumes, due to afferent signaling which increases inspiratory neural activity during lung deflation.
3. Bronchial J receptors are named for their juxtacapillary location. These lung mechanoreceptors project centrally through unmyelinated (in contrast to the first two types) fibers, and respond to pulmonary vascular congestion associated with increases in pulmonary artery and capillary pressure. Stimulation contributes to the increase in respiratory frequency and a decrease in tidal volume in response to pulmonary edema.
4. Bronchial C receptors are named for their sensitivity to capsaicin, and are located in the airway wall. Similar to type J receptors, these lung receptors project centrally through unmyelinated fibers. Activation of C fibers with capsaicin or bradykinin produces cough and a rapid, shallow breathing pattern. Unlike other lung receptors described here, bronchial C receptors are relatively insensitive to mechanical stimulation and changes in lung volume.
5. Muscle spindles transduce muscle length. The diaphragm has few if any muscle spindles, but these mechanoreceptors are plentiful in the intercostal muscles. Muscle spindles tend to augment breathing when activated.
6. Muscle tendon organs are located in series with muscle fibers in the tendon and are activated as muscle fibers generate force. Thus, these mechanoreceptors sense the efficiency of force generation and inhibit breathing when activated. The central tendon of the diaphragm contains tendon organs, as do the tendons of accessory muscles of respiration.
7. The rib cage joints and upper airways (larynx, pharynx, and nasal cavity) also contain receptors that impact control of ventilation. For example, cold air stimulation of the pharynx initiates the cough reflex, and can reduce the ventilatory response to carbon dioxide.

UPPER AIRWAY AND PUMP MUSCLES

The upper airway muscles are described more completely elsewhere but are addressed briefly here for completeness. The pharyngeal dilator muscles can be broadly classified into those with phasic activity (burst with inspiration) and tonic activity (constant activity throughout the respiratory cycle). The genioglossus is a frequently studied muscle as it is a representative phasic muscle which is readily accessible for intramuscular recordings and is controlled by the hypoglossal motor nucleus. The genioglossus is a major dilator muscle, which serves to protrude the tongue and protect pharyngeal patency in the face of collapsing perturbations. The tensor palatini, in contrast, is a representative tonic muscle controlled by trigeminal motor branches. Recent insights from recordings of single motor units have defined the complexity of these various muscles and provided insights into brainstem control in humans.[13] Although robust activity of the pharyngeal dilator muscles have been observed in obstructive sleep apnea patients during wakefulness, the fall in activity of these muscles at sleep onset likely contributes to a propensity to upper airway collapse in susceptible individuals. Some data also support evidence of structural neural remodeling and reinnervation of genioglossus muscle fibers suggesting neural injury may also be present in people with sleep apnea.[14] Given the recent realization that sleep apnea has multiple underlying mechanisms, there is likely a subset of OSA patients who have dysfunction in upper airway muscles as a major pathogenic factor. Various approaches are being considered to augment upper airway dilator muscle activity, including the possibility of pharmacological manipulation of hypoglossal output or electrical stimulation of the hypoglossal nerve. Pharmacological targets

are being defined through careful studies of premotor inputs to the hypoglossal motor nucleus, although as yet no human trials have shown clear augmentation of genioglossus activity with pharmacotherapy. While the role of hypoglossal nerve stimulation in treating sleep apnea remains incompletely defined, recent work highlights the clinical promise of this approach.[15]

STABILITY OF VENTILATORY CONTROL: LOOP GAIN

Loop gain is an engineering term that is used to define the stability or instability of a negative feedback control system. Overall loop gain can be thought of as the integration of controller and plant factors and is thus the product of controller gain and plant gain (Fig. 11-1). A system with a high loop gain is prone to instability whereas a system with low loop gain is one which is intrinsically stable. The concept of loop gain can be considered in the context of the thermostat analogy, which is a common example of a negative feedback control system designed to regulate room temperature. Situations that lead to oscillations in room temperature can be considered analogous to situations in humans in which CO_2 levels fluctuate. For example, a highly sensitive thermostat is one that responds to trivial fluctuations in room temperature with major changes in output from the air conditioner or furnace; thus, a very sensitive thermostat will lead to marked fluctuations in room temperature. By analogy, exquisite sensitivity of chemoreceptors will contribute to marked fluctuations in CO_2 levels. Another example is a furnace, which is too powerful such that a minor drop in room temperature leads to major elevations in room temperature as a result of the output of the furnace. By analogy, if a minor increase in Pa_{CO_2} led to major increases in ventilation yielding marked reductions in Pa_{CO_2}, the system would be considered unstable, that is, elevated loop gain. Thus, situations, which lead to fluctuations in room temperature, can be considered to understand the factors underlying CO_2 fluctuations in the human.

In the case of ventilation, the propensity for CO_2 fluctuations is a function of an individual's loop gain. That is, an individual with a high loop gain is prone to developing periodic breathing or Cheyne–Stokes breathing, even with minimal perturbation. On the other hand, an individual with low loop gain will maintain relatively stable breathing patterns even with major perturbations. The mechanism underlying a high loop gain can be highly varied, but can generally be considered due to either an elevation of controller gain or plant gain. Controller gain is also known as chemoresponsiveness, which includes chemosensitivity (i.e., how much chemoreceptors fire with a given CO_2 stimulus) in addition to the actual change in ventilation for a given CO_2 stimulus (e.g.,which includes upper airway patency). In addition, plant gain describes the efficiency of CO_2 excretion, that is, how much the CO_2 actually changes for a given change in ventilation. Individuals with congestive heart failure are at risk of Cheyne–Stokes respiration (CSR) likely due to elevated chemoreflex gain as well as elevated plant gain compared to matched controls.

The delay in the circulation, sometimes defined by a mixing gain, is also an important factor in determining breathing pattern. The ability for the human ventilatory control system to develop instabilities is a result of chemoreceptors being located in the brainstem and carotid bodies rather than in the lung. Circulatory delay can also contribute to an unstable breathing pattern, although most studies suggest that marked prolongation of circulatory delay is not present in CSR patients with congestive heart failure compared to heart failure patients without CSR. In classic Guyton experiments, several minute delays were occasionally required to induce periodic breathing in dogs; such circulatory delays are beyond the range of what occurs in humans even in pathological states (e.g., end-stage congestive heart failure). Thus, circulatory delay is considered necessary but not sufficient to induce periodic breathing or CSR. Some interventional studies suggest improvements in sleep apnea with reduction in circulatory delay, emphasizing the importance of this variable in some individuals.[16]

The measurement of loop gain is cumbersome currently as it requires overnight experimental measurements and considerable expertise. However, the concepts are useful in a qualitative manner even if quantitative data are not available. In addition, efforts are ongoing to simplify the loop gain measurement to determine expeditiously which patients may respond to particular interventions.[17] The importance of loop gain is receiving increasing attention given the recognition of its importance in obstructive sleep apnea,[18] central sleep apnea,[19] periodic breathing at high altitude and other conditions. Indeed, manipulation of loop gain using interventions such as oxygen or acetazolamide can lead to improvements in sleep apnea in small physiological studies.[20,21] Thus, further work on ventilatory loop gain is required to define the optimal diagnostic and therapeutic approaches.

CONTROL OF VENTILATION IN HEALTH AND DISEASE: ILLUSTRATIVE EXAMPLES

The afferent, efferent, and central neural systems described earlier, respond to a variety of challenges that affect both normal individuals and patients with respiratory disease. These pathophysiological changes will affect the level of ventilation, the respiratory rhythm, or both. The impact of ventilatory control on specific disease states is addressed as appropriate in relevant sections elsewhere in this text. Following are illustrative examples which are considered to highlight how the respiratory control system adapts in clinically important conditions.

VENTILATORY ACCLIMATIZATION TO OXYGEN DISTURBANCES

There are many pathophysiological mechanisms that cause hypoxemia, and it has been well known for more than a century that hypoxia stimulates the respiratory and cardiovascular systems.[22] Heymans et al., among others, demonstrated the importance of carotid body chemoreceptors for the hypoxic ventilatory response.[23,24] Comroe and Mortimer[6] established the idea that arterial chemoreceptors are the dominant O_2-sensitive chemoreceptors for cardiopulmonary control. Elimination of the carotid and aortic body chemoreceptors elicits hypoventilation and essentially obliterates the acute ventilatory response to hypoxemia.[25] Therefore, it has been assumed that central O_2 sensitivity may not play a major role in this response.[26] In fact, chronic hypoxia reportedly has a depressive effect on the brain, limiting its response to further hypoxia. This hypoxic depression spreads rostral caudally in the brain; and may be the result of slowed removal of inhibitory neurotransmitters like GABA during hypoxia due to the buildup of lactic acid in the brain. However, in some experimental preparations, hypoxia continues to stimulate ventilation and the cardiovascular system in the absence of carotid body chemoreceptors, suggesting that other arterial chemoreceptors or sites in the CNS must be sensitive to hypoxia.[6] Focal hypoxia produced by cyanide in the medulla excites sympathoexcitatory neurons,[27] and experimental evidence supports central O_2 sensitivity in the C1 sympathoexcitatory region of the rostral ventrolateral medulla, the posterior hypothalamus, the pre-BötC, and the nucleus tractus solitarius.[25]

Hypoxic Ventilatory Response: The hypoxic ventilatory response is characterized by discrete, time-dependent mechanisms that depend on the severity, duration, and pattern of hypoxic exposure. A reduction in the partial pressure of oxygen produces an immediate increase in ventilation mediated through the peripheral chemoreceptors.[28] While the ventilatory response to hypoxia is independent of the source of hypoxemia, the brain has multiple time domains of O_2 sensitivity that can elicit different ventilatory responses to acute versus chronic hypoxia. Furthermore, this ventilatory response has several unique forms of respiratory plasticity.[29]

Acute and chronic exposure to high altitude: The hypoxic and hypobaric environment encountered at high altitude results in a reduction

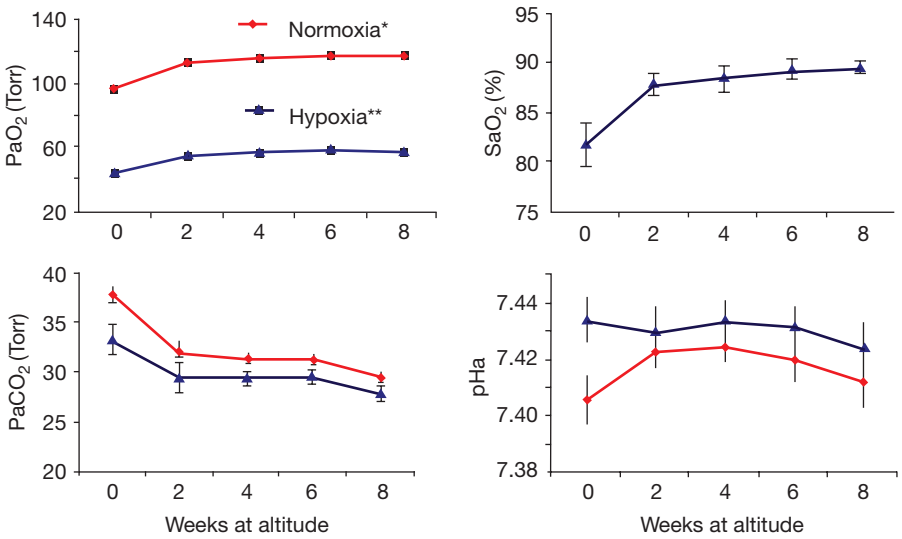

Figure 11-4 Arterial oxygenation increases and arterial CO_2 decreases during time at altitude. These changes persist in normoxia, indicating hyperventilation. pHa is partially compensated during acclimatization. *(Data from Hupperets MD, Hopkins SR, Pronk MG, et al. Increased hypoxic ventilatory response during 8 weeks at 3800 m altitude. Respiratory physiology & neurobiology. 2004;142(2–3):145–152.)* *Normoxia is from data collected breathing at sea level. **Hypoxia is from data collected breathing at 3800-m altitude.

in the available inspired oxygen (inspiratory partial pressure of O_2 [$P_{I_{O_2}}$]). Acute exposure to altitude results in hypoxemia, which produces an immediate increase in minute ventilation mediated through the peripheral chemoreceptors and characterized by an increase in frequency (respiratory rate) and amplitude (tidal volume). With ongoing exposure, ventilation continues to increase for several days resulting in a sustained gradual decrease in arterial P_{O_2}. Chronic exposure to high altitude, lasting from several hours to months, results in acclimatization. This adaptation to high altitude is characterized by a gradual rise in minute ventilation with a time course depending on the altitude. In humans, at very high altitudes (~8000 m), this process may take at least 30 days. At less extreme altitudes, complete adaptation may be achieved in less than 10 days. However, in one study, ventilation and arterial oxygenation were noted to be greater than during the initial ascent to 3800 m after 8 weeks.[30] In addition, there is an increase in CO_2 sensitivity with exposure to altitude. In people living in high altitude for long periods of time the P_{CO_2} falls to the lower level of normal or even less (Fig. 11-4).[30]

A number of physiological mechanisms of ventilatory acclimatization to hypoxia have been identified. They include (a) plasticity in O_2 sensitivity of the carotid body chemoreceptors, (b) the CNS integration of peripheral O_2-sensitive reflexes (e.g., carotid body chemoreflex), (c) plasticity of CNS mechanisms of acute O_2 sensing, and (d) the CNS integration of other nonchemoreflex ventilatory control pathways such as reflexes from pulmonary vagal chemoreceptors or respiratory rhythm generators.[25,31,32] For example, hypoxia-inducible factor-1 (HIF-1) is a key regulator of O_2-sensitive gene expression in the brain, and increases in HIF-1 have been identified in respiratory nuclei of the CNS as soon as 1 hour after hypoxemia. Hence, O_2 sensing by HIF-1α could be involved in the ventilatory acclimatization to high altitude by increasing the expression of genes with products known to modulate the hypoxic ventilatory response.[33]

OXYGEN-INDUCED HYPERCAPNIA IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

In severe chronic obstructive pulmonary disease (COPD), transient falls in ventilation and respiratory acidosis have been reported with breathing 100% oxygen for 20 minutes.[34–36] Initially CO_2 retention with oxygen treatment was thought to result from the suppression of the hypoxic drive mediated by carotid chemoreceptors.[37] Subsequently, additional mechanisms have been shown to contribute to oxygen-induced hypercapnia in COPD as follows:

(1) The increase in oxygen tension in lung units with low ventilation/perfusion (V/Q) ratios can blunt hypoxic pulmonary vasoconstriction in these low V/Q lung units, thus diverting perfusion away from high V/Q lung units yielding higher dead space; (2) the Haldane effect, which refers to the reduction in hemoglobin affinity for CO_2 with the binding of oxygen to hemoglobin. With increased blood oxygen levels, the Haldane effect promotes dissociation of carbon dioxide from hemoglobin and leads to a small increase in Pa_{CO_2}; (3) suppression of hypoxic drive as mentioned earlier. Data on P_{CO_2} recruitment threshold in intubated COPD patients support a change in sensitivity of the CNS to CO_2 during hyperoxia; (4) some patients with acute exacerbations of COPD are susceptible to the development of severe hypercapnia due to sleep deprivation that is common in acute illness; patients with associated obstructive sleep apnea might be susceptible since they have high sleep drive and are likely to lose the wakefulness drive to breathe at sleep onset upon initiation of therapy. For example, patients during acute exacerbations of COPD will commonly be sleep deprived and will typically fall asleep once they receive the anxiolytic and antidyspnea effects of oxygen therapy[36,38]; and (5) increases in Fi_{O_2} which occur with noninvasively delivered oxygen as minute ventilation falls. Actual delivered Fi_{O_2} is a function of inspiratory flow demand and room air entrainment; thus, higher oxygen tensions result as ventilatory drive falls for any reason. Occasionally vicious cycles can occur whereby supplemental oxygen leads to a rise in CO_2 level, which contributes to a further increase in oxygen level due to a resultant decrease in inspiratory flow with reductions in room air entrainment.

Understanding these mechanisms has clinical implications, as maintaining the arterial oxygen saturation between 87% and 92% may be a safer approach in patients with a history of respiratory disease, and is unlikely to compromise tissue oxygen delivery.

RESPONSES TO EXTERNAL MECHANICAL LOADS AND BRONCHOCONSTRICTION

In response to external mechanical loads, several compensatory factors act to maintain ventilation[39]: (1) *Responses intrinsic to the respiratory muscles.* The force that the muscle develops for a fixed electrical input depends on the length of the muscle (the force–length relationship). As the muscle shortens, less force is developed. The generated force also decreases as the velocity of shortening increases (force–velocity relationship). With external mechanical impediments (loading), both the magnitude and the velocity of shortening tend to decrease. (2) *Reflex effects.* At the spinal level, less shortening of the inspiratory muscles increases the signal from muscle spindles that, in turn, augments contraction of these muscles. During loading, afferent information from pulmonary mechanoreceptors also

changes. Since tidal volume is depressed, inspiratory duration tends to be prolonged (Hering–Breuer inspiratory terminating reflex), but this mechanism is of little importance in humans. (3) *Conscious responses.* Loads increase neuromuscular output even in the face of a constant chemical drive. The magnitude of the increase is related to the severity of the mechanical load. This aspect of load compensation is abolished by anesthesia. Furthermore, the intensity of this load-compensating mechanism is variable, and it is reduced in some chronic lung disease like COPD.

While external loading is used experimentally, major differences exist between the neural responses to bronchoconstriction and external loading. In particular, inspiratory muscle activity increases during bronchoconstriction, even in anesthetized animals. Bronchoconstriction increases breathing frequency via reflex changes in respiratory timing. Expiratory duration (especially the second phase of expiration) shortens more than inspiratory duration. In asthma-induced bronchoconstriction, rapidly adapting receptors are stimulated by mechanical changes in the airways and by substances such as histamine and bradykinin.

■ RESPONSE TO EXERCISE

The exercise ventilatory response is the most frequently engaged ventilatory response in everyday life.[29] Despite the increase in CO_2 production and O_2 utilization during exercise, ventilatory control mechanisms normally keep arterial P_{CO_2} and $[H^+]$ remarkably constant over a wide range of metabolic rates.[40] This pattern is achieved by graded increases in minute ventilation (V_E) as the rate of CO_2 production increases, and acts to minimize acidosis that would impair cellular function. This response is tightly controlled; respiratory alkalosis does not typically develop during moderate exercise in normal subjects, although it occasionally occurs in pathophysiological states. With increased intensity of exercise, oxygen demand outstrips oxygen supply, anaerobic pathways start to operate and blood lactate levels increase. With exertion above this anaerobic threshold, the exercise-induced metabolic acidosis becomes more marked due to a net increase in lactic acid production. As a result, high-level exercise results in a large increase in ventilation to enhance carbon dioxide excretion and minimize acidemia.

The minute ventilation required to maintain acid–base equilibrium during exercise is defined by (1) the amount of carbon dioxide produced as a result of metabolism (V_{CO_2}); (2) physiological dead space, and (3) the set point at which P_{CO_2} is regulated by the respiratory control system. There is an incomplete understanding of the reflexes responsible for controlling how pulmonary ventilation matches the increases in metabolic demand during exercise without appreciable changes in arterial blood gas composition. The magnitude of oscillations in ventilation is directly related to metabolic CO_2 production. Thus, it has been proposed that a blood-borne signal helps in the coupling of metabolic production of CO_2 and ventilation. Neurally mediated signals from exercising muscles and from higher brain centers are also likely important in the ventilatory response. Finally, this response is responsible for meeting the increased need for oxygen consumption by exercising limb and respiratory muscles.

The initial phase of the exercise response is a rapid increase in ventilation. Proposed sources include signals arising from the cortex (so-called feedforward control), temperature increases, afferent signals arising as a result of muscle contraction (locomotor muscle afferents and respiratory muscle metaboreflex), accumulation of catecholamines, and increases in potassium in the venous blood.[41] There is also evidence that the abrupt initial increase in ventilation at the onset of exercise is a learned response. That is, the primary drive to breathe at the start of exercise will augment respiration in anticipation of impending metabolic needs based on past exercise experiences.[42] Chemoreceptor feedback may act in concert with the feedforward stimulus to minimize disruptions in homeostasis as the intensity of exercise increases. In addition, there is capacity for modulation and plasticity of the mechanisms controlling breathing during exercise. For example, serotonergic modulation of descending drive is a mechanism for long-term modulation of exercise hyperpnea, which may be important in individuals with underlying cardiorespiratory disease.[43]

■ DISTURBANCES OF RESPIRATORY RHYTHM

Congenital central hypoventilation syndrome (CCHS), occasionally referred to as Ondine's curse, is a rare neurological disorder characterized by inadequate breathing during sleep and, in more severely affected individuals, also during waking periods. Patients congenitally lack or have poor chemosensitivity to both hypercapnia and hypoxia, and suffer from inadequate ventilation. Over 90% of patients with CCHS have an increased polyalanine repeat expansion mutation (PARM) in the paired-like homobox 2B (PHOX2B) gene. Other cases of CCHS are the result of non-PARM mutations of the PHOX2B gene. Most cases are the result of a *de novo* mutation, although patients may have a family history of the disorder. There is a correlation with the number of polyalanine repeat expansion genotype and the need for continuous ventilatory support. The disease typically presents in childhood, but rare adult-onset cases have been reported.[44] A number of conditions are associated with CCHS and reflect the autonomic nervous system dysregulation, including Hirschsprung disease (about 20% of cases) and tumors of neural crest origin (neuroblastomas). While PHOX2B is considered to be the disease-defining gene in CCHS, these patients may have other protein-altering mutations including mutations in the receptor tyrosine kinase, the RET gene, brain derived neurotrophic factor (BDNF), and endothelin1 and 3 genes. Rett syndrome is a neurodevelopmental disorder that occurs almost exclusively in females. After a period of initially normal development, affected patients experience loss of speech and purposeful hand use, stereotypic hand movements, gait abnormalities, and breathing abnormalities among others. Most cases result from mutations in the gene encoding methyl-CpG-binding protein 2 (Mecp2). Loss of Mecp2 function is associated with an irregular breathing pattern. The implicated mechanism has not been established, but may be related to widespread hyperexcitability in respiratory-related regions in the brainstem. Apnea that occurs during wakefulness is typically central, although it may be obstructive. These events may be isolated, or precede or follow hyperventilation. During apneic episodes, the child may stare quietly ahead or smile and appear happy with no evidence of distress, despite severe cyanosis.

Cheyne–Stokes Breathing is one form of periodic breathing characterized by a cyclic rise and fall in ventilation with recurrent periods of apnea or near apnea (Fig. 11-5). It was first observed in patients with cardiac or CNS disease, but it has since been reported in seemingly normal humans. The appearance of Cheyne–Stokes breathing can occur during wakefulness although often masked by behavioral influences, but is more common during nonrapid eye movement (NREM) sleep. The period of the oscillations in ventilation in Cheyne–Stokes breathing often averages 60 to 90 seconds. Cycle length is related to the circulation time measured from the lung to a systemic artery, and increases when circulation time is prolonged. Arousal tends to occur during the hyperpneic phase of the respiratory pattern, a finding which is often associated with paroxysmal nocturnal dyspnea in patients with heart failure.

Cheyne–Stokes breathing has not been consistently produced in animals by lesions in the CNS, but it has been shown to follow manipulations that are likely to produce unstable feedback control of breathing. Cheyne–Stokes breathing is seen in chronic heart failure, as well as in stroke and traumatic brain injury. A similar breathing pattern with a shorter cycle time (~15–30 seconds), often referred to

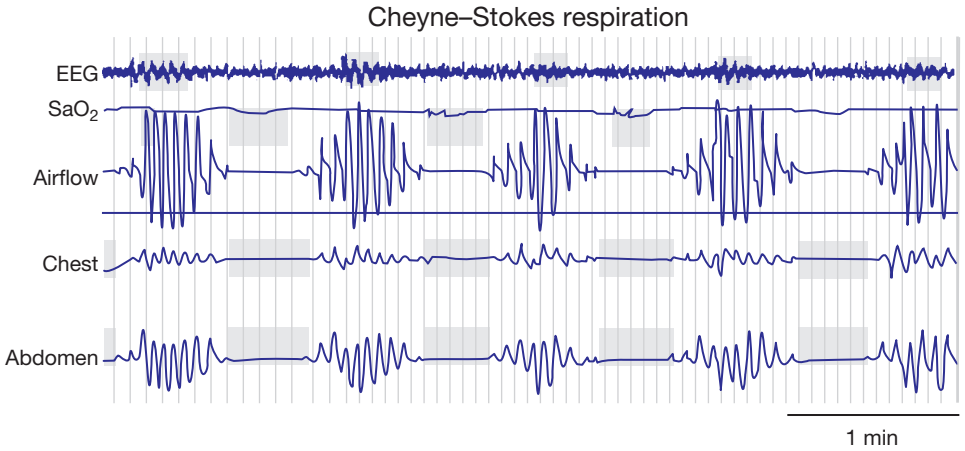

Figure 11-5 An example respiration in a patient with Cheyne–Stokes breathing. Note the characteristic crescendo/decrescendo pattern of breathing, long circulation time (each oxygen desaturation corresponds to the previous apnea), and arousal occurring at the peak of respiratory effort.

as periodic breathing at high altitude, can occur in otherwise healthy individuals at high altitude during the acclimatization period.

Sleep-related abnormalities of ventilatory control: Abnormal ventilatory patterns that can emerge during sleep are increasingly appreciated, including their associations with adverse neurocognitive and cardiovascular consequences. Ventilatory control instability may contribute to both central and obstructive sleep apnea. Indeed, sleep promotes breathing instability because it unmasks a highly sensitive dependence of the respiratory control system on chemoreceptor input. For example, the CO_2 reserve (i.e., the difference between the eupneic Pa_{CO_2} and that required to induce apnea) is labile during sleep and is reduced by hypoventilation, predisposing patients to the development of apneas.[45] Transient cortical arousals promote ventilatory overshoots, upper airway dilator muscle tone is reduced and airway collapsibility is enhanced.[46] In addition, depending on the prevailing pharyngeal mechanics, anatomical factors may cause or contribute to sleep-related disorders. Thus, both basic and clinical investigators have focused on mechanisms that influence upper airway patency during wakefulness and sleep, along with ventilatory control stability during sleep.

There are a number of changes in ventilatory control that occur during sleep; however, most of the same basic mechanisms active during wakefulness are also relevant during sleep. During sleep, there is an elevation of the CO_2 set point (~45 mm Hg as opposed to 40 mm Hg during wakefulness), associated with reduced alveolar ventilation during sleep. In all stages of sleep, there is decreased ability to respond to increments in resistance–load and the work of breathing. Thus, narrowing of the upper airway during sleep is a factor contributing to the rise in Pa_{CO_2}.

Other ventilatory control mechanisms are also affected. Sleep apnea results in recurrent episodes of hypoxemia, which alter the hypoxic ventilatory response resulting in respiratory long-term facilitation (LTF).[47] LTF is a form of neuronal plasticity that is induced by exposure to intermittent hypoxia and causes a persistent increase in ventilation even when normoxia is restored.[29,48] Phrenic (innervating the diaphragm) and hypoglossal (innervating upper airway muscles) nerve activities are both increased. Whereas the impact of LTF on ventilatory stability remains uncertain in the context of sleep apnea at this time, experiments in preclinical animal models suggest that LTF has the potential for both stabilizing and destabilizing influences on breathing that warrant further investigation.[20,49,50]

Apnea is a cessation of airflow for at least 10 seconds, and is probably the most common respiratory rhythm abnormality. Apneas occur often in premature infants and occasionally during sleep in healthy humans. Central apneas arise from complete or partial reductions in central neural outflow to the respiratory muscles during sleep (Fig. 11-6). In contrast to obstructive apneas, in which inspiratory efforts are made against the occluded upper airway, no respiratory effort is generated during central apneas due to cessation of respiratory drive. Thus central apneas are distinguished from obstructive apneas by the absence of respiratory effort, which can be detected by routine monitoring techniques such as respiratory inductive plethysmography combined with assessment of nasal pressure.[19] Mechanisms which can produce central apneas include (1) reduced excitation of chemoreceptors as a consequence of hypocapnia and hyperoxia; (2) functional or actual structural medullary damage which may result in a pattern of grossly irregular ataxic breathing; (3) loss of nonspecific respiratory excitatory stimulation (noise, light, tactile stimuli) in the absence of adequate chemical drive; and (4) active suppression of breathing by respiratory inhibitory reflexes, which is observed in a number of clinical situations including pharmacological therapy with methadone and other opiate medications. Reflex inhibition may arise from the cardiovascular system, from the lung and chest wall, or from somatic and visceral afferents. For example, excitation of receptors located in the upper airway can, via the superior laryngeal nerve, trigger an apnea. Stimulation of J receptors in the lungs by inhaled irritants may produce temporary apnea.

Complex sleep apnea syndrome describes the appearance and persistence of central apneas or hypopneas in patients with obstructive sleep apnea upon successful restoration of airway patency. Patients with complex sleep apnea syndrome present with features of obstructive sleep apnea syndrome. However, when instability of upper airway tone is treated with positive airway pressure therapy, these patients exhibit unstable, chemosensitive ventilatory control leading to repetitive central apneas or periodic breathing during sleep.[51] Adaptive servo-ventilation, which provides both a minimum pressure to hold the airway open as well as a ventilatory assist to minimize persistent cycles of hypo- and hyperventilation, has emerged as an effective treatment. Noninvasive ventilation using bi-level positive airway pressure in the spontaneous-timed mode may also normalize ventilation in some patients.[52]

Central apneas may also occur in critically ill patients as a result of artificial ventilatory support. Application of positive pressure mechanical ventilation may result in a loss of respiratory drive and associated apneas both during and after periods of ventilatory support. This may occur despite normocapnic conditions, and is more frequent during NREM sleep.[52] It is unclear whether these inhibitory effects are dependent on increases in tidal volume (i.e., Hering–Breuer mechanism) or are caused by a resetting of the inherent respiratory rhythm by the externally imposed ventilator frequency.[53,54] In addition, hypocapnia, oversedation, and the presence of CNS disease will also impact the prevalence of apneas during mechanical ventilation.

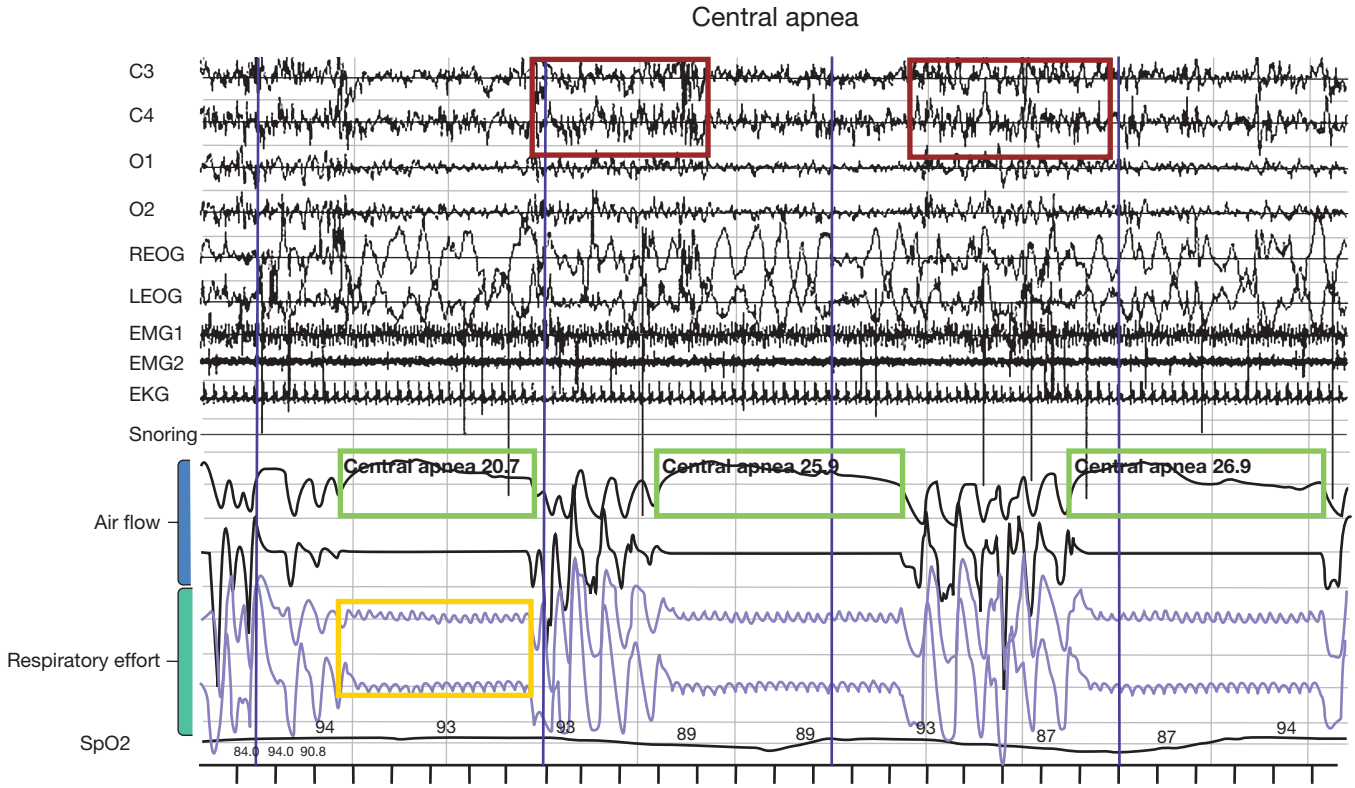

Figure 11-6 An example of respiratory pattern in a patient with central apneas. Note the typical characteristics of central apneas including absence of air flow by both nasal cannula pressure transducer and nasal–oral thermistor (durations in seconds), absence of respiratory effort measured with piezoelectric bands of the thorax and abdomen (orange box), associated oxygen desaturation corresponding to the previous apnea measured by pulse oximeter, and EEG arousal (red box) occurring after an apneic event. EEG channels (C3, C4, O1, O2); electrooculogram channels (REOG, LEOG), chin electromyogram (EMG1), bilateral tibialis anterior EMG2, EKG, snoring microphone.

■ DYSPNEA AND BREATHLESSNESS

Dyspnea is defined as a subjective sensation of difficulty breathing, frequently termed "shortness of breath." Under normal conditions, breathing is not noticeable. However, with increased demands (e.g., during exercise or with progressive cardiopulmonary disease), respiratory movements and forces become more perceptible. When sufficiently intense, respiratory efforts result in symptoms of dyspnea, and patients with lung disease may complain of dyspnea even at rest. The development of dyspnea is a warning signal, which likely serves to protect the body from harm; but since dyspnea itself can become an incapacitating symptom, considerable attention has been given to its etiology.[55–60] Experiments using breath-holding techniques showed that hypercapnia and hypoxia decrease breath-holding times, supporting the idea that increased levels of chemical drive promote dyspnea. In contrast, increased lung volume (increased oxygen stores) lengthened breath-holding time. Other investigations identified that combined blockade of the phrenic and vagus nerves extends the time apnea can be voluntarily maintained, suggesting that signals from respiratory muscles contribute to the sense of dyspnea. Dyspnea also seems to be related to the effort (as a percentage of maximal capacity) required during breathing. In particular, dyspnea increases as the pressures required for tidal breathing grow greater or the maximal inspiratory pressure decreases (e.g., respiratory muscle paresis or fatigue). Taken together, these data suggest dyspnea may manifest as a sense of air hunger (breath holding) and/or as a sense of excessive effort (breathing against a resistance); and it has been proposed that the two types of dyspnea are produced by different mechanisms with different anatomical pathways. In addition, cognitive and affective factors which determine the relative pleasantness and intensity of sensations may affect the level of dyspnea. A corollary discharge hypothesis has emerged whereby dyspnea is related to a mismatch between the central respiratory output and the actual achieved ventilation. During exercise, dyspnea is not profound since elevations in respiratory drive are associated with increases in the achieved minute ventilation. However, in situations where respiratory mechanics are impaired, for example, airway obstruction, dyspnea can be profound since high drive does not translate into high minute ventilation.

SUMMARY

Considerable progress has occurred in the area of control of breathing both in terms of the basic underlying mechanisms as well as the clinical implications of the applied physiology. Given the ubiquitous nature of the associated diseases and conditions, further efforts into the basic and clinical aspects of this field will likely allow new therapeutic strategies to emerge.

CHAPTER 12
Circadian Rhythms and Sleep Biology

Allan I. Pack

Sleep and circadian rhythm are highly coupled processes. In the original formulation they were considered independent but interacting. Borbely et al.[1–4] posited that the circadian process (Process C) had a 24-hour rhythm that interacted with the sleep drive system (Process S) (Fig. 12-1). Process S is envisaged to be like an old-fashioned egg timer. The drive for sleep is at a very low level following the major sleep bout and increases progressively as wakefulness proceeds, that is, the drive to sleep is related to the duration of prior wakefulness.

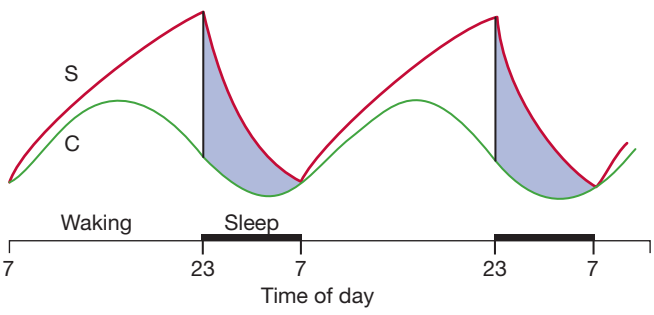

Figure 12-1 Two process model of sleep/wake control. Behavioral state is controlled by the interaction between two processes: (a) Process C, the biological clock and (b) process S, the sleep homeostatic drive. The dark bar below from 23:00 to 07:00 hours is the lights-off period. For further details, see text. *(Reproduced with permission from Kryger MH, Roth T, Dement WC, eds. Principles and Practice of Sleep Medicine, 5th ed. Philadelphia, PA: Elsevier; 2011.)*

Humans are programmed to sustain wakefulness for 16 hours but beyond this develop progressive performance impairments. During the day the drive to sleep is counteracted by an alertness signal from the clock. When this alertness signal declines later in the evening, the sleep drive is unopposed and sleep ensues. During sleep the drive to sleep progressively declines, that is, the egg timer is flipped and the sands recover (Fig. 12-1). The situation is actually more complex than this since sleepiness occurs twice a day, that is, siesta time in early afternoon and late in the evening. While these processes were initially considered independent, they are not at a molecular level.[5,6] Core clock molecules increase their expression in brain when sleep is deprived.[7] Moreover, mutations of a clock-associated gene – DEC2, now called BHLEH41 – result in short sleep in humans (<6 hours) without evidence of daytime performance impairment.[8,9]

In this chapter we describe the basis of the clock and make the point that the lung itself has a clock. We then describe sleep and review recent evidence that sleep alters gene transcription in the lung. The reader will get a background in sleep that will facilitate understanding the cardiopulmonary changes during sleep (see Chapter 101) and sleep-disordered breathing (see Chapter 99).

MOLECULAR MECHANISMS OF THE CLOCK

The fundamental principles of how the clock ticks are conserved across species, although the specific details, that is, genes involved, vary between species (for reviews, see[10,11]).

The original concept that the clock involves a distinct molecular mechanism came from identification of mutant fruit flies (Drosophila) with long circadian periods, short circadian periods, and flies with no circadian rhythm.[12] Subsequently it was determined that these different flies all had different mutations in the same gene which was given the name period (PER), that is, the first clock molecule identified.[13] Later forward genetic studies identified another clock molecule in Drosophila, that is, timeless.[14] The first mammalian clock gene was also identified by forward genetic studies, that is, studying mice that had received a chemical mutagen – ENU – and had an abnormal circadian period.[15] This clock molecule is Clock and is a transcription factor.

In both Drosophila and rodents the major mechanism of oscillation is a negative feedback loop (for mammalian model, Fig. 12-2). There

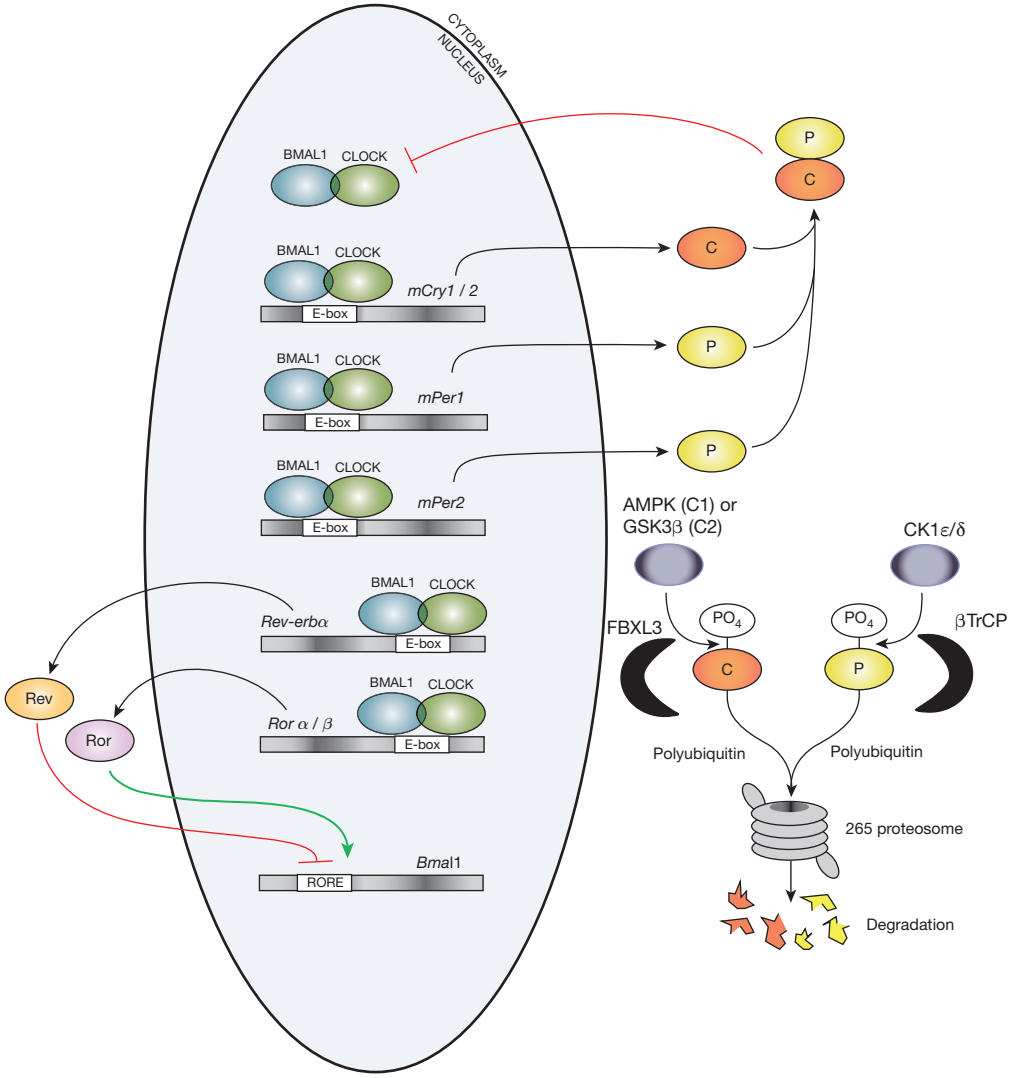

Figure 12-2 The major mechanisms that result in diurnal oscillation of clock genes. For further details, see text. *(Reproduced with permission from Buhr ED, Takahashi JS. Molecular components of the mammalian circadian clock. Handb Exp Pharmacol. 2013;(217):3–27.)*

are also positive feedback loops. In mammals the main clock proteins are the three-period proteins (PER1, PER2, and PER3) and the two cytochrome proteins (CRY1 and CRY2). These proteins form a complex in the cytoplasm that enters the nucleus where they inhibit their own transcription that is controlled by the CLOCK/BMAL1 complex (Fig. 12-2). The degradation of the PER and CRY proteins is important in setting the period of the clock. The PER proteins are phosphorylated by enzymes such as casein kinase 1e and CKII. Once phosphorylated, the PER proteins are targeted for ubiquitination and degradation. In humans mutations in PER2, in the site in which it is phosphorylated[16] and also in CK1 delta,[17] lead to familial phase advance syndrome (for reviews, see[18]). Individuals with this have marked phase advance going to sleep at 7:30 PM and waking up at 4:00 AM.

The other core feedback loop involves the orphan nuclear-receptor genes—REV-ERBα/β and RORα/β. RORs activate BMAL1 while REV-ERBs repress BMAL1 and CLOCK RORs and REV-ERBs are themselves targets of CLOCK-BMAL1 and are negatively regulated by the repressors CRY1 and 2 and PER, particularly PER2.

Thus, the clock is a cell autonomous process and individual cells show circadian oscillation and clock mechanisms can be studied in vitro with cells in culture.

SUPRACHIASMATIC NUCLEUS—THE MASTER CLOCK

The master clock is in the suprachiasmatic nucleus (SCN) of the hypothalamus (for review, see[19]). It contains ~20,000 neurons. Destruction of this nucleus by lesioning results in the animal becoming arrhythmic, that is, with no obvious circadian period.[20,21] The intrinsic period of the clock is not exactly 24 hours and the clock is entrained each day to 24 hours by environmental cues. For the SCN, the main entrainment is by light/dark signals. There is a direct track from the retina to the SCN—the retinohypothalamic tract. Moreover, there is a separate light-sensing mechanism in the eye for entrainment of the clock. This was identified in knockout mice that lacked rods and cones in the retina. While they were blind, there was normal entrainment of the circadian system to light/dark.[22,23] Subsequently, the basis of this light-sensing mechanism was identified (for reviews, see[24,25]). It is the pigment, melanopsin, that is in retinal ganglion cells scattered across the retina.[26–28] This pigment is particularly sensitive to light in the blue color range.[29] This has led to development of blue light boxes, blue light glasses, and glasses that filter out blue light to manipulate the light input to the clock. Following time zone change the output of the master clock is entrained to the new time zone by altered light/dark input. However, this reentrainment is relatively slow with the clock adjusting only about 1 h/d.

PERIPHERAL CLOCKS

Once clock molecules were identified, the surprising result was that they were expressed in all tissues (for review, see[11,30]). It is now realized that there are functioning clocks in all tissues. These peripheral clocks are synchronized with signals from the master clock in the SCN. These peripheral clocks result in rhythmic expression of genes in each tissue and of the order of 3% to 10% of all mRNAs show rhythmic expression in different issues.[31] (The precise number of

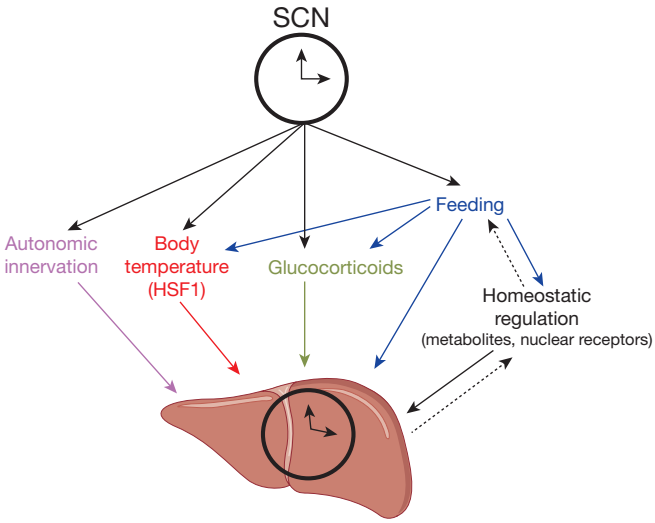

Figure 12-3 There are peripheral clocks in all organs. This diagram is for liver, but there are also clocks in the lung (see text). The "master" clock is in the suprachiasmatic nucleus (SCN) of the hypothalamus. It sends signals to peripheral clocks to synchronize them. There is also local control of clocks by metabolites, etc. *(Reproduced with permission from Mohawk JA, Green CB, Takahashi JS11. Central and peripheral circadian clocks in mammals. Annu. Rev. Neurosci. 2012;35:445–462.)*

genes oscillating depends on the mathematical definition of oscillation such that some estimates of the number of mRNAs oscillating are higher than this.) Thus, there are substantial changes in the molecular functions of different organs at different times of day. The lung is no exception in this regard (see further below).

Peripheral clocks are not only controlled by signals from the master clock but also by signals that occur locally in the particular tissue (Fig. 12-3). Important signals include changes in autonomic nerve activity, body temperature, glucocorticoids, and feeding pattern (Fig. 12-3). Phase shifting of peripheral clocks occurs much more rapidly than for the SCN. Altering the feeding pattern of mice can produce large phase shifts in liver clocks without any effect on the rhythmic expression in genes in the SCN.[32,33]

There is also a molecular clock, not surprisingly, in the lung (for review, see[34]). There is a clock in the Clara cells of the mouse bronchial epithelium.[35] As in other organs, there are a large number of genes that show diurnal changes in expression including genes involved in extracellular matrix, cell cycle, and apoptosis.[36] Genes encoding inflammatory molecules such as chemokine ligands also show diurnal oscillation.[36] The immune response, which is such a critical function of the lung, is under circadian control.[37] Circadian rhythm of other functions of the lung are known to occur, including in FEV_1.[38] Circadian variation also occurs in asthma symptoms[38] as do changes in the cellular content of bronchoalveolar lavage fluids in patients with mild asthma.[39]

Although a new area of inquiry, there are already data that pathological processes may interfere with the normal clock mechanism in the lung. In rats ventilator-induced lung injury results in reduction of REV-ERBα mRNA and protein in lung.[40] The role of REV-ERBα in clock mechanisms at the mRNA and protein level is increased in hyperoxic lung injury.[41] The role of REV-ERBα in clock mechanisms was described briefly earlier. It is likely that in the future the role of clock genes and mechanisms in pathogenesis of lung disease will be further elucidated.

CLOCK GENES AND PHARMACOLOGY

Given that a large part of the genome is regulated by clocks, it is not surprising that clock mechanisms can affect actions of drugs (for reviews, see[42,43]). The absorption of many commonly used drugs show time of day effects as does drug metabolism and drug excretion.[42,43] For example, there is a circadian variation in gene expression of several members of the cytochrome P450 system, the main system for drug oxidation, in liver.[31] Protein levels of cytochrome P450 also oscillate across the day[44] and there is a circadian rhythm of the activity of all cytochrome P450 enzymes.[45]

Thus, efficacy of specific drugs can vary with time of day. The anticoagulant effect of heparin, for example, varies with time of day.[46] When heparin is administered by constant intravenous infusion, the anticoagulant effect varies at different times of day.[46]

The concept of chronopharmacology is most developed for cancer therapy. Levels of plasma 5-fluorouracil vary across the day when the drug is delivered at the same rate.[47–49] There is a circadian variation of the pharmacokinetics of 5-fluorouracil.[50] Clinical trials show that treatment efficacy and toxicity of a chemotherapeutic regimen for metastatic colorectal cancer are enhanced using appropriate chronotherapy compared to constant infusion.[51]

Thus, time of day circadian effects need to be considered in pharmacology. It is likely that there will be a developing interest in this aspect when considering optimal drug regimens.

SLEEP AND ITS STAGES

It is now realized that sleep is universal. While definitions of sleep in mammalian species are based on the electroencephalogram, behavioral criteria[52,53] have led to identification of sleep in many species. In particular, a sleep state has now been identified in Drosophila,[54] zebra fish,[55,56] and most recently in the worm, *Caenorhabditis elegans*.[57] Thus, all model systems are available to study sleep. There are already data that molecular mechanisms regulating sleep are conserved across species.[58]

While there is a suggestion that there are different stages of sleep in Drosophila,[59] rapid eye movement (REM) sleep has only been recognized in mammals and birds. In mammals sleep is divided into two major types—nonrapid eye movement (NREM) sleep and REM sleep (for review, see[60]). REM sleep is a stage with the following: the brain is quite active with flurries of activity resulting in REMs; individuals waking from REM sleep recall their dreams; there is active paralysis of muscles apart from the diaphragm such that normal individuals do not live out their dreams. Individuals with REM behavior disorder do enact their dreams since the atonia of REM sleep is no longer in place. This is a synucleinopathy and a high percentage of individuals with REM behavior disorder go on to develop Parkinson disease (for review, see[61]). Also in REM autonomic instability with variations in heart rate and breathing pattern (for further details, see Chapter 101). NREM sleep is divided into stages based on the electroencephalogram (Fig. 12-4). Originally four stages of NREM sleep were identified but recently stage 3 and stage 4 NREM sleep have been collapsed into one stage—N3. In this stage there is synchronized oscillatory firing of cortical neurons that generate large slow waves which are detected on the electroencephalogram (Fig. 12-4). In all mammalian species there is distinct cycling of the different sleep stages, although the periods of these cycles vary between species. In humans the cycles have approximately a 90-minute duration with episodes of REM sleep occurring every 90 minutes (Fig. 12-5). In the first part of the night individuals cycle down into stage 3 sleep; slow-wave sleep occurs early in the sleep period. Episodes of REM sleep get longer and indeed more phasic, that is, more eye movements etc., as the night progresses. Thus, typically humans are waking up out of REM sleep in the morning. There are major differences in the behavior of the cardiopulmonary system in these different sleep stages. These are discussed in Chapter 101.

MECHANISMS CONTROLLING SLEEP

Sleep is a circuit property, that is, there is no evidence that single neurons sleep, although the intensity of "sleep" may vary across the

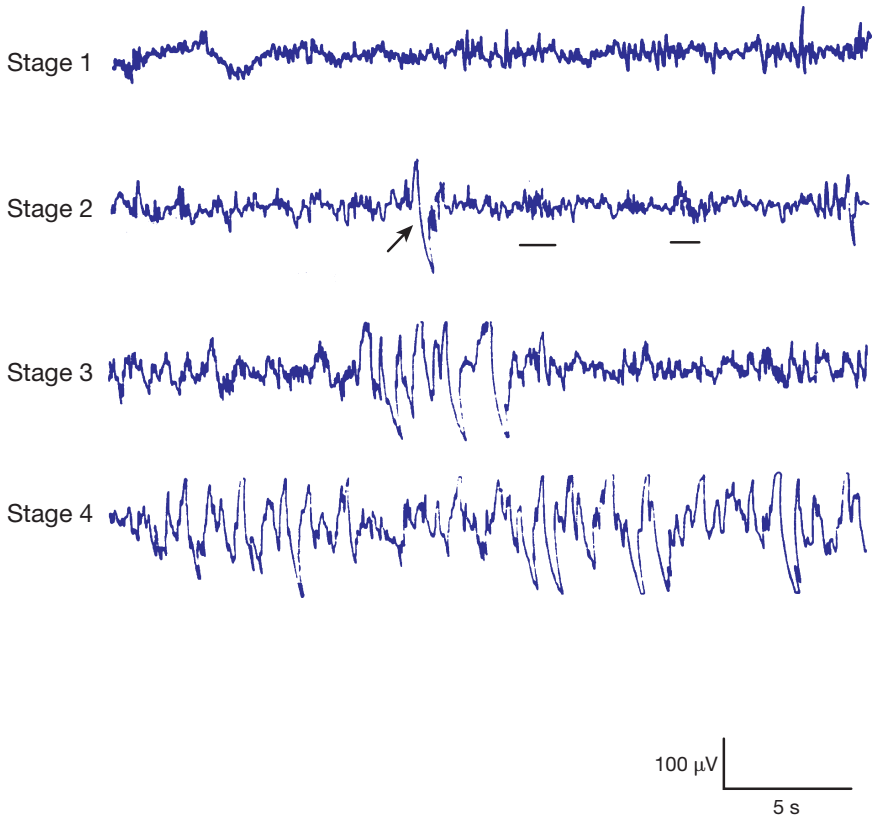

Figure 12-4 Electroencephalographic tracings recorded from a normal young adult demonstrating the four stages of NREM sleep. In the stage 2 recording, the *arrow* points to a characteristic K complex and the underlining to sleep spindles.

brain, that is, local sleep slow waves in NREM sleep are particularly marked over brain regions that have been very active during wakefulness as a result of their involvement in specific tasks.[62,63] Much work over the last two to three decades has identified the neuronal basis for sleep/wake control (for reviews, see[60,64]). Many neuronal groups have increased firing during wakefulness, reduced firing during NREM sleep, and virtually absent firing during REM sleep. These include the following: Cholinergic cells in basal forebrain; orexin (hypocretin) cells in lateral hypothalamus; histamine cells in posterior hypothalamus; dopamine cells in periaqueductal gray; noradrenaline cells in locus coeruleus; and serotonin cells in brain stem raphe nuclei. While these neurons are all more active in waking, they are likely to have different functions during wakefulness. For example, it has been shown that orexin (hypocretin) neurons respond to emotions, for example, positive emotions that result in pleasure increase the level of hypocretin.[65]

While all of these neurons show similar differences in firing between wake and sleep states, there is a different pattern for cholinergic neurons in the pedunculopontine tegmentum (PPT) and lateral–dorsal tegmentum (LDT) in the brain stem. These neurons have reduced firing in NREM sleep compared to wakefulness but higher firing in REM sleep.[60] Thus, REM sleep is thought of as a time with higher cholinergic activity.[60]

While many neurons show increased firing during wakefulness, there are very limited numbers of neurons that increase their activity during sleep. These neurons are in the ventrolateral preoptic (VLPO)[66] and medial preoptic (MPO)[67] area of the hypothalamus. The VLPO has been called the sleep switch.[66] Neurons active during sleep contain the inhibitory neurotransmitter GABA and the neuropeptide galanin.

Since control of wake, sleep and its stage is a circuit property, it has been proposed that behavioral state is controlled by a flip-flop (Fig. 12-6) (for review, see[64]). It is posited that wake-active neurons inhibit sleep-active cells during wakefulness but there are state-dependent changes such that a flip occurs and now sleep cells inhibit wake neurons during sleep. There is a secondary flip-flop that controls oscillation between NREM and REM sleep.[68]

In this proposed mechanism orexin cells play a critical role in stabilizing the flip-flop, that is, preventing too many state transitions. Orexin cells play an important role in narcolepsy. Following the description of this new neuropeptide by two groups – one of which called the neuropeptide, hypocretin[69] while the other called it orexin[70] – it was quickly recognized that it played a key role in narcolepsy. Dogs with a mendelian recessive genetic form of narcolepsy had mutations in the orexin-2 receptor that made it nonfunctional[71] while mice with orexin knockout showed key features of human narcolepsy.[72] Postmortem studies have shown that patients with narcolepsy and cataplexy have loss of orexin (hypocretin) neurons.[73] Thus, narcolepsy is likely an autoimmune disorder in which the main pathogenetic mechanism is destruction of orexin neurons.[74]

Functions of Sleep

Although much effort has been made to understand the neuronal basis of sleep, an equally if not important question is what the

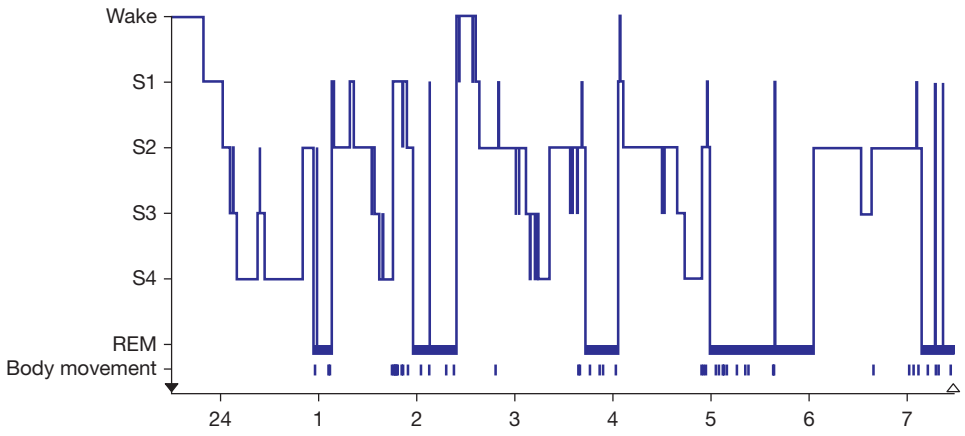

Figure 12-5 The progression of sleep stages across a single night's sleep of a normal young adult. The histogram was drawn on the basis of continuous recordings scored in 30-s epochs.

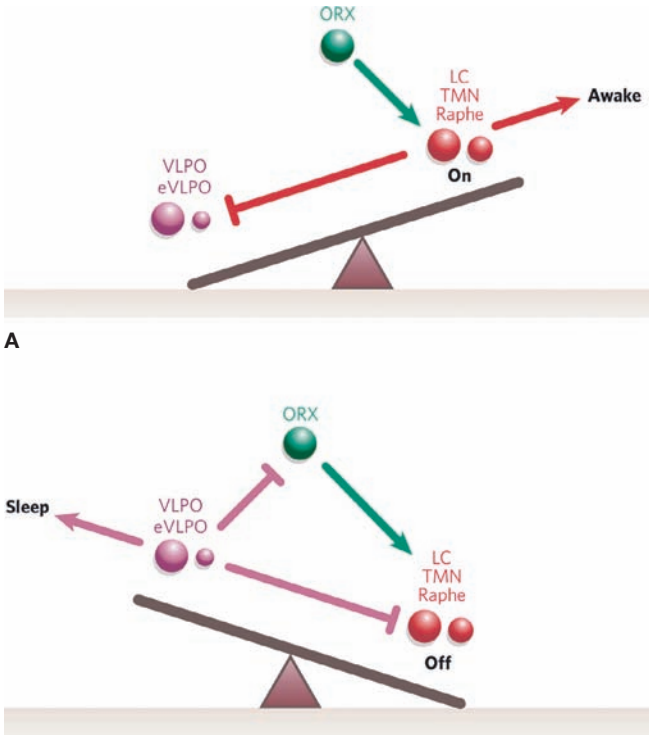

Figure 12-6 A schematic diagram of the flip-flop switch model. During wakefulness (**A**), the monoaminergic nuclei inhibit the ventrolateral preoptic nucleus (VLPO), thereby relieving the inhibition of the monoaminergic cells, and that of the orexin (ORX) neurons, and the cholinergic pedunculopontine (PPT) and laterodorsal tegmental nuclei (LDT). Because the VLPO neurons do not have orexin receptors, the orexin neurons serve primarily to reinforce the monoaminergic tone, rather than directly inhibiting the VLPO on their own. During sleep (**B**), the firing of the VLPO neurons inhibits the monoaminergic cell groups, thereby relieving their own inhibition. This also allows it to inhibit the orexin neurons, further preventing monoaminergic activation that might interrupt sleep. The direct mutual inhibition between the VLPO and the monoaminergic cell groups forms a classic flip-flop switch, which produces sharp transitions in state, but is relatively unstable. The addition of the orexin neurons stabilizes the switch. eVLPO, extended ventrolateral preoptic nucleus.

functions of sleep are. We spend about one-third of our lives sleeping. The question is what benefit do we obtain? Is benefit just for the brain or do other organs, such as the lung, also obtain benefit?

While theories as to the functions of sleep have been proposed for decades, the concepts that have been articulated recently have in large part, although not exclusively, come from microarray studies comparing gene expression between sleeping and wake animals (often enforced with sleep deprivation) sacrificed at the same time of day. The major focus, not surprisingly, has been on the functions of sleep for the brain.

The following functions of sleep for the brain have been proposed.

ENERGY RESTORATION HYPOTHESIS

One of the concepts that has been proposed is the Benington–Heller hypothesis (for review, see[75,76]). It posits that energy stores in brain – primarily glycogen in glia – are depleted during wakefulness and are restored during sleep. There are some data to support this.[77] However, the situation is more complex (for review, see[76]). There is upregulation of key components of the electron transport chain during wakefulness.[78] This is presumably to make ATP to provide increased energy utilization during wakefulness with higher neuronal firing rates.

SYNAPTIC HOMEOSTASIS THEORY

Expression of genes involved in synaptic upscaling such as BDNF and ARC are upregulated during wakefulness and downregulated during sleep.[80] This has led to the concept that there is synaptic upscaling during wakefulness and downscaling during sleep (for review, see[79]). There are data to support this hypothesis. In Drosophila there are increased amounts of synaptic proteins detected during wakefulness and less during sleep.[81]

There is, however, contradictory evidence. In developing animals there is evidence that synaptic plasticity is enhanced during sleep (not wakefulness).[82] It is conceivable, of course, that this phenomenon is specific to the developmental period. Sleep is a critical period for brain development.[83] It is also conceivable that changes in synaptic plasticity with sleep/wake are different in different brain regions (for debate on this, see[84]). Thus, much remains to be determined and it is likely that the situation is more complex than simply strengthening of synapses during wakefulness and downscaling during sleep.

MACROMOLECULAR BIOSYNTHESIS

Microarray studies also suggest that sleep is a stage of macromolecular biosynthesis (for review, see[85]). Among classes of genes whose expression is increased in cerebral cortex and hypothalamus during sleep compared to wakefulness are genes involved in macromolecular biosynthesis.[86] These gene classes are very overrepresented among genes whose expression is increased during sleep.[86] This involves pathways for multiple molecules, for example, all genes in the cholesterol synthesis pathway, six of seven genes in heme synthesis pathway, and genes involved in protein synthesis. Thus, sleep and wake may be part of a metabolic cycle (for concept, see[87]). Energy resources during wakefulness are used for neural activity, that is, ion pumps etc., but during sleep they are used for macromolecular biosynthesis. Thus, sleep is a stage where new molecules are made to restore membranes, vesicles, etc., that is, to prepare for subsequent wakefulness.

RECOVERY FROM ENDOPLASMIC RETICULUM (ER) STRESS

Another concept that arose from microarray studies is that prolonged wakefulness leads to ER stress with protein misfolding.[88,89] This was suggested by the observation that the molecular chaperone, BiP, the master regulator of the unfolded protein response (for review, see[90,91]) is upregulated in multiple brain regions in multiple species with sleep loss.[88,89] The unfolded protein response is a ubiquitous protective mechanism that is activated when ER stress occurs in the ER with misfolding of proteins.[90,91] The UPR results in helping misfolded proteins to fold properly, chaperoning those not folded out for degradation and inhibition of protein translation to reduce protein production (see[90,91]). All components of the unfolded protein response are activated in mouse cerebral cortex following 6 hours of sleep loss.[92] Inhibiting protein translation by administration of the drug salubrinal that is a modulator of the ER stress response, enhances slow-wave sleep and activates sleep promoting neurons in the MPO area.[93]

CLEARANCE OF COMPOUNDS FROM BRAIN

The brain is unique among organs in that it has no lymphatic system (see[94]). Thus, the question is how are compounds cleared from the brain? This has led to the intriguing concept of glia-lymph, that is, glial cells in brain are responsible for clearance of compounds. Recent data show that compounds are much more rapidly cleared during sleep than during wakefulness.[94] Studies with fluorescent-labeled compounds show that there is substantially more convective flux across the brain in sleeping as compared to waking animals.[94] The precise mechanism that allows this increased transport to occur during sleep is unknown, although it seems to be a result of lower levels of the neurotransmitter, noradrenaline during sleep.[94] A compound that is cleared more rapidly during sleep is beta-amyloid that

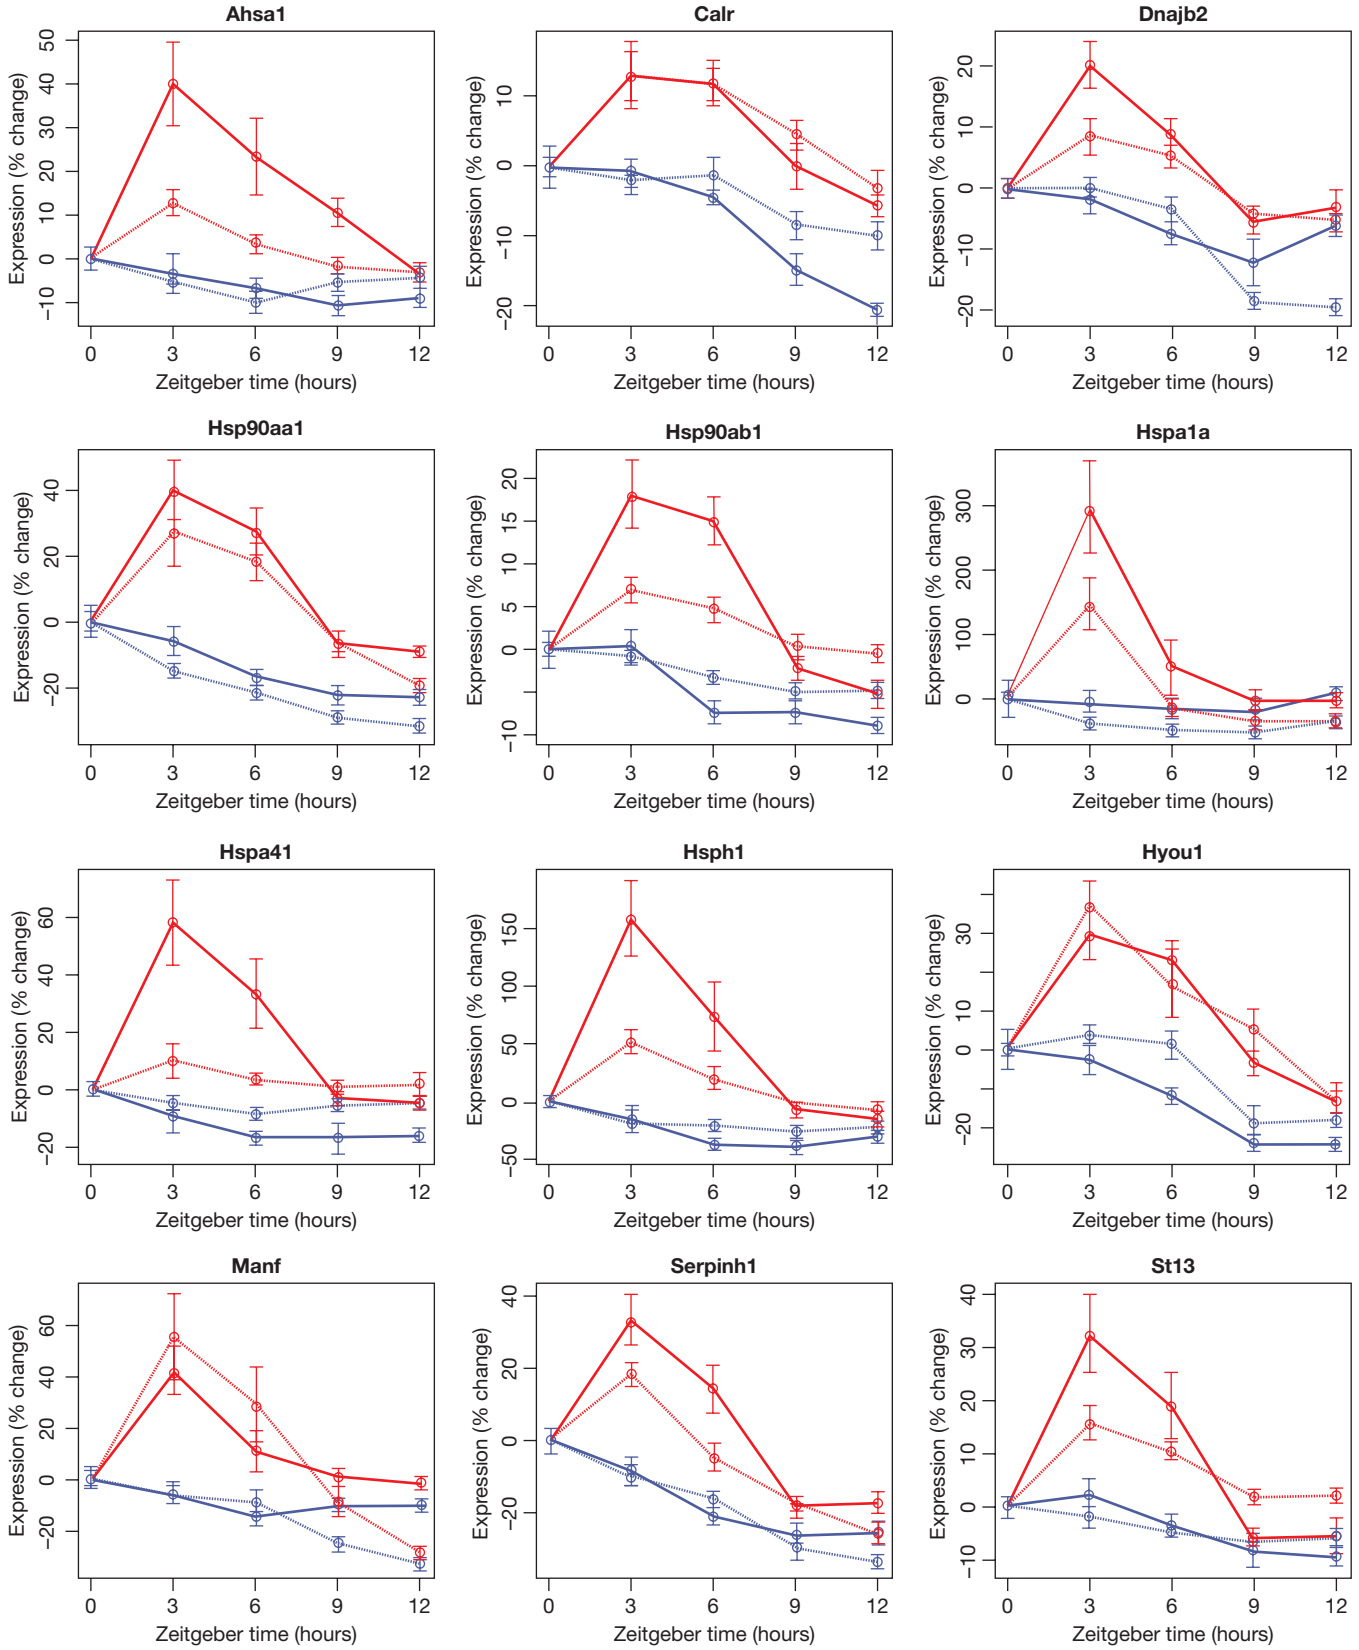

Figure 12-7 Transcript profiles of sleep-repressed genes involved in the unfolded protein response. Temporal profiles of expression for select sleep-responsive genes with annotations relating to protein processing and endoplasmic reticulum (ER) stress. Changes in gene expression from the baseline condition (lights on) are plotted as a percent of baseline expression levels. Maroon curves show data from experimentally sleep-deprived animals and blue curves show data from spontaneously sleeping animals. Data from heart tissue is connected with dashed lines. Data from lung tissue is connected by uninterrupted lines. All genes shown here met statistical criteria for sleep-specific repression in both tissues. Data shown represents mean ± standard error for eight or nine biological replicates. *(Reproduced with permission from Anafi RC, Pellegrino R, Shockley KR, Romer M, Tufik S, Pack AI102. Sleep is not just for the brain: transcriptional responses to sleep in peripheral tissues. BMC Genomics. 2013;362.)*

plays a key role in the pathogenesis of Alzheimer disease. Thus, disturbances of sleep might accelerate Alzheimer's pathology. This has been shown experimentally in mice since sleep loss over many days accelerates plaque development in a mouse model of the disease.[95] Moreover, sleep apnea is now recognized as an independent risk factor for mild cognitive impairment and dementia.[96]

MEMORY CONSOLIDATION

All of the functions described earlier indicate that at a molecular level sleep is an active state with several specific functions (for reviews, see[97,98]). It is not only an active state at a molecular level but also with respect to cognition and memory consolidation. Performance or tasks that require identification of a "hidden rule" are enhanced following sleep, that is, sleep allows the brain to continue to process information and enhances insight.[99] Memory tasks are enhanced after sleep. This is not simply a matter of time since repeating the task several hours later during wakefulness does not result in this enhancement. Enhancement of performance in some tasks is correlated with the amount of slow-wave sleep while for other tasks the correlation is with the amount of REM sleep.[97,98] It has been proposed that REM sleep enhances procedural and emotional memories, while slow-wave sleep enhances declarative memories.[98] Sleep enhancement of memory is reduced with aging.[100]

Thus, sleep seems to have many functions for brain rather than simply one. This is not surprising since it seems logical to ensure maximal benefit from "downtime." The discussion of functions of sleep largely treats sleep as a single entity. We know, however, as described above, that there are specific stages of sleep. Thus, it is conceivable that slow-wave sleep and REM sleep have different functions (see discussion above about memory consolidation). One of the challenges to elucidating function of different stages of sleep is that in mouse models REM sleep episodes are extremely short—of the order of minutes. They are so short that if REM sleep has particular functions they cannot be at the transcriptional level but are likely to be related to posttranslational modifications. It is of interest to consider what the impact of fragmented sleep such as occurs in obstructive sleep apnea (see Chapter 99) will have on the functions described. This has not, however, been studied and is an area of research need and opportunity.

Does the Lung Sleep?

One of the fundamental tenants of sleep biology is that sleep is by the brain and for the brain—a title of a provocative article in *Nature*.[101]

Again, data from microarrays challenge this tenant. Comparing gene expression between sleeping and awake animals sacrificed at the same time of day shows that there are common pathways downregulated in both lung and heart during sleep. As in brain, these pathways are those involved in ER stress, molecular chaperones, and heat shock molecules.[102] There is remarkable similarity in the changes in gene expression in both organs with sleep and sleep deprivation in key genes in these pathways (Fig. 12-7). This suggests that there must be a common signaling mechanism that leads to these dynamic changes in expression of these genes in different tissues in a coordinated way. The nature of this mechanism is unknown. While there are common gene pathways downregulated in sleep in lung and heart, upregulated pathways with sleep are different between organs. In the lung there is upregulation of certain genes for antioxidant enzymes. Thus, is sleep a time for clearing the free radicals produced in the lung during the day? There is a need for more in-depth exploration of the changes in the lung during sleep. These recent data would lead to the conclusion, however, that the lung does indeed sleep.

CONCLUSION

Sleep and circadian biology are dynamic areas of research. New concepts are emerging and some of the fundamental mechanisms are being elucidated. From the point of view of the pulmonologist, there are two major issues. First, both circadian rhythm and sleep have direct effects on molecular mechanisms in the lung. Second, disturbances of sleep like these produced by sleep-disordered breathing will have adverse consequences at a molecular level on the functions of sleep, including potentially in the lung itself.

CHAPTER 13
Pulmonary Circulation

Robert Naeije

INTRODUCTION: HISTORY AND EVOLUTION

The discovery of the pulmonary circulation was reported in the 13th century by Ibn al-Nafis (1213–1288) in the "Commentary on Anatomy in Avicenna's Canon" and, probably independently, in the 16th century by Michael Servetus (1511–1553) in the "The Restoration of Christianity."[1] However, it has only been recently realized that the pulmonary circulation as a separate high-flow low-pressure system is the end result of an evolutionary process aimed at the optimization of gas exchange of endothermic birds and mammals.[2] Evolution from ancestors of fishes to amphibians, reptiles, and finally birds and mammals has led to progressively greater oxygen consumption requiring thinner pulmonary blood–gas barrier. The alveolocapillary membrane in mammals is a vulnerable structure only 0.3 μm thick. Preservation of the integrity of this barrier has been made possible by the complete separation of the pulmonary circulation from the systemic circulation. This evolution has been accompanied by a progressive unloading and reshaping of the right ventricle (RV) as a thin-walled flow generator.

The extreme potential physiological stresses on the pulmonary circulation are exercise and hypoxia. Exercise increases oxygen uptake and carbon dioxide output up to some 20-fold above resting values, and increases cardiac output up to some sixfold. Strenuous exercise may eventually alter gas exchange because of excessive capillary filtration and stress failure, or expose the RV to excessive loading resulting in a limitation of maximum cardiac output. Hypoxia adds the burden of further increase in pulmonary vascular pressures due to hypoxic pulmonary vasoconstriction.

PULMONARY VASCULAR PRESSURES AND RESISTANCE

LIMITS OF NORMAL

The pulmonary circulation is characterized by an inflow pressure or pulmonary artery pressure (Ppa), an outflow pressure or left atrial pressure (Pla), and a pulmonary blood flow (Q) approximately equal to systemic cardiac output. Pulmonary vascular pressures and flows are pulsatile. However, a simple and clinically useful description of the functional state of the pulmonary circulation may be provided by a calculation of pulmonary vascular resistance (PVR) from mean values of Ppa (mPpa), Pla, and Q.

$$PVR = (mPpa - Pla)/Q$$

Measurements of pulmonary vascular pressures and cardiac output are usually performed during a catheterization of the right heart with a fluid-filled balloon-tipped thermodilution catheter (Fig. 13-1). This procedure allows for the estimation of Pla from a balloon-occluded (Ppao) or wedged (Ppw) Ppa and Q by thermodilution.

METHODOLOGICAL ASPECTS

The frequency response of fluid-filled catheters is considered to be sufficient for meaningful measurements of systolic and diastolic Ppa (sPpa and dPpa), and derived calculation of mPpa. However, errors may be caused by overdamping or underdamping of signals related to the insufficient or excessive flushing or excessive length of tubing systems.[3] A comparison of pulse pressure (PP, or sPpa − dPpa) measured with fluid-filled catheters compared to gold standard high fidelity micromanometer-tipped catheters in eight dogs with pulmonary hypertension induced either by ensnarement of the pulmonary arteries or injection of microbeads is illustrated in Figure 13-2.[4] Measurements of PP were highly correlated, with an analysis according to Bland and Altman[5] showing almost no bias, indicating excellent accuracy. However, the limits of agreement reached ± 8 mm Hg, which may be insufficiently precise in certain clinical circumstances.

Estimations of Pla by Ppw are generally believed to be accurate based on earlier reports of high levels of correlations.[6] This was recently revisited in a large quality-control study in almost 4000 patients with pulmonary hypertension who underwent measurements of Ppw during a right heart catheterization and Pla estimated by left ventricular (LV) end-diastolic pressure during a left heart catheterization.[7] The results showed a bias of −3 mm Hg, corresponding to an expected pressure gradient from small pulmonary veins to the left ventricle at end diastole, thus indicating excellent accuracy, but limits of agreement ranged from −15 to +9 mm Hg, indicating insufficient precision for cut off number-derived individual diagnosis.

Thermodilution Q compared to gold standard direct Fick measurements has been reported to present with little bias, ±0.1 L/min, and thus excellent accuracy, even in patients with severe pulmonary hypertension and tricuspid regurgitation (TR). The limits of agreement were ±1 L/min, which is relatively large but probably often of minor clinical relevance.[8]

Fluid-filled catheters measure vascular pressures with a zero-leveled external manometer. The best reference is the hydrostatic indifference point, at the level of the tricuspid valve, where pressure is independent of body position.[9] This is midchest or 5 cm below the Louis angle in the supine position, with midaxillary intersection at the two inferior fourths of the rib cage to consider when measurements are in the upright position. Zero leveling at the catheterization table is associated with an overestimation of Ppa and Ppw.

Measurements are generally performed at end expiration, when the lungs are at functional residual capacity (FRC). Lung volumes below or above FRC are associated with increased PVR, because of predominant increased alveolar vessel resistance at high lung volumes, and increased extra-alveolar vessel resistance at lower lung volumes.[10] Thus patients with obstructed airways as a cause of increased FRC may present with an increased PVR. Furthermore, these patients have important intrathoracic pressure swings, which are predominantly positive during expiration.[11] This is illustrated in Figure 13-3. Measurements at end expiration may then overestimate Ppa and Ppw.

Sometimes a measurement of Pla or Ppao cannot be obtained, and a *total* PVR (TPVR) is calculated as:

$$TPVR = mPpa/Q$$

Since Pla is not negligible with respect to Ppa, TPVR is larger than PVR and this difference may be flow dependent. Thus TPVR is not a correct characterization of the flow-resistive properties of the pulmonary circulation when Pla is increased. On the other hand, TPVR may be a more realistic estimate of RV afterload. The RV is exposed to Ppa and not to the difference between Ppa and Pla.

PULMONARY CAPILLARY PRESSURE

While wedged or occluded Ppa measurements (Ppw) are acceptable estimates of Pla, micropuncture studies have shown that pulmonary

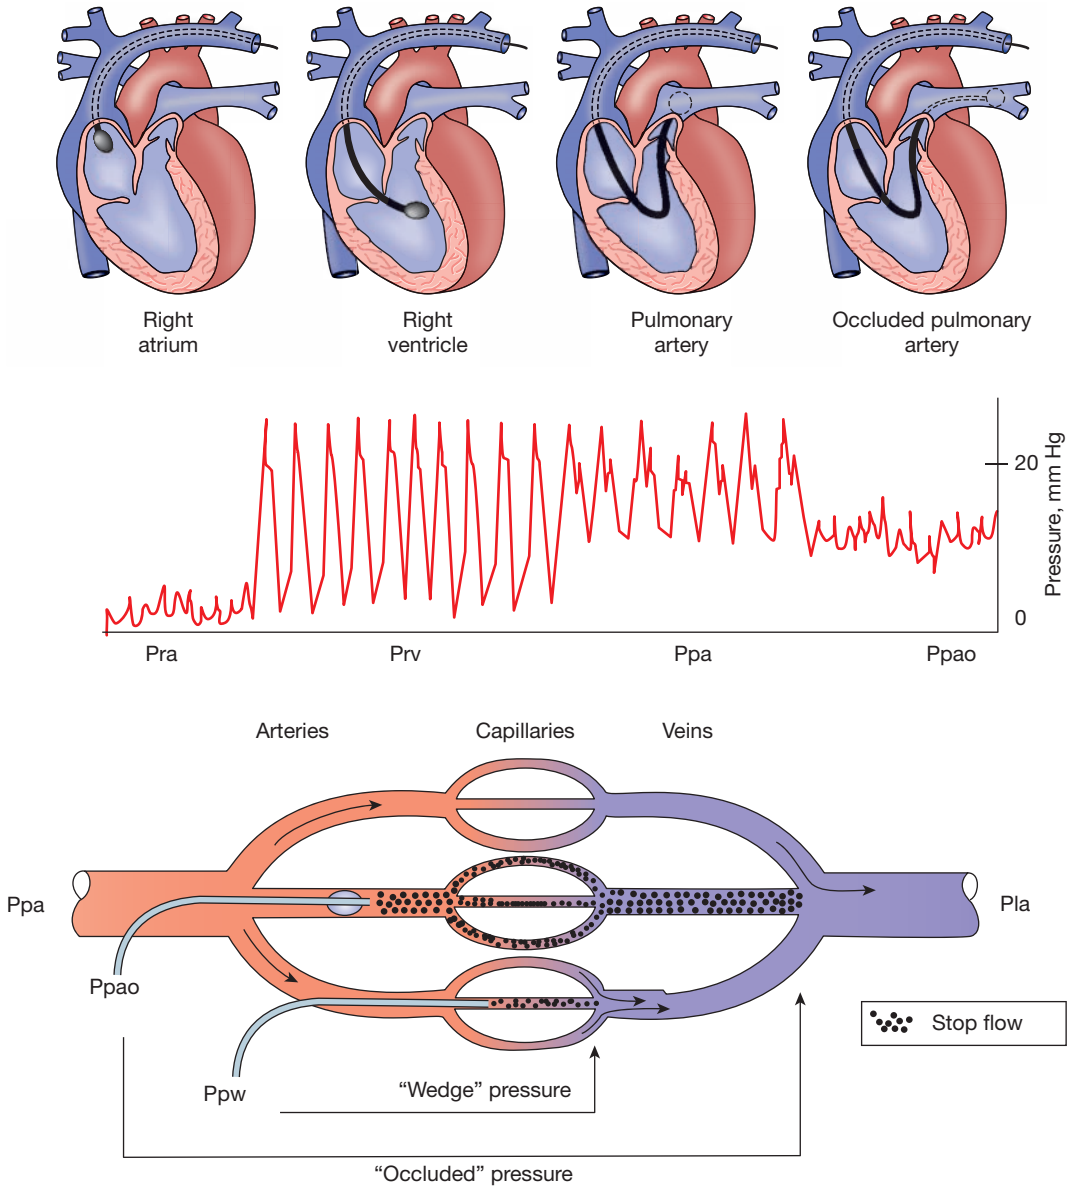

Figure 13-1 Right heart catheterization with flow-directed balloon-tipped catheter with successive measurements of right atrial pressure (Pra), right ventricular pressure (Prv), pulmonary artery pressure (Ppa), and occluded Ppa (Ppao). Because of the fractal structure of the arterial and venous branching of the pulmonary vascular tree, occluded or wedged Ppa prolongs the fluid column of the catheter until same diameter pulmonary vein, which is a satisfactory estimate of left atrial pressure or left ventricular end-diastolic pressure.

capillary pressure (Ppc) is higher than Ppw, about halfway between arterial and venous pressures.[12] Thus wedged or occluded Ppa should not be called "capillary" or "capillary-wedge" pressure. Estimates of Ppc can be obtained from the analysis of Ppa decay curves after arterial occlusion (Fig. 13-4).[13] The limits of normal of Ppc measured in healthy volunteers at rest using single arterial occlusion[14] are shown in Table 13-1. Based on measured distribution of resistances in perfused normal lungs, with 60% arterial resistance and 40% capillary plus venous resistance, Ppc can be estimated from the equation:

$$Ppc = Pla + 0.4 \times (mPpa - Pla)^{15}$$

THE CALCULATION OF PVR

A vascular resistance calculation derives from the physical law that governs laminar flows of newtonian fluids through nondistensible, straight cylindric tubes, originally proposed by the French physician Poiseuille and later put in mathematical equation by the German physicist Hagen. Poiseuille showed experimentally that flow was inversely related to the fourth power of the internal radius, and confirmed previous demonstrations that arterial pressure remains high in arteries down to 2 mm in diameter while venous pressure is low in animals. The Hagen–Poiseuille law states that resistance R to flow of a single tube is equal to the product of the length l of the tube and viscosity η and a constant 8 divided by the product of π and the fourth power of the internal radius r. More generally R can be calculated as a pressure drop ΔP to flow Q ratio:

$$R = l\eta 8/\pi r^4 = \Delta P/Q$$

The ratio of pressure drop to flow through an entire vascular bed accounts for the resistances in series and in parallel of the individual vessels. The fact that *r* in the equation is to the fourth power explains why *R* is exquisitely sensitive to small changes in caliber of these

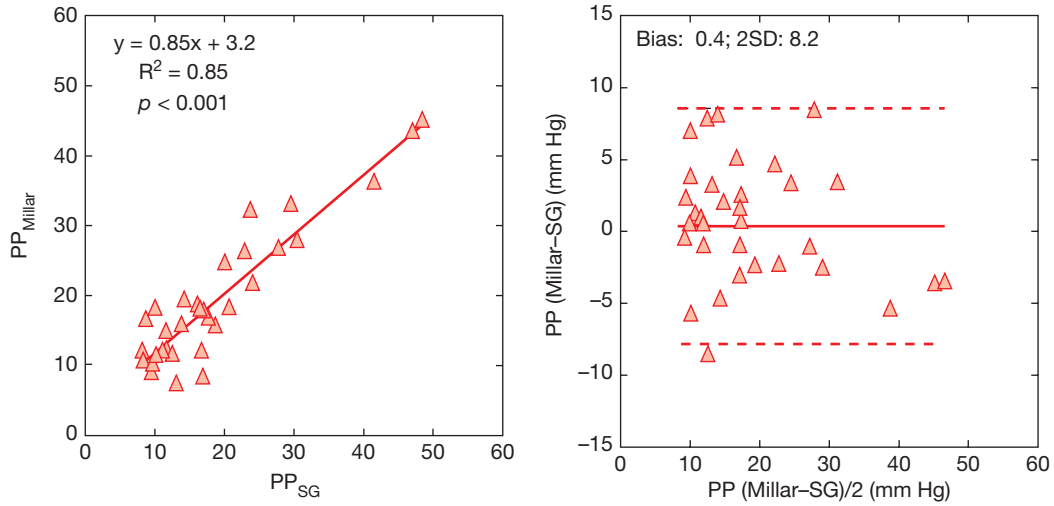

Figure 13-2 Correlation between pulmonary arterial pulse pressure (PP) measured using fluid-filled Swan–Ganz (SG) versus high-fidelity micromanometer-tipped Millar catheters and same measurements presented as Bland and Altman plots. The bias was negligible, indicating accuracy of fluid-filled catheter measurements, but the limits of agreement were of ± 8 mm Hg, indicating limited precision. *(Data from Pagnamenta A, Vanderpool R, Brimioulle S, Naeije R. Proximal pulmonary arterial obstruction decreases the time constant of the pulmonary circulation and increases right ventricular afterload. J Appl Physiol. 2013;114:1586–1592.)*

small vessels (a 10% change in radius results in almost 50% change in resistance). Accordingly, PVR is a good indicator of the state of constriction or dilatation of pulmonary-resistive vessels and is useful for detecting changes in arteriolar vessel caliber due to changes in tone and/or structure.

■ EFFECTS OF AGE, SEX, AND BODY POSITION

The limits of normal of resting pulmonary vascular pressures and flows as derived from invasive measurements in 60 resting supine young adult healthy volunteers[14,16–18] are shown in Table 13-1. In that study population, cardiac output was lower in women, who are smaller than men, and thus PVR in women was higher. However, there were no sex differences in pulmonary hemodynamics after correction for body dimensions. These data have been confirmed by a recent review of invasive measurements reported in 47 studies on a total of 1187 individuals, of whom 225 were identified as women and 717 as men.[19]

Aging is associated with an increase in PVR. This is due to a slight increase in mPpa and a more important decrease in cardiac output leading to a doubling of PVR over a period of five decades.[20,21]

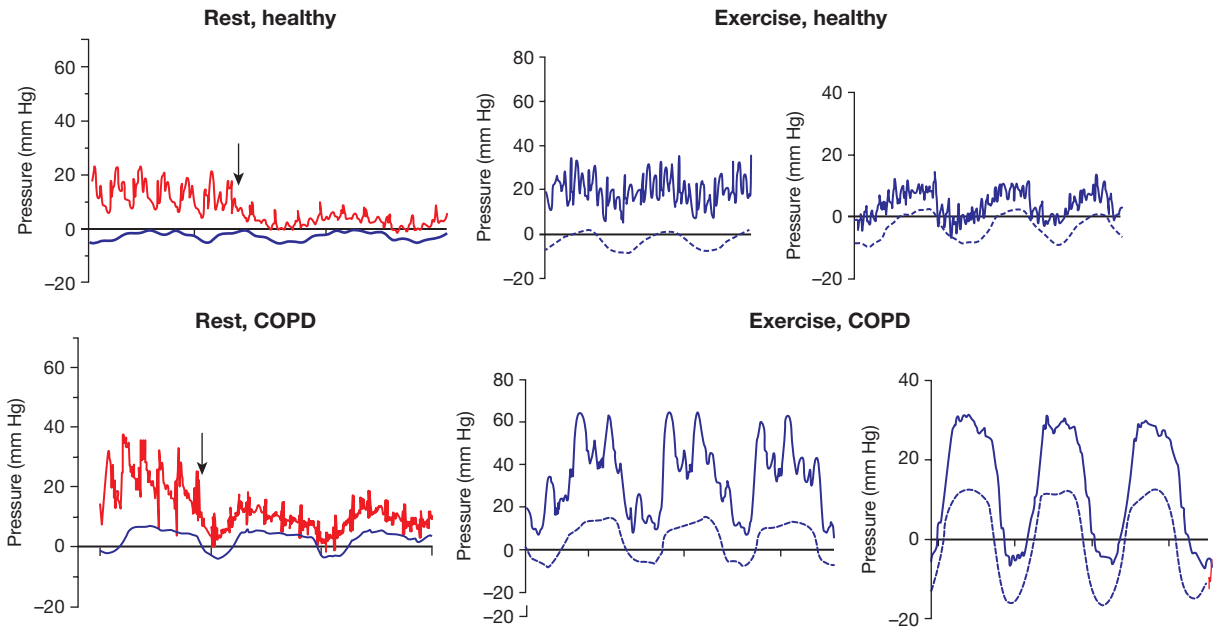

Figure 13-3 Simultaneous pressure recordings of pulmonary artery pressure (Ppa) and wedged Ppa (Ppw) with esophageal pressure (Pes) in a healthy subject and a patient with chronic obstructive pulmonary disease (COPD), at rest and at exercise. The *arrows* represent the moment of balloon inflation. Note the large influence of intrathoracic pressure on the Ppa and Ppw during exercise in COPD. *(Reproduced with permission from Robert Naeije and Bart G. Boerrigter. Pulmonary hypertension at exercise in COPD: does it matter? Eur Respir J. 2013;41:1002–1004.)*

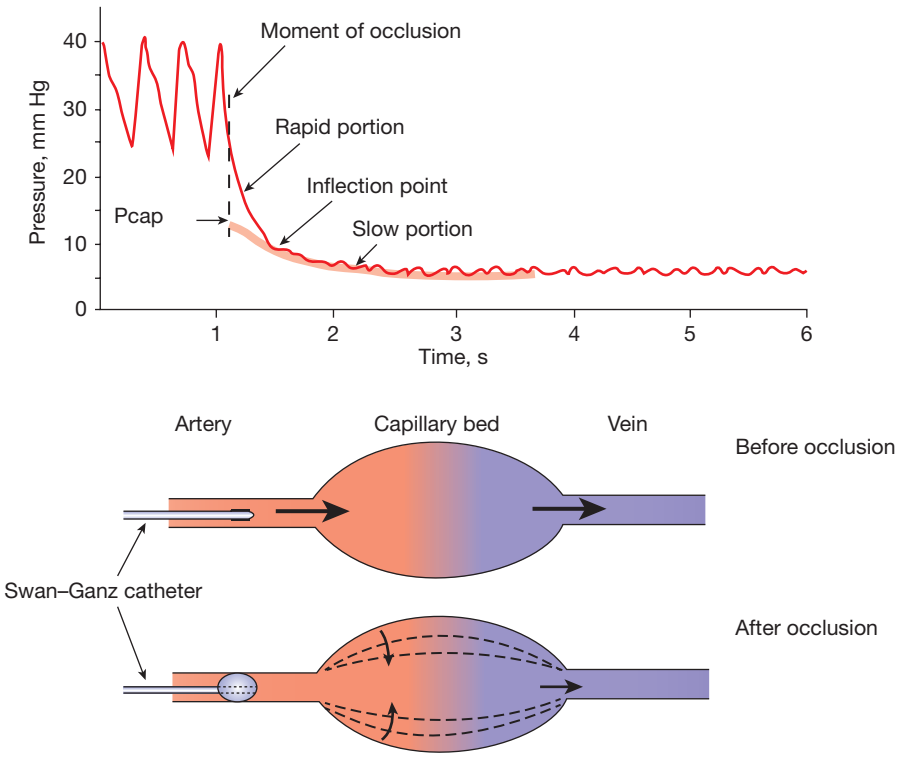

Figure 13-4 Analysis of the pressure transient after pulmonary arterial occlusion for the estimation of pulmonary capillary pressure (Pcap) either by the intersection of the fast and the slow components of the pressure decay curve, or by the extrapolation of the exponential fitting of the slow component of the pressure decay curve to the moment of occlusion.

EFFECTS OF PULMONARY BLOOD FLOW

The inherent assumption in a PVR calculation is that the mPpa–flow relationship is constant and crosses the pressure axis at a value equal to Pla (such that when flow is zero, theoretically, mPpa = Pla). Then, PVR is constant, independent of the absolute pressure or flow.

The relationship between (mPpa–Pla) and Q has been shown to be reasonably well described by a linear approximation over a limited "physiological" range of flows, with a zero extrapolated pressure intercept in well-oxygenated lungs in supine resting intact animals including man, suggesting complete recruitment and minimal distension of the normal well-oxygenated pulmonary circulation. However, hypoxia and a number of cardiac and respiratory diseases increase both the slope and the extrapolated intercepts of multipoint mPpa–Q plots.[23]

While an increase in the slope of mPpa–Q is easily understood as being caused by a decreased cross-sectional area of pulmonary-resistive vessels, the nonzero and typically positive extrapolated pressure intercept has inspired various explanatory models.

However, measurements in healthy elderly individuals are few, so that the exact limits of normal of the pulmonary circulation as a function of age are not exactly known.

Body position affects PVR through associated changes in systemic venous return. In the upright position, Pla, right atrial pressure (Pra), and cardiac output are lower in the supine position. Because of pulmonary vascular derecruitment, mPpa remains essentially the same. Accordingly, PVR is higher upright. This difference in upright versus supine PVR is important to keep in mind when examining PVR changes during exercise performed upright as compared to supine (Fig. 13-5).[22]

TABLE 13-1 Limits of Normal of Pulmonary Vascular Pressures and Pulmonary Blood Flow at Rest

Variables	Mean	Limits of Normal
Q L/min	6.4	4.5–8.5
Heart rate, bpm	67	40–100
Ppa systolic, mm Hg	19	13–26
Ppa diastolic, mm Hg	10	6–16
Ppa, mean, mm Hg	13	8–20
Ppw, mm Hg	9	5–12
Ppc, mm Hg	10	8–12
Pra, mm Hg	5	1–8
PVR, dyne·s·cm^{-5}	55	12–100

Q, pulmonary blood flow; Ppa, pulmonary artery pressure; Ppw, wedged pulmonary artery pressure; Ppc, pulmonary capillary pressure; Pra, right atrial pressure; PVR, pulmonary vascular resistance.

THE STARLING RESISTOR MODEL OF THE PULMONARY CIRCULATION

To explain the nonzero and positive pressure intercept, Permutt et al.[24] conceived a vascular "waterfall" or "Starling resistor" model made of parallel collapsible vessels with a distribution of nonzero and positive closing pressures. The waterfall analogy refers to the fact that the flow rate (Q) over a waterfall is independent of

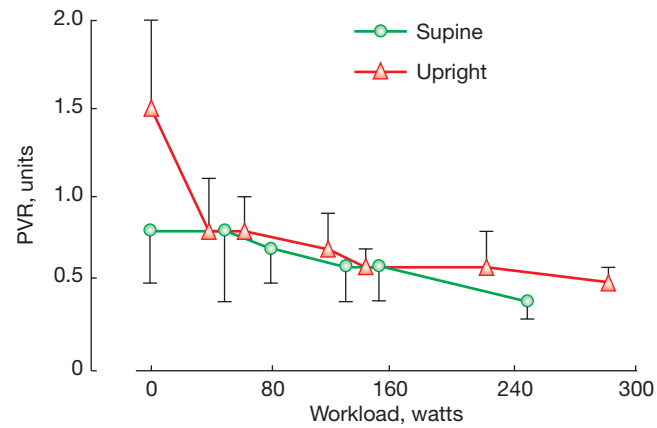

Figure 13-5 Pulmonary vascular resistance (PVR) at rest and during progressively increased workload in healthy volunteers in the upright *(triangles)* versus the supine position *(circles)*. Resting PVR was higher in the upright position. As soon as at moderate workload, upright and supine PVR converge, with mild further decline with increasing levels of exercise. Vertical bars indicate SDs. *(Data from Reeves JT, Dempsey JA and Grover RF. Pulmonary circulation during exercise. In: Pulmonary Vascular Physiology and Physiopathology. Edited by Weir EK and Reeves JT. New York: Marcel Dekker; 1989:107–133.)*

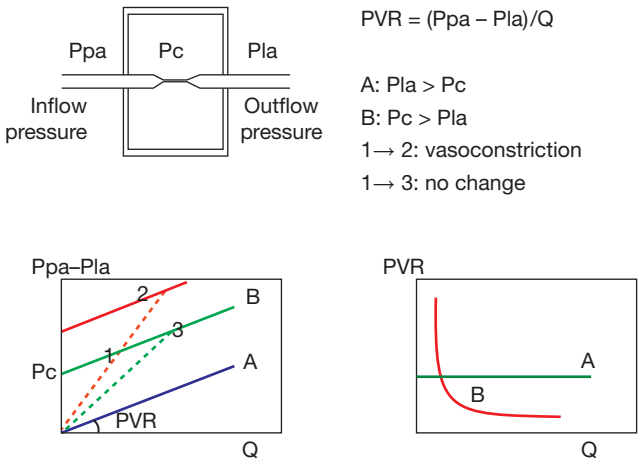

Figure 13-6 Starling resistor model to explain the concept of closing pressure within a circulatory system. Flow (Q) is determined by the gradient between an inflow pressure or mean pulmonary artery pressure (Ppa), and an outflow pressure which is either closing pressure (Pc) or left atrial pressure (Pla). When Pla > Pc, the (Ppa — Pla)/Q relationship crosses the origin (A curve) and PVR is constant. When Pc > Pla, the (Ppa — Pla)/Q relationship has a positive pressure intercept (B curve), and PVR decreases curvilinearly with increasing Q. The B curve is curvilinear a low flow representing recruitment. Also shown are possible misleading PVR calculations: PVR, the slope of (Ppa — Pla)/Q may remain unchanged in the presence of a vasoconstriction (from 1 to 2) or decrease (from 1 to 3) with no change in the functional state of the pulmonary circulation (unchanged pressure/flow line). *(Adapted with permission from Naeije R. Pulmonary vascular resistance: a meaningless variable? Intens Care Med. 2003;29:526–529.)*

its height (the pressure difference between upstream and downstream). Instead, an "external" factor (in the case of a waterfall, fluid momentum) controls the flow rate. The Starling resistor itself was actually a device: A collapsible tube inside of a closed chamber that could be pressurized, thus providing an "external" control over the flow rate through the collapsible tube. Starling used this device in the circuit of his heart–lung preparation to control blood pressure. Permutt postulated that in the pulmonary circulation, as flow decreased, arteries would be progressively derecruited, accounting for a low-flow mPpa–Q curve that is concave to the flow axis, and intercepts the pressure axis at the lowest closing pressure needed to be overcome to generate a flow. At higher flows, complete vessel recruitment and negligible distension account for a linear mPpa–Q curve with an extrapolated pressure intercept representing a weighted mean of closing pressures. In this model, the mean closing pressure is the effective outflow pressure of the pulmonary circulation. At higher flows, Pla is equal to the mean closing pressure. However, at lower flows, Pla is less than the mean closing pressure and becomes irrelevant to flow, analogous to the height of water below a waterfall (Fig. 13-6).

A characteristic typical of a vascular system made up of collapsible vessels is the functional dissociation between inflow pressures, outflow pressures, and flow rate when the closing pressure is higher than the (apparent) outflow pressure (Fig. 13-7). The functional dissociation of inflow and outflow pressures is a feature of derecruited upright upper lung zone 1 described by West et al.[25] It has been reported in pulmonary hypertension associated with acute lung injury[26,27] and in patients who have undergone a cardiac transplantation.[28]

Thu Starling resistor model of the pulmonary circulation appears adequate to explain pressure–flow relationships in derecruited lung regions in healthy states and possibly in certain pathological states associated with an increased surrounding pressure of the small pulmonary-resistive arterioles, such as in lung edema. However, the model has failed to predict correctly mPpa–Q relationships in embolic pulmonary hypertension or after changes in hematocrit.[29] Therefore distensibility models at variable hematocrit have been developed.

DISTENSIBLE MODELS OF THE PULMONARY CIRCULATION

Zhuang modeled the feline pulmonary circulation taking into account not only morphometry but also mechanics (i.e., distensibility) of the pulmonary vascular tree and rheological properties of each of its branched segments.[30] The authors predicted mPpa–Q curves with a slight curvilinearity concave to the flow axis over physiological ranges of flow that was progressively enhanced at decreasing flow. This curvilinearity was generated via arterial, capillary, and venous distensibility based on experimental data with no need to invoke a closing pressure. The distensible or compliant model of Zhuang has been shown to predict parallel shifts of Ppa–Q plots to higher pressures, induced by various interventions such as embolism, changes in lung volume, and hypoxia, and even a functional dissociation between Ppa and Pla at constant Q.[30–32] The model was effective in accurate predictions of mPpa–Q curves at various levels of angiographically determined embolic pulmonary vascular obstruction[33] (Fig. 13-8).

Linehan reasoned that previously reported compliant models were too complex, requiring a large number of parameters not identifiable from pressure and flow measurements alone.[29] Accordingly, he developed a simpler distensibility model and showed its adequacy to describe mPpa–Q relationships at variable hematocrits in

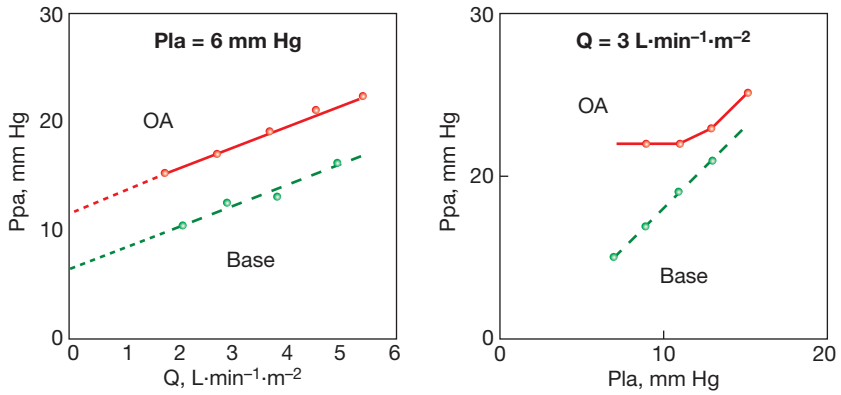

Figure 13-7 Mean pulmonary artery pressure (Ppa) as a function of cardiac output (Q) at constant left atrial pressure (Pla), *left panel*, and Ppa as a function of Pla at constant Q in an anesthetized dog before *(stippled line)* and after *(full line)* injection of oleic acid (OA) to produce an acute lung injury. Lung injury was associated with a shift of linear Ppa–Q relationship to higher pressures, with increased extrapolated pressure intercept *(small stipple line)*. Pla was transmitted to Ppa in a close to 1/1 relationship before oleic acid, but only at a pressure equal to the extrapolated pressure intercept of Ppa–Q after oleic acid, which is compatible with an increased closing pressure becoming the effective downstream pressure of the pulmonary circulation. *(Reproduced with permission from Leeman M, Lejeune P, Closset J, Vachiéry JL, Mélot C and Naeije R. Nature of pulmonary hypertension in canine oleic acid pulmonary edema. J Appl Physiol. 1990;69:293–298.)*

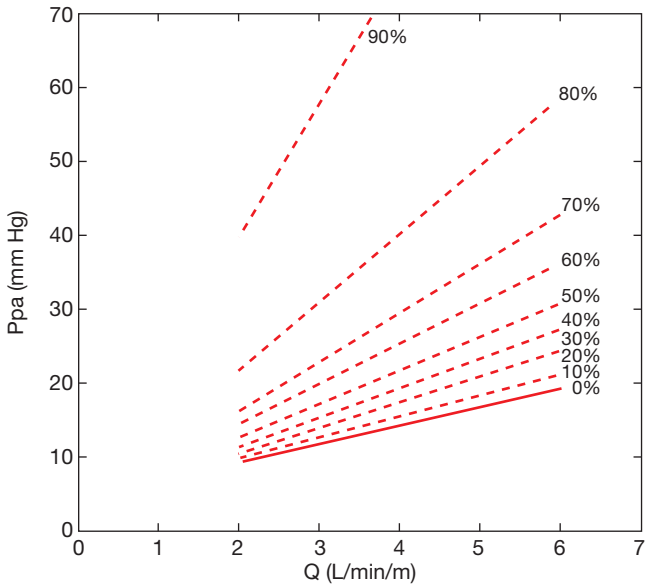

Figure 13-8 Mean pulmonary artery pressure (Ppa)–cardiac output (Q) relationships predicted by the viscoelastic model of Zhuang at increasing levels of angiographically determined embolic obstruction. An increase in mean Ppa above 25 mm Hg corresponding to the definition of pulmonary hypertension occurs after approximately 50% obstruction of the pulmonary vascular bed. A mean Ppa of 50 mm Hg as seen in severe pulmonary hypertension corresponds to 80% obstruction. These estimates are for a Q of 5 L/min, the Ppa–obstruction relationship is flow dependent. *(Data from Mélot C, Delcroix M, Lejeune P, Leeman M and Naeije R. Starling resistor versus viscoelastic models for embolic pulmonary hypertension. Am J Physiol. 1995;267 (Heart Circ Physiol 36):H817–H827.)*

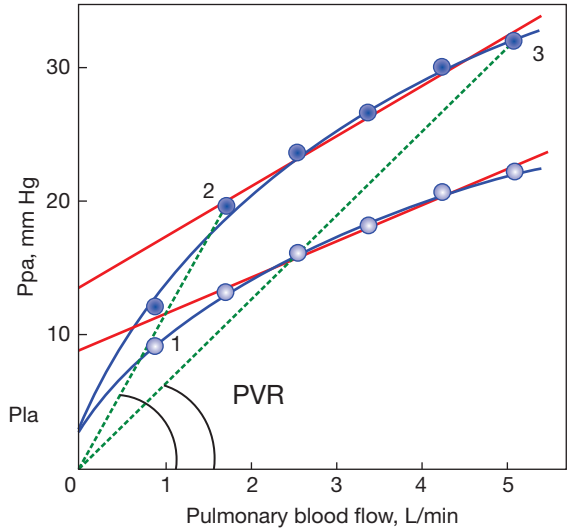

Figure 13-9 Pulmonary artery pressure (Ppa) as a function of blood flow (Q) in normoxia *(empty circles)* and in hypoxia *(full circles)*. Left atrial pressure was 6 mm Hg. Pressure–flow relationships show a slight curvilinearity. Linear adjustment of data points is a cause of positive extrapolated pressure intercepts, and misleading pulmonary vascular resistance (PVR) calculations. Hypoxia-induced increase in Ppa because of hypoxic vasoconstriction is accompanied by unchanged PVR (from 1 to 2) or decreased PVR (from 1 to 3) depending on increased flow. *(Data from Nelin LD, Krenz GS, Rickaby DA, Linehan JH and Dawson CA. A distensible vessel model applied to hypoxic pulmonary vasoconstriction in the neonatal pig. J Appl Physiol. 1992;73:987–994.)*

perfused dog lung lobes. In this model, PVR is calculated with the introduction of a pulmonary-resistive vessel distensibility factor α:

$$PVR = [(1+\alpha Ppa)^5 - (1+\alpha Pla)^5]/5\alpha Q$$

The distensibility factor α corresponds to the % increase in diameter D_0 per mm Hg increase in pressure:

$$D = D_0 + \alpha P$$

This model allows for prediction of mPpa at given levels of resistance Pla, Q, hematocrit, and distensibility.[34]

Multipoint mPpa–Q plots disclose a slight curvilinearity, which is explained by the natural distensibility of resistive vessels (Fig. 13-9). When generated over a limited physiological range of flows, such curves can still be described by a linear approximation. It is then possible to calculate slope for the estimation of average resistance and an extrapolated pressure intercept to suggest a closing pressure. The slope of multipoint mPpa–Q plots offers a refined definition of the resistive properties of the pulmonary circulation, superior to isolated PVR calculations.[23] Extrapolated pressure intercepts are of unclear significance and would overestimate any possible pulmonary closing pressure in proportion to increased distensibility (Fig. 13-9).

Alternatively, from a given set of values of resistance, Ppa_m, Pla, and Q and at rest and during exercise, the Linehan equation permits recalculation of the distensibility coefficient α. Reeves et al.[35] used reported pulmonary hemodynamic data obtained by right heart catheterization at rest and during exercise in healthy volunteers, and were able to recalculate a value of α equal to 2 ± 0.2%/mm Hg in normoxia. This value was remarkably identical on average to the 2%/mm Hg measured on isolated vessels from a variety of various mammalian species.[36] Reeves also showed that α tends to decrease with aging, and with chronic but not acute hypoxic exposure.[35] Similar values of α were calculated by Argiento et al.[37] from Doppler echocardiographic measurements of pulmonary vascular pressures and flows in normal volunteers. In that study, α was lower in men compared to premenopausal women and decreased with age. The same noninvasive approach revealed a decreased α with chronic hypoxic exposure.[38]

VISCOSITY

Chronic hypoxic exposure is associated with an increased expression of erythropoietin, resulting in increased red blood cell mass, hematocrit, and hemoglobin levels. The upper limits of normal of hemoglobin in healthy subjects chronically exposed to hypobaric hypoxia at high-altitude dwellers has been estimated to be at 21 g/dL in men and 19 g/dL in women.[39] In the Poiseuille–Hagen equation, resistance is directly proportional to viscosity.

The most often used reference equation describing a linear relationship between resistance and hematocrit was reported by Whittaker and Winton based on studies on hind limb vessels[40]:

$$R_0(45\%) = R_0(\mathrm{HCT})\frac{1-\varphi^{1/3}}{0.234}$$

where R_0 is PVR at a hematocrit (HCT) of 45% and φ the measured hematocrit.

Linehan et al.[29] reported an exponential relationship to explain the effect of hematocrit on mPpa–Q relationships in isolated dog lung experiments,

$$R_0(45\%) = R_0(HCT)\frac{1}{\exp(2(\varphi-0.45))}$$

The effect of altered hematocrit on representative mPpa–Q relationships in healthy sea level and high-altitude dwellers[38] is

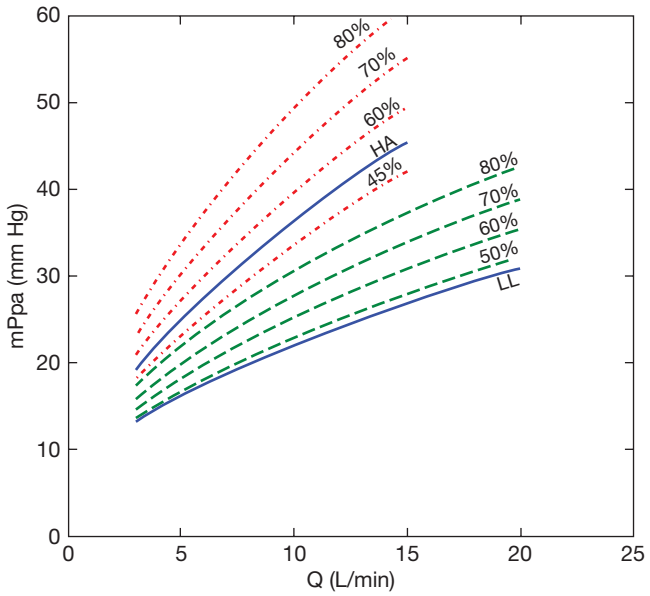

Figure 13-10 Averaged mean pulmonary artery pressure (mPpa)–flow (Q) relationships measured at high altitude in 15 high altitude dwellers (HA) and in 15 lowlander sojourners (LL), *full lines* at the hematocrit of 45% for LL and 52% for HH. The mPpa–Q curves where shifted to higher pressures due to increased hematocrits up to 80%, as modeled from measurements at increasing levels of exercise[37] adjusted with the distensible model of Linehan and associated corrections for hematocrit.[28] Increased hematocrit may be a cause of marked pulmonary hypertension at high altitudes.

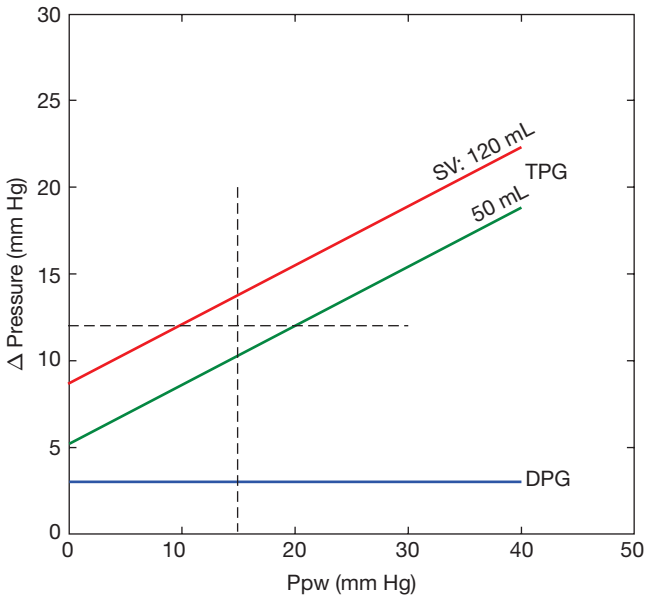

Figure 13-11 Effects of increased pulmonary artery wedge pressure (Ppw) on systolic, diastolic, and mean pulmonary artery pressures (sPpa, dPpa, mPpa) showing progressive increase of the transpulmonary pressure gradient mPpa — Ppw (TPG) with almost unchanged diastolic pressure gradient dPpa — Ppw (DPG). *(Data from Naeije R, Vachiery J, Yerly P, Vanderpool R. The transpulmonary pressure gradient for the diagnosis of pulmonary vascular disease. Eur Respir J. 2013;41:217–223.)*

shown in Figure 13-10. Hematocrit was increased from 45% to 80% in both groups. There was a proportionally more important contribution of increased hematocrit to slope of mPpa–Q in the high-altitude dwellers due to their less distensible pulmonary circulation. Thus the impact of hematocrit on mPpa is enhanced in less distensible pulmonary circulations, for example, typically in old and chronically hypoxic subjects.

LEFT ATRIAL PRESSURE AND THE TRANSPULMONARY PRESSURE GRADIENT

An increase in Pla is transmitted upstream to mPpa. The PVR equation assumes that this is in a 1/1 ratio at any given level of Q. Chronic increase in Pla may induce pulmonary vascular remodeling, and therefore lead to an "out of proportion" increase in mPpa.[41] For this reason, clinicians like to reason in terms of a transpulmonary pressure gradient (TPG) for the differential diagnosis of purely passive increase in mPpa and increased mPpa resulting from pulmonary vascular disease.[42] The TPG is equal to the difference between mPpa and Pla.

$$TPG = mPpa - Pla$$

The upper limit of normal of the TPG is usually assumed to be 12 mm Hg.[42] This corresponds to a PVR of 1.5 Wood units at a cardiac output at the upper limit of normal of 8 L/min. However, it has been recently realized that the TPG is often higher than 12 mm Hg in patients with left heart failure in whom purely passive upstream transmission could be demonstrated by observing an acute return of the TPG to <12 mm Hg after active diuresis or after a cardiac transplantation.[28] In steady-flow conditions, an increase in Pla is transmitted upstream in a less than 1:1 ratio because the pulmonary-resistive vessels are distensible.[43] In pulsatile flow conditions, an increased Pla increases pulse pressure (PP, or sPpa — dPpa) because of a decreased pulmonary arterial compliance.[44] The latter effect is largely predominant.[43] Furthermore, the TPG increases with Q because at any increase in flow mPpa increases more than Pla.[43] These problems are limited or even avoided by using the gradient between dPpa and Pla, or the diastolic pressure gradient (DPG) instead.[43] The upper limit of normal of the DPG is ~5 mm Hg. The effects of increased Ppw on the TPG versus the DPG are modeled in Figure 13-11. Assuming an unchanged dPpa as a function of Ppw, which is reasonable, it can be seen that high Ppw is associated with a passive increase in TPG to more than 12 mm Hg because of a proportionally greater increase in mPpa.[43]

GRAVITY

Pulmonary blood flow increases almost linearly from nondependent to dependent lung regions. This inequality of pulmonary perfusion is best demonstrated in an upright lung.[25] The vertical height of a lung is on average about 30 cm. The difference in pressure between the extremities of a vertical column of blood of the same size amounts to 23 mm Hg, which is large compared to the mean perfusion pressure of the pulmonary circulation. Accordingly, the physiological inequality of the distribution of perfusion of a normal lung can be explained by a gravity-dependent interplay between arterial, venous, and alveolar pressures. At the top of the lung, alveolar pressure (P_A) is higher than mPpa and pulmonary venous pressure (Ppv). In this *zone 1*, flow may be present only during systole, or not at all. Zone 1 is extended in clinical situations of low flow, such as hypovolemic shock, or increased alveolar pressure such as during ventilation with a positive end-expiratory pressure. Further down the lung there is a *zone 2* where Ppa > P_A > Ppv. In this zone 2, alveolar pressure is an effective closing pressure, and the driving pressure for flow is the gradient between mean mPpa and P_A. As mentioned before, such a flow condition can be likened to a waterfall since Ppv, the apparent outflow pressure, is irrelevant to

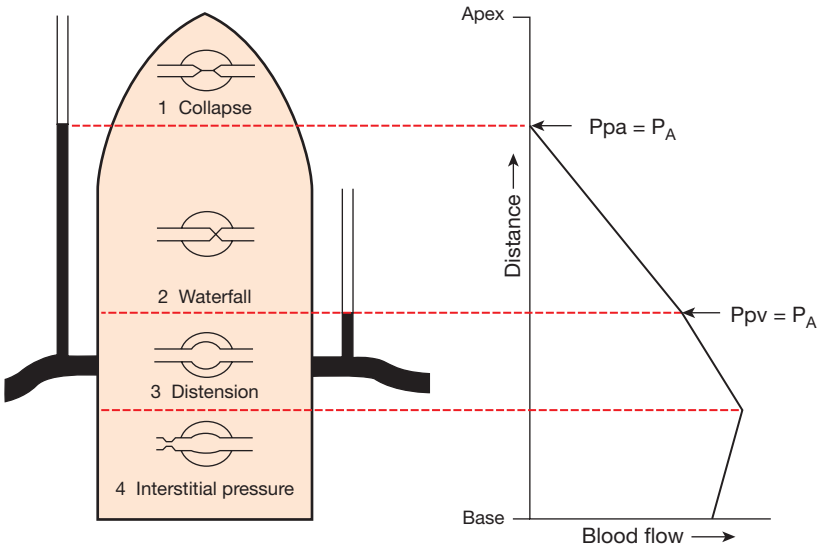

Figure 13-12 Zonal distribution of pulmonary perfusion in an upright lung as determined by the interrelationships between arterial (Part), alveolar (Palv), and venous pressures (Pv), explaining a gravity-determined progressive increase in perfusion from zones 1 and 2 to 3. There is a zone 4 of decreased perfusion at the most dependent part of the lung. *(Adapted with permission from Hughes JM, Glazier JB, Maloney JR, West JB. Effect of lung volume on the distribution of pulmonary blood flow in man. Respir Physiol. 1968;4:58–72.)*

flow as is the height of a waterfall. In *zone 3*, Ppv is higher than P_A, so that the driving pressure for flow is mPpa − Ppv. West's zones are illustrated in Figure 13-12.

At the most dependent regions of upright lung, there is an additional region where flow decreases.[45] This *zone 4* has been attributed to an increase in the resistance of extra-alveolar vessels, because this zone expands when lung volume is reduced or in the presence of lung edema. Active tone may be an additional explanation for zone 4 as it is also reduced by the administration of vasodilators.

The vertical height of lung tissue in a supine human subject is of course reduced compared to the upright position, and accordingly, the lung is then normally almost completely in zone 3. There is however a still measurable increase in flow from nondependent to dependent lung regions (Fig. 13-13).

Three-dimensional reconstructions using single photon emission computed tomography have shown that there is also a decrease in blood flow from the center of the lung to the periphery.[46] High-resolution methods and fractal modeling of the pulmonary circulation have actually led to the notion of a nongravity-dependent distribution of pulmonary blood flow.[47] Subtle differences in arterial branching ratios may indeed influence flow distribution with increased heterogeneity as the scale of the inquiry narrows.[48] However, the overwhelming evidence remains in favor of the thesis that gravity is the single most important determinant of pulmonary blood flow distribution.[48] Vascular geometry-related small unit heterogeneity of pulmonary blood flow distribution has not been shown to be relevant to gas exchange.

HYPOXIA

There is an active intrapulmonary control mechanism able to some extent to correct the passive gravity-dependent distribution of pulmonary blood flow: A decrease in P_{O_2} increases pulmonary vascular tone. Hypoxic pulmonary vasoconstriction was first demonstrated on isolated cat lungs by von Euler and Liljestrand,[49] who proposed a functional interpretation that can still be considered valid. In lung tissue, P_{O_2} is determined by a ratio between O_2 carried to the lung by alveolar ventilation (V_A) and O_2 carried away from the lung by blood flow (Q):

$$P_{O_2} = V_A / Q$$

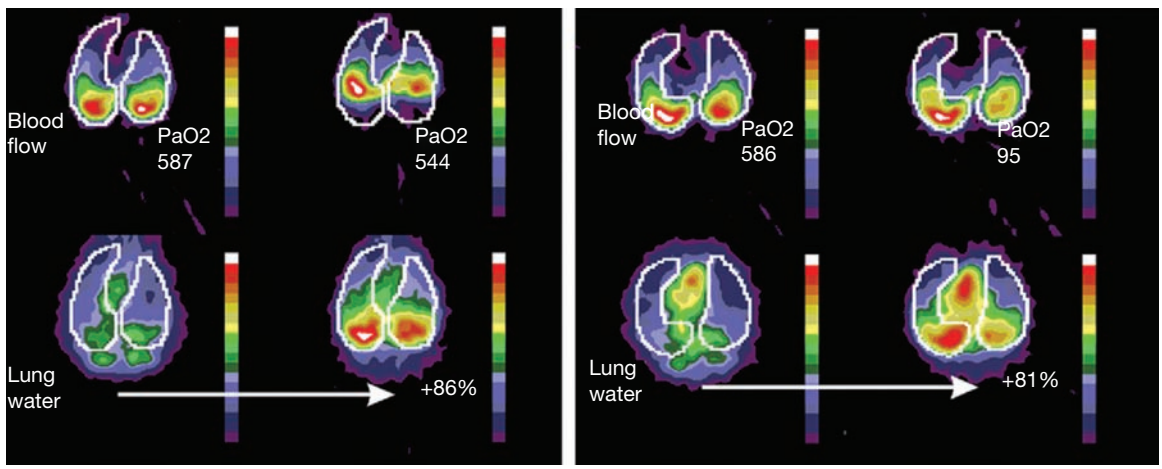

Figure 13-13 PET scan measurements of blood flow and lung water in a supine dog before and after induction of acute lung injury, with preserved hypoxic vasoconstriction (**A**) or without hypoxic vasoconstriction (**B**). In the normal lung, blood flow and water increase to the most dependent lung regions (from *blue* to *red*). Acute lung injury approximately doubles lung water, but arterial P_{O_2} (Pa_{O_2}) is preserved because of a hypoxic vasoconstriction redirecting flow to better aerated lung regions. Prevention of hypoxic vasoconstriction increases flow to the dependent edematous lung regions, and this is associated with a marked decrease in Pa_{O_2}. *(Reproduced with permission from Gust R, Kozlowski J, Stephenson AH, et al. Synergistic hemodynamic effects of low-dose endotoxin and acute lung injury. Am J Respir Crit Care Med. 1998;157(6 Pt 1):1919–1926.)*

In contrast, in systemic tissue, local P_{O_2} is accordingly determined by a ratio of O_2 carried to the tissues by blood flow (Q) and local O_2 consumption (V_{O_2})

$$P_{O_2} = Q/V_{O_2}$$

The attributes of hypoxic pulmonary vasoconstriction have been recently extensively reviewed.[50] The hypoxic pulmonary pressor response is universal in mammals and in birds, but with considerable interspecies and interindividual variability. It is intense in pig, horse, and cow, moderate in rodents and humans, and very low in dog, guinea pig, yak, and llama. Chronic hypoxia induces pulmonary hypertension, in proportion to initial vasoconstriction. Initial hypoxic vasoconstriction is a quasi-immediate response with subsequent modulation depending on the experimental model or preparation. Hypoxic vasoconstriction strengthens during the first few hours of hypoxic exposure in humans. The temporal sequence of hypoxia-induced remodeling is less well known. After 6 hours of hypoxic exposure, reoxygenation immediately decreases PVR, without however a complete return to normal.[51] The reversibility of increased PVR with reoxygenation is largely lost after 24 to 48 hours exposure to hypoxia.[14]

Hypoxic vasoconstriction is observed in lungs devoid of nervous connections, and indeed also in isolated pulmonary arterial smooth muscle cells.[50] The response is enhanced by acidosis, a decrease in mixed venous P_{O_2}, repeated hypoxic exposure (in some experimental models), perinatal hypoxia, decreased lung segment size, cyclooxygenase inhibition, nitric oxide inhibition, and certain drugs or mediators that include almitrine and low-dose serotonin. The response is inhibited by alkalosis, hypercapnia, an increase in pulmonary vascular or alveolar pressures, vasodilating prostaglandins, nitric oxide, complement activation, low-dose endotoxin, calcium channel blockers, β_2-stimulants, nitroprusside, and, paradoxically, by peripheral chemoreceptor stimulation. The hypoxic pressor response is biphasic, with a progressive increase as P_{O_2} is progressively decreased to approximately 35 to 40 mm Hg, followed by a decrease ("hypoxic vasodilatation") with more profound hypoxia.

The hypoxia-induced increase in PVR is mainly caused by a constriction of precapillary small arterioles.[50] Small pulmonary veins also constrict in response to hypoxia, but this should not normally contribute to more than 20% to 30% of the total change in PVR.[52]

While hypoxic pulmonary vasoconstriction has been shown to be an only moderately efficient feedback mechanism,[18,53] it may still produce substantial improvements in arterial oxygenation of patients with inhomogenous lungs such as in chronic obstructive pulmonary disease (hypoxemia mainly explained by low V_A/Q ratios) or in the acute respiratory distress syndrome (hypoxemia mainly explained by V_A/Q ratios equal to zero, or shunt).[54]

Topographical blood flow distribution measured by PET scan and arterial P_{O_2} can be shown to conform to the expected functional effects of hypoxic pulmonary vasoconstriction in experimental acute lung injury models, as an inhibition of the response prevents redistribution of blood flow to nondependent lung regions and markedly aggravates shunt and arterial hypoxemia.[55] This is illustrated in Figure 13-13, in an experiment which also shows the predominant effects of gravity on the distribution of pulmonary blood flow and its relevance to gas exchange.

The biochemical mechanism of hypoxic pulmonary vasoconstriction remains incompletely understood.[50] Current thought is that a decrease in P_{O_2} inhibits smooth muscle cell voltage-gated potassium channels, resulting in membrane depolarization, influx of calcium, and cell shortening. However, the nature of the low P_{O_2}-sensing mechanism remains elusive. Mitochondria and nicotinamide adenine dinucleotide phosphate oxidases are discussed as oxygen sensors. Reactive oxygen species, redox couples, and adenosine monophosphate-activated kinases are candidate mediators. The reversal of hypoxic vasoconstriction by profound hypoxia, in the range of 25 to 30 mm Hg and lower, is due to an activation of ATP-dependent potassium channels.

MAINTENANCE OF VASCULAR TONE

Normal as well as abnormal pulmonary vascular tone is modulated by a series of endothelium-derived and circulating mediators.[50] Endothelium-derived relaxing factors include nitric oxide, prostacyclin, and the endothelium-derived hyperpolarizing factor. The major endothelium-derived contracting factor is endothelin. These observations have been on the basis of efficient treatments of pulmonary arterial hypertension with prostacyclin derivatives, phosphodiesterase-5 inhibitors to enhance nitric oxide signaling, and endothelin receptor blockers.

The pulmonary circulation is richly innerved by the autonomic nervous system, which includes adrenergic, cholinergic, and nonadrenergic noncholinergic signaling systems.[56] However, the role played by the autonomic nervous system in the control of pulmonary vascular tone appears to be minor. Sympathetic innervation of the pulmonary arterial tree is predominantly proximal and plays a role in the modulation of proximal compliance.

EXERCISE

PULMONARY ARTERY PRESSURE

Exercise stresses the pulmonary circulation by an increase in cardiac output and in left atrial pressure.[22] In 1989, Reeves et al.[57] reviewed the published data on invasive pulmonary hemodynamic measurements during supine or upright exercise in a total of nearly 100 normal subjects. This analysis established that supine exercise is associated with a slight decrease in PVR, which is explained by pulmonary vascular distension of fully recruited lungs in West's zone 3 conditions. In the upright position, the resting PVR was found to be higher, which is explained by pulmonary vascular derecruitment caused by a lower cardiac output (via decreased venous return). A higher resting PVR accounts for the more marked and hyperbolic decrease of PVR with exercise reported in upright subjects (Fig. 13-5).

Reeves et al. were able to find measurements at rest and at least two levels of exercise in 63 subjects (including 21 women), so that they could calculate linear regressions relating mPpa to Q in each of them. On average, each liter per minute of increase in cardiac output was accompanied by 1 mm Hg increase in mPpa in young adult men and women. Advanced age (60–80 years) was found to be associated with a more than doubling of the slope of mPpa–Q relationships, to an average of 2.5 mm Hg/L/min. However, there was large interindividual variation, with standard deviations on the order of the means, which makes it difficult to estimate the limits of normal.

A more recent review of the literature of invasive pulmonary hemodynamic data in normal subjects confirmed this data.[58] Invasive measurements of PVR were found in only 13 subjects aged more than 50 years. The review otherwise confirmed an only moderate decrease in PVR with exercise, which was, however, less important or absent in older subjects; and slopes of mPAP–Q of ~1 mm Hg/L/min in subjects of less than 50 years.[58]

The pulmonary circulation during exercise has been more recently reevaluated, using Doppler echocardiography in a total of 177 healthy subjects[37,38,59,60] and a right heart catheterization in 24 other healthy volunteers.[61] In these studies at least four mPpa–Q coordinates were measured at increasing levels of workload. There was a perfect agreement between invasive and noninvasive measurements The results confirmed that the linear adjustment of multipoint mPpa–Q relationships should not exceed 3 mm Hg/L/min, which corresponds to an mPpa at a Q <10 L/min, or a maximum exercise TPVR <3 Wood units. Fitting the data using

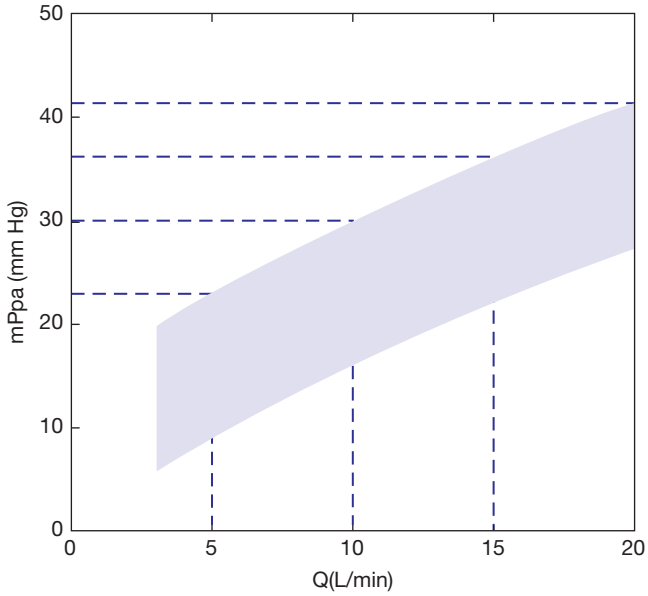

Figure 13-14 Limits of normal of mean pulmonary artery pressure (mPpa) as a function of increasing flow (Q) with exercise in healthy young adults, constructed from noninvasive and invasive data reported.[60] *Stippled lines* indicate upper limits of mPpa increasing from 25 mm Hg at a Q of 5 L/min to 45 mm Hg at Q of 20 L/min. *(Data from Bossone E, D'Andrea A, D'Alto M, et al. Echocardiography in pulmonary arterial hypertension: from diagnosis to prognosis. J Am Soc Echocardiogr. 2013;26(1):1–14.)*

Linehan's distensible model of the pulmonary circulation allowed for the calculation of normal α values <2%/mm Hg, decreasing at increasing levels of exercise.[37,38,59,60] These results have also been recently confirmed by invasive measurements,[61] allowing for a definition of the limits of normal of mPpa as a function of Q at exercise (Fig. 13-14).

After exercise, mPpa and Q rapidly return to resting values. Measurements within 5 minutes after a maximum exercise test in normal subjects are nearly back to resting normal.[59] Rapid return to normal of pulmonary vascular pressures and flows decreases the relevance of postexercise measurements as a reflection of exercise-induced changes. On the other hand, the workload–Q relationship is quite variable.[37] It is therefore preferable to express mPpa at exercise as a function of cardiac output rather than of workload to define the functional state of the pulmonary circulation.[61]

■ LEFT ATRIAL PRESSURE

Left atrial pressure increases with exercise. Strenuous exercise may be associated with very high Pla, up to 20 to 30 mm Hg in athletes.[20,21,62,63] At levels of exercise corresponding to increases in Q to less than 15 L/min, Pla remains more or less within the limits of normal or slightly above.[22] Increased Pla at very high levels of exercise is explained by progressive decrease in LV diastolic compliance in part related to competition for space with the RV within a nonacutely distensible pericardium.[64]

■ SHUNTING OF AGITATED CONTRAST

In 2004, Eldridge and Stickland independently reported on the occurrence of exercise-induced shunting demonstrated by agitated saline contrast echocardiography in subjects with otherwise no evidence of intrapulmonary or intracardiac shunt at rest.[65,66] In these studies, exercise-induced pulmonary shunting of bubbles was shown to be correlated with cardiac output, mPpa, and alveolar-to-arterial P_{O_2} gradient at exercise, suggesting an impact on gas exchange.[66] Agitated saline or gelatine contrast echocardiography is standard practice for the detection of cardiac right-to-left shunts. The contrast bubbles are of 10 to 35 μm in size, and do not normally traverse the pulmonary circulation. In the case of a cardiac right-to-left shunt, the appearance of contrast in the left heart chambers is immediate. In the case of pulmonary shunt, the appearance of contrast in the left heart chambers is delayed by 3 to 5 beats. The most likely explanation for positive pulmonary transit of agitated contrast is pulmonary capillary distension.[60,67]

In addition to variable LV diastolic compliance resulting in variable increase in Pla transmitted upstream to Ppa, much of the variability of the mPpa and PVR responses is related to pulmonary-resistive vessel distensibility. Data are emerging supporting the notion that low PVR at high levels of exercise is associated with an increased pulmonary vascular reserve defined by a combination of high α and lung diffusing capacity and positive pulmonary transit of agitated saline at Doppler echocardiography.[60,67]

PULSATILE FLOW PULMONARY HEMODYNAMICS

The study of the pulmonary circulation as a steady-flow system is a simplification. Pulmonary pulse pressure, or the difference between sPpa and dPpa, is proportionally much higher than systemic pulse pressure. Instantaneous pulmonary blood flow varies from a maximum at midsystole to around zero in diastole.

The morphology of pulmonary pressure and flow waves changes with the development of pulmonary hypertension. In patients with severe pulmonary hypertension, the RV pressure wave is characterized by a sharp initial upstroke, followed by a short plateau, and by a late systolic peaking, and the Ppa pressure wave is characterized by a huge pulse pressure and a late systolic peaking as well,[68] while the pulmonary flow wave presents with a shortened acceleration time and late or midsystolic deceleration.[69] In the most severe forms of pulmonary hypertension the pulmonary artery pressure wave looks "ventricularized."[68] These morphological aspects are entirely explained by the combined effects of decreased compliance[70] and wave reflection.[71]

■ PULMONARY VASCULAR IMPEDANCE

A complete evaluation of pulmonary vascular function relies on the calculation of the relationship between pulsatile pressure and flow or pulmonary vascular impedance (PVZ) instead of the relationship between mean pressure and flow (PVR). PVZ is calculated from a spectral analysis of the pulmonary arterial pressure and flow waves.[72] This analysis is possible because the pulmonary circulation behaves nearly linearly. This means that a purely sinusoidal flow oscillation produces a purely sinusoidal pressure oscillation of the same frequency. The sinusoidal pressure and flow waves can be related by the ratio of their amplitudes (modulus) and the difference in their phases (phase angle). A typical PVZ spectrum in a dog is illustrated in Figure 13-15.

Pulmonary arterial impedance at zero Hz, Z_0, (the ratio of mean pressure to mean flow, mPpa/Q) corresponds to TPVR. This parameter is mainly determined by the small resistance vessels as well as Pla. As frequency increases, the impedance is affected by more proximal elements of the arterial tree. The modulus of the impedance decreases from Z_0 rapidly to a first minimum at 2 to 3 times the heart rate and then oscillates about a constant value. The impedance phase increases from a negative value at low frequencies, indicating that flow leads pressure to zero at higher frequencies. The precipitous fall in modulus and the negative phase of the impedance are a measure of the total arterial compliance. At high frequencies the rather constant modulus and nearly zero phase angle are a measure of the proximal arterial compliance.

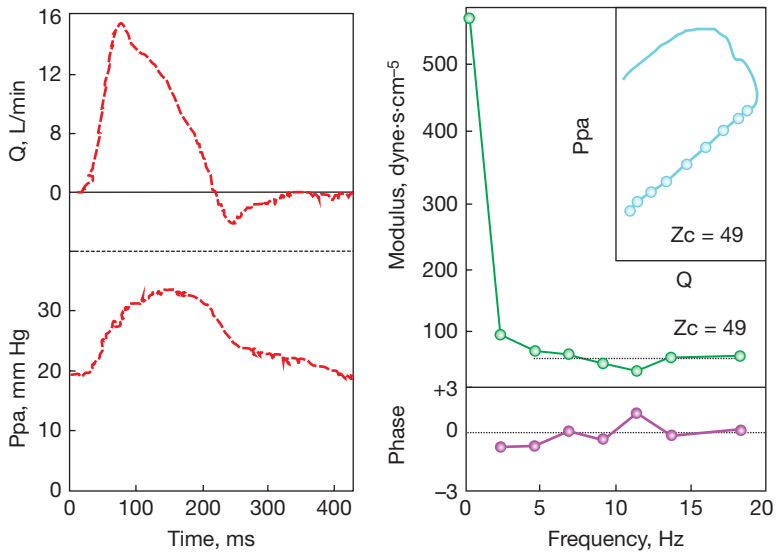

Figure 13-15 Pulmonary artery flow (Q) and pressure (Ppa) waves and pulmonary arterial input impedance spectrum. At 0 Hz the total PVR is obtained (mean pressure over mean flow). Between 0 and 4 Hz the impedance is mainly determined by total arterial compliance. The averaged input impedance for high frequencies, usually taken between 4 and 8 Hz, equals the characteristic impedance (Zc). The oscillation of the impedance about the characteristic impedance results from wave reflection. Zc is also the slope of early-systolic Ppa–Q relationship.

The impedance modulus at high frequencies, when impedance phase is nearly zero and therefore wave reflections can be ignored, is the characteristic impedance Zc. It is typically measured as the average modulus at higher frequencies (usually 10–20 times the heart rate). It can also be measured as the slope of the early systolic pulmonary artery pressure–flow relationship in the time domain (Fig. 13-15).[73]

The oscillations of the impedance modulus about its mean value result from distinct wave reflections. Increased magnitude of these oscillations implies increased reflections. A shift of the first minimum of modulus to higher frequencies indicates an increased wave velocity or a decreased distance to the dominant reflection site.

Characteristic impedance depends on the ratio of inertia to compliance of the proximal pulmonary circulation, and can be approximated by the equation:

$$Zc = [(\rho/\pi r^4)/(\Delta\pi r^2/\Delta P)]$$

where ρ is the density of blood, r the mean internal radius, $\rho/\pi r^4$ the inertance, and $\Delta\pi r^2/\Delta P$ the compliance of the pulmonary arterial tree.

The human PVZ spectrum has the same pattern as reported in canine studies, but with lower Z_0 and Zc values due to greater body size and thus relatively higher pulmonary blood flow.

Distal small vessel obstruction such as caused by microembolism, hypoxia, or pulmonary arterial hypertension increases Z_0 but have limited effects on the PVZ spectrum, with some shift of first minimum and maximum of Ppa/Q to higher frequencies, but unchanged or sometimes even a decrease in Zc.[71,74] Proximal vessel disease such as by experimental proximal ensnarement of the pulmonary arteries or clinical chronic thromboembolic pulmonary hypertension shifts the entire PVZ spectrum to higher ratios of pressure and flow moduli.[71,74] Very high Ppa due to major peripheral small vessel obstruction may also increase Zc because of extreme stiffening of the pulmonary arteries and increased reflected wave speed.[75,76]

Exercise has been reported in an animal study to decrease PVR but to shift the PVZ spectrum to higher pressure and flow moduli at all frequencies with an increase in Zc, a shift of the first minimum of the ratio of pressure and flow moduli to higher frequencies and more negative phase angle.[77] The authors explained the increase in Zc by a decreased area compliance of the proximal pulmonary arterial tree because of increased distending pressure related to increased flow, with possibly a contribution of exercise-associated sympathetic nervous system activation. It had indeed already been shown experimentally that sympathetic nervous system activation may increase Zc without significantly changing PVR.[78] However, the authors could not exclude a spurious increase in Zc caused by too tight fitting of the electromagnetic flow probe placed around the main pulmonary artery.[77]

There has been one small study on the effects of exercise on pulmonary arterial compliance (Ca), Zc, and PVR in eight normal subjects.[79] Exercise was associated with a 50% decrease in PVR and a 30% increase in pulmonary arterial compliance (Ca), while Zc did not change (Fig. 13-16). The apparent discrepancy between changes in Zc and Ca is explained by the sensitivity of Zc to proximal stiffness and dimensions, while Ca integrates the distensibility of the entire pulmonary circulation. Thus unchanged Zc would be explained by the balanced effects of proximal stiffening and increased cross-sectional area.

THE TIME CONSTANT OF THE PULMONARY CIRCULATION

A few decades ago, Reuben[80] had noted an inverse relationship between PVR and Ca in the normal or diseased pulmonary circulation. This was recently revisited in a series of studies that showed that the product of PVR and Ca, or the time constant (RC-time) of the pulmonary circulation remains constant over a wide range of severities, etiologies, and treatments of pulmonary hypertension (Fig. 13-17).[81–83] This remarkable property of the pulmonary circulation has two consequences. The first is that Ca becomes a more important determinant of RV afterload than PVR when mPpa and

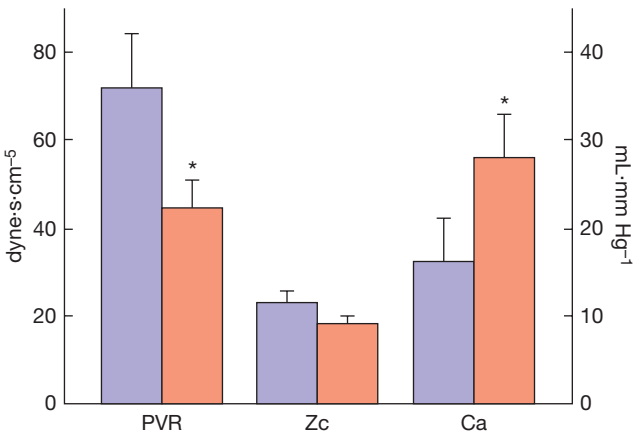

Figure 13-16 Effects of exercise on pulmonary vascular resistance (PVR), characteristic impedance (Zc), and arterial compliance (Ca) in healthy human subjects. Compared to resting state (blue bars), exercise (red bars) decreased PVR and increased Ca, while there was no significant (*) change in Zc. *(Data from Slife DM, Latham RD, Sipkema P and Westerhof N. Pulmonary arterial compliance at res and at exercise in normal humans. Am J Physiol. 1990;258 (Heart Circ Physiol 27): H1823–H1828.)*

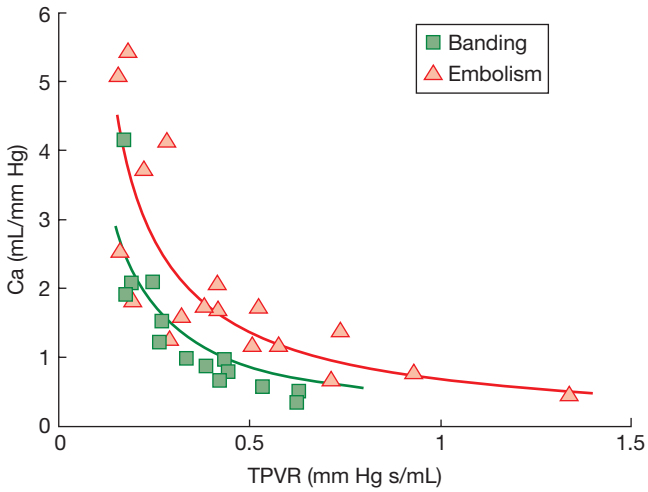

Figure 13-17 Pulmonary arterial compliance (Ca) as a function of total pulmonary vascular resistance (TPVR) in dogs with pulmonary hypertension induced either by an ensnarement of the pulmonary arteries (banding, proximal obstruction) or the injection of microbeads (embolism, distal obstruction). The time constant Ca × TPVR is shorter with proximal obstruction.

PVR are only modestly elevated.[84] The second is that RV oscillatory power (Wosc) remains a constant fraction of total power (Wtot) irrespective of Ppa.[80,85]

The only noticeable exception to the constancy of RC-time is pulmonary hypertension secondary to LV failure.[86] In these patients, RC-time is decreased because of a stiffer pulmonary arterial tree caused by increased pulmonary venous pressure.[43] One would expect proximal obstruction of the pulmonary circulation, like in patients with proximal chronic thromboembolic pulmonary hypertension, to be a cause of shorter RC-time as well (Fig. 13-17). A slight but significant decrease in RC-time has indeed recently been reported in such patients[87] like in experimental pulmonary hypertension on proximal pulmonary arterial banding.[4] It must however be underscored that a constancy or near constancy of RC-time in the pulmonary circulation contrasts with the absence of relationship between resistance and compliance in the systemic circulation.

The stability of the time constant of the pulmonary circulation explains the reported tight correlation between systolic, diastolic, and mean Ppa in normal subjects and in patients with pulmonary hypertension of all possible etiologies.[88] Accordingly, mPpa can be calculated from sPpa using a simple formula:

$$\text{mPpa} = 0.6 \times \text{sPpa} + 2$$

This notion is of practical relevance as noninvasive evaluations of the pulmonary circulation in clinical practice often rely on the measurement of a maximum velocity of TR to calculate a sPpa using the simplified form of the Bernoulli equation and a measurement or estimate of Pra[89]:

$$\text{sPpa} = (\text{TR}^2 + 4) + \text{Pra}$$

RIGHT VENTRICULAR FUNCTION

The RV is functionally coupled to the pulmonary circulation.[90] Because of the normally low pulmonary vascular pressures taking the entire cardiac output, the RV acts as a thin-walled flow generator. The structural and functional characteristics of the RV allow for the accommodation of large increases in flow, less so small increases in afterload. However, the basic laws of the heart remain applicable, that is rapid beat-to-beat heterometric adaptations (Starling law of the heart) and otherwise progressive structural and inotropic homeometric adaptations (Anrep's law of the heart) to changes in loading conditions.[91] Thus the RV adaptation to pulmonary hypertension is homeometric with increased contractility, eventual hypertrophy, and preserved dimensions. Failure of this mechanism depends on rate of onset and magnitude of increase in Ppa and results in heterometric adaptation, with increased RV dimensions and systemic congestion.[88,89]

RIGHT VENTRICULAR HYDRAULIC LOAD

Increased Ppa requires increased RV hydraulic power to sustain adequate forward flow. Hydraulic power is made of two components: The energy per unit time (power) to produce steady flow, which is the product of mPpa and Q, and the power to produce the pulsatile component of Ppa and Q. The latter can be calculated from the difference between the product of the integrations of instantaneous Ppa and Q waves and the product of mPpa and Q. Since mean flow determines oxygen transport, mean power may be considered useful whereas oscillatory power is "wasted." As a consequence, the ratio of oscillatory to mean power, or oscillatory to total (mean plus oscillatory) power, should preferably be small.[92]

Because of the proportional relationship between systolic, diastolic, and mPpa, one would expect the ratio of oscillatory to total RV power to remain constant. This was indeed recently reported in a study of 49 patients with pulmonary hypertensions of variable severities.[85] Total power increased with severity of pulmonary hypertension, but the ratio of oscillatory to total power remained reasonably constant, at 23%. Accordingly, the authors proposed that the total power of the RV should be equal to 1.3 times mean power in all circumstances. As the proportionality of pulmonary artery pressures appears to be maintained at exercise[93] the calculation of total RV power as 1.3 times mean power is probably transposable, but this will require confirmation by further studies. On the other hand, situations of shortened RC-time like heart failure[87] or purely proximal pulmonary arterial obstruction[4,87] are associated with an increased oscillatory component of total RV power.

RIGHT VENTRICULOARTERIAL COUPLING

The calculation of power includes a measurement of cardiac output, and thus depends not only on the mechanical properties of the pulmonary circulation, but also on ventricular function. It has been suggested that power transfer and ventricular efficiency are near maximal in normal subjects. A simplified approach to test this has been given by Sunagawa et al.[94] These authors proposed a graphical analysis based on the right ventricular pressure–volume diagram[91,95] and a characterization of the arterial system by means of its arterial elastance (Fig. 13-18).

The diagram allows for the determination of maximal ventricular elastance (Emax), which is the best possible load-independent measurement of contractility, and of arterial elastance, Ea, as a measurement of afterload as it is "seen" by the ventricle, and the calculation of an Emax/Ea ratio as a measurement of the coupling of ventricular to arterial function.

Mathematical modeling shows that the optimal matching of systolic ventricular and arterial elastances occurs at an Emax/Ea ratio around 1.5. Isolated increase in Ea, or decrease in Emax, decreases the Emax/Ea ratio, indicating uncoupling of the ventricle from its arterial system. Everything else being the same, a decrease in Emax/Ea is necessarily accompanied by a decrease in stroke volume. On the other hand, an isolated increase in preload is associated with an increase in stroke volume with unaltered ventriculoarterial coupling.[91]

However, the complex geometry of the RV makes functional evaluations with measurement of instantaneous volume changes

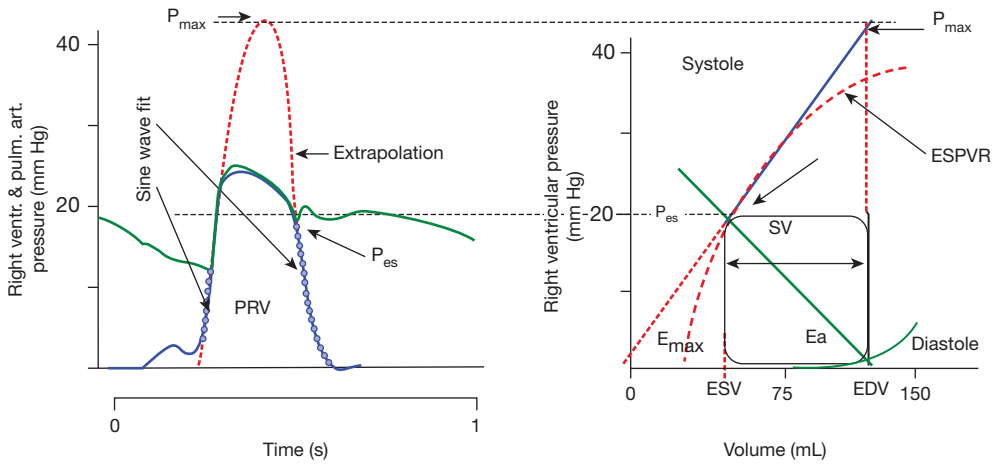

Figure 13-18 Single-beat method to measure right ventriculoarterial coupling. A maximum pressure (*P*max) is calculated from nonlinear extrapolation of early and late isovolumic portions of the right ventricular pressure curve. A *straight line* is drawn from *P*max and the end-diastolic volume (EDV) to *P*es and the end-systolic volume (ESV), thus *E*max = (*P*max — *P*es)/SV, where SV is the stroke volume. The arterial elastance *E*a is defined by the ratio *P*es/SV. ESPVR, end-systolic pressure-volume relationship.

technically difficult, and the determination of Emax may be unreliable because of the particular shape of the RV pressure–volume loop and noncoincidence of end-ejection and end-systole. This problem can be overcome by measuring pressure–volume loops at several levels of preload,[96] but bedside manipulations of venous return are too invasive to be ethically acceptable. In addition, when applied to intact beings, changes in venous return are associated with reflex sympathetic nervous system activation, which affects the ventricular function that is measured.

These concerns have been addressed by a single-beat method allowing for a direct quantification of the coupling of the RV to the pulmonary circulation.[97] The approach had been initially proposed for the left ventricle.[98] In its principle, the method avoids absolute volume measurements and related technical complexities, to calculate Emax and Ea from instantaneous RV pressure and flow output measurements. As shown in Figure 13-18, a Pmax is estimated from a nonlinear extrapolation of the early- and late-systolic isovolumic portions of the right ventricular pressure curve. This estimated Pmax has been shown to be tightly correlated with Pmax directly measured during a nonejecting beat.[97] A straight line drawn from Pmax to the RV pressure versus relative change in volume curve allows for the determination of Emax. A straight line drawn from the Emax point to the end-diastolic relative volume point determines Ea.

The Emax/Ea ratio as determined by the single-beat method has been shown to be decreased by propranolol and increased by dobutamine, and maintained in the presence of increased Ea due to hypoxic pulmonary vasoconstriction.[97] In fact, Emax increases adaptively to increased Ea in hypoxia, even in the presence of adrenergic blockade, which is compatible with the notion of homeometric adaptation of right ventricular contractility. The method has been used to show that acutely administered prostacyclin does not have a positive inotropic effect as the explanation for the increased cardiac output associated with its use.[99]

Kuehne et al.[100] used magnetic resonance imaging (MRI) together with RV pressure measurements with Pmax calculations to generate pressure–volume loops and Emax and Ea determinations in patients with pulmonary arterial hypertension. As compared to controls, Emax was almost doubled, but Emax/Ea was decreased, indicating insufficient homeometric adaptation and pending RV failure. The importance of RV systolic function adaptation for the preservation of RV–arterial coupling in patients with severe pulmonary hypertension PAH has been confirmed by a study that used conductance catheter measurements of pressure and volume, and the Valsalva maneuver to decrease venous return and generate a family of pressure–volume loops.[101]

Since Emax/Ea can be simplified to a ratio of volumes, Sanz et al. reported on the estimation of RV–arterial coupling estimated by the ratio of stroke volume to end-systolic volume measured by MRI in 139 patients referred for pulmonary hypertension. The resulting "Emax/Ea" was shown to decrease progressively with increasing severity of pulmonary hypertension.[102]

An alternative approach was developed by Elzinga and Westerhof in 1978.[103] The authors described RV pump function curves by plotting mean RV pressure as a function of stroke volume. As shown in Figure 13-19, the pump function curve is built from measurements of mean RV pressure and stroke volume, a calculated maximum pressure at zero stroke volume, and a parabolic extrapolation to a zero pressure stroke volume. In this representation, an increase in preload shifts the curve to greater stroke volumes with no shape change, while an increased contractility leads to a higher maximum pressure with no change in maximum stroke volume. This analysis has been used to explain the more severe RV failure in pulmonary arterial hypertension associated with systemic sclerosis,[104] in agreement with pressure–volume loop-derived estimations of RV–arterial coupling.[101] A derived simplified measure of the adequacy of RV systolic function adaptation to afterload is contractile reserve, defined by the increase in RV systolic pressure during an exercise stress. RV

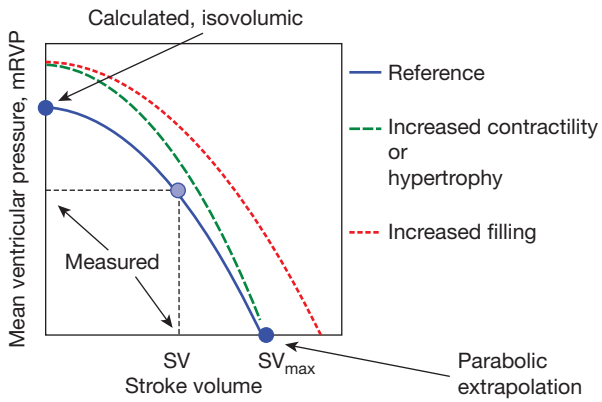

Figure 13-19 Pump function curve defined by mean right ventricular pressure as a function of stroke volume. The zero stroke volume point is calculated from a maximum pressure determination (see Fig. 13-18). The zero pressure point results from a parabolic extrapolation, from measured and zero stroke volume points. *(Data from Elzinga G, Westerhof N. The effect of an increase in inotropic state and end-diastolic volume on the pumping ability of the feline left heart Circ Res. 1978;42:620–628.)*

contractile reserve has been reported to be an important predictor of survival in patients with severe pulmonary hypertension.[105]

CHAPTER 14

Ventilation, Pulmonary Blood Flow, and Ventilation–Perfusion Relationships

Peter D. Wagner

This chapter and the two succeeding it together share responsibility for presenting the physiological basis of normal pulmonary gas exchange. Gas exchange occurs by an integrated series of gas transport steps between the environmental air we breathe and the Hb molecule of the red cells passing through the pulmonary capillaries. These transport steps are of two types—diffusive and convective, and a number of conceptually separate diffusive as well as convective processes interact to accomplish the gas exchange mission. This is true both for gases that are taken up from the environment into the blood (i.e., O_2 and occasional toxic gases or volatile anesthetics) and for gases that are eliminated from the body (i.e., CO_2 and volatile anesthetic agents).

This chapter deals principally with the convective processes and Chapter 16 with those involving diffusion. However, since the two types of process occur simultaneously they are closely linked.

BASIC OUTLINE OF THE GAS EXCHANGE PATHWAY

This section dwells on O_2, being the gas of principal physiological interest. However, the pathway components are of course identical for all gases and furthermore do not depend on whether the gas is being taken up (O_2) or eliminated (CO_2). On the other hand, distinct quantitative differences in the uptake or elimination patterns of different gases exist, but those are readily explained by differences in their fundamental physical or chemical properties, and not by transport pathway differences.

To understand the gas transport pathway one must first appreciate the anatomy of the lungs, laid out in detail in Chapter 2. The salient functional features are presented in Figure 14-1.

The chest wall (rib cage and diaphragm) contains muscles that on contraction expand the volume of the chest cavity and thus reduce the hydrostatic pressure of the pleural space, expanding the

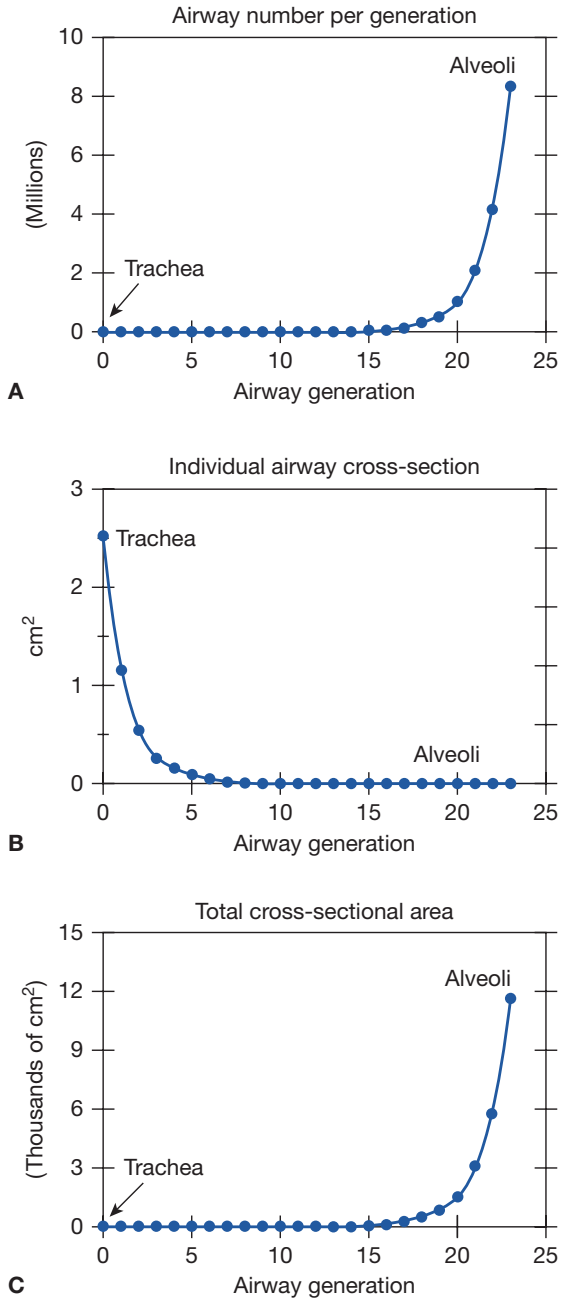

Figure 14-2 Relationship between number (**A**) and cross-sectional area (**B**) of the airways at a given generation. Note that total airway cross-sectional area (**C**) increases extremely rapidly beyond airway generation 15 or so, the beginning of the respiratory zone for gas exchange.

lungs with air drawn in via the mouth and nose. Although there is but a single air passage in the neck (i.e., the trachea), this soon branches into right and left main bronchi. These also divide many times, essentially dichotomously. There are some 16 such orders of branching of these bronchi, resulting in a structure that resembles an inverted deciduous tree without its leaves in winter.[1] With each successive branch the airways become shorter and narrower, but ever greater in number, usually doubling at each branching. Thus, although the cross-sectional area of any one airway becomes smaller with each branching, the greater number of airways more than makes up for loss of individual cross-sectional area such that the sum of cross-sectional areas of all airways of a given generation rises essentially exponentially with each branching (Fig. 14-2). The total volume of gas in these 16 conducting airway generations is called the anatomic or conducting airway dead space, and approximates 1 mL per pound of body weight. After these 16 or so successive branches, the tubular, purely conducting airways begin to show alveolar units in their wall (generations 17–19 or so) and these finally give way to fully alveolated structures (in succession: alveolar ducts, alveolar sacs, and alveoli). There are some 300 million alveoli, each about 300 μm in diameter. They are blind structures so that ventilation has to be accomplished by a tidal, in-and-out process (rather than a flow-through process as for pulmonary blood flow). The alveoli can be seen in Figure 14-1, from a different perspective. For gas exchange to occur, O_2 must be moved from the mouth all the way to the alveoli—it is only within alveoli that gas exchange occurs.

Each alveolus is densely covered in a capillary network, seen from various perspectives in Figure 14-1. This network is closely applied to the alveolar gas space as Figure 14-1 shows, with on average only about 1/2 μm of cellular and interstitial tissue between the blood inside the capillary and the alveolar gas outside.[2] The capillary network is fed by the pulmonary arterial tree which branches alongside the airways in a very similar pattern as the airways. The capillaries then drain into venules that join to form larger and larger vessels, eventually becoming the pulmonary veins that drain oxygenated blood into the left atrium. This coalescence of venous vessels forms a similar branching tree to the pulmonary arteries and airways, but in reverse. The right ventricle is responsible for unidirectional pumping of blood through this vascular system.

The gas exchange pathway from the lips to the left atrium is therefore highly complex structurally, and understanding how gases pass along the pathway requires following the events an O_2 molecule must participate in between the lips and the left atrium.

1. The first step is inspiration of air into the trachea via mouth and nose. Accomplished by inspiratory chest wall muscle contraction which reduces intrathoracic pressure, this step is convective (like water flowing from a region of high to low pressure along a garden hose). All the respired air must pass the trachea but at the first branch point some air goes to the right lung, the rest to the left. At each successive branch point, similar mass-conserving distribution of air must occur between the daughter branches of each parent pathway. Remembering that there are some 23 total branchings from the mouth to the 300 million alveoli, there is a very real risk of quite uneven distribution of that inspired air amongst those alveoli.[3] The principal determinants of how air is distributed at branch points (i.e., between daughter branches) are the mechanical properties of the respiratory system: the compliance (elastic properties), the resistance, and the inertial properties. These concepts are more fully treated in Chapter 10.
2. During normal resting inspiration, flow is laminar in most of the airways. Thus inspired gas develops a parabolic profile due to higher molecular velocities in the center than periphery of the airway (Fig. 14-3). The parabolic "tongue" of inspired gas in Figure 14-3 moves down an airway, while around the tongue is gas remaining from the previous expiration. The tongue therefore has O_2 at a concentration of 21% and essentially no CO_2. The gas around the tongue, having undergone gas exchange during the preceding breath, has about 14% O_2 and 5% CO_2. Consequently, during forward motion of this tongue toward the alveoli, O_2 will diffuse from the tongue to its surrounding gas while CO_2 will diffuse in the opposite direction. This is called Taylor dispersion,[4] and it reduces the forward transport of O_2 produced by the onward convective movement of the tongue. This effect however is considered quite small and is generally not of significance to overall gas exchange.

   Note that if inspiration occurs at high rates as in exercise, such laminar flow may not occur in the larger airways—it may be turbulent and then Taylor dispersion is essentially noncontributory, as the turbulent mixing evens gas concentrations across the airway lumen.
3. Figure 14-2 shows the exponential increase in airway cross-sectional surface area as one proceeds deeper and deeper into the lungs. The significance of this curve is that since the mass flow rate of inspired gas is the same at every generation (because the airways are simply a conducting system), the forward velocity of O_2 molecules falls (since flow rate is the product of velocity and cross-sectional area). As it happens, by about generations 17 to 19, where the alveoli are just beginning to appear, this forward velocity has become so low that passage of O_2 from here on out to the alveoli is heavily dependent on simple gaseous diffusion, not just on continuing convective flow.
4. If alveoli are not equally ventilated with gas (and equally perfused with blood), their alveolar O_2 concentration will differ, as explained later in this chapter. Because adjacent alveoli are so physically close, there can be considerable diffusion of O_2 between such alveoli when their O_2 levels are different. This passive process tends to reduce concentration differences between these alveoli. However, although it can be detected experimentally, it is of probably minor clinical significance. Step 3 (and to some extent Step 4) are responsible for most of the alveolar gas mixing that must occur for gas exchange to take place—that is, the mixing of each breath of newly inspired gas with alveolar gas still present from prior breaths.
5. The heart acts as a massaging pump to further enhance gas mixing into the alveolar gas spaces. Alternate filling and emptying of the cardiac chambers respectively facilitates exhaling and inhaling of airway gas into those alveoli physically close to the heart,[5] but has little effect on more distant alveoli. Although a well-known and easily demonstrated phenomenon, this so-called cardiogenic mixing is probably also of minimal physiological impact for gas exchange.
6. Once the dominant convective and diffusive gas transport steps have brought O_2 from the lips to the alveolar gas spaces, O_2 physically dissolves in the tissues separating alveolar gas from capillary blood, the blood–gas barrier (Fig. 14-1). O_2 then moves by diffusion through the blood–gas barrier and into the plasma. Over 98% of these O_2 molecules diffuse further, that is, into the red cell interior, and then bind rapidly to hemoglobin. The remaining 2% or so remain physically dissolved in the plasma and red cell water.

   This transport process from alveolar gas to hemoglobin is accomplished passively by simple diffusion: No convective forces or active transport processes are involved. The diffusion process is discussed more fully in Chapter 16. In normal lungs at rest, this process is very rapid and causes no O_2 transport limitation.
7. Finally, the red cells are transported convectively by cardiac pumping action out of the pulmonary capillaries and into the pulmonary veins and then to the left atrium, and left ventricle, finally reaching the various body tissues.

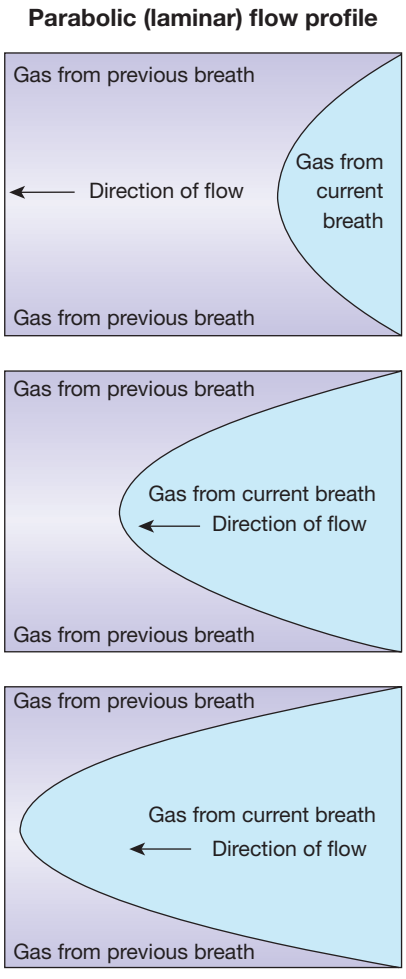

Figure 14-3 The parabolic profile of laminar flow. The three panels indicate sequential points in time during a single inspiration proceeding from right to left. Because the gas remaining from the previous breath has a low oxygen concentration and high CO_2 concentration relative to that of the inspired gas in the current breath, there will be diffusive exchange between the parabolic tongue and the surrounding gas (Taylor dispersion).

POTENTIAL DISRUPTIONS OF THE GAS TRANSPORT PATHWAY

If all the above elements of the transport pathway mentioned previously were functionally perfect, the partial pressure of O_2 (and other gases) would be identical in the gas of all 300 million alveoli and equal to that in systemic arterial blood. The system comes close to perfection in health,[6] but there is never complete equivalence of alveolar and arterial pressures, even in healthy young, normal people. Aging further leads to a progressive impairment of the pathway with arterial P_{O_2} falling from 95 to 100 mm Hg at age 20 to 75 to 80 mm Hg at age 80 or thereabouts.[7] However, alveolar P_{O_2} tends to be invariant with age. Thus, the difference between alveolar and arterial P_{O_2} steadily increases from about 5 to 10 mm Hg to about 20 to 25 mm Hg over this age range. Pulmonary diseases such as asthma, emphysema and bronchitis, fibrosis, pneumonia, and many others can greatly disrupt gas transport to the point of causing death from insufficient tissue O_2 supply.

Consequently, it is essential to have a good understanding of the O_2 transport pathway and what may affect it even in health, in order to appreciate the problems seen in pulmonary diseases.

A traditional view of how to consider abnormalities of the transport pathway has evolved over the years and is very useful as a framework for discussion. It is based upon the end result of gas exchange – the arterial P_{O_2} – and there are different reasons why this variable can fall below normal values.

Four principal potential mechanisms of failure of the O_2 transport pathway can lead to a reduced arterial P_{O_2} (i.e., to arterial hypoxemia):

1. Hypoventilation
2. Diffusion limitation
3. Shunt
4. Ventilation–perfusion ($\dot{V}_A/\dot{Q}$) inequality.

These are the so-called "intrapulmonary" factors that directly cause hypoxemia. Modulating "extrapulmonary" factors are also important. These include changes in inspired O_2 concentration, in total cardiac output, in overall metabolic rate, and in Hb concentration.

The four "intrapulmonary" factors are now defined and discussed.

HYPOVENTILATION

Normal levels of ventilation produce a tightly regulated arterial P_{CO_2} at 40 ± 2 mm Hg in normal subjects with several control systems in place to ensure this (for details, see Chapter 11). However, if overall ventilation is reduced for any reason, alveolar P_{CO_2} ($P_{A_{CO_2}}$), and therefore arterial P_{CO_2}, must rise to maintain constant the elimination of metabolically produced CO_2. Reciprocally, alveolar P_{O_2} ($P_{A_{O_2}}$), and hence arterial P_{O_2}, will fall (and by relatively similar amounts as P_{CO_2} will rise). The alveolar gas equation[8] quantitatively relates $P_{A_{O_2}}$ and $P_{A_{CO_2}}$, and is used to calculate how much $P_{A_{O_2}}$ will change for a change in $P_{A_{CO_2}}$:

$$P_{A_{O_2}} = P_{I_{O_2}} - \frac{Pa_{CO_2}}{R} + P_{A_{CO_2}} \cdot F_{I_{O_2}} \cdot \frac{(1-R)}{R} \qquad (1)$$

$P_{I_{O_2}}$ and $F_{I_{O_2}}$ are inspired O_2 partial pressure and fractional concentration, respectively, and R is the respiratory exchange ratio, normally 0.8.

Hypoventilation represents a failure of step 1 of the gas transport pathway (see above) and can occur for several reasons: (1) the control centers in the nervous system that regulate ventilation could malfunction due to trauma, diseases, drugs, or anesthetics; (2) there could be neuronal or neuromuscular dysfunction of the nerves supplying the chest wall muscles of respiration; (3) the chest wall muscles could be fatigued, damaged, or paralyzed; or (4) the airways or chest wall could be disrupted from trauma or other mechanical derangement such as compression, or in the case of airways, obstruction.

Conceptually this type of problem is usually thought of as a whole-lung issue, usually with obvious causes, and can be reversed by recognizing the cause and taking appropriate reparative and/or ventilatory supportive steps.

DIFFUSION LIMITATION

Whereas diffusive transport plays a recognizable, if small, role within the airways and alveolar gas (see above), the concept of diffusive limitation affecting arterial P_{O_2} is more usually associated with transport step 6 – diffusion of O_2 from alveolar gas into the capillary and red cell.

This topic is specifically the focus of Chapter 16 and is not dealt with here. Indeed, the ensuing discussion of other factors sets aside diffusion limitation of O_2 transport for the sake of simplicity and assumes that the diffusive exchange of O_2 (and CO_2) between alveolar gas and capillary blood proceeds to completion within a single red cell's passage through the pulmonary microcirculation. This is reasonable under most conditions. Diffusion limitation in health is seen at sea level in some but not all athletes[9] but only at or near maximal exercise. It is universally seen in normal subjects exercising at altitude.[10,11]

SHUNT

A shunt is a blood pathway that does not allow any contact between alveolar gas and red cells, so that no gas exchange occurs in the affected region. Consequently, blood passes through a shunt maintaining a mixed venous blood composition. When this blood reaches pulmonary veins, the left atrium and eventually arterial blood, it mixes with other blood that has undergone alveolar gas exchange. The result is a fall in arterial P_{O_2} and potentially an increase in arterial P_{CO_2} (arterial P_{CO_2} may not increase if the patient raises his or her level of ventilation, but hypoxemia will persist).

Classical pathophysiological scenarios giving rise to shunts are: (1) pulmonary edema, which fills alveoli with fluid, thereby abolishing their ventilation and any gas exchange; (2) alveolar filling with cellular and micro-organismal debris as in pneumonia, with the same result as in edema; (3) collapse of a region of lung due to pneumothorax, gas absorption distal to a fully obstructed airway, or to external compression; (4) rarely, the presence of abnormal arteriovenous vascular channels in the lungs, that can occur in, for example, hepatic cirrhosis; and (5) direct right-to-left vascular communications at the level of the heart or great (extrapulmonary) blood vessels.

VENTILATION–PERFUSION ($\dot{V}_A/\dot{Q}$) INEQUALITY

The exquisite and complex branching architecture of the airways and of the blood vessels makes the lungs very susceptible to the potential problem of nonuniform distribution of alveolar ventilation and of pulmonary blood flow. Whenever alveoli are ventilated at less than average rates, for example if their feeding airways become partially obstructed for any reason, the ratio of ventilation to blood flow ($\dot{V}_A/\dot{Q}$ ratio) will fall (assuming their blood flow does not fall similarly). In certain other conditions, lung regions may suffer a reduction in local blood flow rather than ventilation, so that the $\dot{V}_A/\dot{Q}$ ratio rises above the average value in those areas.

Whenever there is a range of $\dot{V}_A/\dot{Q}$ ratios in a lung such that the $\dot{V}_A/\dot{Q}$ ratio is not identical everywhere, it is said that $\dot{V}_A/\dot{Q}$ inequality exists. The pathological cause of $\dot{V}_A/\dot{Q}$ inequality does not matter in this definition, nor whether the problem originates in the airways or blood vessels. The principal concept is that, compared to a lung having the same total alveolar ventilation and blood flow, a lung that has $\dot{V}_A/\dot{Q}$ inequality will exchange (all) gases in an inefficient manner.[12] The result is hypoxemia and, potentially, hypercapnia (raised arterial P_{CO_2}). A large section of this chapter presents the physiological reasons for this effect of $\dot{V}_A/\dot{Q}$ inequality.

Understanding of $\dot{V}_A/\dot{Q}$ inequality can be demanding, but no matter what its pathologic origins, the concepts are similar. $\dot{V}_A/\dot{Q}$

inequality can occur at many different scales. Not uncommonly, it can be manifest on a large scale as differences between the right and left lungs. Classical examples of this include unilateral atelectasis, pneumothorax, pulmonary embolus, or pneumonia. All these are relatively common phenomena that can lead to severe gas exchange disturbances. At the other end of the scale, there can be $\dot{V}_A/\dot{Q}$ ratio differences between essentially adjacent alveoli. However, research has shown that small groups of contiguous alveoli can maintain functional homogeneity of $\dot{V}_A/\dot{Q}$ ratios via rapid gas diffusion rates, possibly augmented by collateral ventilation and/or blood flow.[13] It is likely that all alveoli distal to individual respiratory (or perhaps terminal) bronchioles can retain functional homogeneity for gas exchange through these mechanisms.[14]

In between these two extremes of scale, vascular or airway obstruction at all levels will produce $\dot{V}_A/\dot{Q}$ inequality that, depending on how widespread it is, causes hypoxemia and potentially hypercapnia.

Even the young normal lung usually contains $\dot{V}_A/\dot{Q}$ inequality, which explains the 5 to 10 mm Hg P_{O_2} difference between alveolar gas and arterial blood generally observed in healthy young subjects.[15] There are several mechanisms for the existence of such $\dot{V}_A/\dot{Q}$ inequality.

Gravity-Based Inequality

Ventilation, and, even more so, blood flow are unevenly distributed in a manner systematically influenced by gravity.[6,16] This is due respectively to the weight of the lungs and of the blood in the blood vessels. Thus, dependent lung regions receive far more blood flow than nondependent regions, a finding that is in concept independent of body position. It turns out that the gravitational gradient in blood flow considerably exceeds that of ventilation. As a result, the nondependent lung regions are of higher than average $\dot{V}_A/\dot{Q}$ ratio, and the dependent regions are of lower than average $\dot{V}_A/\dot{Q}$ ratio.[6] Average $\dot{V}_A/\dot{Q}$ ratio is about 1.0, because total alveolar ventilation and blood flow are similar. At the apex of the upright human lung, the $\dot{V}_A/\dot{Q}$ ratio is about 3; at the base it is about 0.6, 5-fold lower. There is a smooth gradation between the two extremes as depicted in Figure 14-4. This large-scale

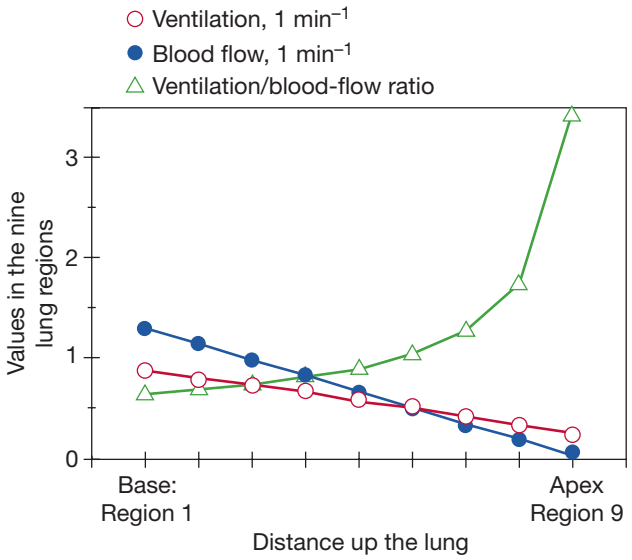

Figure 14-4 Topographical relationships between ventilation and blood flow as a function of distance up and down the upright lung (divided into nine contiguous regions). Although both ventilation and blood flow are higher at the base than at the apex, the ventilation–perfusion ratio ($\dot{V}_A/\dot{Q}$) rises exponentially from the bottom to the top of the lung. *(Adapted with permission from West JB. Ventilation/blood flow and gas exchange, 5th ed. Chicago, IL. Blackwell Scientific Publications; 1990.)*

apex-to-base gradient in $\dot{V}_A/\dot{Q}$ ratios does not produce more than about a 4 mm Hg drop in arterial P_{O_2} (compared to expectations in the absence of this phenomenon), and thus a 4 mm Hg alveolar–arterial P_{O_2} difference.[6]

Fractally Based $\dot{V}_A/\dot{Q}$ Inequality

The branching airway and blood vessel structure of the lung constitutes a fractal system that is innately susceptible to $\dot{V}_A/\dot{Q}$ inequality independent of gravity.[17] A fractal system is one in which the geometric pattern (e.g., of airway branching) is repeated at ever smaller scales. In the case of the airway tree it means in essence that the division of an airway into two "daughter" branches is a repeating feature from the large to the small airways. With some 23 sequential orders of branching, very small random inequalities in gas or blood flow distribution repeated at each branch point of the system can rapidly escalate into very significant degrees of nonuniform ventilation or blood flow. To illustrate, consider a branching system of just 16 dichotomous sequences—at each of the 16 branch points, air is not precisely split 50/50 between each daughter pair. Rather, suppose a 49%/51% split—a nonuniform effect of trivial proportions at any one airway branch. The most poorly ventilated regions (receiving 49% of the split at every one of the 16 branchings) end up with only about half as much ventilation as the best ventilated regions that receive 51% of the split at each branch.

Unless the fractal structure somehow distributes both ventilation and blood flow in a correlated manner to preserve $\dot{V}_A/\dot{Q}$ ratios (even as $\dot{V}_A$ or $\dot{Q}$ individually vary), significant hypoxemia could result. Understanding the consequences of the fractal nature of the lung is a topic of much current interest. It appears that there must be correlation of $\dot{V}_A$ with $\dot{Q}$ since the large potential for fractally based hypoxemia is not generally realized.

Longitudinally Based Inequality

As airways and blood vessels progressively narrow with each branch point, resistance to gas and blood flow increases. Not all alveoli receive gas or blood from airways that have gone through the exact same number of branchings. Hence, some alveoli will be more and some will be less distant from the mouth. Such simple principles suggest the possibility of reduced $\dot{V}_A$ and/or $\dot{Q}$ of those alveoli further from the mouth compared to more proximal alveoli, and therefore the chance of a central to peripheral, or longitudinal, gradient in ventilation and blood flow. Although not universally observed, there is a fair amount of evidence that such inequality exists,[18] but its contribution to gas exchange is hard to establish. To the extent that similar physical principles apply to both gas and blood flow in the present context, one can theorize that more distant alveoli have both less ventilation and blood flow, so that again there is a natural tendency to preserve the $\dot{V}_A/\dot{Q}$ ratio between central and peripheral regions.

Anatomically Based Inequality

Another potential reason for nonuniform gas or blood flow distribution is intrinsic anatomical differences between lung regions. Perhaps the best example is in the dog and horse where, independent of body position in relation to gravity, the dorsal regions of the lower lobes often can be shown to have an unduly high share of total pulmonary perfusion. This tendency, presumably based on the overall branching architectural differences between lobes or within lobes, becomes important in concept when patients are moved from one body position to another, in order to best understand consequent changes in gas exchange.[19]

Collateral Ventilation and Blood Flow

To this point, a picture has been painted of a branching architecture that has no lateral connections between either adjacent airways or

blood vessels at any level of branching. Such lateral connections can exist at several airway levels from large airways down to alveoli.[13,20] This is a species-dependent phenomenon, so that while the pig has little or no such collateral pathway structures, the dog has extensive collateral ventilatory channels. Humans are somewhere between these extremes.

Whatever the evolutionary pressure for collateral channel development, the ability to move gas around obstructions in airways by the use of collateral channels appears to be a useful property of human lungs. This is because total airway obstruction in the absence of collateral channels often leads to rapid alveolar gas absorption into the blood from the alveoli distal to the obstructed airway, and this in turn leads to atelectasis and therefore vascular shunts and hypoxemia. Remarkably, chronic human lung diseases typified by airway obstruction – chronic obstructive pulmonary disease (COPD), asthma – produce $\dot{V}_A/\dot{Q}$ inequality due to presence of poorly ventilated areas, but only uncommonly lead to true shunts.[21,22] The likely explanation for the paucity of shunts in COPD and asthma is the existence of collateral ventilation.

Collateral ventilation in man therefore appears to be a naturally occurring structural phenomenon that can to some extent counteract the gas exchange consequences of diseases.

Collateral perfusion must also occur in the alveolar capillary network. This is deduced simply from the richly interconnecting microvascular network that has the potential to allow blood to flow easily around microvascular obstructions into adjacent vessels. Just how much collateral blood flow potential exists at a larger scale is not clear, being difficult to study. However, well-documented connections occur between the bronchial and pulmonary circulations,[23] creating a different kind of collateral circulatory network. The importance of this connection is evident when the pulmonary artery is either absent or embolized. Then, the bronchial circulation expands considerably and can support function of the affected lung regions long term.

Reactive Vasoconstriction and Bronchoconstriction

The distribution of ventilation or blood flow in the lung can be modified by vasoreactive or bronchoreactive functional changes that appear triggered by changes in alveolar gas composition. The most well-documented phenomenon is that of hypoxic pulmonary vasoconstriction.[24,25] Here, in response to local alveolar hypoxia produced by locally reduced ventilation, local pulmonary arterial constriction reduces blood flow in the hypoxic region. Whether this system developed to counteract disease or to cope with intrauterine life and the abrupt transition to air-breathing is arguable, although most people favor the latter explanation.

Irrespective of the reasons, the effect of hypoxic vasoconstriction is to help return the local ratio of ventilation to blood flow towards normal. This automatic effect (mediated by O_2-sensitive potassium channels in pulmonary arterial smooth muscle cells) is rarely able to fully restore $\dot{V}_A/\dot{Q}$ ratios to normal, but even partial improvements in $\dot{V}_A/\dot{Q}$ ratio facilitate gas exchange significantly. The negative aspect of hypoxic vasoconstriction is a rise in pulmonary vascular resistance. If this is substantial and protracted over time, pulmonary arterial hypertension can develop, eventually leading to right heart failure. However, factors other than hypoxic vasoconstriction are then also generally present – microvascular destruction and alveolar distortion – and these may be more important to heart failure than hypoxia per se. However, hypoxic vasoconstriction has provided a rationale for enriched O_2 therapy in patients with chronic disease to reduce the severity, or to delay the progression, of pulmonary hypertension.

To a much less obvious extent, a counterpart to hypoxic vasoconstriction occurs in the airways: hypocapnic bronchoconstriction.[26] Here, especially when pulmonary embolism occurs, the $\dot{V}_A/\dot{Q}$ ratio in the embolized area rises due to loss of blood flow from vascular obstruction. This increase in $\dot{V}_A/\dot{Q}$ ratio leads to a lower local P_{CO_2} (see below), which causes bronchoconstriction in the local area. This reduces local ventilation and thus tends to normalize the local $\dot{V}_A/\dot{Q}$ ratio. Radioactive tracer ventilation scans may show evidence of this as a modest reduction in the ventilation of embolized regions.

THE $\dot{V}_A/\dot{Q}$ RATIO AND GAS EXCHANGE

To this point, much space has been given to the concepts underlying the distribution of ventilation ($\dot{V}_A$), blood flow ($\dot{Q}$), and hence their ratio, $\dot{V}_A/\dot{Q}$. The reason for this lies in the importance of $\dot{V}_A/\dot{Q}$ ratios to the basic function of the lung—to exchange O_2 and CO_2 between the blood and the air. $\dot{V}_A/\dot{Q}$ inequality, no matter what its physiological basis or pathological cause, interferes with gas exchange and causes hypoxemia and sometimes hypercapnia.

The following section will explain the relationship of $\dot{V}_A/\dot{Q}$ inequality to gas exchange. The subject is complex and must be considered at several "concentric" levels. To start, we will consider how the $\dot{V}_A/\dot{Q}$ ratio in a small local lung region controls local P_{O_2}, P_{CO_2}, and therefore how much O_2 and CO_2 are exchanged in that region. This isolated approach requires at first some key assumptions. Removing the restrictions of these assumptions is the next "concentric" step in understanding $\dot{V}_A/\dot{Q}$ relationships. A final outer shell of modifying factors that can further affect gas exchange forms a third level of the analysis.

THE $\dot{V}_A/\dot{Q}$ RATIO OF A SMALL HOMOGENEOUS UNIT OF LUNG AND GAS EXCHANGE

How the $\dot{V}_A/\dot{Q}$ ratio determines gas exchange is best explained by considering the flux of O_2 from the environment into and out of the alveolus with each breath as well as from the alveolar gas into the capillary blood. Equations that describe these processes and follow the fundamental principle of mass conservation must be used. Original descriptions of these appeared more than 50 years ago.[8,27–30] Figure 14-5 provides a model of the lung and specifies the total ventilation ($\dot{V}_A$) and blood flow ($\dot{Q}$) of this model together with the key locations of the relevant O_2 levels. It can be used to consider a small homogeneous unit of lung.

Convention has long considered ventilation over a period of time as a constant in spite of the tidal nature of breathing. This is in fact a very reasonable approximation that has stood the test of

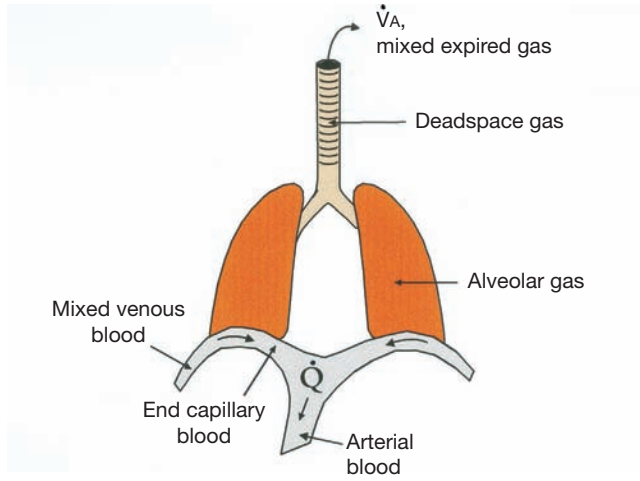

Figure 14-5 Conceptual model of the lungs indicating main sites in which oxygen and carbon dioxide partial pressures are different, together with the principal convective processes accomplishing gas exchange, ventilation ($\dot{V}_A$), and blood flow ($\dot{Q}$).

time. Similarly, blood flow is considered constant, and this too has proved reasonable. If $\dot{V}_A$ and $\dot{Q}$ are therefore considered as alveolar minute ventilation and blood flow of a small homogeneous unit respectively, the following simple mass conservation equations can be written for O_2:

$$\dot{V}_{O_2} = \dot{V}_I \cdot F_{I_{O_2}} - \dot{V}_A \cdot F_{A_{O_2}} \quad (2)$$

and

$$\dot{V}_{O_2} = Q \cdot Cc'_{O_2} - \dot{Q} \cdot C\bar{v}_{O_2} \quad (3)$$

In these equations, $\dot{V}_{O_2}$ is amount of O_2 transferred from the environment into the blood per unit time and, given the assumption of steady state conditions, this, when summed over all such units in the lungs, equals metabolic rate. $\dot{V}_I$ and $\dot{V}_A$ are, respectively, the inspired and expired volumes of gas respired per minute, less than the amount remaining in the conducting airways. As anticipated, $\dot{V}_I$ and $\dot{V}_A$ are close to being identical, otherwise the lungs would blow up or collapse in a short period of time. However, $\dot{V}_I$ does not generally equal $\dot{V}_A$ because slightly more O_2 is consumed per minute than is CO_2 produced (i.e., the respiratory quotient is in general not 1.0). Thus, $\dot{V}_A = \dot{V}_I - \dot{V}_{O_2} + \dot{V}_{CO_2}$. Mostly, the inequality of $\dot{V}_I$ and $\dot{V}_A$ can be ignored because the difference is only about 1%—if $\dot{V}_I$ is 6 L/min and $\dot{V}_{O_2}$ is 300 mL/min with $\dot{V}_{CO_2}$ at 240 mL/min, $\dot{V}_A$ = 5.94 L/min. Although this small difference is not ignored in research applications, it can be for the present purposes, so that $\dot{V}_I$ is replaced by $\dot{V}_A$ in Equation (1), simplifying the analysis. In Equation (1), $F_{I_{O_2}}$ and $F_{A_{O_2}}$ are the fractional concentrations (F) of O_2 in inspired (I) and exhaled alveolar (A) gas, respectively, from a small unit in Figure 14-5. In Equation (2), Cc'_{O_2} and $C\bar{v}_{O_2}$ are the O_2 concentrations (C) in the oxygenated end capillary blood leaving (c′) and the deoxygenated blood entering ($\bar{v}$) the vasculature respectively. The abbreviation c′ stands for end capillary blood; $\bar{v}$ for mixed venous (pulmonary arterial) blood.

Since Equations (1) and (2) both describe the same O_2 flux rate ($\dot{V}_{O_2}$) they may be set equal to each other:

$$\dot{V}_A [F_{I_{O_2}} - F_{A_{O_2}}] = \dot{Q} [Cc'_{O_2} - C\bar{v}_{O_2}] \quad (4)$$

and rearranged so that:

$$\dot{V}_A/\dot{Q} = [Cc'_{O_2} - C\bar{v}_{O_2}]/[F_{I_{O_2}} - A_{O_2}] \quad (5)$$

It should further be noted that because diffusion equilibration of O_2 transfer across the alveolar–capillary membrane is assumed to be complete, alveolar P_{O_2} and end capillary P_{O_2} are identical. Hence, the relationship between $F_{A_{O_2}}$ and Cc'_{O_2} is uniquely dictated by the O_2-Hb dissociation curve such that knowing $F_{A_{O_2}}$ allows us to determine directly Cc'_{O_2} (or vice versa).

Equation (5) is very revealing and explains directly the role of the $\dot{V}_A/\dot{Q}$ ratio in governing alveolar gas exchange. This equation states that for a given set of what may be called boundary conditions (i.e., composition of inspired gas and mixed venous blood, represented here by $F_{I_{O_2}}$ and $C\bar{v}_{O_2}$, respectively) and for a known O_2–Hb dissociation curve, alveolar (and thus end capillary) P_{O_2} is uniquely determined by the ratio of alveolar ventilation ($\dot{V}_A$) to blood flow ($\dot{Q}$).

Under the given assumptions, summarized as (1) continuous and constant ventilation and blood flow; (2) steady state conditions; (3) diffusion equilibration of alveolar–capillary exchange; and (4) equality of inspired and expired ventilation, equations identical in construct to Equation (5) can be written for any gas being exchanged by the lung.

For CO_2, this produces Equation (6):

$$\dot{V}_A/\dot{Q} = [C\bar{v}_{CO_2} - Cc'_{CO_2}]/[F_{A_{CO_2}} - F_{I_{CO_2}}] \quad (6)$$

The order of bracketed terms on the right is reversed to maintain positive numbers, since CO_2 is being eliminated from the blood. Of course, $F_{I_{CO_2}}$ is essentially zero and thus drops out of the equation.

Unfortunately, neither Equation (5) nor (6) is amenable to simple quantitative solutions, because of the complexity of the O_2 and CO_2 dissociation curves. The equations are however readily explored by appropriate computerized numerical analyses.[31–35] Using such programs, one can explore the relationship between $\dot{V}_A/\dot{Q}$ ratio and alveolar P_{O_2} and P_{CO_2}, and this is done in Figure 14-6. These relationships are important because they indicate what degrees of $\dot{V}_A/\dot{Q}$ abnormality are required to affect gas exchange for both O_2 and CO_2. The four panels of Figure 14-6 show alveolar P_{O_2} and P_{CO_2} as well as end capillary O_2 and CO_2 concentrations. The latter better reflect total gas exchange as a function of $\dot{V}_A/\dot{Q}$ ratio. Specific conditions for Figure 14-6 are that mixed venous blood P_{O_2} is 40 mm Hg and P_{CO_2} 45 mm Hg, normal resting values. Also, inspired gas is room air, and [Hb] is 15 g/dL. In each panel, the three solid circles are positioned at the normal $\dot{V}_A/\dot{Q}$ ratio (of about 1.0) and at $\dot{V}_A/\dot{Q}$ ratios 10 times greater and less. All four relationships are highly non-linear. Focusing on the two lower panels, it is evident for O_2 that a 10-fold reduction in $\dot{V}_A/\dot{Q}$ greatly reduces local O_2 transport, whereas a 10-fold increase barely improves it. Furthermore, as $\dot{V}_A/\dot{Q}$ falls even lower than 0.1, there is little further loss in O_2 transport. There is however little protection against a fall in $\dot{V}_A/\dot{Q}$ below 1.0, because the curve is very steep below a $\dot{V}_A/\dot{Q}$ of 1.0, as the lower left panel shows. For CO_2, the curves are opposite in slope (P_{CO_2} falls as $\dot{V}_A/\dot{Q}$ increases).

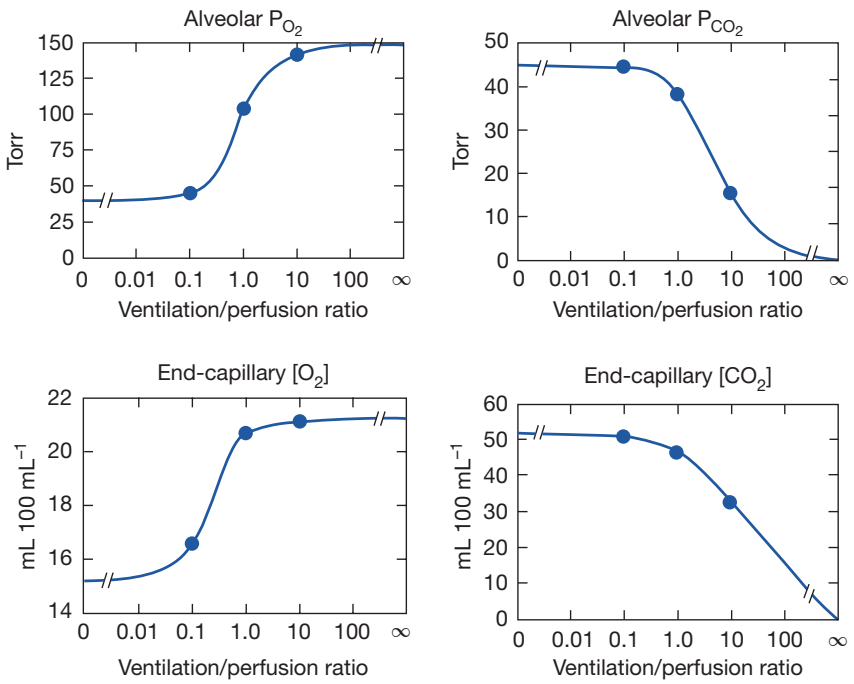

Figure 14-6 Calculated relationships between alveolar P_{O_2} and P_{CO_2} and the ventilation–perfusion ratio *(top panels)* and their corresponding end-capillary blood concentrations *(lower panels)*. The three solid circles in each case represent values for ventilation–perfusion ratios of 0.1, 1.0, and 10. (See text for further details.)

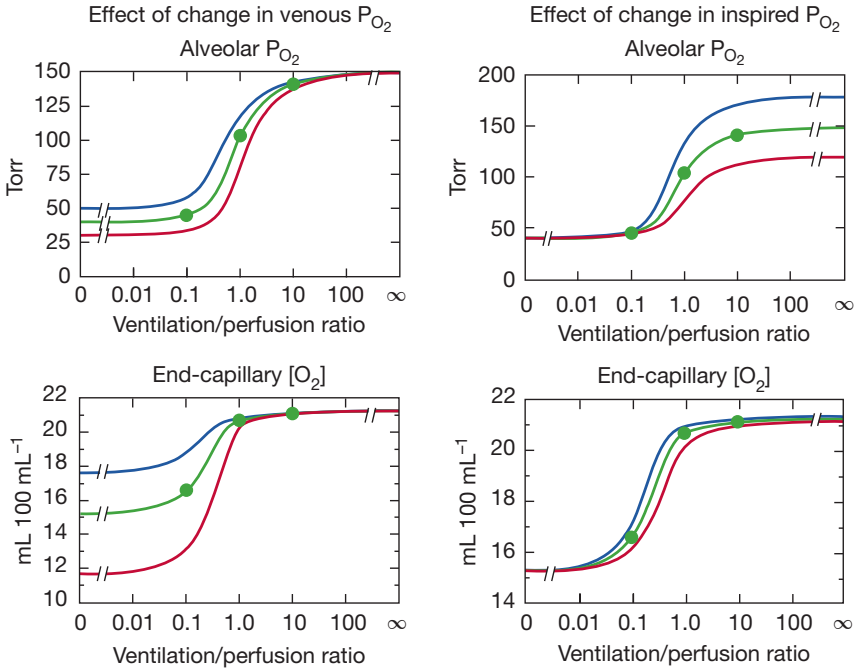

Figure 14-7 Effects of changes in mixed venous P_{O_2} *(left panels)* or inspired P_{O_2} *(right panels)* on alveolar P_{O_2} and associated end-capillary oxygen concentrations. Note that changes in venous P_{O_2} mostly affect values associated with low ventilation–perfusion ratios, whereas changes in inspired P_{O_2} affect units throughout the $\dot{V}_A/\dot{Q}$ range, especially those with medium to high $\dot{V}_A/\dot{Q}$ ratios.

However, unlike the case for O_2, there is little difference between a $\dot{V}_A/\dot{Q}$ of 1.0 and a 10-fold reduction, whereas an increase in $\dot{V}_A/\dot{Q}$ considerably reduces alveolar P_{CO_2} and end capillary CO_2 concentration. The reason for the differences between O_2 and CO_2 lies mainly in the slopes of their dissociation curves: that for CO_2 is about 10-fold greater than that for O_2. It has been shown that the higher the slope of the dissociation curve (or equivalently for an anesthetic gas, its solubility) the more it is sensitive to areas of high $\dot{V}_A/\dot{Q}$. The lower the slope or solubility, the more the gas is affected by areas of low $\dot{V}_A/\dot{Q}$. Consequently, areas of low $\dot{V}_A/\dot{Q}$ predictably cause more reduction in arterial P_{O_2} than increase in arterial P_{CO_2}. Although Figure 14-6 is true strictly only for the stated "boundary" conditions (i.e., mixed venous blood and inspired gas composition), the principles hold even for different such conditions, as shown in Figure 14-7 for O_2. The left panels illustrate how changes in mixed venous P_{O_2} alone will affect alveolar P_{O_2} and end capillary $[O_2]$ via Equation (4). The right panels correspondingly show how change in inspired P_{O_2} affects O_2. Venous P_{O_2} is selected at 30, 40, and 50 mm Hg, and inspired P_{O_2} is chosen to be 120, 150, and 180 mm Hg. Changes in venous P_{O_2} dramatically affect P_{O_2} and $[O_2]$ in unventilated and poorly ventilated regions as well as regions approaching normal, but have no real effect on high $\dot{V}_A/\dot{Q}$ alveoli. Altering inspired P_{O_2} (but not venous) has the converse effect if P_{O_2} is examined (top right panel), but, due to the nonlinear shape of the O_2–Hb dissociation curve, effects on $[O_2]$ are minimal in high $\dot{V}_A/\dot{Q}$ areas, small in very low $\dot{V}_A/\dot{Q}$ areas, and more significant between $\dot{V}_A/\dot{Q}$ ratios of 0.1 and 1.0 (bottom right panel). This figure shows how the inspired and mixed venous "boundary conditions" alter the magnitude (but not basic patterns) of alveolar gas exchange.

If one returns to the normal boundary conditions ($P\bar{v}_{O_2}$ = 40 mm Hg, $P_{I_{O_2}}$ = 150 mm Hg), one can explore the consequences of $\dot{V}_A/\dot{Q}$ inequality on gas exchange. In reality, the complex structure of the lungs defies a simple analysis but conceptually even a two-compartment model is an invaluable aid to understanding this conceptually difficult area.

Figure 14-8 shows such a simple two-compartment model in three configurations: (1) each compartment equally ventilated and perfused such that there is no $\dot{V}_A/\dot{Q}$ inequality; (2) the left compartment hypoventilated due to airway obstruction, causing $\dot{V}_A/\dot{Q}$ inequality; and (3) the left compartment hypoperfused from vascular obstruction. Table 14-1 shows the corresponding O_2 and CO_2 calculations for each compartment. Specific assumptions common to all three models are (1) the mixed venous P_{O_2} remains at 40 mm Hg; inspired P_{O_2} is constant at 150 mm Hg; total alveolar ventilation summed over both compartments is constant as is total blood flow, both taken to be 6 L/min; [Hb] is constant at 15 g/dL. Further, airways obstruction reduces L-hand compartmental ventilation from 3.0 to 0.3 L/min, redistributing the balance to the R-hand compartment. Vascular obstruction is of the same order as the right panel of the figure shows. Note that for both obstructive models, one compartment has developed a $\dot{V}_A/\dot{Q}$ ratio less than average and the other a $\dot{V}_A/\dot{Q}$ ratio greater than average, irrespective of the location of the obstruction.

Using the curves of Figure 14-6, for $P\bar{v}_{O_2}$ = 40 mm Hg and $P_{I_{O_2}}$ = 150 mm Hg, $P\bar{v}_{CO_2}$ = 45 mm Hg and $P_{I_{CO_2}}$ = 0 mm Hg, alveolar P_{O_2} and P_{CO_2} are listed for each compartment of Figure 14-8 in Table 14-1.

In Table 14-1, alveolar diffusion equilibration is assumed to be complete such that alveolar P_{O_2} ($P_{A_{O_2}}$) equals end capillary P_{O_2} (Pc'_{O_2}); the same holds for P_{CO_2}. In each obstructive model, the low $\dot{V}_A/\dot{Q}$ compartment has a lower-than-average P_{O_2} and higher-than-average P_{CO_2} as Figure 14-6 dictates. The converse is seen for the compartment of high $\dot{V}_A/\dot{Q}$ ratio. Corresponding end capillary O_2 and CO_2 concentrations are also listed in Table 14-1.

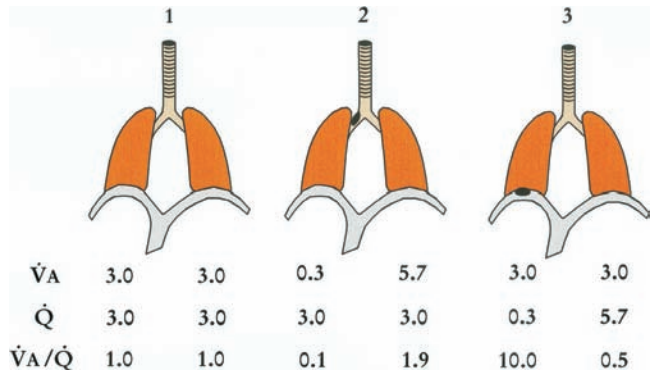

Figure 14-8 Three two-compartment models of ventilation–perfusion relationships. *Model 1* represents an ideal lung without ventilation–perfusion mismatch. *Model 2* represents a lung in which one compartment has a 90% reduction in its alveolar ventilation due to airway obstruction, and *Model 3* is a lung in which one compartment has a 90% reduction in capillary blood flow due to vascular obstruction. Ventilation, blood flow, and ventilation–perfusion ratio of each compartment are indicated. Total ventilation and total blood flow remain the same among the three models. (See text for further details.)

TABLE 14-1 O_2 and CO_2 Calculations for the Models of Figure 14-8

	Normal		Airway Obstruction Model		Vascular Obstruction Model	
	Left	Right	Left	Right	Left	Right
$P_{A_{O_2}}$, Pc'_{O_2}, mm Hg	103.0	103.0	45.0	120.0	142.0	77.0
$P_{A_{CO_2}}$, Pc'_{CO_2}, mm Hg	38.8	38.8	44.9	32.5	15.5	42.7
Cc'_{O_2}, mL·dL^{-1}	20.7	20.7	16.7	20.9	21.1	20.1
Cc'_{CO_2}, mL·dL^{-1}	46.9	46.9	50.8	43.9	32.5	48.8
Ca_{O_2}, mL·dL^{-1}	20.7		18.8		20.1	
Ca_{CO_2}, mL·dL^{-1}	46.9		47.5		48.0	
Pa_{O_2}, mm Hg	103.0		55.0		77.0	
Pa_{CO_2}, mm Hg	38.8		39.0		40.9	
$P\bar{A}_{O_2}$, mm Hg	103.0		118.0		110.0	
$P\bar{A}_{CO_2}$, mm Hg	38.8		33.7		29.2	
Total O_2 exchange, mL·min^{-1}	328.0		212 (65%)		294 (90%)	
Total CO_2 exchange, mL·min^{-1}	270.0		234 (87%)		203 (75%)	
$P\bar{A}_{O_2}$—$P_{A_{O_2}}$, mm Hg	0.0		63.0		33.0	
$P_{A_{CO_2}}$—$P\bar{A}_{CO_2}$, mm Hg	0.0		5.0		11.7	

The question is what will the mixed arterial blood and mixed expired gas O_2 and CO_2 levels change to as a result of obstruction of one compartment, and how will this affect the ability of the total system to exchange O_2 and CO_2? To answer these questions one applies simple mixing questions to the two individual compartments [left (L) and right (R)]:

For O_2 :

$$P\bar{A}_{O_2} = (P_{AO_{2L}} \cdot \dot{V}_{A_L} + P_{AO_{2R}} \cdot \dot{V}_{A_R})/(\dot{V}_{A_L} + V_{A_R})$$

$$Ca_{O_2} = (Cc'_{O_{2L}} \cdot \dot{Q}_L + Cc'_{O_{2R}} \cdot \dot{Q}_R)/(\dot{Q}_L + \dot{Q}_R) \quad (7)$$

For CO_2, identical equations apply. These mixing equations conserve mass and use the principle that the two gas or blood streams combine in a manner proportional to their relative ventilation and blood flow, respectively. Table 14-1 lists the results of these calculations, giving mixed alveolar partial pressure ($P\bar{A}_{O_2}$, $P\bar{A}_{CO_2}$) and mixed arterial concentrations (Ca_{O_2}, Ca_{CO_2}). From the blood–gas concentration, corresponding arterial partial pressures (Pa_{O_2}, Pa_{CO_2}) are read directly off the O_2 and CO_2 dissociation curves. Finally, whole-lung computations of O_2 and CO_2 exchange rates (mL/min) are determined using either Equations (1) or (2) and the mixed alveolar or arterial data respectively, and the mixed alveolar to arterial partial pressure differences expressed for each gas.

The results are very instructive. Both obstructive models result in hypoxemia and slight hypercapnia, but the effects on arterial P_{O_2} and on the alveolar–arterial P_{O_2} difference greatly exceed those for CO_2 due to both shape and slope differences between the dissociation curves of the two gases. Airways obstruction produces more hypoxemia but *less* hypercapnia than the identical degree of vascular obstruction. This reflects the 10-fold greater dissociation curve slope of CO_2 compared to O_2, rendering O_2 relatively more susceptible to the lower $\dot{V}_A/\dot{Q}$ areas seen in the airway obstruction model (0.1 vs. 0.5) (Fig. 14-8) and CO_2 relatively more susceptible to the higher $\dot{V}_A/\dot{Q}$ areas of vascular obstruction (10.0 vs. 1.9) (Fig. 14-8) as Figure 14-6 would predict.

Both models have impaired overall O_2 and CO_2 exchange (recall that venous blood, inspired gas, total ventilation, and blood flow were all considered fixed and identical for all three models) as a result of the development of $\dot{V}_A/\dot{Q}$ mismatch. In keeping with the differential sensitivity of O_2 and CO_2 to regions of low and high $\dot{V}_A/\dot{Q}$ discussed earlier, total O_2 transport is diminished to a greater extent in the airway obstruction model than in the vascular obstruction model (Table 14-1). The converse is true for CO_2, also shown in Table 14-1.

The principal effects of $\dot{V}_A/\dot{Q}$ inequality as they apply to O_2 and CO_2 exchange may thus be listed.

$\dot{V}_A/\dot{Q}$ inequality:

a. Affects both gases, no matter what the pathological basis of the inequality.
b. Causes arterial hypoxemia and hypercapnia.
c. Causes usually more severe hypoxemia than hypercapnia.
d. Affects O_2 more than CO_2 when very low $\dot{V}_A/\dot{Q}$ regions develop.
e. Affects CO_2 more than O_2 when very high $\dot{V}_A/\dot{Q}$ regions develop.
f. Impairs total O_2 and CO_2 exchange by the lung.
g. Creates alveolar–arterial differences for both gases.

COMPENSATION FOR THE EFFECTS OF $\dot{V}_A/\dot{Q}$ MISMATCH

The preceding analysis shows that if no changes in total ventilation, blood flow, mixed venous blood, or inspired gas composition occur, O_2 and CO_2 transfer across the lung is compromised. This is not viable in the steady state: the lungs must find a way to restore total O_2 and CO_2 transfer to levels equal to metabolic use of O_2 and production of CO_2. This leads to the next concentric level of consideration of $\dot{V}_A/\dot{Q}$ inequality referred to at the start of this section.

Here we ask what compensatory mechanisms exist to achieve restoration of O_2 and CO_2 transfer assuming that the initial pathophysiological insults have persisted unchanged. The same models as in Figure 14-8 and Table 14-1 will be used.

CHANGES IN MIXED VENOUS BLOOD

The only possible short-term compensatory changes are in mixed venous blood, total ventilation, and cardiac output. (Hb change in response to tissue hypoxia requires days to weeks to develop and then is by no means always observed; changing inspired P_{O_2} is not usually an option until the patient seeks medical attention.) To reduce complexity, changes in venous blood alone are first addressed.

TABLE 14-2 Gas Exchange Effects of Passive Changes in Mixed Venous Blood—Gas Values Required to Restore $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ to Normal in the Models of Figure 14-8

	Airway Obstruction Model		Vascular Obstruction Model	
	Before Change	After Change	Before Change	After Change
$P\bar{v}_{O_2}$, mm Hg	40.0	30.4	40.0	39.5
$P\bar{v}_{CO_2}$, mm Hg	45.0	50.7	45.0	62.4
Pa_{O_2}, mm Hg	55	46	77	67
Pa_{CO_2}, mm Hg	39.0	44.5	40.9	55.6
$\dot{V}_{O_2}$, mL·min^{-1}	212.0	328 (normal)	294.0	328.0 (normal)
$\dot{V}_{CO_2}$, mL·min^{-1}	234.0	270 (normal)	203.0	270.0 (normal)

If it is assumed that there is no limit to how much O_2 can be extracted from the arterial blood by the peripheral tissues, it is evident that $\dot{V}_A/\dot{Q}$ inequality will passively lead to a reduced venous P_{O_2} and increased venous P_{CO_2}. This is deduced simply from the hypoxemia and hypercapnia initially produced by the $\dot{V}_A/\dot{Q}$ insult, together with the need to extract the same amount of O_2 from (and add CO_2 to) each mL of blood perfusing the tissues as before the $\dot{V}_A/\dot{Q}$ insult developed.

If venous P_{O_2} falls (and P_{CO_2} rises), Figure 14-7 indicates that alveolar P_{O_2} will fall in each $\dot{V}_A/\dot{Q}$ compartment (as will P_{CO_2} rise). Thus a circle of events is set up such that if a single red cell were followed around the circulation, at each passage through the lungs and then tissues, P_{O_2} would fall progressively with each circuit of the body.

Although not intuitively obvious, this reduction in both arterial and venous P_{O_2} will not "bottom out" at zero (or in the case of CO_2 rise toward infinity) unless the $\dot{V}_A/\dot{Q}$ insult was fatally overwhelming in the first place. Both arterial and venous P_{O_2} will restabilize at new lower values (P_{CO_2} values will be higher) than were present immediately after the $\dot{V}_A/\dot{Q}$ insult developed. In so doing, $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ will have been restored to normal values.

To explore this quantitatively, we will continue on with the models of Figure 14-8 and Table 14-1 to show just what changes in venous and arterial P_{O_2} and P_{CO_2} must occur as a result of this process in order to restore pulmonary O_2 and CO_2 exchange to normal. The values are shown in Table 14-2. For the airways obstruction model, the passive blood gas changes are greater for O_2 than CO_2, consonant with the greater initial decrement in O_2 exchange caused by airways obstruction in the first place. For the vascular obstruction model, the effects are more marked for CO_2, for corresponding reasons. To restore $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ in the airways obstruction model, hypoxemia is now more severe, but hypercapnia is mild. However, with vascular obstruction, hypoxemia remains mild while hypercapnia is severe. In both cases, the lung is meeting the original healthy requirement of transferring 328 and 270 mL/min of O_2 and CO_2, respectively.

The speed of passive venous blood composition changes is very rapid, taking place in seconds to minutes as the blood moves continuously around the vascular system between lungs and tissues. The principal effects of the changes can be summarized as follows:

a. Following development of $\dot{V}_A/\dot{Q}$ mismatch, and a fall in $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ at the lungs, mixed venous P_{O_2} will fall and mixed venous P_{CO_2} will rise to restore pulmonary $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ to equal the original metabolic requirements for O_2 and CO_2 transport.

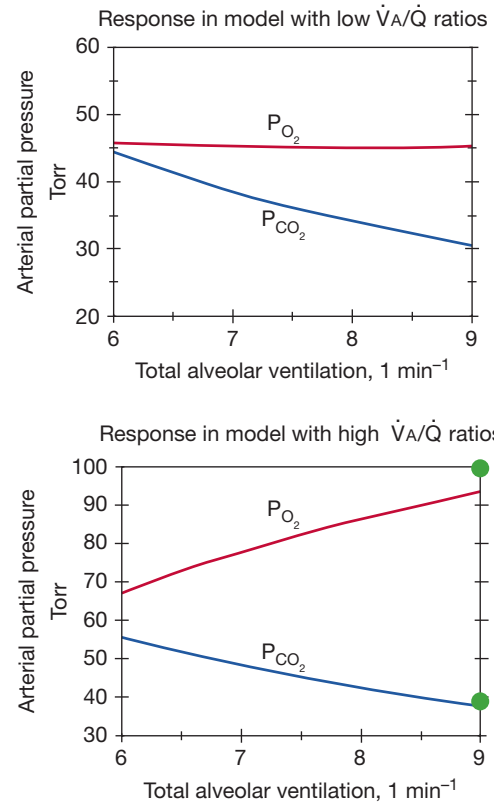

Figure 14-9 Effect of increasing alveolar ventilation on arterial P_{O_2} and P_{CO_2} in the two models with ventilation–perfusion inequalities in Figure 14-8. *Top panel* is that for Model 2 and *bottom panel* is that for Model 3. Increasing ventilation is ineffective in restoring arterial P_{O_2} in the low $\dot{V}_A/\dot{Q}$ Model 2, but much more effective in the high $\dot{V}_A/\dot{Q}$ Model 3. Both models respond in terms of P_{CO_2}.

b. As a result, there will always be a further fall in arterial P_{O_2} and rise in arterial P_{CO_2}, compared to conditions prior to mixed venous blood changes.
c. When the $\dot{V}_A/\dot{Q}$ insult primarily involves development of extremely low $\dot{V}_A/\dot{Q}$ areas, those effects are more marked for O_2 than for CO_2.
d. When the $\dot{V}_A/\dot{Q}$ insult primarily consists of high $\dot{V}_A/\dot{Q}$ areas, CO_2 is affected more than O_2.

■ CHANGES IN TOTAL VENTILATION

When either low or high $\dot{V}_A/\dot{Q}$ areas develop and the mixed venous and arterial adjustments occur as described earlier, there is hypoxemia and hypercapnia. Either or both may well stimulate an immediate increase in total ventilation,[36] which will alleviate to some extent both the hypoxemia and hypercapnia. Figure 14-9 shows for the same two examples used earlier how increases in alveolar ventilation (distributed in the same proportions as in each of the two $\dot{V}_A/\dot{Q}$ models of Fig. 14-8) variably improves arterial P_{O_2} and P_{CO_2}. In the low $\dot{V}_A/\dot{Q}$ (airways obstruction) model, a 50% increase in total alveolar ventilation from the normal value of 6 to 9 L/min drops arterial P_{CO_2} to almost 30 mm Hg, well below the normal standard value of 40 mm Hg. Arterial P_{O_2}, however, is not affected at all. This is because even a 50% increase in ventilation of the very poorly ventilated unit fails to significantly increase end capillary P_{O_2} of that unit (Fig. 14-6), whereas in the better ventilated unit of that model, Hb in the end capillary blood was already virtually fully saturated before the increase in ventilation.

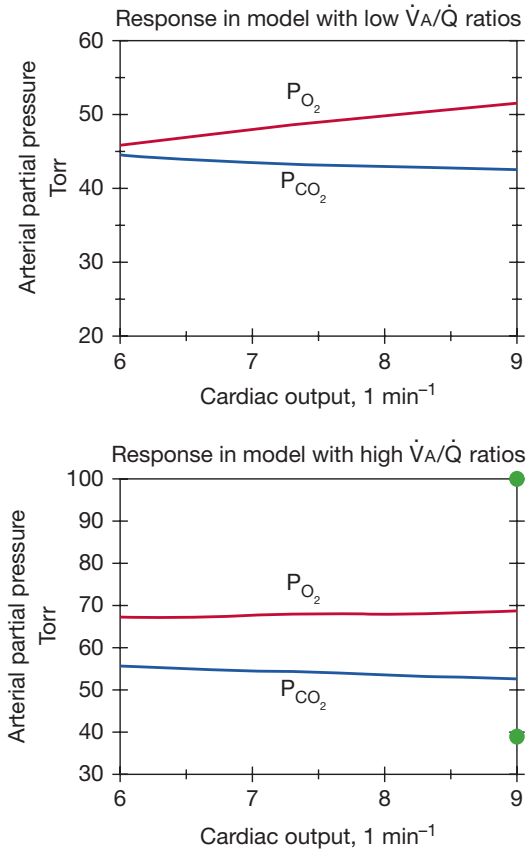

Figure 14-10 Effects of increases in cardiac output on arterial P_{O_2} and P_{CO_2} in Models 2 and 3 of Figure 14-8. Cardiac output produces a significant rise in P_{O_2} in the presence of regions of very low ventilation–perfusion ratio *(top panel)* but has little influence in the presence of higher ventilation–perfusion ratios *(bottom panel)*. P_{CO_2} is affected only minimally in either case.

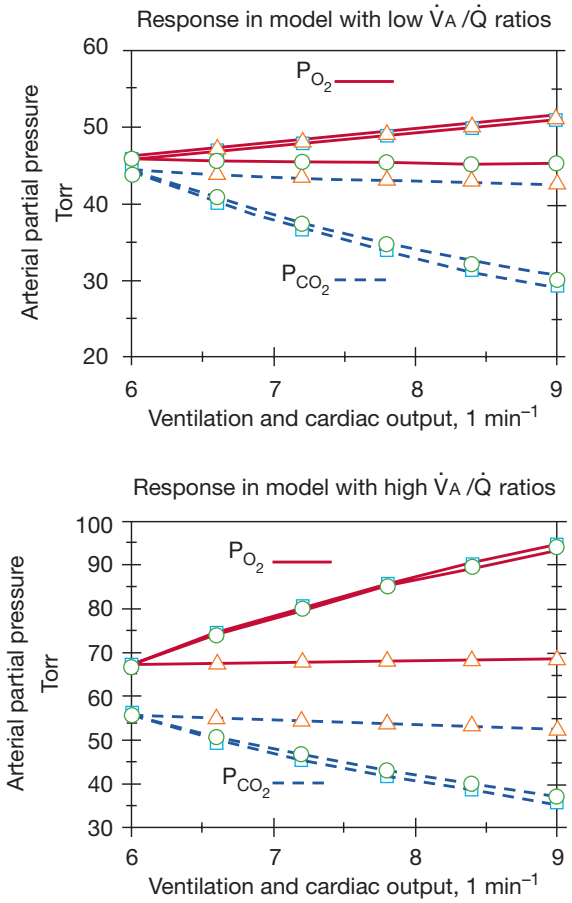

Figure 14-11 Responses to simultaneous increases in ventilation and cardiac output (compared to responses to individual increases as shown in Figs. 14-9 and 14-10). Simultaneous increases do not provide for significantly more improvement than with either alone. o-o, response to increased ventilation only; Δ-Δ, response to increased cardiac output only; □-□, response to simultaneously increased ventilation and cardiac output.

For the model with vascular obstruction, a 50% increase in alveolar ventilation returns both P_{O_2} and P_{CO_2} to near-normal values (Fig. 14-9, lower panel). The difference in the two model responses to ventilation reflects the original $\dot{V}_A/\dot{Q}$ ratios of the two compartments—that is, where they lie on the curves of Figure 14-6.

■ CHANGES IN CARDIAC OUTPUT

One final compensatory adjustment is possible—an increase in cardiac output. Adrenergic stimulation by arterial hypoxemia can raise cardiac output by 50% or more, and this will also tend to improve arterial blood gases by raising mixed venous P_{O_2} (and lowering mixed venous P_{CO_2}). Figure 14-10 shows the effects on arterial P_{O_2} and P_{CO_2} of such increases, as was done for ventilation in Figure 14-9, again assuming that the relative distribution of blood flow remains unaltered between the two compartments as total blood flow is increased. For a lung with airways obstruction causing very low $\dot{V}_A/\dot{Q}$ regions (upper panel), an increase in cardiac output significantly improves arterial oxygenation—more so than does the same relative increase in ventilation. However, arterial P_{CO_2} is only slightly improved. In stark contrast, increases in cardiac output barely alter arterial P_{O_2} and P_{CO_2} in the high $\dot{V}_A/\dot{Q}$ ratio model, especially when it is recalled (Fig. 14-9) how effective an increase in ventilation is in restoring arterial P_{O_2} and P_{CO_2}.

When both ventilation and cardiac output are simultaneously increased, there is no real synergistic effect (Fig. 14-11): P_{O_2} and P_{CO_2} are improved as predicted from the individual changes (i.e., as shown in Figs. 14-9 and 14-10).

In all the calculations depicted in Figures 14-9 to 14-11, the two-compartment models are exchanging the necessary amounts of O_2 and CO_2 to sustain normal metabolism. Depending on (a) the ventilatory and cardiovascular responses to the original insult causing $\dot{V}_A/\dot{Q}$ mismatch and (b) the fundamental pattern of $\dot{V}_A/\dot{Q}$ mismatch (i.e., the preponderance of low and/or high $\dot{V}_A/\dot{Q}$ areas), it is possible to observe hypercapnia, normocapnia, or hypocapnia. However, it is very uncommon for arterial P_{O_2} to be fully normalized by the compensatory mechanisms, and the observed degree of hypoxemia can be extremely variable. As an important clinical corollary, it becomes difficult to establish the severity of the $\dot{V}_A/\dot{Q}$ insult per se when the extent of compensating mechanisms cannot be easily established, since these two aspects are so intertwined in their resulting effect on gas exchange.

ASSESSMENT OF VENTILATION–PERFUSION INEQUALITY

Whereas the preceding discussion highlights the complexity of how $\dot{V}_A/\dot{Q}$ inequality impairs gas exchange, there is a need for methods to assess the extent of such mismatch in the clinical setting. The multiple inert gas elimination technique was developed expressly for this purpose.[37,38] Although the technique provides the necessary

descriptions of the extent and pattern of inequality, it remains a complex technique that is not well suited to routine clinical use. Several traditional quantifying indices of $\dot{V}A/\dot{Q}$ mismatch remain useful on a daily basis. They all make use of O_2 and CO_2 as indicator gases:

1. The first is the alveolar–arterial P_{O_2} difference, $P_{A_{O_2}} - Pa_{O_2}$. This is the difference between alveolar P_{O_2} ($P_{A_{O_2}}$, calculated from the alveolar gas equation presented subsequently) and the measured arterial P_{O_2} (Pa_{O_2}). The $P_{A_{O_2}} - Pa_{O_2}$ is therefore given by

$$PI_{O_2} - Pa_{CO_2}/R + Pa_{CO_2} \cdot FI_{O_2} \cdot (1-R)/R - Pa_{O_2} \quad (8)$$

   Use of this equation requires knowledge of inspired P_{O_2} and $[O_2]$, the respiratory exchange ratio R, and the ideal alveolar P_{CO_2}, which is the P_{CO_2} that would be observed in alveolar gas of a homogeneous lung having the R value of the patient's actual lung at the time. Three problems arise with the application of this equation: First, the result is very dependent on PI_{O_2} even when the amount of $\dot{V}A/\dot{Q}$ inequality does not change as PI_{O_2} is varied. Second, the value of R is generally not known and must be assumed. Suppose $P_{CO_2} = 40$ mm Hg and $Pa_{O_2} = 90$ mm Hg for a subject breathing sea level air. If R were 0.7, $P_{A_{O_2}} - Pa_{O_2}$ would be 7 mm Hg (Equation 8). But if R were 1.0, $P_{A_{O_2}} - Pa_{O_2}$ would be 20 mm Hg, a quite different value. Third, in some cases, the usual substitution for the ideal alveolar P_{CO_2}, the measured arterial P_{CO_2}, leads to a systematic error because arterial P_{CO_2} can be significantly higher than the ideal alveolar value. However, $P_{A_{O_2}} - Pa_{O_2}$ remains a very useful index of $\dot{V}A/\dot{Q}$ inequality providing these limitations are kept in mind.
2. The second index is simply the ratio of arterial P_{O_2} to FI_{O_2} which in a perfectly normal lung is virtually insensitive to PI_{O_2}, a major advantage. However, even that is an over-simplification, because this ratio may not be as constant as hoped for depending on the pattern of $\dot{V}A/\dot{Q}$ inequality present.
3. A third index is venous admixture (QsQT) or, equivalently, physiological shunt. This is a parameter that expresses what magnitude shunt would have to be present in a particular case to explain a patient's arterial P_{O_2} if that shunt were the sole cause of hypoxemia. The formula is:

$$\%\ QsQT = 100 \cdot [Cc'_{O_2} - Ca_{O_2}]/[Cc'_{O_2} - C\bar{v}_{O_2}] \quad (9)$$

   where Cc'_{O_2} is the calculated end capillary $[O_2]$ of blood perfusing a hypothetical alveolus exchanging gas at the overall respiratory exchange ratio of the patient's actual lungs. Ca_{O_2} is arterial and $C\bar{v}_{O_2}$ mixed venous $[O_2]$, respectively. This parameter, working in the O_2 concentration domain (rather than the partial pressure domain of the $P_{A_{O_2}} - Pa_{O_2}$), better reflects the degree of the gas exchange defect but requires knowledge of the ideal alveolar conditions to calculate Cc'_{O_2}, as well as [Hb]. It also is sensitive to PI_{O_2} in that when $\dot{V}A/\dot{Q}$ inequality is present, its contribution to QsQT diminishes progressively as PI_{O_2} is raised. The most limiting aspect of this parameter however is the need to know the value of $C\bar{v}_{O_2}$, reflecting mixed venous blood. If this must be assumed rather than measured, the value of QsQT will be only as good as the assumption, which may be extremely misleading if changes in $C\bar{v}_{O_2}$ in fact occur but are not accounted for in the QsQT calculation.
4. Finally, as a fourth index, using the arterial and mixed expired partial pressures of CO_2 (Pa_{CO_2}, $P\bar{E}_{CO_2}$, respectively), a very similar calculation to QsQT can be performed to compute the percentage of total ventilation that is wasted on nongas exchanging ("deadspace") areas of the lungs. As for QsQT, the calculation determines the magnitude of the deadspace that would have to be present to dilute the alveolar P_{CO_2} down to the mixed expired level if that deadspace were the only abnormality in ventilation. Expressed as deadspace (VD)/tidal volume (VT) percentage,

$$\%\ VD/VT = 100 \cdot [Pa_{CO_2} - P\bar{E}_{CO_2}]/[Pa_{CO_2}] \quad (10)$$

This parameter is independent of PI_{O_2}, but is weakened by the fact that the normal airway conducting volume is included in the computed result. Thus it may be difficult to separate how much the VD/VT value represents this normal anatomic deadspace as opposed to reflecting $\dot{V}A/\dot{Q}$ inequality amongst the alveoli. This problem is amplified because even normally VD/VT is very dependent on the size of the tidal volume even if the deadspace volume itself is essentially constant. Thus, for a deadspace volume of 150 mL and a tidal volume of 500 mL, VD/VT is 30%, but if tidal volume were to drop to 400 mL, VD/VT now becomes 38%—not because $\dot{V}A/\dot{Q}$ inequality has developed, but simply because smaller breaths are being taken.

In summary, no index of $\dot{V}A/\dot{Q}$ inequality is without potentially significant limitations, both quantitative and qualitative. However, if these limitations are recognized and the data interpreted accordingly, they still remain very useful indices of clinical gas exchange function.

CHAPTER 15
Blood-Gas Transport

Adrian Shifren
Robert A. Klocke

OXYGEN TRANSPORT

Oxygen is relatively insoluble in aqueous solutions like blood. Dissolved oxygen alone is insufficient to meet the demands of tissue metabolism. Therefore, an alternate means of transporting oxygen is essential. Oxygen binds reversibly to hemoglobin, enhancing the effective solubility of O_2 in blood, and enabling the transport of significant amounts of oxygen—approximately 20 mL/100 mL of blood at a hemoglobin concentration of 150 g/L.

■ OXYGEN DISSOCIATION CURVE

The oxygen dissociation curve represents the relationship between the oxygen content of blood and the partial pressure of oxygen to which it is exposed (Fig. 15-1).[1] Oxygen content is expressed as the volume of oxygen contained in 100 mL of blood, but may also be expressed as either volumes % or mL/dL. The standard oxygen dissociation curve (Fig. 15-1) demonstrates the effects of oxygen–hemoglobin interaction at standard pH (7.40), temperature (37°C), and atmospheric pressure (760 mm Hg). The blue line at the bottom of the graph in Figure 15-1 shows the amount of oxygen dissolved in blood, and the red line shows the total amount of oxygen in blood at any given oxygen tension. Almost the entire quantity of oxygen transported in blood is bound to hemoglobin. However, the role of dissolved oxygen cannot be ignored. Oxygen diffuses across the alveolar–capillary membrane, enters the plasma, traverses the red cell membrane, and enters the erythrocyte interior—all while dissolved in aqueous solutions. It then combines with hemoglobin enabling the transport of large amounts of oxygen to the metabolizing tissues. Dissolved oxygen, although present in very low concentration in blood, is a critical component of the process of O_2 exchange.

Changes in the quaternary structure of hemoglobin that accompany oxygen binding result in a sigmoid, rather than hyperbolic, oxygen dissociation curve. The S-shaped dissociation curve is the result of changes in oxygen affinity of unbound heme groups following the binding of oxygen to another heme group in the same

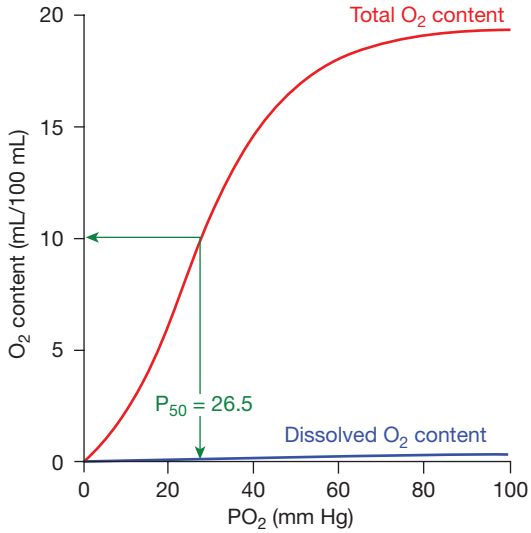

Figure 15-1 Oxygen dissociation curve. Relationship between oxygen content and pressure in normal human blood. The total oxygen content of blood as a function of the partial pressure of oxygen is indicated by the *red line*. The *blue line* indicates the content of dissolved oxygen resulting from changes in P_{O_2}. The partial pressure of oxygen (P_{50}) necessary to saturate one-half of hemoglobin in blood is indicated in *green*.

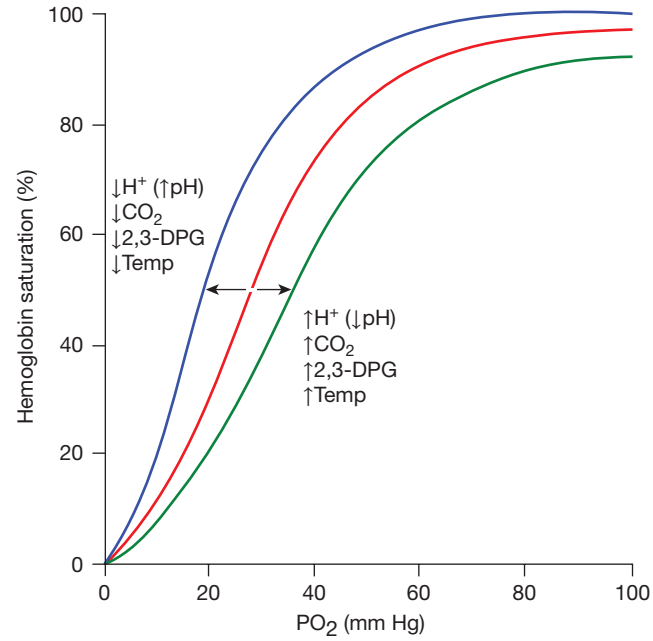

Figure 15-2 Oxygen dissociation curve. The ordinate is % saturation, the percentage of the maximum possible oxygen content. The normal oxygen dissociation curve is shown in *red*. The *blue curve* is shifted to the left of the normal curve (increased oxygen affinity of hemoglobin) as a result of decreased blood hydrogen ion, decreased carbon dioxide, and 2,3-DPG concentrations or decreased temperature. The *green curve* is shifted to the right (decreased oxygen affinity) of the normal curve caused by increases of these factors.

hemoglobin molecule. As illustrated in Figure 15-1, once the partial pressure of oxygen reaches 90 to 100 mm Hg, hemoglobin is almost completely saturated with bound oxygen. There is little additional oxygen binding even at higher oxygen tensions. The flatness of the curve in the arterial oxygen tension range is an advantage because reductions in arterial P_{O_2} (as might be caused by lung disease) will still allow for a relatively normal arterial O_2 content as long as arterial P_{O_2} remains ≥60 mm Hg. The normal partial pressure of oxygen in mixed venous blood at rest is ~40 mm Hg with an oxygen content of ~75% of maximum oxygen capacity. Thus, at rest only one-quarter of the oxygen delivered to body tissues is extracted from blood. However, oxygen extraction varies widely in different tissues. In addition, oxygen utilization changes appreciably during states of increased metabolism. In the tissues, the steep slope of the oxygen dissociation curve between 20 and 60 mm Hg facilitates the release of large amounts of oxygen with relatively moderate decrease in oxygen tension. This permits maintenance of blood oxygen tensions that promote diffusion of oxygen from the capillary blood into metabolizing tissues.

The maximum quantity of oxygen transported in blood is dependent upon hemoglobin concentration, which varies moderately in normal circumstances and substantially in disease states. To facilitate comparison of oxygen dissociation curves with different hemoglobin concentrations, the ordinate of the curve can be normalized by expressing oxygen content at any given pressure as a percentage of the maximum possible oxygen content. This approach substitutes % saturation of hemoglobin for oxygen content, as illustrated in Figure 15-2. Using this format, all normal oxygen dissociation curves are superimposable, regardless of differing hemoglobin concentrations.

■ ALTERATIONS OF OXYGEN AFFINITY

The relationship between oxygen content and pressure can be affected by several factors. Increases in temperature, carbon dioxide pressure, hydrogen ions (decreased pH), and 2,3-diphosphoglycerate (2,3-DPG) all shift the oxygen dissociation curve to the right.[1] This results in a decrease in the affinity of hemoglobin for oxygen, that is, a greater oxygen tension is required to bind the same amount of oxygen to hemoglobin (Fig. 15-2). Conversely, decreases in temperature, carbon dioxide tension, hydrogen ion (increased pH), and 2,3-DPG shift the curve to the left, that is, increase the affinity of hemoglobin for oxygen.[1] The degree of shift of the oxygen dissociation curve is described by the P_{50}, the partial pressure of oxygen required to achieve 50% oxygen saturation of hemoglobin. The normal P_{50} for human blood is 26.5 mm Hg (Fig. 15-1). The basic sigmoid nature of the relation between oxygen and hemoglobin does not change with alterations in the P_{50}. Rather, the curve is uniformly either stretched or compressed along the P_{O_2} axis.

The human erythrocyte contains large quantities of 2,3-DPG, an organic phosphate that binds to hemoglobin and affects O_2 affinity. The normal concentration of 2,3-DPG in erythrocytes is approximately 5 mM. However, this concentration can change significantly, markedly altering the P_{50}. There is a substantial change in the configuration of the hemoglobin molecule between the oxygenated and deoxygenated states. Oxygen and 2,3-DPG bind at different sites on the hemoglobin molecule, and binding of both molecules changes the overall configuration of hemoglobin, but in different ways. The β-chains are more widely separated in the deoxygenated state than in the oxygenated state, and have positive charges surrounding the central cavity of the hemoglobin tetramer. The widened gap between the β-chains of the deoxygenated molecule enables the highly negatively charged 2,3-DPG molecule to enter the cavity between the β-chains and bind electrostatically to positively charged amino acids of the hemoglobin molecule. This tends to stabilize the hemoglobin molecule in the deoxygenated configuration. Higher pressures of oxygen are thus required to force the change in molecular configuration to the oxygenated form, resulting in a shift of the dissociation curve to the right along the P_{O_2} axis.

The Donnan effect results from the presence of charged macromolecules on one side of a semipermeable membrane failing to distribute

evenly across the membrane. This leads to an uneven distribution of charge across the membrane that, in turn, affects the distribution of small, permeable ions across the same membrane. At body pH 2,3-DPG has four negative charges and reduces intraerythrocytic pH by the Donnan effect since 2,3-DPG does not cross the cell membrane. The reduction in intracellular pH resulting from the presence of intracellular 2,3-DPG causes a decrease in oxygen affinity of hemoglobin through the Bohr effect (see below Carbon Dioxide).

Most abnormal hemoglobins have normal oxygen equilibrium curves despite differences in amino acid sequences. Although some hemoglobinopathies are accompanied by changes in oxygen affinity, this usually is due to other factors, such as altered DPG concentration or mean corpuscular hemoglobin concentration. Some relatively rare mutant hemoglobins are exceptions to this rule and exhibit increased O_2 affinity that is accompanied by erythrocytosis. Previously, measurements of P_{50} were advocated to investigate erythrocytosis, but identification of mutant hemoglobins with current molecular techniques is far more likely to identify this rare cause of erythrocytosis.

Large quantities of carbon monoxide (CO) bound to hemoglobin can increase the affinity for oxygen of the remaining unbound sites on hemoglobin. The adverse effects of CO poisoning are twofold: (1) Binding of CO to hemoglobin interferes with oxygen binding and produces a functional anemia; and (2) binding of CO to hemoglobin also increases the affinity of hemoglobin for oxygen, thereby shifting the oxygen equilibrium curve to the left. This increased affinity hinders the release of oxygen in the tissues, but is not as important as the functional anemia caused by CO binding.

BOHR EFFECT

The shift of the oxygen dissociation curve produced by changes in P_{CO_2} and pH is known as the Bohr effect, after the individual who first described this phenomenon. Similar to 2,3-DPG, both hydrogen ions and carbon dioxide bind at sites on the hemoglobin molecule that differ from the oxygen-binding sites.[2] However, binding of these two moieties at different sites alters the oxygen affinity of hemoglobin through their effects on the configuration of the hemoglobin molecule.[3]

It has been speculated that the increased carbon dioxide tension and hydrogen ion content in blood perfusing metabolizing tissues facilitate the release of oxygen bound to hemoglobin at a higher P_{O_2} by shifting the oxygen dissociation curve to the right.[4] However, quantitative analysis indicates that this mechanism results in minimal augmentation of oxygen release in tissues at rest (2%–3%) because of the minute difference in pH between arterial and venous blood (0.03–0.05 pH units).[5] This effect does become significant during exercise, with the addition of lactic acid, from muscle to venous blood.[6] This is an adaptive response for improving oxygen delivery at high levels of exercise. However, the main benefit of the Bohr effect is the increased buffering capacity of hemoglobin that accompanies deoxygenation of the molecule.[2,4] Figure 15-3 illustrates the buffering curves of normal arterial and venous blood. Both exhibit effective, but parallel, buffering curves. As hemoglobin is deoxygenated, its buffering curve shifts upward and significant amounts of hydrogen ion can be buffered with a smaller change in pH.[2] Approximately half of the hydrogen ions released in aerobic metabolism are buffered in this manner (see section Haldane Effect).

CARBON DIOXIDE TRANSPORT

Carbon dioxide (CO_2) is primarily the by-product of aerobic metabolism. It is also generated through the buffering of hydrogen ions (H^+) from organic acids, such as lactic acid and ketoacids. This buffering occurs through chemical reaction of H^+ ions with intracellular and extracellular bicarbonate ions (HCO_3^-). The CO_2 produced by these reactions diffuses into capillary blood and is carried

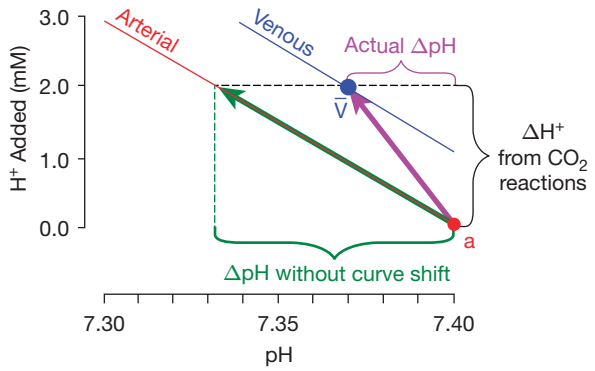

Figure 15-3 Buffer curves (change in pH produced by binding of hydrogen ions) of normal arterial (a) and mixed venous ($\bar{V}$) blood. With release of oxygen bound to hemoglobin in tissues, buffering sites on the hemoglobin molecule increase their affinity for hydrogen ions, thereby shifting the buffer curve upward. The quantity of hydrogen ions (ΔH^+) added to blood by production of CO_2 in normal metabolizing tissues at rest is indicated by the *black bracket*. The figure shows the change in pH *(green bracket)* that would occur if buffering occurred only along the arterial buffer curve *(green arrow)*. The actual, much smaller change in pH *(purple bracket)* that accompanies buffering *(purple arrow)* is due to the upward shift of the arterial buffering curve to the venous relationship that accompanies release of oxygen in the tissues. *(Reproduced with permission from Klocke RA: Encyclopedia of Respiratory Medicine. Philadelphia: Elsevier; 2007.)*

in both chemical combination and physical solution to the lungs, where it is eliminated through expired ventilation (see Chapter 16, p. 200). Similar to O_2 transport, most CO_2 in blood is not carried as gas, but rather in chemical forms directly or indirectly dependent on hemoglobin.

THE CARBON DIOXIDE DISSOCIATION CURVE

Carbon dioxide is transported in three forms in blood: Dissolved CO_2, bicarbonate ions, and carbamate compounds. The relationship between the blood content and partial pressure of CO_2 differs noticeably from that of O_2. The total quantity of CO_2 contained in arterial blood is more than twice that of O_2 despite the lower partial pressures of CO_2. The CO_2 dissociation curve is very steep (Fig. 15-4). As a result, the difference in partial pressures of CO_2 between arterial and venous blood is small when compared to the large arterial–venous differences in blood P_{O_2}.[7] The total content of blood CO_2, that is, the vertical axis of the CO_2 dissociation curve, is the sum of all three forms of CO_2 (dissolved CO_2, bicarbonate, and carbamate).

DISSOLVED CO_2

Carbon dioxide is 20 times more soluble in aqueous solution than oxygen.[8] However, this increased solubility is insufficient to facilitate transport of all the CO_2 produced by metabolism. Approximately 5% of total CO_2 content in blood exists as dissolved CO_2 in plasma and red cell water. Despite this, dissolved CO_2 has a critical role in gas exchange since only dissolved CO_2 crosses the alveolar–capillary membrane. Therefore, regardless of how CO_2 is transported in blood, each molecule must be converted into the dissolved form for excretion through ventilation. The quantity of dissolved CO_2 is directly proportional to the partial pressure of carbon dioxide in blood, that is, the P_{CO_2}.

BICARBONATE

Carbon dioxide combines with water to form carbonic acid, which dissociates into hydrogen and bicarbonate ions. At normal blood

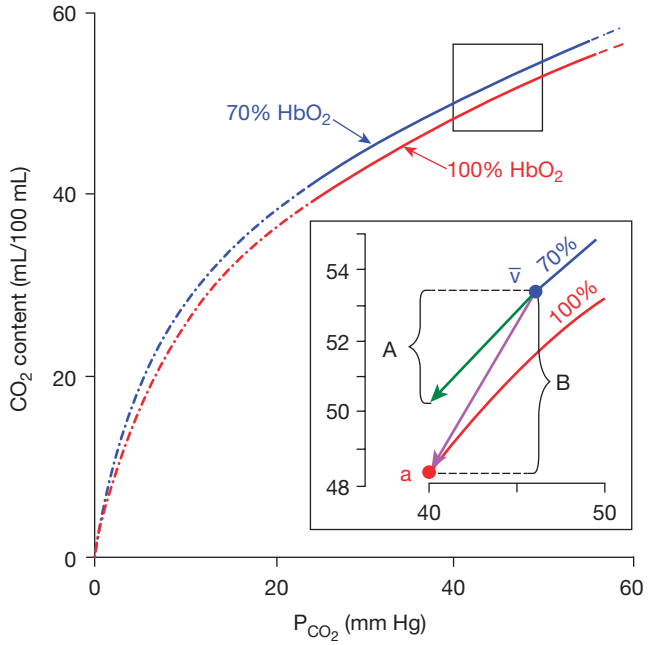

Figure 15-4 The Haldane effect showing the carbon dioxide dissociation curves of blood with 70% *(blue)* and 100% *(red)* oxygen saturations. The portions of the curves most commonly involved in gas exchange are drawn with *solid lines*. The P_{CO_2} and CO_2 contents of mixed venous ($\bar{v}$) and arterial blood (a) normally present at rest are shown in the enlarged inset. If there were no change in the CO_2 dissociation curve with oxygenation in the lung, the decrease in P_{CO_2} would take place along the venous curve *(green arrow)*. This would produce a decrease in blood CO_2 content indicated by the vertical bracket A. The course of CO_2 exchange between arterial and mixed venous points is shown by the *magenta arrow*. The enhanced CO_2 exchange produced by the Haldane effect is indicated by the greater vertical height of bracket B.

pH, carbonic acid dissociates into hydrogen ions and bicarbonate ions.

$$CO_2 + H_2O \xleftrightarrow{CA} H_2CO_3 \leftrightarrow H^+ + HCO_3^- \quad (1)$$

The pKa for reaction (1), including hydration and dissociation, is 6.1.[8] The natural rate of formation of carbonic acid from CO_2 and water is slow and takes seconds to minutes to reach completion in simple aqueous solutions. Under the influence of the carbonic anhydrase (CA) enzyme in the cytosol of erythrocytes, this reaction is increased by a factor of approximately 15,000.[7] CA occurs as two isoenzymes: CA I is present in high concentrations in erythrocytes, but its activity is inhibited by intracellular chloride ions. CA II is present at one-sixth the concentration of CA I within red cells, but is not inhibited by chloride ion and has a sevenfold greater intrinsic activity than CA I. CA II is therefore responsible for almost all the CO_2–bicarbonate catalysis in vivo.[7]

CARBAMATE

Carbon dioxide is also transported as carbamate compounds. Less than 10% of all CO_2 binds to hemoglobin as carbamate, which are salts of carbamic acid formed by the reaction of CO_2 with amino groups on proteins. CO_2 combines with uncharged terminal amino groups on the α and β chains of hemoglobin.

$$R\text{-}NH_3^+ \rightarrow H^+ + R\text{-}NH_2 \quad (2)$$

$$R\text{-}NH_2 + CO_2 \rightarrow R\text{-}NHCOOH \rightarrow R\text{-}NHCOO^- + H^+ \quad (3)$$

where R represents either an α or β chain of hemoglobin.[7] While any NH_2 group on hemoglobin can potentially bind CO_2 as a carbamate compound, only the terminal amino groups of the α and β chains participate in carbamate generation. At the pH present inside red cells, carbamic acid (R-NHCOOH) dissociates completely into a carbamate ion and a hydrogen ion. These H^+ ions, like those liberated by the formation of bicarbonate ions, are buffered principally by hemoglobin (see section Haldane Effect).

Changes in the quaternary structure of hemoglobin accompanying binding and release of oxygen affect the pK's of reactions (2) and (3), altering the equilibrium between the NH_2 and NH_3^+ forms of the terminal amino groups. Because deoxygenated hemoglobin binds more CO_2 than oxygenated hemoglobin, more CO_2 can be carried in venous blood at any given P_{CO_2} than in oxygenated (arterial) blood. The change in CO_2 binding between oxygenated and deoxygenated hemoglobin accounts for approximately one-eighth of the difference between the arterial and venous CO_2 contents during normal gas exchange. The physiological importance of this process would be twice as great but is reduced by interactions between DPG and hemoglobin that limit carbamate formation.[7] Binding of the highly negatively charged DPG molecule to hemoglobin induces change of the amino-NH_2 moieties to the positively charged amino-NH_3^+ forms that do not bind CO_2 as carbamate.

HALDANE EFFECT

Oxygenated blood at any partial pressure of CO_2 contains less total CO_2 content than deoxygenated blood at the same partial pressure (Fig. 15-4). This is known as the *Haldane effect*, after one of the investigators who first described the phenomenon.

Transport of CO_2 in blood as bicarbonate or carbamate is altered by blood oxygenation. These changes are described as "oxylabile" since they are dependent upon the state of hemoglobin oxygenation.[7] Changes in configuration of the hemoglobin molecule accompanying the release of oxygen facilitate binding of CO_2 to hemoglobin as carbamate, that is, *oxylabile carbamate formation*. This increases the total CO_2 content in deoxygenated blood compared with oxygenated blood.[9]

Formation of both bicarbonate ions and carbamate compounds releases large quantities of hydrogen ions. It is essential to buffer these hydrogen ions effectively to promote CO_2 transport. Deoxygenation of hemoglobin also results in a shift of the buffering curve of hemoglobin since deoxygenated hemoglobin is a stronger base than oxyhemoglobin. This shift permits binding of a greater number of hydrogen ions (Fig. 15-3). This *oxylabile buffering*, in turn, facilitates formation of larger quantities of carbamate and bicarbonate.[9]

The synergistic effects of oxygen and carbon dioxide transport result in a change in the carbon dioxide dissociation curve as oxygen is bound and released.[10] Approximately equal changes in bicarbonate and carbamate concentrations are responsible for the Haldane effect. Quantitatively, the Haldane effect has a far greater physiological effect on gas transport than does the Bohr effect. Without the change between the oxygenated and partially reduced CO_2 dissociation curves (the Haldane effect), the difference between arterial and venous CO_2 tensions would be approximately twice the normal value, thereby increasing tissue P_{CO_2}. Model calculations and in vitro data suggest that the Haldane effect accounts for 40% to 50% of total CO_2 exchange in the lung under normal conditions.[7–9]

CHAPTER 16

Diffusion, Chemical Reactions, and Diffusing Capacity

Robert A. Klocke
Adrian Shifren

Uptake of oxygen and excretion of carbon dioxide require rapid, efficient exchange in the lung. The quantities of exchanged gases are staggering. For example, a 1800-calorie diet requires absorption of 375 L of oxygen per day, as well as excretion of a slightly smaller volume of carbon dioxide. Because blood remains in the pulmonary capillary bed for a limited time, the process of exchange must be accomplished in less than 0.75 second at rest and 0.5 second during exercise. This rapid, high-volume exchange occurs efficiently despite numerous interacting processes of diffusion and chemical reaction that occur in the lung. The rates of these processes are not only affected by intrinsic characteristics of blood but also determined by a host of other factors, including inspired oxygen fraction, alveolar gas tensions, cardiac output, and metabolic activity. The ease of exchange of respiratory gases belies the complexity of the overall process.

DIFFUSION

The concentration (C) of a gas dissolved in fluid depends upon its partial pressure (P) and solubility (α)

$$C = \alpha P \quad (1)$$

Gases diffuse from a higher to a lower partial pressure, not necessarily from a higher to a lower concentration. This fact is especially pertinent when a gas diffuses between two phases, as occurs when O_2 and CO_2 are exchanged between alveolar gas and blood. For example, dissolved CO_2 diffuses down a partial pressure gradient from blood (46 mm Hg) into the alveolus (40 mm Hg), even though its actual concentration (millimoles of molecular CO_2 per liter of gas or blood) is greater in alveolar gas (2.5) than it is in venous blood (1.4).

INFLUENCE OF PHYSICAL PROPERTIES

The rate of a gas diffusing through an aqueous membrane such as that separating alveolar gas and capillary blood is influenced by five factors. The rate is directly proportional to the surface area of the membrane, but inversely proportional to the thickness of the membrane. The rate increases in direct proportion to the difference in gas pressure between alveolar gas and capillary blood, and the diffusion and solubility coefficients of the gas in the membrane.

The diffusion coefficient of a gas in the alveolar–capillary membrane is largely a function of the size of the gas molecule, which is inversely proportional to the square root of its molecular weight (MW). Oxygen (MW 32) has a slightly greater diffusion coefficient than carbon dioxide (MW 44) in the alveolar membrane. However, the solubility of CO_2 in water, the major component of tissue composing the membrane, is much greater than the solubility of O_2. This difference far outweighs the effect of the slightly smaller size of the oxygen molecule. Thus, the rate of CO_2 transfer across the alveolar membrane is approximately 20 times greater than that of O_2 when both gases diffuse under the same partial pressure gradient. As a result, a much greater P_{O_2} gradient across the membrane is required to maintain O_2 transfer equal to that of CO_2.

On the other hand, the rate of carbon monoxide (CO) transfer is very similar to that of oxygen when both gases diffuse across the alveolar–capillary membrane under the same partial pressure gradient. CO (MW 28) is a slightly smaller molecule than oxygen so its diffusion coefficient is slightly greater. This diffusive advantage is offset by a slightly lower aqueous solubility of CO compared to oxygen. As a result, CO and O_2 transfer across the membrane have approximately equal rates at the same transmembrane partial pressure gradient.

The rate of diffusion is affected by the viscosity of the medium through which the diffusion occurs. Diffusion of a gas in air occurs at a rate that is four orders of magnitude greater than diffusion in water. Diffusion coefficients in tissues are only moderately less than those in water, since most tissues are composed primarily of water. The interior of the erythrocyte is an exception to this general rule. As a consequence of the high concentration of hemoglobin inside the red cell, the viscosity of the cell contents is substantially greater than that of water. This greater viscosity reduces the diffusion coefficient for oxygen to one-third of its aqueous coefficient. The combination of increased viscosity and the large size of the hemoglobin molecule decreases the diffusion coefficient of hemoglobin within the red cell to less than 10% of its diffusion coefficient in a dilute aqueous solution. As a result, significant diffusion gradients are thought to exist within the red cell even though the distance between the cell membrane and the innermost portion of the cell is only a few microns.

EFFECT OF DIFFERENT CAPACITANCES

The alveolar–capillary membrane provides a barrier to diffusion of gases between the alveoli and the capillaries. The rate of approach to diffusion equilibrium of a gas in the lung is dependent on the

capacitances of the gas in the alveoli and blood relative to its solubility in the alveolar–capillary membrane. Normal ventilation of alveoli results in a large reservoir of oxygen with a pressure of ~100 mm Hg to promote diffusive transfer across the alveolar–capillary membrane. The ability of hemoglobin to bind O_2 increases the oxygen capacity of blood by two orders of magnitude compared with that of the alveolar–capillary membrane. This large capacitance for oxygen in blood requires substantial oxygen transfer across the membrane to reach diffusion equilibrium. Because the solubility of oxygen in the membrane is small relative to the large capacitances in alveolar gas and blood, oxygen exchange across the membrane requires 0.2 to 0.4 second to reach equilibrium.[1] Fortunately, this delay in reaching equilibrium is less than the average of 0.75 second that blood remains in the pulmonary capillary bed. These same conditions are present during carbon monoxide transfer. The large capacitance and the low aqueous solubility of CO lead to similar impediments in gas exchange.

In contrast to oxygen and carbon monoxide, the solubility of carbon dioxide in the membrane is sufficiently great compared to the capacitances of CO_2 in blood and alveoli to permit rapid equilibration of CO_2 across the alveolar–capillary membrane. As discussed (see below Carbon Dioxide) CO_2 exchange requires a finite time for completion, but this delay is the result of the time needed to complete chemical and transport processes in blood, and is not the result of slow diffusive transport across the alveolar–capillary membrane.

Gases transported in blood only in dissolved form are exchanged almost instantaneously across the alveolar–capillary membrane. As long as gas solubilities in the membrane and blood are similar, diffusion equilibrium between alveolar contents and blood is reached within 0.01 second because the normal alveolar–capillary membrane is extremely thin (median thickness of 0.3 μm). Only gases such as oxygen and carbon monoxide that have large alveolar and blood capacitances and reduced solubility in the alveolar–capillary membrane will require a finite time to reach diffusive equilibrium.

CHEMICAL REACTIONS OF GASES

Transport of respiratory gases entails numerous chemical reactions with components of the blood. Like diffusive transport of oxygen, these chemical reactions are not instantaneous and require finite periods of time to reach completion. It is commonly thought that diffusion provides the greatest time-dependent impediment to gas exchange, but in actuality, chemical processes, especially those occurring in combination with diffusion or other chemical reactions, are more likely to slow rates of exchange.

OXYGEN AND CARBON MONOXIDE

From a stoichiometric viewpoint, the successive binding of O_2 to the heme moieties of hemoglobin is described by successive steps, each with separate association and dissociation rate constants. If the heme rings acted independently, these constants would be the same for each heme ring and the resulting dissociation curve would have a hyperbolic shape. However, binding of oxygen to one of the heme rings affects the affinity for O_2 of the remaining heme moieties of the molecule, leading to the familiar sigmoid shape of the oxygen dissociation curve.

Reactions of oxygen and hemoglobin during capillary transit are further complicated by the rate of oxygen diffusion through the viscous interior of the red cell. The chemical reactions of oxygen and hemoglobin occur quite rapidly in dilute hemoglobin solutions but proceed more slowly in red cell suspensions. Because of the large size of the hemoglobin molecule and increased viscosity of the red cell contents, hemoglobin remains relatively immobile. As the red cell enters the pulmonary capillary, oxygen molecules bind to reduced hemoglobin molecules just inside the erythrocyte membrane. As these hemoglobin molecules become saturated, subsequent oxygen molecules entering the red cell must diffuse more deeply into the interior of the cell to reach reduced hemoglobin molecules. This combination of diffusion and chemical reaction causes oxygen uptake to occur as an "advancing front" that proceeds at a rate that is an order of magnitude slower than O_2 uptake in well-mixed, dilute hemoglobin solution. This combined process is complex and not easily described from a theoretical standpoint. As a result, the rate of oxygen uptake by hemoglobin contained in red cells is described by a single overall descriptive parameter, θ_{O_2}, which incorporates all the processes into a single phenomenological value. θ_{O_2} varies with oxygen saturation, pH, and hemoglobin type. The same approach is used to describe carbon monoxide uptake in blood. The rate at which CO replaces bound O_2 in blood with a normal hemoglobin concentration is described by θ_{CO}.

The rates of O_2 and CO uptake by erythrocyte suspensions are determined in vitro and assumed to be representative of the rates of gas exchange in vivo. However, measurements of these rate constants in red cell suspensions in vitro may be affected adversely by methodological artifacts. The actual rates of combination of O_2 and CO with red cells in vivo have not been measured and this lack of data leads to uncertainties in our understanding of exchange of the two gases in the lung.

CARBON DIOXIDE

CO_2 is transported in blood as dissolved molecular CO_2, bicarbonate ion, and carbamate ion.[2] The latter is a salt of a carbamic acid formed by reaction of CO_2 with terminal amino groups of the four chains comprising the hemoglobin molecule. The relation between the partial pressure of CO_2 and the total content of CO_2 in all forms is described by the CO_2 dissociation curve of blood (see Chapter 15, Fig. 15-4). Because CO_2 is more soluble than O_2 in the alveolar–capillary membrane, it often is assumed that CO_2 exchange occurs much more rapidly than O_2 exchange. However, only dissolved CO_2 can cross the alveolar–capillary membrane, and conversion of bicarbonate and carbamate to dissolved CO_2 limits the rate of CO_2 exchange. As indicated in Figure 16-1, *Upper Panel*, when a bolus of dissolved CO_2 is injected into an isolated lung perfused with saline buffer, CO_2 is rapidly exchanged similar to the inert gas acetylene.[3] In contrast, when a bicarbonate bolus is injected into the same preparation (Fig. 16-1, *Lower Panel*), CO_2 exchange lags behind acetylene excretion because a finite period of time is required to convert bicarbonate into dissolved CO_2 that can cross the alveolar–capillary membrane.

As blood enters the pulmonary capillary bed, dissolved CO_2 immediately diffuses into the alveoli and capillary blood P_{CO_2} falls to the level present in the alveolar gas. The majority (>85%) of the CO_2 content in blood entering the capillary bed exists as bicarbonate ion.[2,4] The rapid decrease in capillary P_{CO_2} disturbs the equilibrium between bicarbonate ion and dissolved CO_2 in both the plasma and the red cell. Bicarbonate ion combines with hydrogen ion extremely rapidly to form carbonic acid (H_2CO_3). The natural rate of dehydration of carbonic acid to CO_2 and water is a slow process, requiring 60 to 90 seconds to reach completion. However, the reaction is catalyzed inside the red cell by a factor of ~15,000 by the large concentration of carbonic anhydrase (CA) in red cells.

$$HCO_3^- + H^+ \rightarrow H_2CO_3 \xrightarrow{CA} CO_2 + H_2O \qquad (2)$$

The substantial buffering capacity of hemoglobin inside the erythrocyte, augmented by the simultaneous conversion of reduced to oxygenated hemoglobin, provides the hydrogen ions required for this reaction.[4] The dissolved CO_2 formed by this reaction inside the red cell immediately leaves the blood and enters the alveoli.

There is a minimal amount of CA attached to the interior surface of the pulmonary capillaries, but its activity is <1% of the erythrocytic enzyme. As a result, little or no conversion of bicarbonate to dissolved CO_2 occurs in the plasma during the short

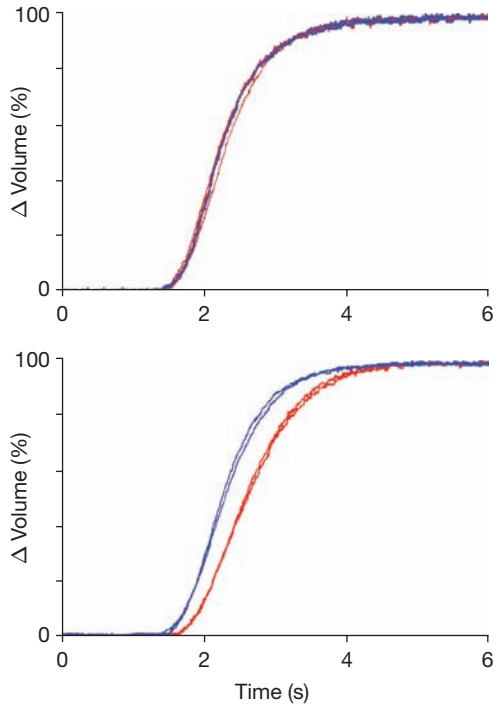

Figure 16-1 Rates of acetylene *(blue curves)* and CO_2 *(red curves)* excretion after two pairs of injections into the pulmonary artery of a single isolated lung preparation perfused with buffer. Volume changes are normalized to facilitate comparison. *Upper Panel*: The excretion of both acetylene and CO_2 proceed at the same rate after injections of buffer containing either dissolved CO_2 or acetylene. Differences in mean transit times for CO_2 and acetylene were −0.027 second for first pair and +0.022 second for second pair of injections. Thus, CO_2 crosses the alveolar–capillary membrane at the same rapid rate as the inert gas acetylene. *Lower Panel*: The excretion of CO_2 generated from injections of bicarbonate *(red curves)* lags behind the excretion of dissolved acetylene (*blue curves*) by +0.301 second in the first set of paired injections of acetylene and bicarbonate and 0.312 second in the second set of paired injections. This slower excretion of CO_2 is caused by the time required to convert bicarbonate to CO_2 with catalysis in this experiment provided by carbonic anhydrase localized to the capillary endothelium. *(Reproduced with permission from Schunemann HJ, Klocke RA: Influence of CO_2 kinetics on pulmonary carbon dioxide exchange. J Appl Physiol. 1993;74:715.)*

pulmonary capillary transit time (0.75 second at rest, 0.5 second during exercise). Inside the red cell, the catalyzed formation of dissolved CO_2 rapidly (~0.1 second) depletes the concentration of intracellular bicarbonate and the production of CO_2 slows substantially[1,5] However, as the intracellular concentration of bicarbonate decreases, plasma bicarbonate enters the cell in exchange for intracellular chloride. Bicarbonate–chloride movement across the erythrocyte membrane occurs in an electrically neutral, one-for-one exchange that is facilitated by an anion exchange protein present in the erythrocyte membrane.[2] Despite the presence of approximately one million anion exchangers with an extremely rapid turnover (50,000 ions per second) in each red cell membrane, bicarbonate–chloride exchange requires 0.3 to 0.4 second to reach completion.[1]

Besides exchange of dissolved CO_2 and bicarbonate, a modest amount of CO_2 excretion (13%) results from release of CO_2 bound to hemoglobin as carbamate.[2] The release of CO_2 bound as carbamate is caused by the alteration of the molecular conformation of hemoglobin that accompanies oxygenation. The carbamate reaction is complete in 0.2 to 0.3 second, but cannot occur until hemoglobin is first oxygenated. The process of oxygenation further delays conversion of carbamate to dissolved CO_2.

Thus, exchange of CO_2 in the lung is thought to require at least ~0.4 to 0.5 second because of the series of processes that are necessary to convert CO_2 carried as bicarbonate and carbamate to dissolved CO_2.[1,5] In fact, computational models of CO_2 exchange suggest that in some circumstances exchange is not quite completed prior to blood leaving the pulmonary capillary.[1,5] Even in the worst case, the degree of disequilibrium is small and a minimal increase in ventilation can easily compensate for a slight impairment of CO_2 exchange.

SOURCES OF CO_2 EXCRETED IN THE LUNGS

Bicarbonate accounts for the majority (>85%) of the total CO_2 content transported in arterial and venous blood. Dissolved CO_2 (~5%–6%) and carbamate (<10%) contribute substantially less to the total CO_2 content of blood. The quantity of bicarbonate transported in plasma is much greater than that carried within the red cells for three reasons. First, plasma volume constitutes 55% and erythrocytes only 45% of the total blood volume. Second, bicarbonate is present only in the volume of water in each component; plasma water content (95%) is substantially greater than erythrocyte water content (72%). Third, because of the Donnan distribution of anions across the erythrocyte membrane, bicarbonate concentration inside the red cell is only 63% of the plasma concentration.

The relative contributions of each form of CO_2 content to the quantity of CO_2 excreted during gas exchange in the lung are not exactly proportional to their blood contents. Analysis of the differences between arterial and venous blood CO_2 contents can be used to calculate the amounts of each form of carbon dioxide content excreted in expired ventilation.[2,6,7] This analysis of differences between arterial and venous blood CO_2 contents is shown in Figure 16-2. The vast majority of expired CO_2 enters the lung as bicarbonate and is converted into CO_2 during capillary transit. The contribution of plasma bicarbonate (49%) is greater than the erythrocytic bicarbonate (30%) that is converted into CO_2 and excreted in expired ventilation. Essentially all the CO_2 derived from bicarbonate, whether in plasma or erythrocytes, has to be exposed to CA within the red cells to allow for reaction catalysis during the

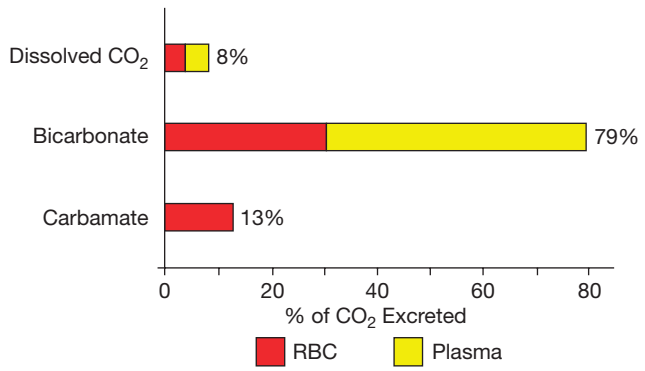

Figure 16-2 Sources of carbon dioxide excreted during passage of blood through the lungs in resting humans. The bars indicate the quantities of the different sources of CO_2 leaving blood from red cells *(red)* and plasma *(yellow)*. Bicarbonate contributes the overwhelming majority of CO_2 to the expired ventilation. As indicated in the figure, the majority of excreted bicarbonate enters the lung in plasma and is exchanged for chloride to reach carbonic anhydrase and hemoglobin buffering capacity within the red cell. *(Data from Klocke RA. Carbon Dioxide Transport, in Handbook of Physiology. Section 3, The Respiratory System, vol 4, edited by LE Farhi, SM Tenney SM. Bethesda: American Physiological Society; 1987.)*

brief capillary transit. This emphasizes the importance of anion exchange across the erythrocyte membrane in the process of carbon dioxide excretion.

The contributions of dissolved CO_2 and carbamate to the quantity of CO_2 in expired ventilation are modest, but are slightly greater than their relative concentrations in blood. Slightly more dissolved CO_2 originates in the plasma than in the red cells because of the greater amount of water in plasma. All excreted CO_2 derived from carbamate entered the lung bound to hemoglobin inside the erythrocytes.

DIFFUSING CAPACITY

The pulmonary diffusing capacity (D_L) of a gas provides an estimate of its rate of transfer from the alveoli into capillary blood. Initially investigators thought that only diffusion of gas across the membrane limited exchange. This is the case for inert gases and, as noted earlier, equilibrium of these gases is achieved rapidly even in disease. However, transfer of gases that combine with hemoglobin are limited both by diffusion across the alveolar membrane and by the rate of reactions inside red blood cells.[8] The only gases that have measurable diffusing capacities are those with low solubility in the pulmonary membrane and high capacitance in blood as a result of binding to hemoglobin. These gases include oxygen (O_2), carbon monoxide (CO), and nitric oxide (NO).

DIFFUSING CAPACITY OF OXYGEN ($D_{L_{O_2}}$)

The diffusing capacity is calculated as the volume of gas absorbed by pulmonary blood per unit time ($\dot{V}$) divided by the pressure gradient between alveolar gas (P_A) and pulmonary capillary blood (Pcap).

For oxygen,

$$D_{L_{O_2}} = \frac{\dot{V}_{O_2}}{PA_{O_2} - Pcap_{O_2}} \quad (3)$$

Measurement of $D_{L_{O_2}}$ is difficult because, in addition to diffusion, O_2 transfer may be limited by other mechanisms, such as ventilation–perfusion mismatching and shunting. The measurement is further complicated by a changing capillary P_{O_2} during capillary transit that cannot be accurately determined. These difficulties have led investigators to abandon attempts to measure the diffusing capacity of oxygen.

DIFFUSING CAPACITY OF CARBON MONOXIDE ($D_{L_{CO}}$)

Carbon monoxide provides an excellent alternative to measuring diffusing capacity because CO normally is present in minimal amounts in blood and binds to hemoglobin similar to O_2. Because capillary P_{CO} is extremely low in usual circumstances, it can be assumed to be negligible and $D_{L_{CO}}$ is calculated by dividing CO uptake ($\dot{V}_{CO}$) by alveolar P_{CO}. However, like oxygen, CO uptake is limited both by diffusion across the alveolar–capillary membrane and by chemical reaction of CO with intracellular hemoglobin. As described by Roughton and Forster,[8] $D_{L_{CO}}$ comprises two elements:

$$\frac{1}{D_{L_{CO}}} = \frac{1}{Dm_{CO}} + \frac{1}{\theta_{CO} V_c} \quad (4)$$

where

Dm_{CO} = the diffusing capacity of the alveolar–capillary membrane for CO

θ_{CO} = the rate of displacement of O_2 from intracellular hemoglobin by CO

V_c = the volume of blood in the pulmonary capillary bed

Because O_2 and CO compete for binding sites on hemoglobin, CO binding is inhibited by increases in P_{O_2}. Thus, $D_{L_{CO}}$ and θ_{CO} vary inversely with P_{O_2}. Using known in vitro values of θ_{CO} and two measurements of $D_{L_{CO}}$ at normal and elevated inspired O_2 concentrations, Eq. (4) can be solved to provide values of both Dm_{CO} and V_c. Calculation of the diffusing capacity is based on the assumption that the lung is homogeneous, that is, all portions of the lung have the same relative ventilation, perfusion, alveolar volume, and diffusing capacity.

DIFFUSING CAPACITY OF NITRIC OXIDE ($D_{L_{NO}}$)

Nitric oxide binds to hemoglobin at the same sites as O_2 and CO, but the rate of NO binding is much more rapid. Since NO binds to hemoglobin in solution two orders of magnitude faster than the rate of CO binding, it has been postulated that θ_{NO} is much greater than θ_{CO} and approaches a value of infinity. If this is the case, then the term $1/\theta_{NO}V_c$ (analogous to Eq. (4) for CO) approaches zero and the diffusing capacity measured with NO should reflect only the resistance to gas transfer provided by the alveolar–capillary membrane, that is, the Dm_{CO} component of the CO diffusing capacity. If NO binds to intracellular hemoglobin instantaneously, D_L (and hence Dm) measured with NO should be 1.97 times Dm measured with CO because NO has a greater aqueous solubility and a minimally larger diffusion coefficient than CO. Phansalkar et al.[9] performed simultaneous measurements of $D_{L_{NO}}$ and the components of $D_{L_{CO}}$ in both normal individuals and patients with sarcoidosis at varying levels of exercise intensity. The ratio of $D_{L_{NO}}/Dm_{CO}$ did not differ in the two groups and averaged 2.42, moderately greater than the theoretical value of 1.97 (Fig. 16-3, *Lower Panel*). The ratio of

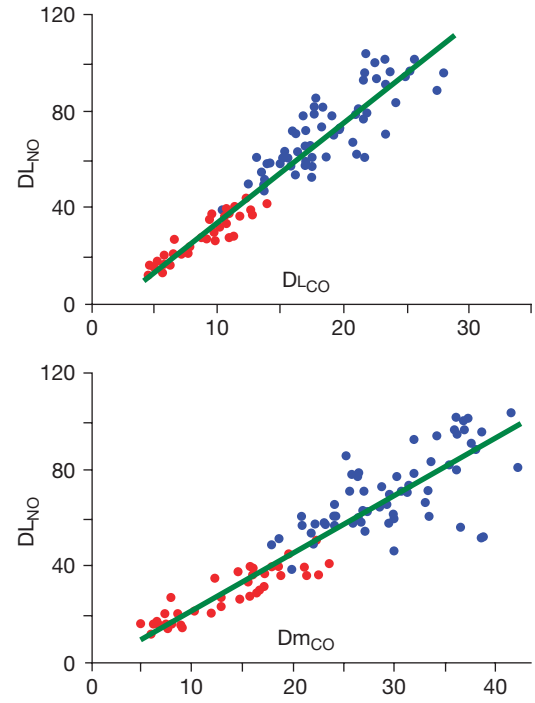

Figure 16-3 Relationships between simultaneous measurements of *(Upper Panel)* $D_{L_{NO}}$ and $D_{L_{CO}}$ and *(Lower Panel)* $D_{L_{NO}}$ and Dm_{CO} in patients with sarcoidosis *(red circles)* and normal subjects *(blue circles)*. The units of all parameters in the figure are mL/min/mm Hg/m^2. $D_{L_{CO}}$ was expressed under standardized conditions of hemoglobin concentration (14.6 mg/dL) and alveolar O_2 tension ($P_{A_{CO_2}}$ 120 mm Hg). Regression lines through the pooled data are *(Upper Panel)* $D_{L_{NO}} = 4.16D_{L_{CO}} - 6.82$, $r^2 = 0.918$ and *(Lower Panel)* $D_{L_{NO}} = 2.42\ Dm_{CO} - 1.87$, $r^2 = 0.865$. *(Reproduced with permission from Phansalkar AR, Hanson CM, Shakir AR, et al. Nitric oxide diffusing capacity and alveolar microvascular recruitment in sarcoidosis. Am J Respir Crit Care Med. 2004;169(9):1034–1040.)*

$D_{L_{NO}}/D_{L_{CO}}$ in both groups did not differ and averaged 4.16 (Fig. 16-3, *Upper Panel*).

More recent work challenges the postulate that θ_{NO} has a value of infinity and $D_{L_{NO}}$ can be used to calculate Dm_{CO}. Borland et al.[10] have shown that $D_{L_{NO}}$ increases progressively as red blood cells are replaced with hemolyzed blood or cell-free heme-based blood substitute, an observation that should not occur if θ_{NO} truly has a value of infinity. As a result, it is premature to speculate on the potential clinical value of measurements of $D_{L_{NO}}$ until the underlying physiology of the measurement of $D_{L_{NO}}$ is clarified. The technique of the measurement itself varies among laboratories. In addition, it requires sophisticated equipment and technical expertise that only are present in research settings.

METHODS FOR MEASURING THE DIFFUSING CAPACITY

Several different techniques are used to measure the carbon monoxide diffusing capacity. In clinical settings the single breath method is utilized almost exclusively. The steady-state and rebreathing methods of determining $D_{L_{CO}}$ are employed primarily in research. The steady-state method usually is performed in subjects who are exercising, thereby limiting its clinical application in patients with restricted ability to exercise. The rebreathing methodology requires rapid-responding gas analyzers and has technical requirements that are not available in most clinical laboratories.

Single Breath Method

With the single breath technique the subject exhales to residual volume, inhales a maximal breath of 0.3% CO, a tracer gas (usually 10% helium), 21% oxygen, and balance nitrogen. The breath is held for approximately 10 seconds followed by a maximal exhalation. After sufficient expiration to clear the dead space, a gas sample is collected to estimate final alveolar CO and helium fractions. After inspiration, the alveolar partial pressure of CO falls exponentially as CO enters the capillary blood. The volume of CO absorbed in the lungs can be calculated from the alveolar volume and the initial and final concentrations of CO in alveolar gas. The rate of CO uptake during the breath-hold is a function of the alveolar $P_{A_{CO}}$, which falls exponentially during the breath-hold. Capillary CO pressure is assumed to be equal to zero. The single-breath diffusing capacity is calculated by:

$$D_{L_{CO}} = \frac{60 V_A}{t_{bh}(P_B - 47)} \ln \frac{F_{A_{CO\ initial}}}{F_{A_{CO\ final}}} \quad (5)$$

where

- 60 = the number of seconds per minute
- V_A = the alveolar volume of gas (mL_{STPD}) present in the lung at the start of the breath-hold
- t_{bh} = the duration of the breath-hold (seconds)
- P_B = the barometric pressure (mm Hg)
- $F_{A_{CO}}$ = the alveolar fraction of carbon monoxide at the initial and final times of the breath-holding period

The insoluble inert gas (usually helium) included in the inspired volume is not absorbed in capillary blood and is diluted in the residual volume present at the start of the maximal inspiration. V_A is calculated from the dilution of the helium and the inspired volume (V_I):

$$V_A = V_I \frac{F_{I_{He}}}{F_{A_{He}}} \quad (6)$$

where

$F_{I_{He}}$ and $F_{A_{He}}$ = the inspired and alveolar helium concentrations

The alveolar fraction of He and the final alveolar CO fraction are obtained by measuring CO and He concentrations in the expired alveolar gas sample. The initial alveolar CO fraction is calculated from the dilution of the inspired CO in the volume of gas present in the lung during the breath-hold,

$$F_{A_{CO}} = F_{I_{CO}} \frac{V_I}{V_A} \quad (7)$$

where

$F_{I_{CO}}$ = the inspired CO fraction

The single breath method requires some degree of patient cooperation to perform the necessary respiratory maneuvers. A patient with an extremely reduced lung volume may not have a vital capacity large enough to clear the dead space and provide a sufficient sample for analysis of alveolar gas concentrations. The ability to hold the breath for 10 seconds also limits applicability to some patients. Finally, this method can be employed only in the resting state since few patients can hold their breath during exercise. Despite these limitations, the single breath $D_{L_{CO}}$ is the most practical and widely used method for measuring $D_{L_{CO}}$. The technical aspects of the test have been standardized so that the same methodology is utilized in most laboratories.[11]

MEASUREMENT OF Dm AND V_c

Using values of θ_{CO} measured in vitro and values of $D_{L_{CO}}$ determined with different inspired O_2 concentrations, Eq. (4) can be solved for the membrane diffusing capacity (Dm_{CO}) and capillary blood volume (V_c).[8] However, there is considerable uncertainty regarding values of θ, the rate of red cell uptake of gases that bind to hemoglobin. Most in vitro measurements of θ have utilized rapid reaction techniques that may be flawed due to unstirred layers of fluid surrounding the red cells in the experimental apparatus. This artifact is greater the more rapidly that the gas reacts with hemoglobin ($NO > O_2 > CO$). Furthermore, the rate of gas uptake by erythrocytes may be influenced by the ability of the red cells to be deformed during passage through the pulmonary capillaries, a factor not present during in vitro measurements of θ. Mathematical models suggest that the rate of uptake of gases also depends on erythrocyte orientation and spacing within capillaries. Since the characteristics of erythrocyte transit in the capillary bed have not been defined, extrapolation of in vitro measurements to the in vivo situation introduces elements of uncertainty. Despite these reservations, solution of Eq. (4) using values of θ_{CO} determined in vitro yields values of Dm_{CO} and V_c that agree with independent estimates of these variables using alternate techniques.

Calculation of pulmonary capillary blood volume (V_c) from measurements of $D_{L_{CO}}$ is dependent upon the value of θ_{CO} chosen for the computation. Using in vitro data for θ_{CO} yields values at rest of 75 to 100 mL for men and slightly less for women. V_c measured by the CO method is dependent upon the quantity of hemoglobin present in the capillary bed in addition to the actual capillary volume. Calculation of V_c assumes a normal hemoglobin concentration in capillary blood and variation in this parameter affects the $\theta_{CO}V_c$ component of $D_{L_{CO}}$.

Dm and V_c have been estimated from morphometric data obtained from excised, fixed canine lungs.[12] Calculations of $D_{L_{CO}}$ using these postmortem morphometric values and in vitro values of θ_{CO} have yielded estimates of $D_{L_{CO}}$ that are much greater than measurements of $D_{L_{CO}}$ under resting conditions in the same intact animal. This discrepancy arises because morphometric measurements are obtained in maximally inflated lungs. The morphometric estimates reflect a fully recruited alveolar surface area and V_C, a circumstance seen during maximal oxygen uptake during exercise. When $D_{L_{CO}}$ calculated from morphometric data is compared to $D_{L_{CO}}$ measured in intact animals under conditions of maximum exercise, there is good agreement between the two estimates.

FACTORS INFLUENCING DIFFUSING CAPACITY

The CO diffusing capacity originally was thought to reflect the resistance of the alveolar–capillary membrane to transfer of CO from

the alveoli to capillary blood. The classic work of Roughton and Forster[8] elucidated the influence of chemical reactions on transfer of CO. D_{LCO} may be a measure of decreased gas transfer caused by abnormal diffusion, but also can reflect reduction in hemoglobin concentration, nonuniform distribution of physiological properties throughout the lung, loss of lung tissue, or artifacts in measurement. Because multiple factors in addition to diffusion can affect D_{LCO}, in Europe this test is often termed the CO transfer factor, rather than the CO diffusing capacity.

Hemoglobin Concentration

Capillary blood volume (V_c) is a prime variable in the diffusing capacity; its importance is due to the quantity of hemoglobin available to combine with CO within the capillary bed. The calculated value of V_c can be reduced directly by diseases that decrease capillary volume, but also can vary with the concentration of hemoglobin in blood. For this reason, the predicted D_{LCO} can be corrected for alterations in hemoglobin concentration.[11] For adult males and adolescents:

$$\text{Predicted } D_{LCO} \text{ (Corrected)} = \text{Predicted } D_{LCO} \, (1.7 \, Hb/(10.22 + Hb)) \quad (8)$$

where

Hb = hemoglobin concentration expressed in g/dL

For adult women and children less than age 15, the factor of 10.22 in Eq. (8) is replaced by a factor of 9.38. However, most clinical laboratories do not correct the predicted value of D_{LCO} for abnormal hemoglobin values.

Partial Pressure of Alveolar Oxygen

As indicated previously, θ_{CO} depends on P_{O_2}. Increased alveolar P_{O_2} will reduce measured D_{LCO}. Therefore, D_{LCO} will be lowered if patients receive supplemental oxygen during the measurement. Conversely, reduced alveolar P_{O_2} will lead to an increment in measured D_{LCO}. This has led to the suggestion to apply a correction to D_{LCO} if the measurement was made with an altered inspired oxygen fraction or at altitude. Even when alveolar P_{O_2} is kept at a sea level value during the measurement, lifelong residents of a community located 10,000 ft above sea level have demonstrated moderately greater diffusing capacities than sea-level residents.[13] Short-term residence (6 weeks) at altitude does not cause an increase in D_{LCO}. Beagles raised at altitude, even after reacclimation to sea level, still have moderately greater diffusing capacities than beagles raised at sea level. However, adult dogs taken to altitude for 3 years do not exhibit an increased D_{LCO}, suggesting that residence at altitude during growth is the basis for the increased D_{LCO}.

Body Position

D_{LCO} is 5% to 15% greater in the supine position than in the erect position. Blood volume shifts from the lower trunk and legs to the lungs when in the supine position. Most of the increase in D_{LCO} appears to be due to a 13% to 27% increase in V_c accompanying the fluid shift. However, there is also a minimal increase in Dm_{CO} in the supine position, possibly the result of recruitment of capillaries by the increased intravascular volume. The effect of posture on D_{LCO} decreases with age, but the reasons underlying this observation remain unknown.

Exercise

D_{LCO} can increase as much as twofold during exercise. This increase is attributed to proportionally equal increases in both Dm and V_c. Both alveolar–capillary surface area and capillary volume are recruited by the increase in cardiac output that accompanies exercise. The transit time through the capillary bed decreases, but not to the same degree as would be predicted in a vascular bed with fixed resistance. The potential reduction in transit time is partially offset by recruitment and distention of the pulmonary capillary bed.

Theoretically, D_{LCO} must have a maximum that cannot be exceeded when the entire pulmonary capillary bed and alveolar surface have been recruited. This should lead to a plateau in measured D_{LCO} even though the level of exercise continues to increase. This has never been observed in humans. Using a unique animal model of conscious greyhounds exercising on a treadmill, Carlin et al.[12] could not demonstrate a plateau in D_{LCO} with increasing exercise even though oxygen uptake reached a level of approximately 120 mL/kg/min. This level of O_2 uptake is almost twice that is seen in highly trained humans. Thus, it seems unlikely that the diffusing capacity in humans reaches a plateau during maximal exercise, but this does not rule out the possibility that gas exchange is limited by diffusion in this circumstance. Disequilibrium may occur before maximum recruitment of the diffusing capacity because capillary transit time may be less than the time required for O_2 exchange to be completed. Evidence in humans suggests that blood may leave the capillary bed without attaining complete equilibrium between alveolar P_{O_2} and capillary P_{O_2} at sea level in some patients with lung disease during exercise and in some highly trained athletes during maximal exercise. This also can occur in normal individuals at extremely high altitude with a marked reduction in the inspired P_{O_2}.

Alveolar Volume

D_{LCO} decreases with reduction in alveolar volume due to accompanying decreases in Dm_{CO} and V_c. This occurs with an inadequate inspiration to total lung capacity in persons with normal lungs, or with maximal inspiration in patients whose total lung capacities have been reduced by disease. In an effort to correct for alterations in alveolar volume rather than a true loss of diffusing capacity, some clinicians and investigators normalize D_{LCO} by dividing the observed D_{LCO} by the alveolar volume present during the measurement. This ratio of D_{LCO}/V_A will be a useful index only if two assumptions are valid. First, there must be an approximately linear relation between D_{LCO} and V_A. This assumption is reasonable at lung volumes greater than 50% of total lung capacity, but not at lower lung volumes. Second, the relation between D_{LCO} and V_A must be directly proportional (i.e., a graph of D_{LCO} vs. V_A must pass through the origin of the graph). This clearly is not the case. D_{LCO}/V_A is not constant in normal persons and varies as alveolar volume changes.[14] Although frequently used, the D_{LCO}/V_A ratio alone does not provide a valid index of the effect of changes in alveolar volume.[14,15]

Nonuniform Distribution of Physiological Properties

Calculation of D_{LCO}, regardless of the method used to make the measurement, implicitly assumes that the lung is completely uniform with regard to ventilation, alveolar volume, perfusion, and diffusive properties. This requires that each gas exchange unit possesses the same relationship between all these physiological properties, an assumption that is not completely valid even in normal, healthy persons. The most important factor determining CO uptake is the relationship of local diffusing capacity to local blood flow, the ratio of D_{LCO}/Q. Nonuniform distribution of important physiological variables throughout the lung produces a decrease in diffusing capacity and, by analogy, a reduced ability to transfer oxygen from the inspired air to capillary blood. Transfer is further complicated by the nonlinear nature of the processes involved. For example, the oxygen dissociation curve of hemoglobin has a sigmoid shape and a change in alveolar P_{O_2} may have a large or a minimal effect on the quantity of O_2 exchanged depending on the absolute value of the P_{O_2}. Disruptions of these complex relationships among physiological parameters have variable effects on O_2 transfer. The contributions of individual pathophysiological deviations cannot be assessed

by a global measurement such as the diffusing capacity. Thus, D_{LCO} provides a means of assessing overall oxygen exchange but does not indicate specific defects in gas exchange.

■ TECHNICAL CONSIDERATIONS

Measurements of D_{LCO} have greater variation than spirometric observations such as the forced vital capacity (FVC) or forced expiratory volume in 1 second (FEV_1). Criteria for acceptable measurements of D_{LCO} have been based upon relative or absolute differences between repeated measurements. The American Thoracic Society/European Respiratory Society (ATS/ERS) consensus statement[11] recommends reporting the average of two measurements, both of which agree within 3.0 mL/min/mm Hg or within 10% of the higher measured value. Punjabi et al.[16] reported that an absolute difference of 2.5 mL/min/mm Hg between duplicate measurements could be achieved in 96% of patients. This criterion was deemed more reasonable than a percentage variation because it remained constant over a wide range of measured values in contrast to a changing percentage criterion. The strength of this study is in its size (over 6000 patients) and its performance during routine pulmonary testing in a single clinical setting. A drawback to its universal application is that three or more determinations of D_{LCO} were required in one-half of patients to meet criteria of acceptability. It is important to note that some clinical laboratories will perform only a single diffusing capacity measurement and report this value rather than reporting the mean of at least two acceptable determinations. This obviously increases the variability of reported values and lessens the ability to compare measurements over a period of time.

There is considerable variation in measurements of D_{LCO} among different clinical laboratories. These differences can be overcome by following strict technical protocols. In a carefully controlled multicenter (33 sites) clinical trial, Wise et al.[17] reported that 75% and 95% of the differences between duplicate D_{LCO} determinations with acceptable subject efforts (4797 pairs) were within <1 and <2 mL/min/mm Hg, respectively (Fig. 16-4). Acceptable criteria included inspired volume >90% of the FVC and a breath-hold time between 9 and 11 seconds.

The time of the breath-holding maneuver in the single breath method requires patient cooperation. Because of nonuniform distribution of physiological variables, CO uptake does not occur in a strictly exponential fashion even in healthy persons. As a result, measured D_{LCO} decreases slightly with prolonged breath-hold in normal subjects. This decrement can be substantially greater in patients with lung disease. The empirical breath-holding time of 10 seconds was chosen as a practical compromise to permit measurable CO uptake but still be feasible for patients to perform. Many laboratories set a breath-hold range of 9 to 11 seconds as acceptable, although the ATS/ERS consensus report[11] accepts a range of 8 to 12 seconds. Patients with lung disease often cannot perform rapid respiratory maneuvers mandated by the single breath D_{LCO} measurement. Slower flow rates prolong the time required for inspiration and expiration. As a result, instantaneous, uniform mixing of alveolar contents assumed in the calculation of D_{LCO} is not achieved. This may lead to a decrement in the reported measurement.

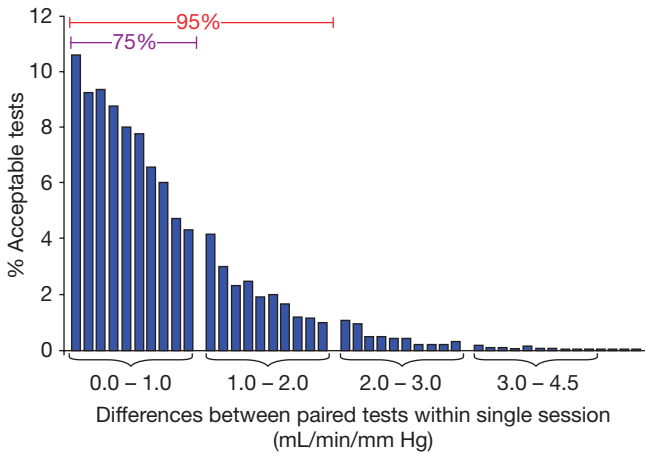

Figure 16-4 Differences between pairs of D_{LCO} measured within a single session in 4732 patients who had acceptable D_{LCO} efforts. The bars in the figure include differences in 75% of paired measurements *(purple)* and the differences in 95% of paired measurements *(red). (Data from Wise RA, Teeter JG, Jensen RL, et al. Standardization of the single breath diffusing capacity in a multicenter clinical trial. Chest. 2007;132:1191.)*

Most laboratories request that patients refrain from smoking for variable periods of time prior to measurement of D_{LCO} to avoid accumulation of CO in blood. Significant elevation of carboxyhemoglobin reduces measured D_{LCO} in two ways. First, the presence of carboxyhemoglobin produces a functional anemia, lessening the capacity of hemoglobin to bind O_2 or CO. This reduces the $\theta_{CO}V_c$ component of D_{LCO}. Second, calculation of D_{LCO} assumes that the back pressure of CO in the capillary is zero, and the gradient for CO transfer is equal to $P_{A_{CO}}$. The presence of carboxyhemoglobin in blood produces an actual alveolar–capillary PCO gradient less than that assumed in the calculation, thereby leading to a lower calculated value of D_{LCO}. Graham et al.[18] measured the effect of experimental elevation of carboxyhemoglobin in normal individuals. Values of D_{LCO} obtained with the usual single breath calculation decreased approximately 1.5% from the true value for each 1.0% elevation of blood carboxyhemoglobin. Although algorithms are available to correct observed D_{LCO} for carboxyhemoglobin effects, it is preferable to make the measurement without a significant elevation of carboxyhemoglobin. At a minimum, 12 hours of abstinence from smoking is advisable in patients who smoke extensively because carboxyhemoglobin levels as great as 6% to 12% are observed immediately following tobacco usage.

■ CONTROVERSIES IN INTERPRETATION OF D_{LCO}

As noted previously, D_{LCO} is affected by a number of circumstances. Alveolar P_{O_2} and body position do not present significant problems since a standard inspired P_{O_2} and the sitting position are utilized during measurements in most clinical laboratories. Equations to correct for alterations of alveolar P_{O_2} are available if needed. Empirical equations also can adjust the predicted value of D_{LCO} to compensate for anemia or polycythemia.

Variability in cardiac output and the alveolar volume present during the measurement provides more significant problems. The increases in D_{LCO} observed during exercise are the result of large increases in cardiac output. Increasing cardiac output together with enlargement of the capillary bed increases not only V_c, but also increases Dm because capillary volume and surface area of the alveolar–capillary membrane are related variables. Clinical measurements of D_{LCO} are accomplished under resting conditions, minimizing but not obviating, variability in cardiac output. In addition, disease can alter the distribution of blood flow in the lung in patterns that do not match the distribution of diffusive properties. Unfortunately, measurements of pulmonary blood flow and its distribution are not conveniently measured in clinical laboratories. As a result, the effect of cardiac output on D_{LCO} may not be appreciated in routine determinations. The only practical alternative is to minimize conditions that might alter pulmonary blood flow.

Reduction in alveolar volume by disease is the largest potential source of error in interpreting D_{LCO}. Correction for the effect of altered alveolar volume has been attempted by reporting the ratio of D_{LCO}/V_A. However, this attempt to normalize measurements by

alveolar volume leads to errors because D_{LCO}/VA does not remain constant as alveolar volume changes. Stam et al.[14] reported values of D_{LCO} and D_{LCO}/VA obtained at several alveolar volumes in normal subjects. They recommend using predicted values of D_{LCO} or D_{LCO}/VA for patients with reduced alveolar volumes equal to values in normal subjects measured at the same reduced alveolar volume. This assumes that disease processes that reduce alveolar volume in patients produce the same changes in D_{LCO} as voluntary reduction in alveolar volume in normal subjects. In a subsequent report,[19] they demonstrated this to be the case in patients with normal lung function tested before, during, and after undergoing treatment with bleomycin for malignancies. In these patients, the linear relationship of D_{LCO}/VA measured at different alveolar volumes shifted downward in parallel fashion as bleomycin produced lung injury. This finding supports the adjustment of predicted values on the basis of reduced alveolar volumes in normal subjects since the slope of the D_{LCO}/VA ratio in relation to VA was the same before and after lung injury. These data were obtained by measuring D_{LCO} at a variety of alveolar volumes prior to and after the pulmonary insult, a situation that is rarely possible in clinical practice. Data obtained in patients with sarcoidosis also support the concept of using predicted values obtained at lower lung volumes in normal subjects.[9] However, other reports in different clinical conditions suggest that some diseases may not affect D_{LCO} in the same manner as voluntary changes in normal subjects. These uncertainties have led to substantial controversy regarding the value of the ratio D_{LCO}/VA.[15,20] Final judgment will require collection of extensive data in a variety of disease states. Regardless of the outcome of this controversy, it is apparent that if D_{LCO}/VA is used in the interpretation of measurements of D_{LCO}, there must be some adjustment of predicted values of D_{LCO}/VA to reflect reductions in alveolar volume. D_{LCO}/VA, whether expressed as a ratio of these two linked measurements or as a rate constant for CO uptake (K_{CO}), is basically the same. The value of using either expression for clinical use is uncertain.

Measurements of Dm_{CO} and V_c can be useful in a carefully controlled, research setting, but there is little or no value of using isolated measurements of these two parameters to aid in diagnosis and clinical management.[21] Calculation of Dm_{CO} and V_c involves both a number of assumptions and extrapolations of data in the literature to a specific clinical setting. Even more cogent is the lack of sufficient data to validate the use of these measurements in clinical practice.

CHAPTER 17

Acid–Base Balance

Stanley Goldfarb
Kumar Sharma

Regulation of $[H^+]$ is of crucial importance for maintenance of normal cellular functions. The normal $[H^+]$ is maintained at about 40 nEq/L. When there is even a small change in the $[H^+]$, intracellular proteins gain or lose H^+ ions resulting in alterations in charge distribution which may affect molecular structure and protein function. The hydrogen ion concentration in bodily fluids is largely regulated by the ratio of the concentrations of carbon dioxide and bicarbonate. This is predicated upon the relationship demonstrated in the Henderson–Hasselbalch equation:

$$pH = pKa + \frac{[HCO_3^-]}{0.03P_{CO_2}} \quad (1)$$

where $pH = -\log[H^+]$ (the H^+ concentration measured in moles per liter) and $pKa = 6.10$. The lungs are responsible for modulating arterial P_{CO_2}, whereas the kidneys are primarily responsible for modulating the concentration of bicarbonate in plasma. In concert, these organs maintain a stable extracellular acid–base milieu that is readily assessed by measuring arterial pH.

The normal internal environment is maintained within narrow limits: The arterial blood pH is kept remarkably close to 7.40, the bicarbonate concentration is maintained around 24.5 mEq/L, and the P_{CO_2} is maintained at about 40 mm Hg. Deviations of the pH with accompanying changes in the P_{CO_2} and $[HCO_3^-]$ result in the four major categories denoted in Table 17-1. Metabolic acidosis is characterized by acidemia ($pH < 7.35$) that is due to reduced plasma $[HCO_3^-]$. Metabolic alkalosis is characterized by an alkalemia ($pH > 7.45$) that results from an elevation in the plasma $[HCO_3^-]$. Respiratory acidosis is due to hypoventilation resulting in a net increase in P_{CO_2} (hypercapnia) and a concomitant fall in pH. Respiratory alkalosis is due to primary hyperventilation leading to a fall in P_{CO_2} (hypocapnia) and a rise in pH.

TABLE 17-1 Patterns of P_{CO_2} and HCO_3 Changes in Acid–Base Disorders

Primary Disturbance	Initial Abnormality	Compensatory Response	Expected Compensation
Metabolic acidosis	Decreased pH, decreased $[HCO_3^-]$	Decreased P_{CO_2}	$P_{CO_2} = 1.5 \times [HCO_3^-] + 8 \pm 2$ (Winter's formula)
Metabolic alkalosis	Increased pH, increased $[HCO_3^-]$	Increased P_{CO_2}	P_{CO_2} increases 0.6 mm Hg per mEq/L rise in $[HCO_3^-]$
Respiratory acidosis	Decreased pH, increased P_{CO_2}	Increased $[HCO_3^-]$	Acute: $[HCO_3^-]$ increases 1 mEq/L per 10 mm Hg rise in P_{CO_2} Chronic: $[HCO_3^-]$ increases 3.5 mEq/L per 10 mm Hg rise in P_{CO_2}
Respiratory alkalosis	Increased pH, increased P_{CO_2}	Decreased $[HCO_3^-]$	Acute: $[HCO_3^-]$ falls 2 mEq/L per 10 mm Hg fall in P_{CO_2} Chronic: $[HCO_3^-]$ falls 5 mEq/L per 10 mm Hg fall in P_{CO_2}

In this chapter, we first review the basic physiologic roles that the kidneys and lungs play in maintaining acid–base balance and then discuss their adaptation in primary acid–base disorders. The following section then focuses on clinical application of physiologic concepts in analyzing acid–base problems as encountered by the clinician.

BASIC PHYSIOLOGY OF THE ROLE OF THE KIDNEY IN ACID–BASE BALANCE

Normal metabolism generates large quantities of volatile acid (CO_2) and nonvolatile acid daily. The complete metabolism of carbohydrates and fats generates 15,000 mmol of CO_2 daily. This leads to acid generation as the CO_2 combines with H_2O to form carbonic acid (H_2CO_3). As the volatile fraction is excreted by the lungs during respiration, acid accumulation does not occur. The nonvolatile or "fixed" fraction is produced at a rate of 1 mEq/kg per day. The major source of the nonvolatile acid fraction is the oxidation of sulfur-containing proteins from the diet to sulfuric acid. If this amount of nonvolatile acid is not excreted, life-threatening metabolic acidosis ensues; therefore, for a normal individual to maintain acid–base balance, 50 to 100 mEq of nonvolatile acid must be excreted daily by the kidneys.

The addition of 50 to 100 mEq of acid requires initial buffering before it can be excreted. Whole-body buffering capacity is composed of interacting buffer systems: the bicarbonate and nonbicarbonate buffers (Buf^-), consisting primarily of hemoglobin, proteins, and phosphates. The sum of the buffer anions $[HCO_3^-]$ and $[Buf^-]$ is the total buffer base and defines total-body buffering capacity. Since all body buffer systems are in equilibrium, a change in the serum $[HCO_3^-]$ reflects concurrent changes in the other body buffer systems. The importance of bicarbonate in buffering is due to its relationship with CO_2. As H^+ ions are buffered by HCO_3^-, there is a decrease in the $[HCO_3^-]$ and a concurrent increase in the dissolved $[CO_2]$. As the $[CO_2]$ can be excreted by the lungs to maintain a constant $[CO_2]$, this substantially increases the buffering capacity of bicarbonate. Since the kidney plays a major role in controlling the $[HCO_3^-]$ and $[HCO_3^-]$ is easily measured in serum, the HCO_3^- anion is a useful parameter to evaluate the renal response to an acid load.

The H^+ ions released from the dissociation of sulfuric acid are titrated by blood bicarbonate and nonbicarbonate buffers.

$$H_2SO_4 + 2NaHCO_3 \rightarrow Na_2SO_4 + 2H_2CO_3 \rightarrow 2H_2O + CO_2 \quad (2)$$

Although the added H^+ is excreted via CO_2 elimination by the lungs, this occurs at the cost of depletion of $[HCO_3^-]$. To *replenish* the consumed base, bicarbonate is reabsorbed by the kidneys and returned to the blood. This process does not accomplish the replacement of consumed base, since continuous metabolic production of acid will ultimately decrease the available base present. The process of renal *regeneration* of base requires the urinary excretion of acid or H^+ ions in the absence of any urinary bicarbonate. For every H^+ ion excreted, a bicarbonate is returned to the body. If there is any bicarbonate in the urine, there will be a net gain of H^+. Therefore the kidney has two major functions in this context: (1) reabsorption of all the filtered bicarbonate—this takes place primarily in the proximal tubule and (2) the base consumed by metabolism must be generated in the process of urinary acid excretion. This takes place

in the distal portions of the nephron, the distal collecting tubule, and the collecting ducts.

BICARBONATE RECLAMATION

The proximal tubule is responsible for reclaiming 70% to 90% of the filtered bicarbonate. This may occur either by direct bicarbonate absorption at the proximal tubule or via proton secretion into the lumen of the tubule. The latter mechanism appears to be the predominant pathway.[1] Acid excretion across the apical membrane of the proximal tubule occurs by an Na^+/H^+ antiporter (NHE3)[2] and to a lesser extent by a proton pump. The secreted proton enters the tubular fluid and combines with filtered bicarbonate ions leading to carbonic acid formation. Under the influence of carbonic anhydrase, carbonic acid is then split into CO_2 and H_2O. The CO_2 diffuses into the cell where it is rehydrated to carbonic acid and then again split into protons and bicarbonate. The bicarbonate ion exits from the cell through the basolateral membrane into the interstitium via a $3HCO_3/Na$ (NBCe1) symporter, while the proton is secreted into the lumen. The basolateral membrane Na^+/K^+ ATPase antiporter, maintaining a low intracellular sodium concentration, further enhances the NHE3 activity.

In summary, reabsorption of bicarbonate is a cyclic phenomenon and requires carbonic anhydrase and is strictly associated to sodium reabsorption.

Biochemical studies show that total NHE3 and NBCe1 protein abundance are upregulated by chronic respiratory acidosis.[3] However, the main mechanism responsible for the elevation in serum bicarbonate is the increased excretion of titratable acid and ammonium which are stimulated by persistently elevated P_{CO_2} (see Fig. 17-1).[4] It is important to understand that this process reclaims filtered bicarbonate but does not result in a net gain of bicarbonate. At the end of the proximal tubule there is a lowering of the luminal pH from 7.26 to 6.70, and the bicarbonate concentration is lowered from 24 mEq/L to 8 mEq/L.[5] The fluid delivered to the distal tubule is essentially the same with respect to pH and bicarbonate concentration as that which leaves the proximal tubule. The reclamation of the remaining bicarbonate occurs in the thick ascending limb and in the outer medullary collecting tubule. At the collecting tubule, H^+ secretion occurs primarily by an H^+ ATPase pump at the luminal membrane and bicarbonate entry to the blood is via a Cl^-/HCO_3^- exchanger at the basolateral membrane.[6]

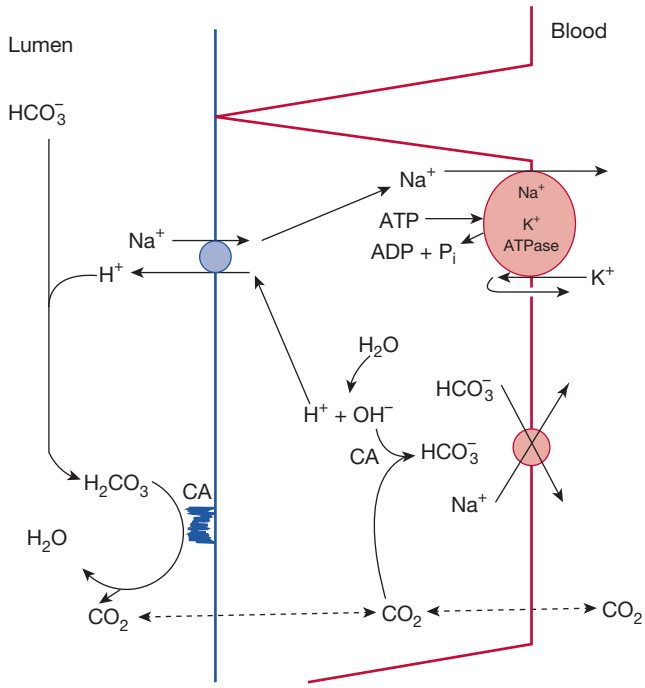

Figure 17-1 Schematic representation of proximal tubular reclamation of filtered bicarbonate. In the lumen, filtered bicarbonate reacts with secreted H^+, generating carbonic acid, which is dehydrated by carbonic anhydrase, CA, located on the brush border. The cell secretes H^+ by a process that exchanges H^+ for filtered Na^+. The source of secreted H^+ is water, which in turn generates OH^- and subsequently bicarbonate because of the presence of intracellular CA. Bicarbonate exits the basolateral side of the cell linked in some fashion with Na^+; sodium is also actively pumped out of the cell.

The crucial role of carbonic anhydrase is demonstrated by the fact that carbonic anhydrase inhibitors, that is, acetazolamide, result in bicarbonate wasting and the generation and maintenance of metabolic acidosis. The most physiologically important regulators of reclamation of bicarbonate are the pH, the P_{CO_2}, and the extracellular volume status of the patient. In states of acidosis, there is enhanced luminal Na^+/H^+ exchange that may be mediated by an increase in intracellular H^+ ions and by increasing the number of new exchangers and increased activity of the Na^+/HCO_3^- cotransporter at the basolateral membrane. Elevation of the P_{CO_2} will promote higher proximal tubular concentration of CO_2 and lead to intracellular acidosis, giving rise to further secretion of H^+ ions and reclamation of bicarbonate. If there is volume depletion, there will be avid Na^+ reabsorption at the proximal tubule in exchange for H^+ and thus greater reabsorption of bicarbonate. Other factors that are important include the luminal bicarbonate concentration, the tubular flow rate, and the serum potassium.

NET RENAL ACID EXCRETION

Net excretion of acid occurs primarily in the distal nephron and is largely mediated by the active secretory pumps, H^+-K^+ ATPase and H^+ ATPase. The latter appears to be linked in some way to Cl^- reabsorption to preserve electroneutrality. By definition, to produce net H^+ excretion the secreted H^+ will have to be excreted in processes that do not consume bicarbonate.

To achieve net secretion of protons in the luminal fluid of the distal nephron requires association of the protons with urinary buffers other than bicarbonate. Although secreted protons lower the urinary pH to 4.5 resulting in a 3 pH unit differential from arterial pH (a 1000-fold increase in H^+ concentration), the quantity of acid excreted as free H^+ is trivial. For example, daily excretion of 2 L of urine with a pH of 5 would result in excretion of only 0.02 mEq of dissociated H^+ ions in contrast to the 50 to 100 mEq of H^+ generated each day from dietary sources. The nonbicarbonate buffers present in the urine that carry out the role of net acid excretion are the titratable buffers, primarily phosphate, which accounts for 40% of net acid excretion, and ammonia, which accounts for the remainder.

The ability of phosphate to act as proton acceptor in the urine is based on its pKa of 6.8. As the urine pH is lowered below the pKa of 6.8, there is conversion of HPO_4^- to H_2PO_4. This transfer continues until the urine pH reaches 5.5, at which point almost all the phosphate present is in the associated form, H_2PO_4. Other components of this system are uric acid (pKa = 5.75) and creatinine (pKa = 4.97). Although the titratable buffers account for a sizable fraction of net basal acid excretion, they cannot increase in amount to enhance acid excretion in settings of acid loading since phosphate excretion depends on phosphate intake and not on synthesis as is the case for ammonia excretion.

The rate of ammonium (NH_4^+) production and excretion can, however, be varied according to physiologic needs. Ammonia (NH_3) combines with H^+ to form ammonium, which is trapped in the collecting tubule lumen and excreted in the urine. The pKa for this reaction is 9.0. The majority of ammonia is synthesized in the proximal tubular cell by the enzymatic breakdown of glutamine.

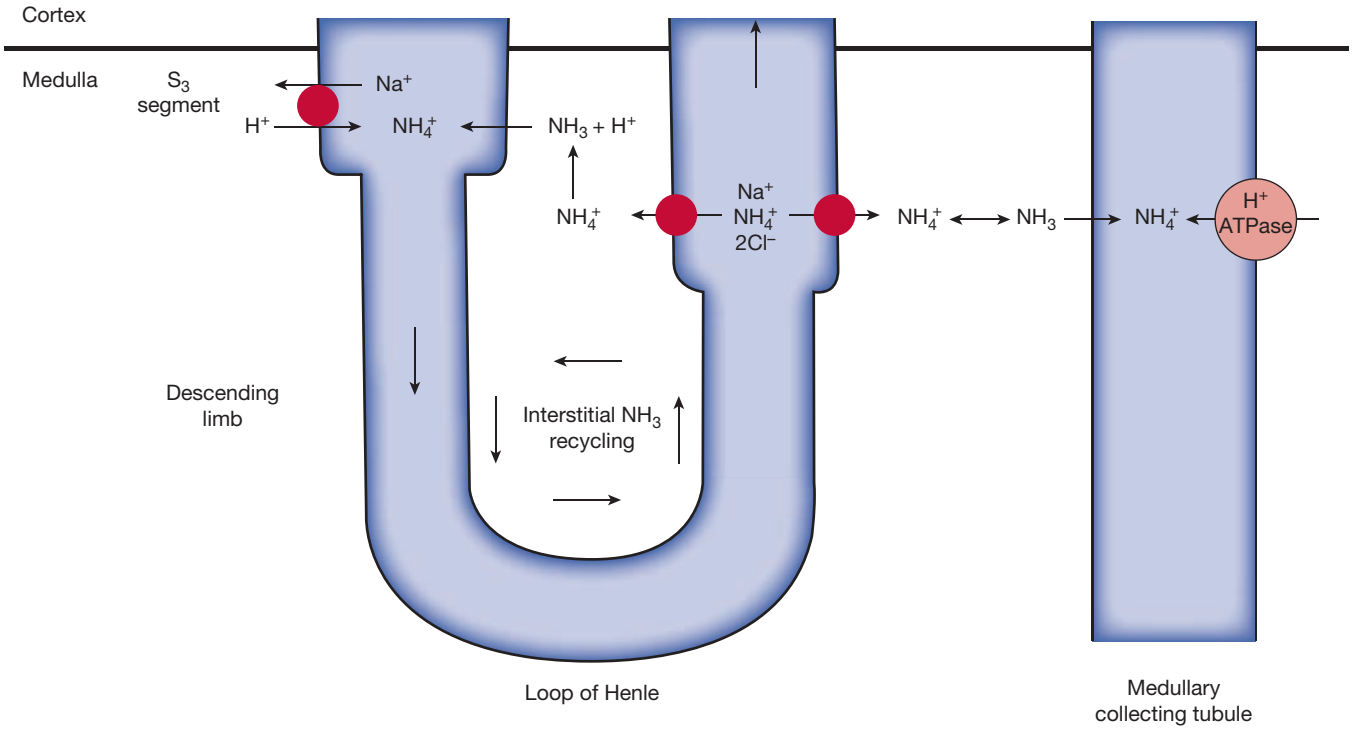

Figure 17-2 Schematic representation of ammonia recycling within the renal medulla. Although NH_4^+ production occurs predominantly in the proximal tubule, most of the NH_4^+ is then reabsorbed in the thick ascending limb, apparently by substitution for K^+ on the Na^+-K^+-$2Cl^-$ carrier in the luminal membrane. Partial dissociation into NH_3 and H^+ then occurs in the less acid tubular cell. The NH_3 diffuses into the medullary interstitium, where it reaches relatively high concentrations; it then diffuses back into those segments that have the lowest pH and therefore have the most favorable gradient: the S_3 segment of the late proximal tubule and, more important, the medullary collecting tubule, where the secreted NH_3 is trapped as NH_4^+ and then excreted. *(Reproduced with permission from Rose B. Clinical Physiology of Acid-Base and Electrolyte Disorders, 4th ed. New York: McGraw-Hill; 1994.)*

Glutamine is actively taken up by the proximal tubule at the apical and basolateral membranes and transported to mitochondria.[1] Deamidation by glutaminase forms ammonium and glutamate. The latter is further metabolized by glutamate dehydrogenase to form ammonium and α-ketoglutarate. Metabolism of α-ketoglutarate to bicarbonate in the liver leads to return of bicarbonate to the systemic circulation (Fig. 17-2).

The ammonium that is formed is transported into the proximal tubular lumen via the Na^+-H^+ antiporter, working in this case as an Na^+–NH_4^+ antiporter. The ammonium is then reabsorbed in the thick ascending limb by substitution of NH_4^+ for K^+ on the Na^+–K^+–$2Cl^-$ carrier. The intracellular ammonium in the thick ascending limb cell is then dissociated into ammonia and H^+. The ammonia accumulates in the medullary interstitium and is finally secreted into the lumen of the medullary collecting tubule. At this site, due to the low lumen pH (4.5–5) the ammonia accepts an H^+ and is trapped in the lumen and excreted in the urine as NH_4Cl.

The importance of the ammonia system is that it can be regulated by the systemic acid–base state. An acid load initially leads to an increase in ammonium excretion within 2 hours due to formation of a more acidic urine which enhances ammonia diffusion into the lumen at the collecting duct. After 5 to 6 days there is maximal NH_4^+ excretion due to increased glutamine uptake and enhanced activity of phosphate-dependent glutaminase and glutamate dehydrogenase to produce more ammonium in the proximal tubule.[6] This is presumably mediated by intracellular acidosis of the proximal tubular cell. The net effect is that NH_4^+ excretion can increase from about 30 mEq per day to as much as 300 mEq/d in severe metabolic acidosis. The plasma potassium is an important regulator of ammonia synthesis as hyperkalemia will result in a transcellular influx of K^+ in exchange for H^+ resulting in lowering of the intracellular H^+ concentration, thus causing an intracellular alkalosis with consequent inhibition of ammonia synthesis. Hypokalemia would have the opposite effect. Urinary acidification is also very important, since an inability to lower urinary pH will result in a reduction in NH_3 trapping in the collecting duct lumen and a subsequent inhibition of the degree of ammonium formation. Inadequate acidification of the urine will also inhibit H_2PO_4 formation.

RESPIRATORY CONTRIBUTION TO ACID–BASE BALANCE

The major roles of the lungs in acid–base balance are to excrete the CO_2 produced daily by aerobic metabolism and to compensate for primary metabolic acid–base disturbances by altering the rate and depth of ventilation. The CO_2 generated by the tissues diffuses into the plasma, at the peripheral capillaries, and is present in the blood in three compartments. Part of the CO_2 remains in the gas phase, but the amount is limited by the solubility coefficient of CO_2 (0.03 mM/mm Hg). CO_2 may also react with amino groups of proteins and form carbamino compounds. The majority of the CO_2 is carried within red blood cells.[7] The red cells contain carbonic anhydrase, which hydrates the CO_2 and thus forms carbonic acid, which dissociates to H^+ and HCO_3^-. The protons are buffered by hemoglobin which has an increased affinity for H^+ at the low oxygen tension present in the peripheral capillaries and venous blood. The bicarbonate produced in the red cell leaves the cell in exchange for chloride. This chloride shift is a characteristic response to elevation of CO_2 in the blood resulting in an acute elevation of bicarbonate in exchange for a drop in serum chloride. When the blood enters the pulmonary circulation, the enhanced oxygenation of hemoglobin promotes release of bound H^+. The H^+ and HCO_3^-, via carbonic

anhydrase, combine to reform CO_2, which passively diffuses from the blood into the pulmonary interstitium where the CO_2 tension is very low. Subsequently, CO_2 is lost into the alveolar space.

The rate of minute ventilation is controlled by two sets of chemoreceptors: Those in the respiratory center in the brain stem and those in the carotid and aortic bodies located at the bifurcation of the carotid arteries and in the aortic arch, respectively. The central chemoreceptors are stimulated by an increase in the P_{CO_2} or by metabolic acidosis, both of which appear to be sensed by a fall in the pH of the surrounding cerebral interstitial fluid. The peripheral chemoreceptors are primarily stimulated by hypoxemia, although they may also respond to acidemia. The level of alveolar or effective ventilation varies in accord with the total minute ventilation. Level of total ventilation changes as a function of metabolic demand. Under normal circumstances, P_{CO_2} is well controlled between 38 and 42 mm Hg according to the relationship:

$$P_{CO_2} = \frac{\dot{V}_{CO_2}}{\dot{V}_A} \quad (3)$$

where $\dot{V}_{CO_2}$ is CO_2 production (reflecting metabolic rate) and $\dot{V}_A$ is alveolar ventilation (reflecting CO_2 clearance).

Under basal conditions the volatile acid production or CO_2 that is metabolically generated is completely eliminated by the lungs. The mechanism of the central stimulation of respiration in response to an elevated CO_2 is a topic of intense debate and will not be focused upon in this section (see further details in Chapter 11). However, intracranial adjustments to pH have been consistently observed and have interesting parallels to the effects of acidosis on the proximal tubular cell in the kidney. Increased concentrations of CO_2 in the cerebrospinal fluid (CSF) result in intracellular acidosis, an increase in CSF bicarbonate concentration, and an equimolar reduction in CSF chloride concentration.[7] As brain cells increase their bicarbonate concentration, there is increased buffering, and intracellular brain pH is returned toward normal. The major group of cells within the central nervous system (CNS) responsible for acid–base regulation are the glial cells and the cells of the choroid plexus.[7,8] These cells contain carbonic anhydrase[9] which converts intracellular CO_2H_2O to H^+ and HCO_3^-. The H^+ is exchanged for Na^+ on the blood side, allowing the intracellular pH to increase. The administration of acetazolamide into the cerebral ventricles blocks the expected increase in CSF bicarbonate in response to hypercapnia.[8] In addition to changes in bicarbonate concentration in the CSF in response to hypercapnia, there are also changes in the levels of ammonia.[10] Brain and CSF ammonia increase in hypercapnia; ammonia acts to enhance H^+ buffering thereby preventing a fall in the bicarbonate concentration.

ACUTE AND CHRONIC ADAPTATION TO RESPIRATORY ACIDOSIS

Figure 17-3 depicts the acute steady-state relationships among P_{CO_2}, plasma bicarbonate concentration, and plasma hydrogen concentration during graded degrees of acute hypercapnia.[11,12] These observations were obtained by sequentially exposing unanesthetized normal human volunteers to increasing concentrations of inspired carbon dioxide in a large environmental chamber. Increasing degrees of hypercapnia are associated with a curvilinear rise in plasma bicarbonate concentration, with higher levels of P_{CO_2} resulting in lesser incremental changes in bicarbonate concentration. This acute rise in bicarbonate is largely due to the chloride shift as described earlier. As a result of the modest increment in bicarbonate, the average rise in plasma $[H^+]$ is limited to 0.75 nEq/L per mm Hg rise in P_{CO_2} rather than the 1 nEq/mm Hg rise that would have occurred if the plasma bicarbonate concentration did not change.[13]

The quantitative aspects of the adaptive response to acute hypercapnia are influenced markedly by the baseline acid–base

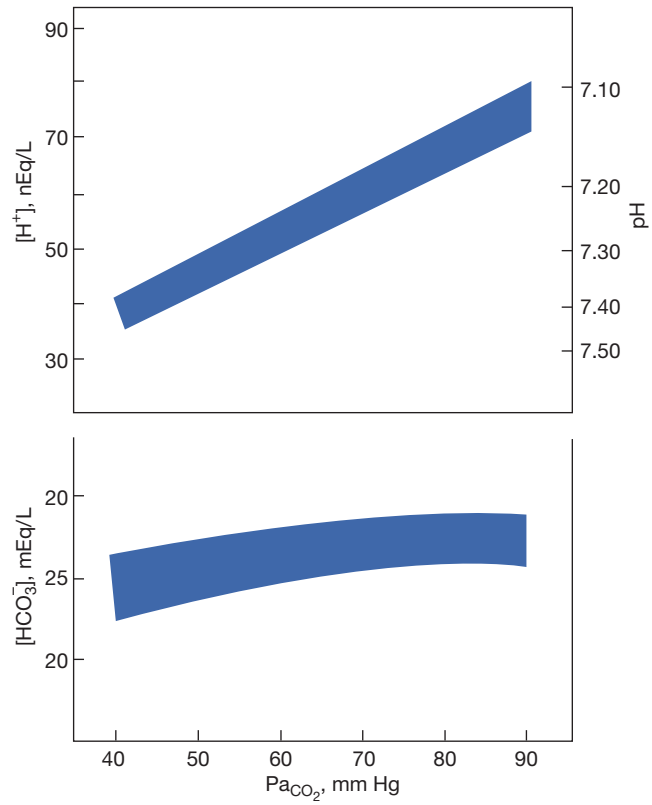

Figure 17-3 Ninety-five percent confidence bands for plasma hydrogen ion and bicarbonate concentrations during acute hypercapnia in normal humans. *(Adapted with permission from Brackett NC Jr, Cohen JJ, Schwartz WB. Carbon dioxide titration curve of normal man: effect of increasing degrees of acute hypercapnia on acid-base equilibrium. New Engl J Med. 1965;272:6–12.)*

status. Acute hypercapnia induces a larger increment in both plasma bicarbonate and H^+ ion concentrations in animals with pre-existing hypobicarbonatemia (whether from metabolic acidosis or from chronic respiratory alkalosis) than in animals with pre-existing hyperbicarbonatemia (whether from metabolic alkalosis or from chronic respiratory acidosis).[14] This points out that the factor controlling the amount of bicarbonate generated from an acute rise in P_{CO_2} is not only the initial pH but also the initial bicarbonate concentration. Although the rise in bicarbonate in response to hypercapnia limits the fall in pH acutely, to excrete the gain of H^+ produced from the rise in P_{CO_2} requires renal compensatory mechanisms.

During the initial period of respiratory acidosis, renal compensation takes about 3 to 5 days, during which time there is enhanced reabsorption of proximal tubular bicarbonate, enhanced secretion of H^+, and increased ammonia production.[15]

These processes will lead to an increase of the serum bicarbonate concentration and a rise in the systemic pH toward normal. However, when a steady state is achieved and a stable P_{CO_2} is present, there is no longer an increase in ammonia production. As filtered bicarbonate is increased, there is enhanced proximal secretion of H^+ and a normalization of intracellular pH removing the stimulus for ammonia synthesis.[15]

RENAL ADAPTATION TO RESPIRATORY ALKALOSIS

The adaptive responses to respiratory alkalosis occur in two distinct steps, in close analogy with respiratory acidosis. Hypocapnia reduces the carbonic acid concentration and causes a prompt fall

in H^+.[16] Acutely, this alkalemia is ameliorated by a secondary, adaptive reduction in plasma bicarbonate concentration that stems principally from titration of nonbicarbonate body buffers.[17] During protracted hypocapnia, renal adaptive mechanisms yield a further and larger secondary reduction in plasma bicarbonate that results in still greater amelioration of the alkalemia.[17]

In acute uncomplicated respiratory alkalosis the plasma bicarbonate concentration falls by approximately 0.2 mEq/L for each mm Hg reduction in P_{CO_2}. Thus, a reduction in plasma bicarbonate of 3 to 4 mEq/L occurs within minutes after P_{CO_2} is lowered to 20 to 25 mm Hg. The resulting change in plasma H^+ concentration is approximately 0.75 mEq/L for each mm Hg fall in P_{CO_2}, similar to the relationship between P_{CO_2} and H^+ in acute hypercapnia.

When hypocapnia persists beyond the acute phase, the additional decrement in plasma bicarbonate concentration is a consequence of renal adaptive responses and reflects a dampening of hydrogen ion secretion by the renal tubule.[5] As a result, a transient suppression of net acid excretion occurs, largely manifested by a fall in ammonium excretion and by an increase in net bicarbonate excretion. These changes lead, in turn, to a positive hydrogen ion balance and a reduction in the body's bicarbonate stores. Persistence of the resulting hypobicarbonatemia is explained by the continued inhibition of tubular hydrogen ion secretion and suppression of bicarbonate reabsorption.

The adaptive retention of acid during chronic hypocapnia is normally accompanied by a loss of sodium into the urine; the resultant decrease in the extracellular volume promotes chloride retention and the typical hyperchloremia of chronic respiratory alkalosis.[18] Upon reaching a new steady state, the net excretion of acid returns to control levels, and the altered anionic concentration of the extracellular fluid (ECF), namely hypobicarbonatemia and hyperchloremia, is maintained by a reduced bicarbonate reabsorption and enhanced chloride reabsorption. On average, the combined effect of cell buffers and renal compensation results in a new steady state in which the plasma HCO_3^- concentration falls approximately 4 mEq/L for each 10 mm Hg reduction in the P_{CO_2}.[19] The renal adaptation to persistent hypocapnia appears to be mediated by some direct effect of P_{CO_2} itself, not the systemic pH. In animals in which plasma bicarbonate was reduced by HCl loading prior to adaptation to sustained hypocapnia, the renal response to a primary reduction in P_{CO_2} was the same as in normal individuals, even though the net effect of this adaptation was an overt fall in pH.

RESPIRATORY ADJUSTMENT TO METABOLIC ACIDOSIS

Metabolic acidosis stimulates both central and peripheral chemoreceptors to increase alveolar ventilation and decrease P_{CO_2} to limit the fall in pH. Although peripheral chemoreceptors appear to play a small role, in animal experiments the same degree of respiratory compensation occurs with intact and with ablated peripheral chemoreceptors. The increase in ventilation begins within 1 to 2 hours and reaches its maximal level at 12 to 24 hours. The stereotype is Kussmaul's breathing in acute diabetic ketoacidosis, in which tidal volume is characteristically large with minute ventilation increasing by as much as 35 L. On average, studies in otherwise normal patients with metabolic acidosis reveal that the P_{CO_2} will fall 1.2 mm Hg for every 1.0 mEq/L reduction in plasma HCO_3^- down to a minimum P_{CO_2} of 10 to 15 mm Hg.[20]

On the other hand, failure to mount the expected ventilatory response to metabolic acidosis is an important indicator of respiratory decompensation. Daniel et al.[21] in 140 critically ill trauma patients with metabolic acidosis applied the traditional formula derived from patients with chronic metabolic acidosis. Those whose Pa_{CO_2} exceeded the predicted Pa_{CO_2} by 2 mm Hg or more were 4.2 times more likely to be intubated and compensation status was an independent predictor of intubation as early as 60 minutes after episodes of significant hypotension.

RESPIRATORY ADJUSTMENT TO METABOLIC ALKALOSIS

The development of metabolic alkalosis is sensed by the respiratory chemoreceptors resulting in a decline in alveolar ventilation and an elevation of the P_{CO_2}. On average, the P_{CO_2} rises 0.7 mm Hg for every 1.0 mEq/L increment in the plasma HCO_3^- concentration.[18] Values significantly different from the predicted value represent superimposed respiratory acidosis or alkalosis. However, it is unclear whether this response significantly protects the pH from rising. In experimental animals, the rise in P_{CO_2} in metabolic alkalosis increases net H^+ excretion leading to an increase in the HCO_3^- concentration. The effect after several days is that the arterial pH is the same as it would have been if there had been no respiratory compensation.[6,18]

Ventilation may be strongly affected by influences other than acid–base balance. Among these influences are body temperature, increases in circulating catecholamines, changes in cerebral blood flow, changes in systemic blood pressure, and changes in metabolic activities of different organs (e.g., liver), as well as the physiologic state of the lung itself. Perhaps for teleologic reasons, the defense of chronic metabolic acid–base imbalances by ventilatory compensation is not of major importance.

ALTERNATIVE CONCEPTS OF ACID–BASE BALANCE

The preceding discussion has tacitly assumed that the systemic pH is the final control that affects the renal and respiratory response to an acid–base disorder; however, this issue is certainly not settled. The proximal tubular cell of the kidney can often have effects that are more predictably based on the P_{CO_2} rather than the arterial pH. If P_{CO_2} is elevated, the proximal tubular cells act to secrete protons and reabsorb bicarbonate whether or not there is systemic alkalosis or acidosis. This may be explained if an elevation in P_{CO_2} results in intracellular acidosis and the cell is responding appropriately to its internal milieu.[6,18] Similarly, in the central control of respiration, it is controversial as to whether it is CSF pH, interstitial pH, P_{CO_2}, or the bicarbonate concentration that stimulates compensatory changes in ventilation.[7]

In addition to the previously mentioned observations, it is also known that changes in salt and water balance may affect acid–base status. For example, Schwartz's group[18] found that a low dietary sodium chloride intake in dogs with a stable amount of water intake results in hypoventilation, increased P_{CO_2}, and increased HCO_3^- concentration. Studies in dogs have demonstrated that increasing dietary NaCl with a fixed water intake increases the acidity of body fluids, whereas decreasing the NaCl in diet with a fixed water intake decreases the acidity of body fluids.[22]

An alternative view to understanding acid–base disorders and the regulatory response of the lungs and kidneys is offered by the theories initially proposed by Stewart.[23,24] Based on physicochemistry, Stewart emphasized the important principle that H^+ and HCO_3^- as well as the acidic and anionic forms of weak acids are actually dependent variables in a solution. The three independent variables, P_{CO_2}, the strong ion difference (SID), and the total weak anion concentration, can be manipulated externally and serve to determine the concentration of the dependent variables, H^+ and HCO_3^-. The major components of the weak anions in plasma are the albumin and inorganic phosphate concentrations. The SID is the difference between the sums of all strong cations and all strong anions:

$$[SID] = [Na^+] + [K^+] + [Ca^{2+}] + [MG^{2+}] - [CL^-] - [\text{Other Strong Anions}] \quad (4)$$

This equation is based on the principles of: (1) electroneutrality, (2) dissociation equilibria of all incompletely dissociated substances, and (3) conservation of mass. This concept appears to better explain the basis for renal and ventilatory response in a variety of states

which also affects acid–base balance. Practically, it is observed that the plasma SID is primarily regulated by the kidneys, whereas the P_{CO_2} is regulated by alveolar ventilation. The weak anion concentration is generally not regulated and may often be assumed to be stable.

This concept has primarily been used by investigators in relation to the study of central regulation of ventilation.[7] As albumin and other proteins are not present in the CSF, it is the SID and P_{CO_2} that determine the concentration of weakly dissociating electrolytes, H^+, OH^-, and HCO_3^-. In analyzing various acid–base disturbances, it appears that the change in CSF SID can predict the concentration of CSF bicarbonate.[7]

In evaluating acid–base balance in many species, there is a consistent inverse relationship between the pH and body temperature, whereas the CO_2 content remains stable.[4,25] To explain this relationship Reeves and his coworkers provided evidence that the imidazole ring structure of histidine is responsible for the pH–temperature relationship.[26] This is because imidazole has a pKa in the physiologic range (7.00), is relatively ubiquitous, and has total energy of ionization (7 kcal/mol). To integrate acid–base regulation with receptor function and control of respiration, Reeves and Rahn[4] have proposed the hypothesis that it is not the arterial or intracellular pH that is being regulated per se but rather the constancy of the fractional dissociation of the imidazole moiety of histidine contained in proteins throughout the body.

α-Imidazole is defined as the ratio of the absolute amount of unprotonated imidazole (Im) to total imidazole (HIm + Im):

$$\alpha\text{-Imidazole} = \frac{\text{Im}}{\text{HIm} + \text{Im}} \quad (5)$$

α-Imidazole regulation (alphastat regulation) would have the effect of maintaining cellular protein charge states and enzymatic functions constant. It would also maintain the OH^-/H^+ ratio constant in all compartments. There is also evidence that alphastat regulation directly influences ventilatory status. For example, application of an imidazole blocker to the chemosensitive area of the medulla in cats blocked increases in ventilation caused by local application of acid.[27] Thus, changes in P_{CO_2}, reflecting alveolar ventilation, may be determined by alphastat regulation, which maintains the OH^-/H^+ ratio constant in membranes of the cells in the chemosensitive areas of the medulla.

The difficulty with using these concepts lies in the practical measurement of the relevant molecules. For example, although the imidazole moiety of histidine is considered the most important of the intracellular buffers,[26] its pKa and total energy of ionization may vary widely due to the influence of the local configuration of molecules into which they are incorporated. Thus, even in lower animals such as fish under different temperatures, calculations based on the alphastat model do not accurately predict the acid–base disturbance, since the pKa and enthalpy of ionization vary with temperature and are difficult to measure.

Similarly, measurement of the plasma SID is problematic and is often replaced by the "SID effective," which is roughly equal to the bicarbonate concentration plus albumin and inorganic phosphate.[23] Calculation of the anion gap (AG) – $[Na^+] - [Cl^-] - [HCO_3^-]$ – accounts for the roles of the strong ions Na^+ and Cl^- as well as bicarbonate but does not account for the role of inorganic phosphate or plasma proteins. Although the bicarbonate concentration may not be, strictly speaking, an independent variable, the AG calculation does indicate the quantity of unmeasured anions and hence is an indirect measure of the SID. If one considers the impact of serum proteins and inorganic phosphate in the unmeasured anion pool, the AG gives a very useful parameter in evaluating acid–base disturbances. Many studies have compared the utility of SID versus corrected AG (corrected for the level of serum albumin) and found that it was no more accurate in making a diagnosis. One study of patients in an intensive care unit, reported that Stewart's method diagnosed underlying metabolic acidosis in 22 patients (of the total of 152 patients in the study) with normal plasma bicarbonate level. However, when the AG was corrected for hypoalbuminemia, it was elevated in all of the samples with normal bicarbonate showing the effectiveness of the traditional approach.[28] In another study of 935 ICU patients, the Stewart method detected metabolic acidosis in 14% patients with normal bicarbonate levels, whereas the traditional method made a similar diagnosis in 13% of patients.[29] A recent study in patients with septic shock and liver transplantation found an excellent correlation between SID and corrected AG.[30]

Thus, as will be described in more detail in the following section, the use of the AG is still the most clinically useful tool to determine the contribution of different metabolic etiologies of metabolic acidosis.

APPROACH TO PATIENTS WITH AN ACID–BASE DISTURBANCE

In this section, we examine the diagnostic approach to disorders of acid–base balance with a particular emphasis on the ventilatory response and its role in mitigating or exacerbating acid–base disorders. We will also review the approach to the patient with complex acid–base disorders.

■ ANALYSIS OF CLINICAL INFORMATION

Table 17-1 summarizes the pattern of abnormality of arterial blood acid–base parameters in the four classic acid–base disorders. It also indicates the physiologic or compensatory response induced in pulmonary or renal function in response to the initial disturbance.

Base Excess and Base Deficit Notations

Base excess and *base deficit* are terms applied to an analytic method for determination of the appropriateness of responses to disorders of acid–base metabolism.[31] The base excess or deficit is determined by measuring blood pH against ambient P_{CO_2} and against a P_{CO_2} of 40 mm Hg. If the calculated HCO_3^- is below 25 when the P_{CO_2} is 40 mm Hg and the original pH is low, a base deficit is indicated. The magnitude of the deficit is expressed as the number of mEq of bicarbonate needed to restore the serum bicarbonate to 25 mEq/L at a P_{CO_2} of 40 mm Hg compared to that at the ambient P_{CO_2}. The use of notations for base excess and deficit has been debated in the medical literature. This notation is favored in the evaluation of acid–base status in the operating room because acute changes in P_{CO_2} and in HCO_3^- can be simply evaluated by this approach. However, this notation can be misleading in chronic respiratory alkalosis or acidosis, since the patient with chronic respiratory alkalosis will be categorized as suffering from a base deficit because of the low serum bicarbonate induced as compensation for the reduced P_{CO_2}. In fact, a "base deficit" is a normal physiologic response to the chronic reduction in P_{CO_2}. Unfortunately, lack of familiarity with the complete analytical paradigm used for this analysis of acid–base disorders has led some to focus on the designations "base deficit" and "base excess" as guides to bicarbonate or acid therapy in chronic respiratory disorders. In addition, discrepancies between the buffering characteristics of plasma, blood, and whole body have also been cited as potential weaknesses in a system for assessing acid–base disorders which relies on in vitro CO_2 titration methods. We, therefore, recommend that the physiologic evaluation of the patient be the mode of analysis of acid–base disorders rather than an emphasis on derived formulae.

Use of Nomograms

As indicated earlier, the body buffers and the kidneys respond in a predictable fashion to a change in P_{CO_2} whereas ventilatory

response to changes in $[HCO_3^-]$ is also predictable. Also, the resulting changes in bicarbonate and pH are time dependent so that a larger change occurs in several days than in the first hours. The confidence bands for changes in P_{CO_2} or HCO_3^- in response to primary disturbances are shown in Figure 17-4.[7] Any deviation can be interpreted as a reflection of processes other than a compensatory response. For example, in a patient with chronic obstructive airways disease, other factors affecting the acid–base status are the concentration of potassium in the plasma, the size of ECF volume, chloride depletion, diuretics, renal hypoperfusion, and coexisting renal disease. The special case of posthypercapnic alkalosis is discussed in the next section.

In evaluating an acid–base disorder, the history and physical examination are invaluable in focusing attention on potential pathologic processes.[32] The composition of blood, with respect to serum electrolytes and blood gases, is then examined for consistency with clinical impressions. However, in using the acid–base map (Fig. 17-4), remember that the map is based on data from individuals who had a single disorder. Therefore, the map does not take into account the possibility of multiple disorders. For example, in a patient with chronic obstructive airways disease whose sputum has turned purulent and who develops nausea and vomiting, the possibility arises of coexistent metabolic alkalosis and acute respiratory acidosis. However, ill-advised application of the arterial blood-gas values from this patient (e.g., pH = 7.25 and P_{CO_2} = 75 mm Hg) to the acid–base map would lead to the erroneous conclusion that a chronic respiratory acidosis is present. Thus, the clinician needs to integrate laboratory data with clinical assessments to properly analyze clinical disorders of acid–base balance.

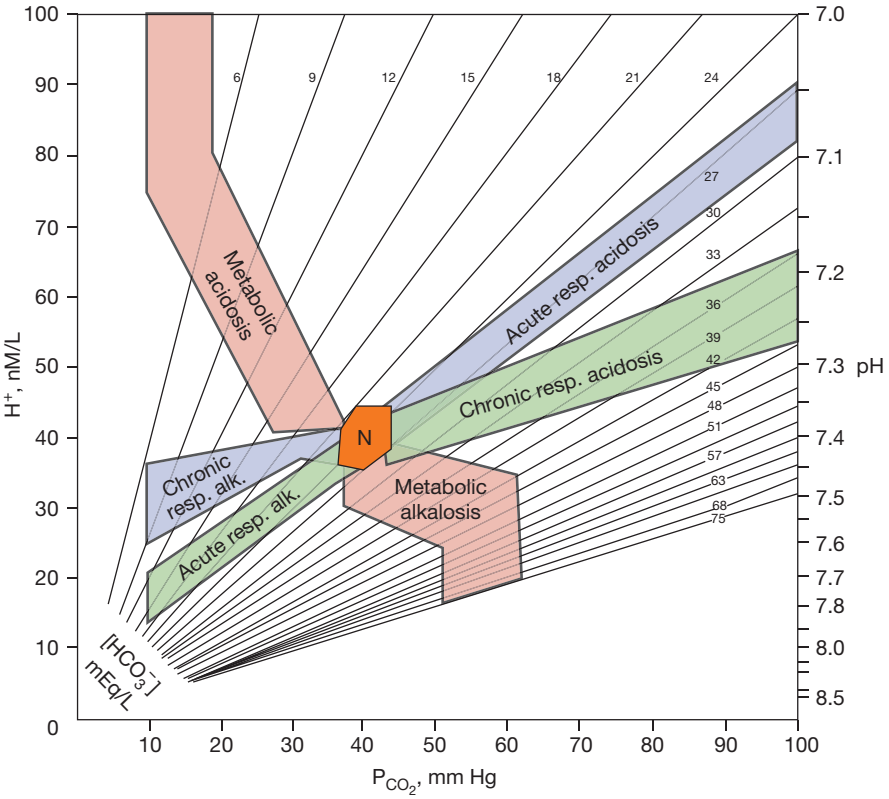

Figure 17-4 Acid–base map showing the normal range (N) and the confidence bands for acute or chronic respiratory and metabolic acid–base disturbances. The ordinates are the partial pressure of CO_2 and the hydrogen-ion activity given in nmol/L and pH units. Isopleths for bicarbonate concentration, in mEq/L, are also shown. *(Reproduced with permission from Goldberg M, Green SB, Moss ML, et al. Computer-based instruction and diagnosis of acid-base disorders. A systematic approach. JAMA. 1973;223(3):269–278.)*

■ APPROACH TO THE PATIENT WITH METABOLIC ACIDOSIS

An increase in the H^+ concentration of the ECF will result in a series of predictable responses which allow the clinician to ascertain the appropriateness of organized homeostatic responses to the perturbation.[20] The pathophysiologic basis for the initiation of metabolic acidosis and homeostatic responses in the defense of systemic pH have been defined earlier in descriptions of the buffering of newly introduced acid [see Eq. (1)] and in the demonstration of the normal confidence band for the ventilatory response to metabolic acidosis as detailed in the acid–base nomogram (Fig. 17-4).

A key clinical distinction in the pathogenesis of metabolic acidosis is whether the production of the acidosis is rapid or slow. If the etiology of the metabolic acidosis is merely the continued ingestion of a diet which generates a variety of fixed acids such as H_2SO_4 [see Eq. (2)] from the metabolism of methionine residues, then the serum HCO_3^- will fall slowly as only that fraction of the 50 to 100 mEq of H^+ generated from diet that is not excreted would be added to the body fluids each day. However, if the addition occurs because of an acute increase in the acid load such as may occur with lactic acidosis, the kidney capacity can be rapidly overwhelmed, and serum bicarbonate may fall precipitously. See Table 17-2 for the common causes of metabolic acidosis.

Utility of the AG

As seen in Eq. (6), the buffering of mineral acids will result in the production of the salt of the acid, NaA.

$$NaHCO_3 + HA \rightarrow NaA + H_2CO_3^- + H^+ \rightarrow CO_2 + H_2O + NaA \quad (6)$$

TABLE 17-2 Causes of Metabolic Acidosis (Common)

Failure to generate new bicarbonate to replace that consumed in buffering dietary acid load
Diminished NH_4^+ production and excretion
Reduced renal mass
Chronic hyperkalemia
Chronic aldosterone deficiency
Decreased H^+ ion secretion (primary)
Distal renal tubular acidosis
Increased H^+ ion production
Lactic acidosis
Ketoacidosis
Toxic ingestion
Bicarbonate or equivalent losses from body fluids
Renal–proximal RTA, carbonic anhydrase inhibitors
GI-diarrhea, villous adenoma, fistula

If the kidney is able to excrete this salt or, in the case of the production of the salts of organic acids such as lactic acid, if the liver can metabolize the anion to HCO_3^-, then there will be no accumulation of the anion in the ECF. Typically, anions associated with strong organic acids are not measured with routine electrolyte determinations and contribute to the so-called anion gap (AG). Determination of the plasma AG is primarily used in the differential diagnosis of metabolic acidosis. However, the AG also changes in other conditions, a finding that may be of diagnostic importance.

The plasma AG is calculated from the following formula based on routine laboratory determination[33]:

$$AG = (\text{cations}) - (\text{anions})$$

Since Na^+ is the primary measured cation and Cl^- and HCO_3^- are the primary measured anions:

$$AG = [Na^+] - ([Cl^-] + [HCO_3^-]) \quad (7)$$

The normal value is 12 ± 2 mEq/L.

An increase in the AG can be produced by an increase in unmeasured anions or by a reduction in unmeasured cations. Hypokalemia, hypocalcemia, or hypomagnesemia can only raise the AG by a few mEq/L, since these ions can only deviate from normal by a mEq/L or less and maintain a physiologic condition. The predominant extracellular unmeasured anion is actually albumin with many negative charge sites per molecule. Hence, a mild elevation in the AG can occur in conditions in which the albumin concentration or the charge characteristics of albumin are altered, for example, in metabolic alkalosis. In that instance, a number of factors may contribute to the increment, including a rise in the plasma albumin concentration due to extracellular volume depletion and contraction of plasma constituents, an increase in the number of negative charges per albumin molecule induced by the rise in extracellular pH titrating protons off the albumin molecule, and a tendency for systemic alkalemia to induce an increase in lactate production. This latter response serves a homeostatically beneficial function.

In forms of metabolic acidosis in which there is buffering of excess hydrochloric acid by extracellular bicarbonate, then

$$HCl + NaHCO_3 \rightarrow NaCl + H_2CO_3 \rightarrow CO_2 + H_2O \quad (8)$$

Bicarbonate is replaced on an equimolar basis by chloride, and there is no change in the AG; this disorder is also called a *hyperchloremic acidosis* because of the rise in the plasma chloride concentration. Both diarrhea and type 2 (proximal) renal tubular acidosis can lead to the loss of $NaHCO_3$. The kidneys compensate by retaining NaCl in an attempt to preserve volume, with the net effect being a mEq-for-mEq exchange of chloride for bicarbonate.

If the retained acid is not HCl but an organic acid whose anion is not routinely measured such as lactic acid, then the increase in the unmeasured lactate anion will raise the AG. It is important to emphasize that the acidosis is due to the retained proton; the anion is irrelevant to the change in acid–base status or systemic pH but is important as a diagnostic tool. The major causes of a high AG metabolic acidosis include those listed in Table 17-2 under disorders of increased H^+ production. Although renal failure produces an acidosis because of failure of H^+ excretion and bicarbonate production, most patients with severe renal failure retain both hydrogen and anions, such as sulfate, phosphate, and urate, and hence demonstrate a high AG.

The diagnostic utility of a high AG is greatest when the AG is above 20 mEq/L; in this setting, renal failure, lactic acidosis, or evidence of a toxic ingestion will almost always be present. When the AG is less than 20 mEq/L, identifying the anions which contribute to the mild elevation[33] is often impossible.

Urine AG

Estimation of the urinary ammonia content may be a useful clue to the etiology of metabolic acidosis as the value will increase in diseases in which kidney function affecting acid–base balance is completely intact but in which bicarbonate is lost from the body fluids.[13] The calculation of the urinary AG is shown in Eq. (9):

$$\text{Urine AG} = (\text{Urine } [Na^+] + \text{Urine } [K^+]) - \text{Urine } [Cl^-] \quad (9)$$

The usual value will be negative, between −25 and −50 mEq/L, as the ammonium content of the urine is typically in this range, and ammonium accounts for the apparent discrepancy between the level of cations and anions in the urine. In states of metabolic acidosis due to diarrhea or to chronic acid ingestion, the value will be >50 mEq/L as ammonium production is stimulated.

In some conditions, the urine AG will be very low or even positive in the face of metabolic acidosis. In all forms of renal insufficiency, ammonia production by the kidney will be deficient and significantly contribute to a reduced urinary AG and to metabolic acidosis. In type I distal RTA, inability to maintain a steep gradient for protons in the distal tubular lumen and in the collecting duct results in a deficiency in ammonia trapping in the luminal fluid and therefore a decreased excretory rate for ammonia. This in turn leads to metabolic acidosis, a low ammonia excretion, and an abnormally low urinary AG. Finally, type IV RTA, a condition in which hyperkalemia and mild renal insufficiency are found, hyperkalemia suppresses renal ammonia production, and a low urinary AG is found.

In any condition associated with hypokalemia, increased intracellular proton accumulation (which results from the exchange of cellular potassium for extracellular protons) will lead to an exaggerated ammonia production in the kidney. Hence, the use of the AG in the urine will be particularly useful to differentiate classic type I RTA from hypokalemia and acidosis due to diarrhea. The former will show a very low urine AG. Typically, a careful history will elicit the crucial information, and measurement of the urine AG will be confirmatory.

Clinical Assessment of Metabolic Acidosis

In approaching a patient with metabolic acidosis, the clinician should first assess the history and clinical circumstances. For example, patients with renal failure or with uncontrolled diabetes may be presumed to have a metabolic acidosis until disproved by laboratory analysis. The next step is to evaluate the serum electrolytes to determine the level of the serum HCO_3^- and the presence of an AG of greater than 12 ± 2 mEq/L. If both are present, then one must consider the possibility of a metabolic acidosis secondary to increased acid production as listed in Table 17-2. If the HCO_3^- is reduced but the serum AG is normal, then one is dealing with either a respiratory alkalosis or a metabolic acidosis due to reduced renal capacity to generate replacement HCO_3^- to compensate for that lost as a result of decreased acid excretion or increased HCO_3^- loss.

At this point arterial blood gases should be assessed to determine the pH and the ventilatory response. Finding a low pH establishes the diagnosis of metabolic acidosis. Reference to the acid–base nomogram (Fig. 17-4) will verify whether the clinical response is consistent with a simple metabolic acidosis with a normal ventilatory response or whether some other disturbance in ventilation is present.

■ APPROACH TO THE PATIENT WITH METABOLIC ALKALOSIS

Two separate processes are involved in metabolic alkalosis: an excess load of base that is generated either endogenously or exogenously (see Table 17-3) and maintenance of an abnormally high

TABLE 17-3 Causes of Metabolic Alkalosis

Gastrointestinal hydrogen loss
Removal of gastric secretions
Renal hydrogen loss
Primary mineralocorticoid excess
Loop or thiazide diuretics
Posthypercapnic alkalosis
Intracellular shift of hydrogen
Hypokalemia
Alkali administration
Contraction alkalosis

concentration of bicarbonate in the plasma.[5] During hypercapnia, the load of base is the result of renal compensation and *de novo* bicarbonate generation; in posthypercapnic alkalosis, the key abnormality is maintaining the bicarbonate level in plasma at inordinately high levels, as will be discussed below.

Generation of Metabolic Alkalosis

Causes of metabolic alkalosis are predominantly events that remove H^+ ions from the body but also include circumstances in which excess base is added to the body fluids. Hydrogen loss can occur from the gastrointestinal tract or in the urine. Each mEq of hydrogen lost generates 1 mEq of bicarbonate, as the source of hydrogen ions in cells which produce and secrete protons is:

$$H_2O \rightarrow H^+ + OH^- + OH^- + CO_2 \rightarrow HCO_3^- \qquad (10)$$

When vomiting or tube drainage prevents stomach acid from reaching the duodenum and combining with HCO_3^- released from pancreatic secretions, the net balance of bicarbonate in body fluids becomes positive, and serum HCO_3^- begins to rise.

Increased renal acid losses may result from enhanced distal hydrogen secretion. Aldosterone acts both by directly stimulating the secretory H^+ ATPase pump and, via the stimulation of sodium reabsorption, by making the lumen more electronegative, thereby favoring hydrogen ion secretion. Increased distal nephron delivery and reabsorption of sodium further stimulates hydrogen ion secretion as the accompanying anion is less avidly reabsorbed than is sodium, and the lumen of the distal nephron becomes more negatively charged. Excess secretion of mineralocorticoids can lead to metabolic alkalosis by this pathway. In patients treated with loop-active or thiazide diuretics, enhanced distal delivery of sodium and increased secretion of aldosterone are usually present, thereby enhancing renal bicarbonate production as a result of enhanced hydrogen ion secretion. This pattern commonly leads to the development of metabolic alkalosis.

Chronic respiratory acidosis leads to a secondary increase in renal hydrogen secretion, as the subsequent rise in the plasma bicarbonate concentration will restore the pH toward normal as a compensatory response. If the patient undergoes a therapeutic maneuver such as rapid lowering of the P_{CO_2} by mechanical ventilation, a posthypercapnic form of metabolic alkalosis will ensue as the patient is left with an elevated plasma bicarbonate concentration.

Hypokalemia is a frequent finding in patients with metabolic alkalosis and may not only be the consequence of some of the disorders which lead to the initiation of metabolic alkalosis but may also actually induce an alkalotic tendency. Gastric drainage, diuretics, and mineralocorticoid excess, all induce potassium as well as hydrogen losses through the GI tract and kidney, respectively. Hypokalemia also induces a transcellular shift in which potassium is exchanged in an electroneutral fashion for hydrogen ions in the ECF. This exchange directly raises the extracellular pH, lowers the intracellular pH, and mitigates the hypokalemia. Intracellular acidosis in renal tubular cells promotes hydrogen secretion and therefore bicarbonate reabsorption (see Section Bicarbonate Reclamation p. 208).

Administering large amounts of alkali does not maintain metabolic alkalosis in normal individuals because of rapid urinary excretion, but it may induce the initiation stage of metabolic alkalosis if factors are active to sustain a high rate of renal HCO_3^- reabsorption. A form of metabolic alkalosis termed *contraction alkalosis* occurs when there is loss of relatively large volumes of bicarbonate-free fluid. Administration of a loop diuretic to induce rapid fluid removal in a markedly edematous patient is the most common cause of a contraction alkalosis. The plasma bicarbonate concentration rises in this setting because there is contraction of the extracellular volume around a relatively constant quantity of extracellular bicarbonate. The degree to which this occurs is in part minimized by intracellular buffering, as the release of hydrogen ions from cell buffers lowers the plasma bicarbonate concentration toward the baseline value. Even this form of alkalosis is probably critically dependent on increases in renal bicarbonate production for its manifestation, since the diuretics promote excess renal hydrogen ion secretion as noted earlier.

Maintenance Phase of Metabolic Alkalosis

Maintenance of metabolic alkalosis requires an increase in the reabsorption of bicarbonate by the renal tubule.[27] Four factors are known to be important in the maintenance phase of metabolic alkalosis: extracellular volume depletion, chloride depletion, hypokalemia, and mineralocorticoid excess.[34]

A reduction in ECF volume and possibly a fall in the glomerular filtration rate (GFR) secondary to extracellular volume depletion are major stimuli for increasing the proximal reabsorption of bicarbonate. The enhanced proximal tubular bicarbonate reabsorption is likely the most important factor. This reabsorption is stimulated by extracellular volume depletion which is a frequent accompaniment of metabolic alkalosis. Enhanced proximal tubular reabsorption of sodium ions is a major factor in the enhanced rate of proton secretion, a key factor in the proximal tubular reabsorptive pathway for bicarbonate. Enhanced activity of the sodium–proton exchanger in the luminal membrane of the proximal tubule is an important component of the transport system.

In addition, an important role is played by the distal nephron in maintaining metabolic alkalosis by way of the secondary phenomena of chloride depletion, extracellular volume depletion, and hypokalemia.[35] Cells of the cortical collecting tubule can either reabsorb or secrete bicarbonate depending on homeostatic requirements. For example, during excess bicarbonate ingestion, the secretory process predominates, and excess bicarbonate is lost into the urine. Chloride depletion enhances the bicarbonate reabsorptive pathway by reducing chloride availability at an anion exchange site on the luminal membrane of the type A intercalated cell. This exchange process normally allows bicarbonate entry into the urine in exchange for chloride absorption. Chloride depletion thus blocks bicarbonate loss.

Hypokalemia acts to stimulate bicarbonate reabsorption through several mechanisms. First, loss of potassium from the ECF leads to a shift of protons into the cell as potassium leaves the cell. Hence, intracellular pH falls, driving enhanced tubular bicarbonate reabsorption. Also, severe potassium depletion produces a defect in tubular fluid chloride reabsorption thus mimicking a chloride depletion state. Finally, excess mineralocorticoid hormone, either as a result of primary overproduction or due to a variety of secondary hyperreninemic states, stimulates H^+ secretion in the cortical

collecting tubule and thereby stimulates increased renal tubular bicarbonate production and helps maintain metabolic alkalosis.

Typically, all four components coexist in patients with metabolic alkalosis secondary to vomiting or gastric drainage following gastric intubation. If any of the factors is present in a patient with metabolic alkalosis, therapy will be only partially successful until all the factors have been eliminated.

Depression of ventilation in metabolic alkalosis is a normal physiologic response to the elevation in serum bicarbonate but is difficult to assess clinically and may not be found in many patients as detailed earlier.[36]

Posthypercapnic Metabolic Alkalosis

In response to sustained hypercapnia, the increased excretion of hydrogen ion in the urine and the increased bicarbonate generated by the acid secretory process increase the concentration of bicarbonate in the plasma as described earlier. During this process, the total sodium content of the body remains stable as does the ECF volume (unless there is a separate reason for a volume abnormality, e.g., right ventricular failure and the use of diuretics). If correction of hypercapnia occurs, for example, through the use of mechanical ventilation without simultaneous replacement of sodium chloride, the urinary loss of sodium bicarbonate may lag for several hours or days. This is particularly true if there is concomitant depletion of the ECF volume. This leads to an increase in the reabsorption of solute, including sodium bicarbonate, by the proximal tubule, sustaining the high bicarbonate concentration in blood. This process is similar to the maintenance phase of metabolic alkalosis described earlier; the other processes outlined also could pertain to this posthypercapnic state and produce a persistent metabolic alkalosis following correction of hypercapnia.[37]

APPROACH TO THE PATIENT WITH A MIXED ACID–BASE DISORDER

The approach to patients with mixed acid–base disorders, that is, more than one disturbance in acid–base metabolism, is particularly challenging because no nomogram, calculation of base excess or deficit, or other formula can allow the clinician to parse the pathophysiologic disorders and allow a rational therapeutic plan.[18] Rather, it is the combination of clinical assessment, application of expected compensatory responses, assessment of the AG, and application of principles of physiology that together allow a successful analysis.

To determine the presence of a mixed or complex acid–base disorder, the clinician must follow a rigorous approach that integrates clinical observation with assessment of a variety of laboratory parameters. No single nomogram or other shortcut device will suffice. The initial step is to perform a history and physical examination to seek processes which could contribute to acid–base disorders. For example, any patient who has vomited has the potential for developing a metabolic alkalosis, and any patient with chronic renal failure surely has metabolic acidosis as an ongoing process for which compensation will be necessary. Moreover, many clinical conditions are typically characterized by the presence of more than one concurrent disorder. Patients with severe liver failure will usually experience respiratory alkalosis as a consequence of hepatic encephalopathy so that any other conditions associated with abnormalities of acid–base balance which may develop in these patients will result in mixed acid–base disorders. Septic shock is associated with the mixed disorders of respiratory alkalosis and metabolic acidosis due to lactic acid production. Immediately, following cardiac arrest, patients will have both a respiratory and a metabolic acidosis. Patients with renal failure who undergo gastric drainage will manifest both metabolic alkalosis and metabolic acidosis as a result of the underlying conditions. The clinician must consider these expected abnormalities in acid–base balance when addressing laboratory results.

The second step in the process is to evaluate a venous blood sample for determination of the electrolytes, blood urea nitrogen (BUN), creatinine, and other parameters indicative of liver function. Here, the evaluation of the $[HCO_3^-]$ and analysis of the AG is invaluable. Decrements or elevations of $[HCO_3^-]$ will point toward a disturbance in the body's buffering system. The AG measurement, if elevated, will clarify whether a metabolic acidosis is present, as described earlier. Also, analyzing the AG together with the venous $[HCO_3^-]$ can provide important information. Because the anions which accumulate in most forms of organic acidosis (lactic acidosis, ketoacidosis, many toxic ingestions) can be metabolized in the liver to bicarbonate through the Kreb's cycle, adding the unmeasured anion concentration to the current plasma HCO_3^- concentration indicates the level of $[HCO_3^-]$ prior to the onset of the metabolic acidosis.

ILLUSTRATIVE CASES

The following cases illustrate the clinical approach to the patient with acid–base disturbances.

METABOLIC ACIDOSIS

A 75-year-old patient presented with a 7-day history of intermittent diarrhea and a 5-lb weight loss. The rest of the history was unrevealing. Physical examination only revealed signs of volume depletion. Laboratory values were as follows:

$$[BUN] = 18 \text{ mg/dL}$$
$$[Na^+] = 138 \text{ mEq/L}$$
$$[K^+] = 3.0 \text{ mEq/L}$$
$$[Cl^-] = 110 \text{ mEq/L}$$
$$[HCO_3^-] = 13 \text{ mEq/L}$$

At this point, the lack of an elevated AG (12 mEq/L) and the reduced bicarbonate concentration together suggest the possibility of either respiratory alkalosis or metabolic acidosis of the non–AG variety, that is, in which the chloride concentration has risen as bicarbonate has been utilized in buffering reactions or has been lost from body fluids. The history of diarrhea strongly suggests that a metabolic acidosis is the culprit in the disorder. The relatively low BUN supports the theory that diarrhea, and not renal insufficiency, is the main etiologic factor.

Arterial blood gases are then obtained:

$$pH = 7.24$$
$$P_{CO_2} = 27 \text{ mm Hg}$$
$$P_{O_2} = 100 \text{ mm Hg}$$
$$[HCO_3^-] = 13 \text{ mEq/L}$$

The low serum bicarbonate in association with a low arterial blood pH indicates that the patient has a metabolic acidosis. Finding that the rate of ventilation produces a P_{CO_2} of 27 is consistent with the expected P_{CO_2} of 27.5 ± 2 mm Hg calculated from Winter's formula (see Table 17-1). Reference to the acid–base nomogram (see Fig. 17-4) reveals the graphical equivalent of this calculation as the values for pH, P_{CO_2}, and $[HCO_3^-]$ fall in the confidence band for metabolic acidosis. Other possible etiologies for this form of non–AG metabolic acidosis would include mild renal insufficiency, wherein the decline of GFR has not reached a level where the unmeasured anions such as SO_4^{2-} would begin to accumulate in plasma, and the ingestion of salts such as ammonium chloride which are metabolized in the liver to urea and hydrochloric acid. Urinary electrolyte analysis confirms the diagnosis:

$$[Na^+] = 50 \text{ mEq/L}$$
$$[K^+] = 20 \text{ mEq/L}$$
$$[Cl^-] = 140 \text{ mEq/L}$$
$$\text{Urine volume} = 2 \text{ L}$$
$$\text{Urinary AG} = -70 \text{ mEq/L}$$

The discrepancy between the sum of urine cations and anions in the negative range indicates that an unmeasured cation, in this case

ammonium, is being excreted into the urine.[13] It is the excretion of protons in association with ammonia that allows the renal excretion of the accumulated acid load and the attempted regeneration of body HCO_3^- stores. If this value was not greater than −20 to −50 mEq/L, a defect in ammonia production or excretion such as could be found in renal insufficiency or in renal tubular acidosis could be present. In this case, the large urinary cation gap suggests that diarrhea is the culprit.

METABOLIC ALKALOSIS

A 65-year-old patient experienced severe and unremitting vomiting for 4 days. He has had a history of peptic ulcer disease, but he decided to medicate himself with an antacid, which he could not keep from vomiting. There was no other significant past medical history. Physical examination showed a moderate degree of orthostatic hypotension as blood pressure fell from 100/70 mm Hg supine to 90/60 mm Hg when seated. The rest of the examination was not remarkable except for some abdominal tenderness.

Laboratory results revealed the following:

$$[BUN] = 28 \text{ mg/dL}$$
$$[Na^+] = 43 \text{ mEq/L}$$
$$[K^+] = 3.0 \text{ mEq/L}$$
$$[Cl^-] = 85 \text{ mEq/L}$$
$$[HCO_3^-] = 39 \text{ mEq/L}$$

The elevation in HCO_3^- content is consistent with either metabolic alkalosis or with chronic respiratory acidosis with renal compensation. The clinical circumstances strongly imply that metabolic alkalosis will be found, since the patient has been vomiting and has therefore been generating new alkali in the body fluids as gastric hydrochloric acid is lost. Also, the vomiting-induced deficit in ECF volume and in body fluid chloride content will likely act to help sustain the metabolic alkalosis by stimulating a high rate of renal bicarbonate transport by the proximal tubule and inhibiting distal nephron bicarbonate secretion.

Arterial blood gases are then obtained:

$$pH = 7.52$$
$$P_{CO_2} = 46 \text{ mm Hg}$$
$$[HCO_3^-] = 36 \text{ mEq/L}$$

These confirm the diagnosis. Note that the hypoventilatory response is modest, probably because of the degree of hypokalemia which tends to acidify the intracellular fluid and stimulate ventilation. Correction of this abnormality will require both replacement of fluid with sodium and chloride and adequate intake of potassium to fully restore acid–base balance to normal.

MIXED ACID–BASE DISTURBANCE

An insulin-dependent diabetic patient with several days of vomiting developed diabetic ketoacidosis. The following set of electrolytes is obtained:

$$[Na^+] = 140 \text{ mEq/L}$$
$$[K^+] = 5 \text{ mEq/L}$$
$$[Cl^-] = 90 \text{ mEq/L}$$
$$[HCO_3^-] = 15 \text{ mEq/L}$$
$$\text{Anion gap (AG)} = 35 \text{ mEq/L}$$

Since the normal AG is 12 ± 2 mEq/L, this individual has utilized 23 mEq/L of HCO_3^- to buffer the ketoacids. If the production of ketoacids ceases and hepatic metabolism is restored through insulin administration, then 23 mEq/L of HCO_3^- could be added to body fluids. The new set of electrolytes would be:

$$[Na^+] = 140 \text{ mEq/L}$$
$$[K^+] = 5 \text{ mEq/L}$$
$$[Cl^-] = 90 \text{ mEq/L}$$
$$[HCO_3^-] = 38 \text{ mEq/L}$$
$$\text{Anion gap (AG)} = 12 \text{ mEq/L}$$

By assessing the value – (AG increment above 12 mEq/L) + (serum $[HCO_3^-]$) – and finding a value greater than 30, one can infer that some process has previously raised the bicarbonate content above normal even if the ambient total CO_2 level is subnormal at the current moment. Hence either metabolic alkalosis or respiratory acidosis is a component process of the acid–base disorder. Conversely, finding a value less than 20 suggests that the patient had a pre-existent metabolic acidosis or a respiratory alkalosis prior to the onset of the organic acidosis. Finally, the clinician may assess the alveolar–arteriolar O_2 gradient to determine the effectiveness of oxygenation as an initial assessment of respiratory gas exchange efficiency.

At this point the clinician is able to ascertain a tentative diagnosis and perform an arterial blood gas determination to conclude the process. Measurement of the blood gas will show whether the respiratory response to a metabolic disturbance (metabolic alkalosis or metabolic acidosis) or the metabolic (renal) response to a respiratory disturbance is as expected. The acid–base disorder could still be labeled a simple disturbance if the initial assessment of the clinical condition and the AG support that conclusion. Consulting the acid–base map (see Fig. 17-4) will provide the expected compensatory response to each disturbance. In the previously mentioned case of a patient with diabetic ketoacidosis and an initially increased (AG + total CO_2) concentration, the following arterial blood gases were obtained:

$$pH = 7.18$$
$$P_{CO_2} = 38 \text{ mm Hg}$$
$$[HCO_3^-] = 15 \text{ mEq/L}$$

In pure metabolic acidosis the ventilatory response to an $[HCO_3^-]$ lowered to 15 mEq/L would be a P_{CO_2} of 25 mm Hg (see Table 17-1 and Fig. 17-4). In this example, the patient shows a P_{CO_2} that is higher than the expected value of 25 for a patient with pure metabolic acidosis and a depressed HCO_3^- value of 15 mEq/L. Hence this patient demonstrates a so-called triple disturbance, metabolic acidosis (low HCO_3^-, high AG), a metabolic alkalosis ([HCO_3^- + AG increment above 12] >30 mEq/L) and a respiratory acidosis (P_{CO_2} higher than expected value given the lowering of HCO_3^- level as determined from the acid–base nomogram or the formula for expected compensation). Therapy for this patient will require awareness of these various processes, since removal of one of multiple disturbances can induce a more severe expression of the still-present abnormality.

CHAPTER 18

Respiratory System Response to Exercise in Health

Jerome A. Dempsey
Anthony J. Jacques

The increases in muscular oxygen consumption ($\dot{V}_{O_2}$) and carbon dioxide production ($\dot{V}_{CO_2}$) accompanying whole-body exercise present a greater challenge to the maintenance of pulmonary gas exchange than any other physiologic stressor. This chapter discusses the responses of the healthy respiratory system to exercise with an emphasis on the following problems: What neurochemical mechanisms regulate the ventilatory response to exercise and what are the consequences of this hyperpnea to the work and to the fatigue of the respiratory muscles? What mechanisms underlie the widening of the alveolar to arterial partial pressure of oxygen (P_{O_2}) difference during exercise? How do the unique characteristics of the pulmonary circulation determine its response to exercise? How does respiration impact the cardiovascular response to exercise? Under what circumstances might the respiratory system provide a limitation to O_2 transport and/or exercise performance? We consider these problems primarily in the healthy, young, normally fit adult, with reference to special cases of the highly trained athlete and to the effects of healthy aging, high altitude hypoxia, and physical training.

EXERCISE HYPERPNEA

In healthy humans, breathing in all physiological states is remarkably well controlled. Accordingly, the partial pressures of oxygen and carbon dioxide, in systemic arterial blood along with its acidity, are regulated precisely throughout mild to moderate exercise.[1–4]

These relationships are shown in the following alveolar gas equations, where alveolar gas partial pressures are approximately equal to the ratio of the metabolic requirement to alveolar ventilation.

$$P_{A_{CO_2}} = [\dot{V}_{CO_2} \div \dot{V}_A] \cdot K \quad (1)$$

$$P_{A_{O_2}} = P_{I_{O_2}} - [\dot{V}_{O_2} \div \dot{V}_A] \cdot K \quad (2)$$

where:

$P_{A_{CO_2}}$ and $P_{A_{O_2}}$ = alveolar carbon dioxide and oxygen partial pressures (it is assumed $P_{A_{CO_2}} \approx$ arterial P_{CO_2})

$\dot{V}_{CO_2}$ and $\dot{V}_{O_2}$ = volumes of carbon dioxide produced and oxygen consumed

$\dot{V}_A$ = alveolar ventilation

$P_{I_{O_2}}$ = inspired partial pressure of oxygen

K = constant (0.863). This constant allows alveolar gases to be calculated from these equations if $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ are expressed in mL/min and $\dot{V}_A$ in L/min.

Table 18-1 illustrates the interrelation of these variables, as one goes from rest to exercise. With exercise, there is an increased metabolic rate, with alveolar ventilation increasing to regulate arterial blood gases near resting levels. In health, dead space (V_D) increases slightly as intrathoracic airways stretch and dilate with increased tidal volume (V_T) – but V_T rises out of proportion; thus, V_D/V_T falls to about one-half its resting value during exercise. In order that $P_{A_{CO_2}}$ be precisely controlled, overall minute ventilation ($\dot{V}_E$) during exercise must be regulated in such a fashion so as to compensate both for the increasing CO_2 production as well as a reduced V_D/V_T. Accordingly, the ratio of $\dot{V}_E$ to $\dot{V}_{CO_2}$ falls from rest to moderate exercise, whereas the $\dot{V}_A$:$\dot{V}_{CO_2}$ ratio and arterial P_{CO_2} are maintained constant until heavy exercise intensities, during which both ratios rise and $P_{A_{CO_2}}$ is reduced. Note the impressive magnitude of ventilatory response required to maintain arterial P_{CO_2} homeostasis during exercise, amounting to a 20-fold increase above resting in the untrained at $\dot{V}_{O_{2\,max}}$ and 30-fold in the highly trained.

REGULATION OF EXERCISE HYPERPNEA

More than a century of highly innovative research on this question has left us with three major stimuli as the primary regulators of exercise hyperpnea. The schematic diagram shown in Figure 18-1 includes these three potential stimuli in a ventilatory control system which features three components, namely a central rhythm generator/integrator in the medulla, mechanical and chemical feedback and feedforward inputs to this integrator, and control of the distribution of efferent output to muscles of both the upper airway and chest and abdominal wall.

CO_2 FLOW

The primary suspects for mediation of the exercise hyperpnea include **humoral stimuli** in the form of CO_2 flow to the lung or the product of blood flow and mixed venous CO_2 content. While still controversial (and mysterious) there is compelling evidence in support of a significant fundamental role for this feedback mechanism. When extracorporeal perfusion is used to increase (or reduce) CO_2 flow to the lung in a resting animal, alveolar ventilation is changed in proportion to $\dot{V}_{CO_2}$ and an isocapnic hyperpnea (or reduced ventilation) is achieved.[5] In human quadriplegic patients, increasing locomotor muscle CO_2 production via electrical stimulation of muscle contraction, increases ventilation. Similarly, increasing $\dot{V}_{CO_2}$ and the respiratory quotient with bicarbonate ingestion in resting humans will increase $\dot{V}_A$ in an isocapnic fashion. Furthermore, when sinusoidal exercise regimens are employed at changing frequencies, the ventilatory response follows the change in $\dot{V}_{CO_2}$ rather than the change in work rate, per se. The case against this purely humoral feedback stimulus in the mediation of exercise hyperpnea is that it has only been tested over a very narrow range of $\dot{V}_{CO_2}$ near resting levels and the exact nature of the stimulus or its site of action has not been identified. Recently, c-fiber receptors in the lung interstitium have been implicated, responding to an increased transport of plasma water into the lung interstitium, secondary to the effects of both increased venous CO_2 content on the osmotic state of blood plasma and increased blood flow on pulmonary capillary pressure.[6] We suspect that $\dot{V}_{CO_2}$ plays an important modulatory role in the control of breathing near resting levels, but it is unlikely to provide sufficient drive to be considered as a primary drive to hyperpnea during exercise.[7]

CENTRAL COMMAND

A purely feedforward input to medullary respiratory controller neurons originates from supramedullary regions of the motor cortex and hypothalamus and operates along synaptic pathways in parallel with

TABLE 18-1 Group Mean Values of Healthy Untrained and Trained Subjects Cardiorespiratory Responses to Steady-State Exercise

Group A experiences little arterial hypoxemia while Group B experiences substantial hypoxemia in heavy intensity exercise.

the motor control of locomotor muscles. Animal models using electrical or pharmacological stimulation of these supramedullary sites show powerful cardioventilatory responses even in the face of paralyzed locomotor muscles, that is, in the absence of neural feedback.[8] Further, in hypnotized humans even the "suggestion" of exercise – while still at rest – elicits exercise-like cardioventilatory responses with coincident PET imaging studies showing an increased blood flow to motor control regions of the cortex.[9] On the other hand, the "exercise-like" ventilatory response to electrical stimulation of the limbs shows that feedforward central command is not obligatory to the hyperpnea and a normal ventilatory response to exercise is also observed in decorticate animals, that is, in the absence of key hypothalamic regions of purported cardioventilatory central command.

MUSCLE AFFERENT FEEDBACK

Lightly and unmyelinated afferents from locomotor muscle sensitive to the metabolic milieu, mechanical deformation, and even vascular distension in the muscle, project via the dorsal horn of the spinal cord and then via the nucleus of the solitary tract to the medullary cardiorespiratory controller neurons. When their effect on ventilation is studied in isolation, using electrical stimulation of muscle, a proportionate increase in $\dot{V}_E$ occurs. However, evidence against a role for muscle afferents in the intact human include the failure of imposed vascular occlusion causing accumulation of muscle metabolites to augment ventilation during recovery from exercise, the failure of spinal cord lesioning to alter the ventilatory response to muscle stimulation, or of epidural anesthesia to reduce the cardioventilatory response to rhythmic exercise. On the other hand, if afferent blockade techniques are employed – such as intrathecal fentanyl which blocks only muscle afferents and leaves efferent motor pathways intact, hypoventilation occurs throughout mild and moderate exercise – uncovering a significant obligatory role for muscle afferents in the steady-state exercise hyperpnea (see Fig. 18-2).[10,11] This inhibitory effect of muscle afferent blockade on exercise hyperpnea has also been shown in patients with COPD and CHF.[12,13] Interestingly, in COPD patients muscle afferent blockade during exercise reduced primarily V_D ventilation, suppressed dyspneic sensations, and substantially improved exercise performance.[12]

In summary, the dilemma of exercise hyperpnea is that findings using isolation of each of these three stimuli support a significant contributory role for each of these mechanisms to the isocapnic hyperpnea of moderate intensity exercise—but there is contradictory evidence against an obligatory major role for any of them. Accordingly, most models emphasize the powerful redundancy of the hyperpnea mechanisms operating under steady-state conditions of exercise or emphasize the importance of compensatory feedback

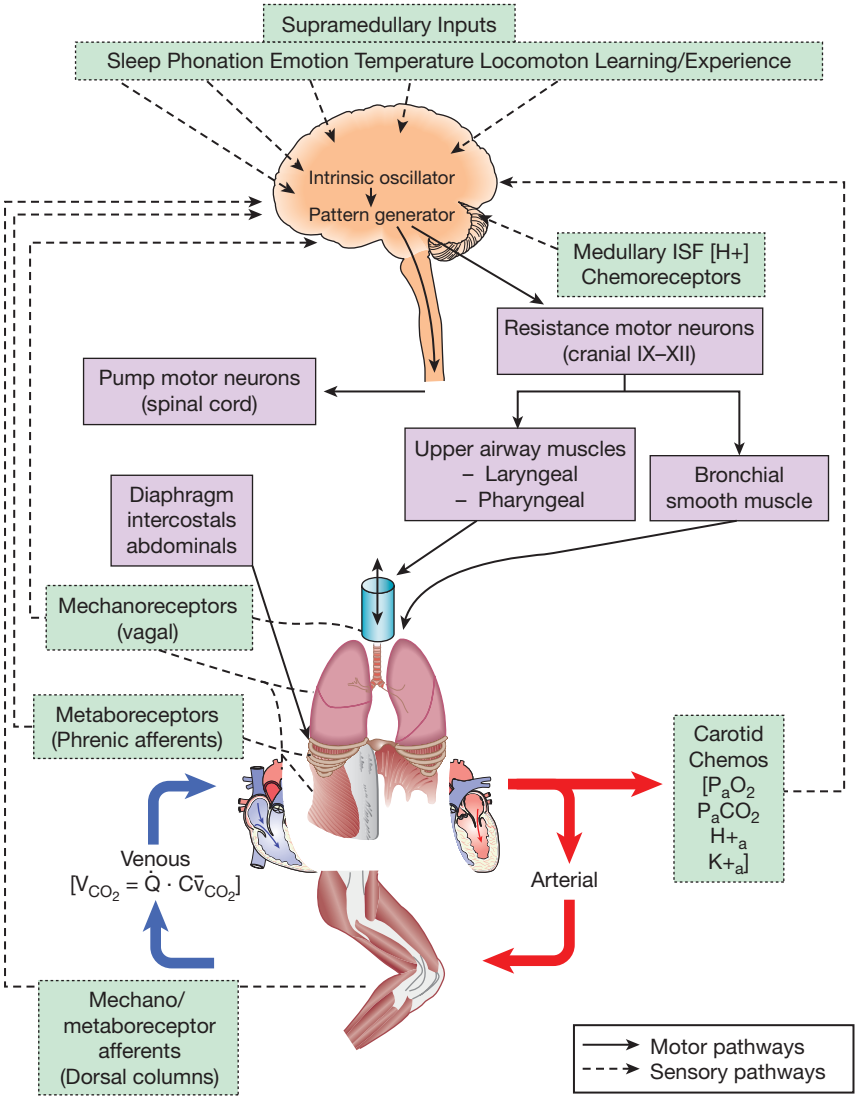

Figure 18-1 Schematic depicting multiple structures contributing to the control of breathing. It is hypothesized that respiratory rhythm originates within a brain stem oscillator which activates brain stem pattern generating neurons that provide for the proper sequential activation of respiratory pump (diaphragm, intercostal, and abdominal) and airway (laryngeal and pharyngeal) muscles. These brain stem neurons receive excitatory and inhibitory input from multiple sources during exercise, including supramedullary central command and mechano/metaboreceptor-initiated spinal afferents from limb and respiratory skeletal muscles. In addition, the brain stem controller neurons receive carotid and intracranial chemoreceptor (RTN, retrotrapezoid nucleus) and vagal mechanoreceptor input critical to meet the appropriate ventilatory and breathing pattern responses to exercise. *(Reproduced with permission from Taylor N. Physiological Bases of Human Performance during work and exercise. New York: Churchill Livinstone; 2008.)*

from carotid and central chemoreceptors if blockade of any of these primary mechanisms was sufficient to cause transient CO_2 retention. There are also suggestions that feedback mechanisms are likely of little consequence; rather, the ventilatory response to exercise depends critically on a "stored memory" of the appropriate ventilatory response by the motor cortex as a result of repetitive trial and error during maturation.[14] We hypothesize – with limited direct evidence – that each of these three mechanisms have an important obligatory role, with CO_2 flow to the lung providing the essential underpinning to ventilatory control in all physiologic states and the interaction of feedforward (central command) and feedback (from muscle afferents) mechanisms providing the primary "exercise" stimulus. The proof for this awaits the appropriate experimental tools – such as was done with the use of opiate receptor agonists (see Fig. 18-2) – to test a specific mechanism without altering the remaining elements of the control system.

Finally, we need to emphasize that this hypothesis applies only to the isocapnic hyperpnea achieved in mild to moderate steady-state levels of exercise. For the hyperventilatory response to heavier intensity exercise we need to add additional mechanisms: an important input from carotid chemoreceptors responding to the changing hydrogen ion, potassium, norepinephrine, temperature, etc. of the arterial blood induced by heavy intensity exercise; the additional powerful inputs from central command responding to the need to recruit more motor units in the presence of fatiguing locomotor muscles; and muscle afferents responding to accumulating ionic changes in the muscle interstitium. Even an obligatory role for carotid chemoreceptors and the hyperventilatory response to heavy exercise has been challenged by the fact that preventing the blood-borne acidity during heavy exercise (via depleting muscle glycogen and preventing acid production) did not prevent the hyperventilatory response.[7] Again multiple, redundant mechanisms are apparently at play. This hyperventilatory response is extremely important in partially compensating for the metabolic acidosis incurred with increasing lactic acid levels in heavy exercise and also for raising alveolar P_{O_2} to maintain arterial P_{O_2} in the face of a widening alveolar to arterial P_{O_2} difference.[15]

■ BREATHING PATTERN DURING EXERCISE

During low to moderate intensity exercise both V_T and breathing frequency (fb) increase roughly in proportion to intensity, while at higher intensities V_T attains a plateau and further increases in $\dot{V}_E$ are accomplished by increases in fb alone (see Fig. 18-3). The increase in fb is accomplished by decreases in both inspiratory time (T_I) and expiratory time (T_E). However the ratio of T_I to total breath cycle duration (T_{TOT}), known as the duty cycle (T_I/T_{TOT}), increases only slightly during exercise (~0.40 at rest to ~0.50 during high-intensity exercise). The fact that the duty cycle remains low is important and beneficial, because prolonged diaphragmatic contractions hinder blood flow to this muscle and may precipitate excessive diaphragmatic fatigue.[16]

The increase in V_T at the onset of exercise is accomplished by both an increase in end-inspiratory lung volume (EILV) and a decrease in end-expiratory lung volume (EELV). However, as exercise intensity increases, EILV does not normally increase beyond 85% to 90% TLC. Beyond this point lung compliance decreases markedly and the respiratory pressure production required for a given change in volume is very large. This inefficiency at high operating lung volumes leads to neuromechanical uncoupling in that a mismatch develops between the required "effort" to inspire and the actual volume of air inhaled. This hyperinflation (secondary to expiratory flow limitation) underlies much of exertional dyspnea, that is, "unsatisfied inspiratory effort" in COPD patients.[17] In health, EELV decreases at the onset of all levels

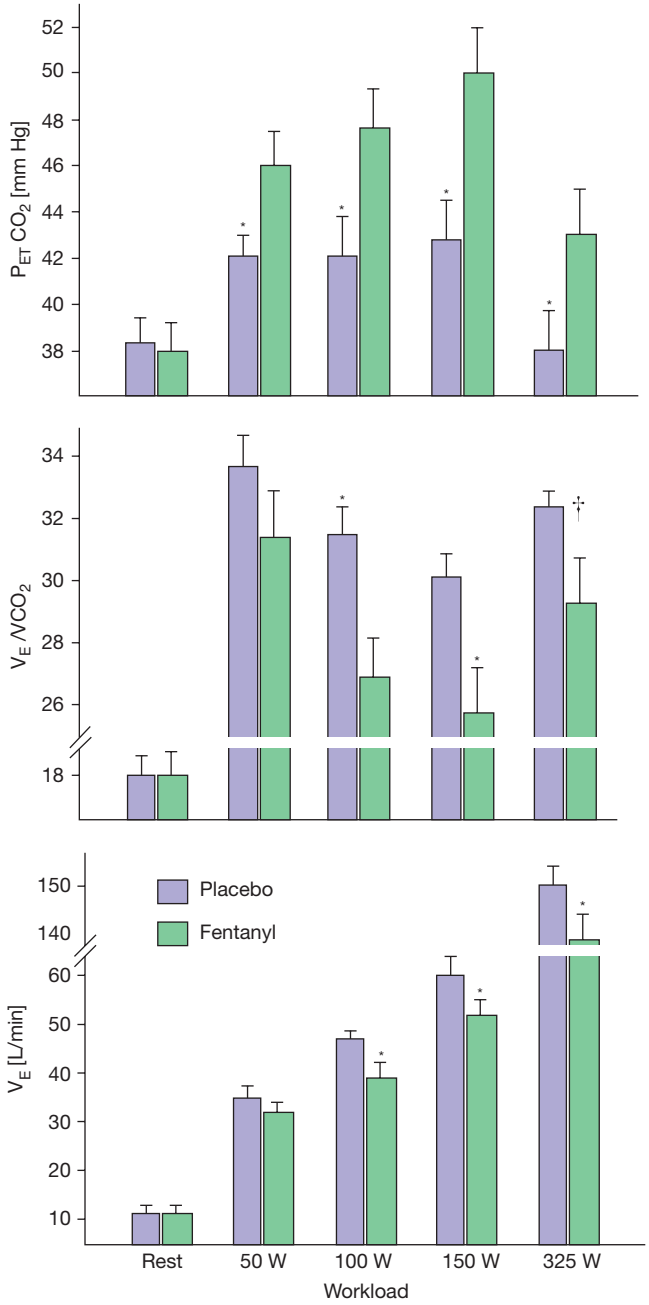

Figure 18-2 Effect of blockage of μ-opioid sensitive type III–IV muscle afferents via intrathecal fentanyl on the steady-state ventilatory response to 3 minutes of cycling exercise at each of four work rates. (*$p < 0.05$, †$p < 0.08$). The fentanyl-induced hypoventilation was due to a reduced breathing frequency. Heart rate, mean arterial blood pressure, and $\dot{V}_E$ were significantly reduced at each work rate. Taking into account the reduced exercise $\dot{V}_E$ with fentanyl plus the ventilatory equivalent of the concomitant rise in $P_{ET_{CO_2}}$, it is estimated that the partial blockage of muscle afferents accounted for 47%, 45%, and 15% of the total exercise hyperpnea at 100, 150, and 325 W, respectively. *(Modified with permission from Amann M, Blain GM, Proctor LT, Sebranek JJ, Pegelow DF, Dempsey JA. Group III and IV muscle afferents contribute to ventilatory and cardiovascular response to rhythmic exercise in humans. J Appl Physiol. 2010;109(4):966–976.)*

of exercise due to active recruitment of the expiratory muscles, and its decrease is roughly proportional to exercise intensity.[18] The drop in EELV maintains operating lung volumes within the linear portion of the pressure–volume relationship, which minimizes the reduction in respiratory system compliance and associated dyspnea that develops at high lung volumes. The reduced EELV also serves to lengthen the diaphragm and place it in a more optimal range of its length–tension relationship. Thus the maximum dynamic capacity of the inspiratory muscles for force production is improved during tidal breathing and they are required to produce only about one-half of their capacity for force production at maximum exercise in the untrained subject (see Fig. 18-3).[19] A reduced EELV also reduces inspiratory muscle work during the ensuing inspiration due to outward recoil of the rib cage at the onset of inspiration.

Tidal exercise flow–volume loops plotted within the maximal volitional flow–volume envelope provide a simple and useful method to analyze alterations in flow rates, V_T, and operating lung volumes during exercise (Fig. 18-4). In normal, healthy untrained young adult humans the maximal attainable flow rates at any given lung volume are usually much greater than the spontaneous tidal flow rates reached during exercise of all intensities. Thus, as shown in Figure 18-4 (at $\dot{V}_{E\,max}$ in the 100–120 L/min range) there is usually a large reserve for increasing $\dot{V}_E$ even at maximal exercise.

CONTROL OF AIRWAY CALIBER DURING EXERCISE

UPPER AIRWAY CALIBER

The upper airway comprises the nose, mouth, pharynx, and larynx, and provides the majority of resistance to airflow at rest and during exercise. In addition, each region of the upper airway has the potential to independently contribute to any alterations in airway resistance during exercise. The work required to produce the large increases in airflow during exercise would become excessive during even low-intensity exercise if several mechanisms were not in place to reduce resistance to airflow in the upper airway during exercise.

First, the route of airflow switches from predominately nasal to oronasal breathing when $\dot{V}_E$ reaches approximately 30 L/min.[20] Second, nasal resistance decreases during exercise in an intensity- and duration-dependent manner secondary to sympathetically mediated vasoconstriction of the nasal mucosal vasculature.[21] Third, the nasal dilator muscles and presumably the skeletal muscles of the pharyngeal and laryngeal regions contract in phase with, but slightly preceding, inspiratory pump muscle recruitment, and this drive to the upper airway muscles is increased at increasing $\dot{V}_E$, resulting in decreased resistance and a larger diameter, stiffer, less collapsible upper airway.[22] Finally, the glottic narrowing that normally occurs during expiration is attenuated during exercise due to laryngeal abductor muscle activation, in addition to a widened mean glottic aperture throughout the respiratory cycle.[23] Thus, the work required to produce the increased airflow that occurs during whole-body exercise is minimized by a variety of adjustments that occur in the upper airway, all of which act to decrease resistance to airflow.

BRONCHIAL CALIBER

Bronchial dilation in response to exercise has been well documented in healthy humans.[24] Furthermore, this bronchodilator influence occurs at exercise onset and is very powerful, as evidenced by the prevention of an increase in pulmonary resistance during exercise after histamine inhalation in asthmatic subjects who exhibited large increases in resistance during histamine inhalation at rest.[25] In addition, forced expiratory volume in 1 second (FEV_1) and the maximum volitional flow:volume envelope increase immediately after exercise in both normal[26] and asthmatic subjects.[27] There are several potential mechanisms contributing to the bronchodilator effect of exercise, including neural, mechanical, and locally released mediator mechanisms.

A primary component of the exercise-induced increase in airway caliber is withdrawal of vagal parasympathetic tone to the airways that occurs at the immediate onset of exercise, resulting in bronchial smooth muscle relaxation.[24] The withdrawal of cholinergic tone is thought to be mediated in part by the stimulation of muscle mechano- and chemosensitive afferents (i.e., the same muscle afferents

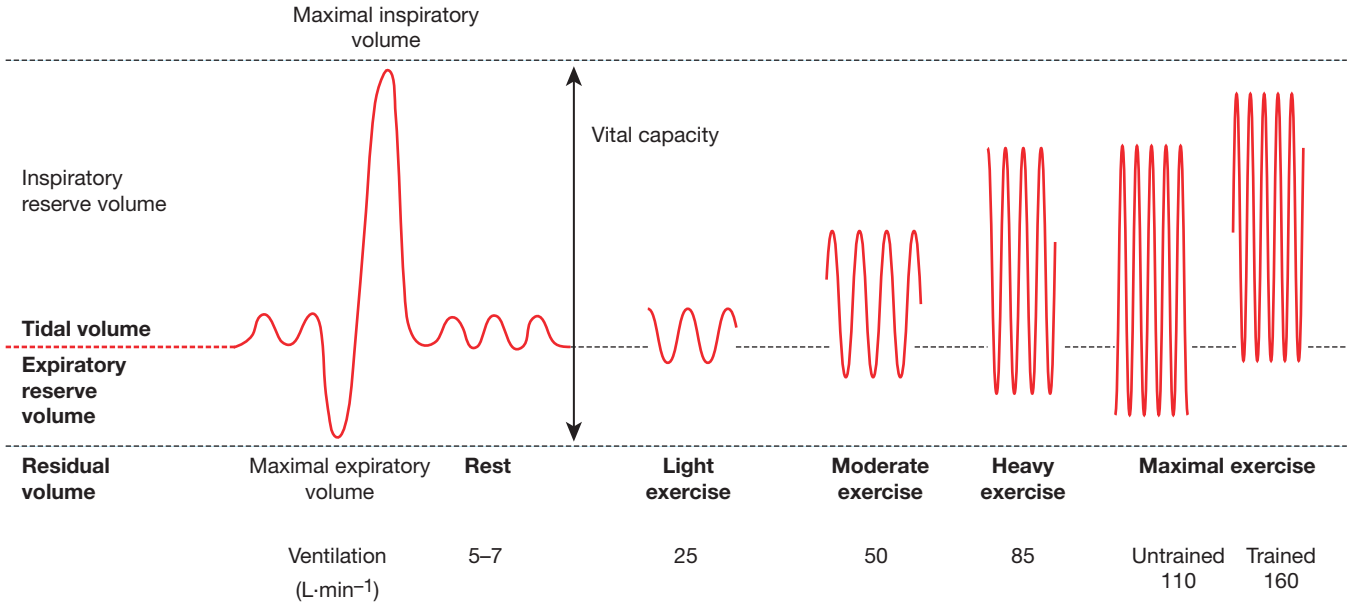

Figure 18-3 Changes in breathing pattern during exercise. The spirograph on the left is from a resting subject showing normal tidal volume, maximum expiration to residual lung volume, then maximal inspiration to total lung capacity. With light to heavy exercise (in both untrained and highly trained subjects) the increase in ventilation is achieved by increasing breathing frequency and tidal volume. Tidal volume increases by encroaching on the expiratory and inspiratory reserve volumes. The reduced end-expiratory lung volume is maintained at maximal exercise in the normally fit subject (maximal oxygen uptake [$\dot{V}_{O_2\,max}$] 45 mL kg^{-1} L min^{-1}). In the trained subject ($\dot{V}_{O_2\,max}$ = 75 mL kg^{-1} L min^{-1}), ventilation, breathing frequency, and tidal volume are all higher and maximal exercise end-expiratory lung volume is increased to near resting values due to expiratory flow limitations. *(Reproduced with permission from Farrell PA, Joyner MJ, Caiozxo VJ. ACSM's Advanced Exercise Physiology, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2012.)*

believed to be involved in the pressor and ventilatory responses to exercise) (see Fig. 18-2).[28] Increased lung stretch and activation of slowly adapting pulmonary stretch receptors (that occurs as EILV is increased during exercise) may contribute to this withdrawal of vagal tone.

Mechanical influences may also play a substantial role in increasing airway caliber during exercise. The airways are tethered open by the lung parenchyma, and the increase in EILV and operating lung volumes during exercise will enlarge airway diameter simply as a result of this airway–parenchymal interdependence. Further, the

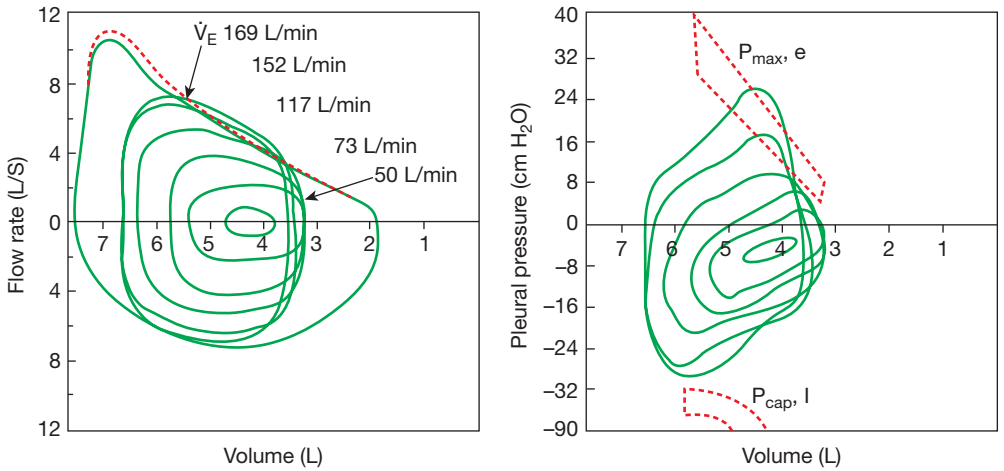

Figure 18-4 Flow–volume and pressure–volume relationships in a young healthy adult, at rest and during exercise. The maximal (outer envelope) flow–volume relationship is obtained via maximal volitional inspiratory and expiratory efforts, before *(solid line)* and immediately following exercise *(broken line)*. For the pressure–volume relationships, only tidal breaths from rest through to maximal exercise are shown. In addition, the maximum inspiratory pleural pressures (P_{cap}, I) are shown at the specific peak volume and flows achieved during tidal breathing in heavy exercise. For minute ventilations up to 115 L min^{-1}, approximating peak exercise in an untrained adult, the inspiratory muscles are activated to only ~40% to 50% of capacity. The more highly trained subject is shown achieving ventilations >150 L min^{-1} at higher metabolic rates. Under these conditions, the tidal flow–volume loop often encroaches on the maximum flow–volume envelope, end-expiratory lung volume rises, and the inspiratory muscles approach 90% of their dynamic capacity for force output and shortening velocity. The broken area on the expiratory side indicates expiratory pressures for any given lung volume (P_{max}, e), beyond which extraexpiratory muscle effort will not produce a higher flow. In almost all instances up to ventilations of ~150 L min^{-1}, this critical expiratory pressure is not exceeded but it is exceeded slightly in the highly trained athlete at maximum exercise. *(Modified with permission from Johnson BD, Saupe KW, Dempsey JA. Mechanical constraints on exercise hyperpnea in endurance athletes. J Appl Physiol. 1992;73(3):874–886.)*

increased outward radial force exerted by the parenchyma on the airways during exercise may induce bronchodilation by a separate mechanism operating at the level of the crossbridges of bronchial smooth muscle.[29] Airway stretch modulates bronchial smooth muscle crossbridge formation, resulting in decreased bronchial smooth muscle force and stiffness and relaxation of airway smooth muscle. Finally, airway mast cells, macrophages, neutrophils, eosinophils, epithelial cells, and smooth muscle cells all have the potential to release a variety of chemical mediators that may alter airway caliber.

WORK, METABOLIC AND CIRCULATORY COST OF BREATHING

During exercise the inspiratory and expiratory muscles perform work on the lung, the abdominal wall, and the rib cage. The work on the lung is composed of elastic work – a function of both the V_T and lung compliance and flow resistive work – a function of airway caliber and flow rate. As the diaphragm descends during inspiration, work is performed on the abdominal wall—a function of abdominal wall compliance. This work maximally contributes about 25% to the total work of breathing during exercise—but in the presence of expiratory flow limitation abdominal muscle tension will persist well into the inspiration which will markedly increase work done by the diaphragm on the abdominal compartment. As shown in Figure 18-5 the total work of breathing rises linearly with the isocapnic hyperpnea of mild and moderate intensity exercise and then rises alinearly with the hyperventilation of heavy intensity exercise.

This severalfold increase in respiratory muscle work requires increases in respiratory muscle $\dot{V}_{O_2}$ and blood flow. Thus, at maximal $\dot{V}_{O_2}$ (~45 mL/kg/min) and cardiac output (~20 L/min) and $\dot{V}_E$ (100–120 L/min), about 8% to 10% of $\dot{V}_{O_2}$ and cardiac output are devoted to breathing in the untrained human and up to 14% to 16% of $\dot{V}_{O_2}$ and cardiac output in the highly trained ($\dot{V}_{O_{2max}}$ ~65 mL/kg, $\dot{V}_E$ >150 L/min, and CO ~30 L/min—see Table 18-1). Respiratory muscle blood flow, was determined directly by using distribution of infused microspheres in exercising animals[30] and indirectly in humans by the reduction in total cardiac output and increased blood flow to the exercising limb muscles measured when respiratory muscle work was reduced during maximal exercise using a mechanical ventilator (see Fig. 18-6).[31,32]

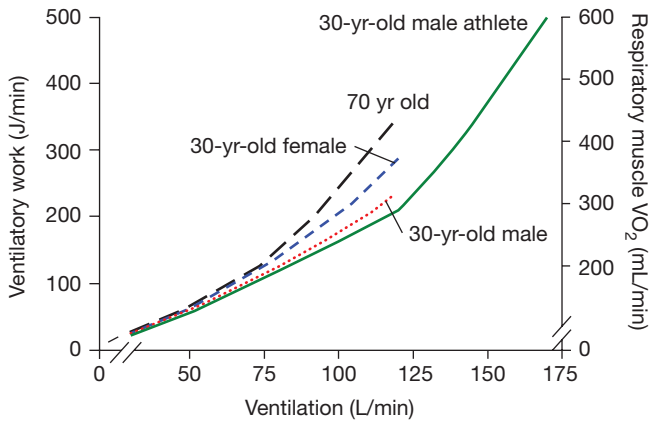

Figure 18-5 Ventilatory work and respiratory muscle $\dot{V}_{O_2}$ during exercise of increasing intensity plotted as a function of $\dot{V}_E$ for sedentary men, active young females, and trained young and older men. In young adult males the O_2 cost of exercise hyperpnea was determined by having subjects mimic the pressure–volume loop, breathing frequency, duty cycle, and ventilation they experienced during submaximal and maximal exercise and measuring the change in $\dot{V}_{O_2}$ from resting eupnea.[108,109] *(Reproduced with permission from Harms CA, Dempsey JA. Cardiovascular consequences of exercise hyperpnea. Exerc Sport Sci Rev. 1999;27:37–62.)*

Several lines of evidence are available in support of the concept that during heavy intensity exercise a metaboreflex is triggered from the diaphragm which travels in phrenic nerve afferent fibers to increase efferent vasoconstrictor outflow from sympathetic neurons in the medulla. For example, studies in healthy humans using muscle microneurography and Doppler blood flow measurements of limb muscle blood flow demonstrated increases in muscle sympathetic nerve activity together with reduced limb vascular conductance and blood flow in the face of inspiratory or expiratory muscle fatigue induced by volitional hyperpnea against increased airway resistive loads.[33] In animals specific acidification of the diaphragm or pharmacologic stimulation of diaphragm afferents caused vasoconstriction in limb muscle and these effects were prevented via ganglionic blockade.[34,35] The finding that vasoconstriction occurs under these conditions of heightened sympathetic outflow in the locomotor muscle vasculature and not in the diaphragm is supported by in situ studies which show feed arteries in the diaphragm to undergo substantially less norepinephrine-induced vasoconstriction than that which occurs in vessels isolated from limb muscle.[36] Apparently these reflex mechanisms and vascular response characteristics combine to protect blood flow to the respiratory muscles during intense exercise.

EXERCISE-INDUCED RESPIRATORY MUSCLE FATIGUE

The structural and functional properties of the respiratory muscles appear to be well suited to the substantial ventilatory requirements of exercise. For example, the human at rest can voluntarily sustain up to 6 to 8 times the resting diaphragmatic pressure production for 10 to 15 minutes without inducing significant fatigue or task failure of the diaphragm.[37] Furthermore, pressures and velocities of shortening sustained by the diaphragm that are 1.5 to 2 times greater than those reached during exhaustive exercise are required to cause diaphragm fatigue when the subject is in the resting state and increases ventilation voluntarily.[37] Nevertheless, significant 15% to 50% reductions in the transdiaphragmatic pressure response to bilateral super maximal phrenic nerve stimulation, across a wide range of stimulation frequencies (1–100 Hz) and lung volumes (residual volume to TLC), have been observed following constant-load, whole-body endurance exercise at >85% $\dot{V}_{O_{2max}}$ to exhaustion.[38–41] Recent studies using phrenic nerve stimulation at multiple time points during high-intensity exercise shows that significant diaphragm fatigue actually begins to occur fairly early in the time course of the exercise.[42] The magnitude of exercise-induced diaphragm fatigue is determined in part by the amount of diaphragm work contributing to the exercise hyperpnea. Thus, substantially reducing the pressures produced by the diaphragm during endurance exercise using a proportional assist ventilator prevented diaphragm fatigue.[40] Whole-body exercise itself appears to lower the threshold of force output by the diaphragm required for its fatigue, likely because a finite blood flow must be distributed to both locomotor and respiratory muscles.[32] Such a disparity between O_2 supply and demand to the diaphragm appears to occur in subjects of varying fitness levels, but only at workloads exceeding 85% of $\dot{V}_{O_{2max}}$,[41] or when arterial O_2 saturation is decreased.[43]

CARDIOVASCULAR EFFECTS OF INTRATHORACIC PRESSURE

Respiration has important and complex effects on stroke volume and cardiac output during exercise through changes in intrathoracic and transventricular pressures. This has been demonstrated in human and animal studies by manipulating inspiratory and expiratory pressures during exercise. During inspiration the negative pressure generated in the intrathoracic space widens the pressure gradient across the walls of the right heart thereby augmenting ventricular filling of venous return from the limbs by lowering the pressures within the heart's chambers and augmenting cardiac preload. Conversely, during expiration ventricular filling is impeded by

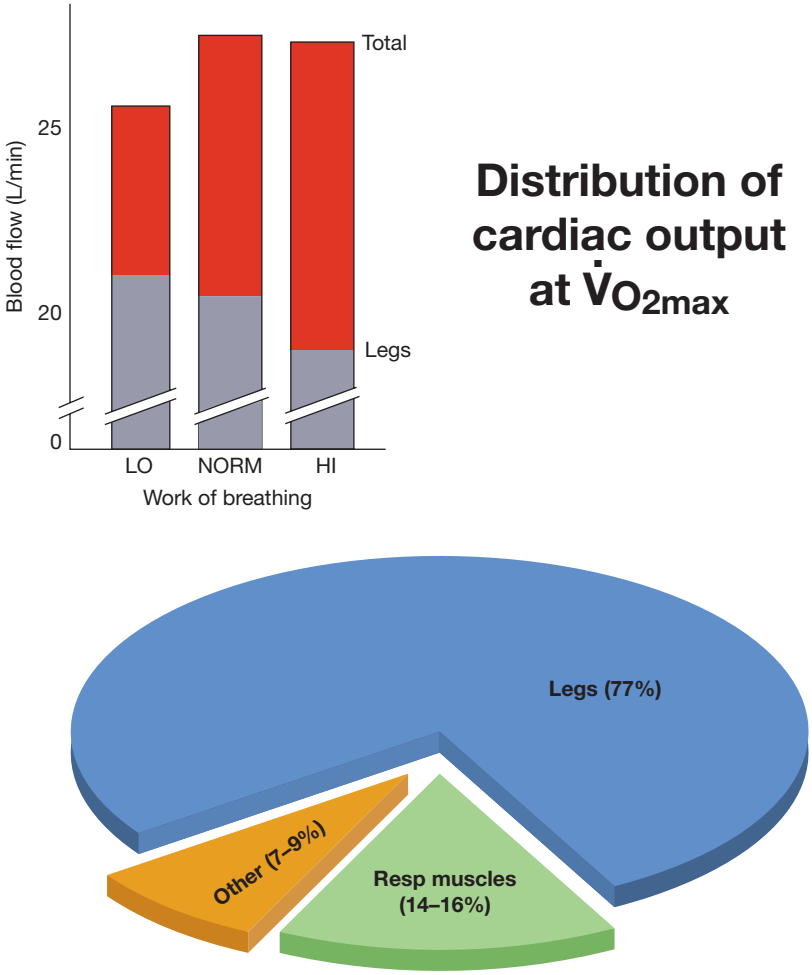

Figure 18-6 Effects of respiratory muscle work during exercise on cardiac output and its distribution in highly fit adult male subjects cycling at $\dot{V}_{O_{2\,max}}$ ($\dot{V}_{O_2}$ = 65 mL/kg/min, cardiac output = 28 L/min), "LO, NORM, HI" refer to the relative level of the work of breathing present during heavy intensity exercise under normal physiologic conditions, with added resistive loads ("HI") and during unloading of the respiratory muscles via mechanical ventilation ("LO"). The top of each bar indicates the total cardiac output and each bar is divided into blood flow to the limbs and to the rest of the body. The estimated distribution of blood flow to the limb locomotor and to the respiratory muscles is shown in the pie chart. These estimates come from three sources: 1. The oxygen cost of breathing at maximum exercise[108]; 2. Measurements based on microsphere distribution to the respiratory muscles during maximum exercise in the equine[110]; and 3. The change in cardiac output and in limb muscle blood flow determined in response to unloading of the respiratory muscles during maximum exercise.[31,32] These effects of respiratory muscle unloading at maximum exercise on limb blood flow and on total cardiac output are shown in the insert. Note that with reduced respiratory muscle work, that is, unloading, the total cardiac output falls and the limb muscle blood flow (and vascular conductance) rises; whereas with respiratory muscle loading and increased work of breathing at maximum exercise the maximum cardiac output remains unchanged whereas the limb blood flow (and vascular conductance) is reduced. *(Reproduced with permission from Farrell PA, Joyner MJ, Caiozzo VJ. ACSM's Advanced Exercise Physiology, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2012.)*

a narrowing of the transmural pressure gradient across the ventricle due to a positive shift in intrathoracic pressure (ITP) which reduces the pressure gradient for venous return. In the steady state these modulatory effects of ITP will be limited by intrinsic "autoregulatory" cardiac mechanisms termed ventricular interdependence, by which the filling of one ventricle shifts the common wall – the IV septum – toward the opposite ventricle which in turn limits its filling. Nevertheless, during exercise – especially in heavy intensity exercise with huge negative shifts in ITP, if positive pressure mechanical ventilation is introduced, stroke volume and cardiac output are reduced – likely due to a less negative inspiratory ITP limiting cardiac preload, that is, reducing ventricular transmural pressure during diastole.[32] Alternatively, with active expiration in heavy exercise – especially in the presence of excessive positive expiratory pressures accompanying expiratory flow limitation – transventricular wall pressures are reduced, diastolic filling is impaired, and stoke volume and cardiac output are compromised.[44,45]

PULMONARY CIRCULATION AND GAS EXCHANGE

The lungs are unique in that they are the only organ that receives all the blood pumped from the heart and thus, the lungs must accommodate the entire increase in cardiac output during exercise. The pulmonary circulation is under limited adrenergic[46] or endothelial[46–51] control during exercise and therefore, because of its unique in-series relationship, the pulmonary circulation is tightly coupled to left (downstream) ventricular function. At the same time, the pulmonary microcirculation has been engineered to maximize gas-exchange efficiency and as a result, vessel walls are very thin, strong, and distensible. Correspondingly, pulmonary vascular resistance and perfusion pressures are about one-fifth of those observed in the systemic circulation at rest.

With upright exercise, there is an increase in venous return to the heart, causing a central shift of blood volume into the thorax.[52] This increases both right and left ventricular filling pressures,[53] helping to maintain, or increase, both end-diastolic volume and stroke volume, despite reductions in filling time secondary to exercise-induced tachycardia. The dominant determinant of pulmonary artery pressure during exercise is left ventricular filling pressure.[54]

The rise in both pulmonary arterial and pulmonary capillary wedge pressures with exercise recruits previously unperfused and distended pulmonary capillaries, increasing capillary blood volume and reducing pulmonary vascular resistance. This increases the surface area for gas diffusion[55] and helps to maintain the red blood cell capillary transit time necessary for complete gas exchange (>0.25 seconds). (Mean pulmonary capillary transit time [seconds] is equal to the ratio of pulmonary capillary blood volume and blood flow [cardiac output].) At peak exercise in untrained subjects, despite the fourfold increase in pulmonary flow (cardiac output) from rest, capillary transit time at maximum exercise is reduced to only about one-half that at rest, due to a doubling of the pulmonary capillary blood volume (see Table 18-1).

It is important for the lung to remain relatively dry for gas exchange. At rest, there is a small outward flow of plasma fluid (~10–20 mL h^{-1}) from the capillaries into the interstitial space of the alveolar wall. The fluid passes into the perivascular and peribronchiolar spaces of the lung, with the lymphatic system transporting this fluid to the hilar lymph nodes. With exercise, thoracic lymph flow increases substantially, due to augmented pulmonary capillary pressures and capillary surface area.[56] In addition, the augmented ventilation with exercise increases lymph flow, acting

as a safety mechanism to oppose edema formation in the alveoli or interstitial space.[57] Thus, the lymphatic system is vitally important in preventing exudation of fluid into the alveoli during exercise.

The efficiency of gas exchange for O_2 within the lung is defined and quantified as the difference in P_{O_2} between the alveolar gas and the arterial blood, and is known as the alveolar to arterial P_{O_2} difference ($A\text{-}aDO_2$). If gas exchange within the lung were perfect, the $A\text{-}aDO_2$ would be equal to zero. However, the $A\text{-}aDO_2$ normally amounts to 5 to 10 mm Hg at rest in young, healthy subject.[58] During exercise, the efficiency of gas exchange worsens in an intensity-dependent manner, and the $A\text{-}aDO_2$ increases to values of 15 to 25 mm Hg or more at maximal exercise (see Table 18-1). In contrast, fixed workload endurance exercise does not result in a time-dependent worsening of gas exchange when compared to the first minute of exercise,[59] indicating that the magnitude of the $A\text{-}aDO_2$ is determined primarily by metabolic rate as opposed to exercise duration.

The $A\text{-}aDO_2$ is a complex physiologic variable and as such is determined by a variety of mechanisms during rest and exercise. The worsening of gas-exchange efficiency during exercise is primarily due to an exaggeration of mechanisms present at rest. The principle contributor to the $A\text{-}aDO_2$ during both rest and exercise is the imperfect matching of the distributions of alveolar ventilation ($\dot{V}_A$) and pulmonary blood flow ($\dot{Q}$), otherwise known as the $\dot{V}_A/\dot{Q}$ ratio (see full discussion on $\dot{V}_A/\dot{Q}$ in Chapter 14). The ratio of $\dot{V}_A$ to $\dot{Q}$ can be partitioned into that occurring *among* lung regions (i.e., interregional, primarily dependent on gravity) and to that *within* an isogravitational plane of the lung (i.e., intraregional, or independent of the effects of gravity). The distributions for $\dot{V}_A$ and $\dot{Q}$ were once thought to be dominated by gravity, however, recent studies have resulted in the realization that there is also a great deal of pulmonary blood flow heterogeneity within an isogravitational plane of the lung.[60] Presumably, much intraregional heterogeneity exists for alveolar ventilation as well. These intraregional inhomogeneities are likely due simply to the normal anatomical heterogeneity of vessel and airway diameters, compliances, and resistances within specific lung regions.

During exercise, overall $\dot{V}_A/\dot{Q}$ nonuniformity increases slightly as measured by the multiple inert gas elimination technique (a technique that is not able to partition the $\dot{V}_A/\dot{Q}$ into separate inter- and intraregional distributions).[61,62] Despite this increasing nonuniformity, both $\dot{V}_A$ and $\dot{Q}$ become more uniform from lung apex to base resulting in a more uniform interregional $\dot{V}_A/\dot{Q}$ distribution.[63] Thus, the increased overall $\dot{V}_A/\dot{Q}$ nonuniformity observed during exercise can be attributed almost entirely to a more maldistributed intraregional $\dot{V}_A/\dot{Q}$, which contributes to the decreased efficiency of gas exchange (i.e., widening of $A\text{-}aDO_2$) at increasing exercise intensities. Counteracting the greater nonuniformity of the $\dot{V}_A/\dot{Q}$ distribution during exercise is the fact that overall $\dot{V}_A$ increases out of proportion to $\dot{Q}$ at increasing exercise intensities (see Table 18-1).[62] Thus, even though the distribution of $\dot{V}_A/\dot{Q}$ becomes more nonuniform, the higher overall $\dot{V}_A/\dot{Q}$ assures that little if any of the lung will be markedly underventilated (i.e., $\dot{V}_A/\dot{Q} < 0.8$). Alveolar P_{O_2} is therefore maintained high throughout the lung and this assures maintenance of end-capillary P_{O_2} near resting levels, even in the face of a progressive reduction in mixed venous O_2 content.

A second contributing factor to the $A\text{-}aDO_2$ is the mixing of shunted blood (i.e., venous blood that does not pass a ventilated alveolus) with arterial blood. There are two types of shunt that may contribute to the $A\text{-}aDO_2$ in health. The first type is known as an extrapulmonary shunt, and – in health – primarily consists of Thebesian venous drainage from the coronary circulation, which drains deoxygenated blood directly into the left ventricle.[64] Extrapulmonary shunts as small as 1% to 2% of the cardiac output have been calculated to account for about half of the $A\text{-}aDO_2$ during moderate intensity exercise.[62] Importantly, these shunts would be expected to increase total venous admixture during exercise of increasing intensity due to both a decreased O_2 content of Thebesian effluent (as a result of increased myocardial O_2 extraction)[65] as well as increased total Thebesian flow.

A second type of shunt that may contribute to the $A\text{-}aDO_2$ is commonly referred to as an intrapulmonary shunt, and is the result of direct anatomic connections between pulmonary arterial and venous vessels. These arteriovenous connections have been shown to exist in isolated, perfused whole human lungs.[66,67] and would be expected to have a greater influence on Pa_{O_2} during exercise of increasing intensity as $P\overline{v}_{O_2}$ falls. To date only indirect methods – using a delayed echo-Doppler visualization of intravenous infused microbubbles in the left atrium – support the concept that the intrapulmonary shunt pathway opens during exercise in healthy humans.[68] While the distensibility of this shunt pathway may modify the rise in pulmonary artery pressure during exercise, there is no evidence to indicate that it influences pulmonary O_2 exchange.[69]

SUMMARY: THE OVERBUILT HEALTHY RESPIRATORY SYSTEM

Based on our discussion to date of the respiratory system response to exercise in the untrained healthy adult there appears to be few exceptions to the conclusion that the respiratory system is substantially "overbuilt" and precisely regulated in meeting metabolic requirements of up to 10 to 12 times the resting levels. Key lines of supportive evidence include the following:

- At least three primary and redundant interrelated feedforward and feedback mechanisms combine – along with carotid chemoreceptors involvement with heavy exercise – to ensure near proportional ventilatory responses up to 10- to 12-fold increases in metabolic CO_2 production, that is, a highly precise isocapnic and mechanically efficient "just right" ventilatory response.
- Exercise-induced bronchodilation minimizes the increase in flow resistance respiratory muscle work and precise regulation of increases in V_T and f and reductions in EELV minimize increases in elastic work and V_D ventilation.
- A 20-fold increase in $\dot{V}_E$ is accomplished using less than 50% of the dynamic capacity of inspiratory muscles for force generation and requiring less than 10% of maximum $\dot{V}_{O_2}$ and cardiac output and with tidal flows and volumes which are well within the healthy airways maximal flow:volume envelope.
- Slight increases in overall $\dot{V}_A$:$\dot{Q}$ maldistribution and a small shunt of desaturated mixed venous blood results in a widened alveolar to arterial P_{O_2} difference signifying some degree of inefficiency in pulmonary gas exchange during exercise. However, high overall $\dot{V}_A$:$\dot{Q}$ raises alveolar P_{O_2} sufficiently to avoid severely low $\dot{V}_A$:$\dot{Q}$ regions and prevent arterial hypoxemia.
- The thin-walled and extensive capillary network and "passive" regulation of the pulmonary circulation during exercise, combined with a high capacity thoracic lymphatic "sump pump" in the lung interstitium, means that up to a fourfold increase in cardiac output and pulmonary blood flow do not result in critical reductions in mean red cell transit time or in accumulation of edematous fluid in the alveoli.

The result of these special structural characteristics and neuroregulation in the healthy lung parenchyma, airways, vasculature, and respiratory muscles is that the respiratory system contributes little to the limitation of O_2 transport to working locomotor muscles or to the symptoms of effort perception accompanying exercise and therefore to the limitation of either $\dot{V}_{O_{2max}}$ or endurance exercise performance.

EXCEPTIONS TO THE RULE—RESPIRATORY SYSTEM LIMITATIONS

There are a growing number of instances being reported in which the healthy respiratory system response to acute exercise appears to be less than "adequate" or inefficient, thereby contributing to exercise

limitation and that repeated bouts of high-intensity exercise experienced in the elite endurance-trained athlete may even be maladaptive.

- In a significant number of highly trained endurance athletes exercise-induced arterial hypoxemia (EIAH) occurs (SaO_2 rest to exercise, ~–5 to –10%) secondary primarily to an excessively widened alveolar to arterial O_2 difference and often in combination with a limited hyperventilatory response (see Fig. 18-7 and Table 18-1).[58,70] Preventing this hypoxemia (via increased FI_{O_2}) raises $\dot{V}_{O_{2max}}$ (up to 15%) or with longer endurance-type performances reduces the rate of development of limb locomotor muscle fatigue and improves performance time.[71,72] Accumulation of edematous fluid and red cells in the alveoli has also been reported at these high work rates – suggesting a disruption in the alveolar–capillary barrier because of excessive pulmonary capillary hydrostatic pressures.[73] There are a number of continuing mysteries surrounding EIAH including, why the excessive A-aDO_2, that is, diffusion, shunt and/or $\dot{V}A$:$\dot{Q}$ nonuniformity? …why does the hypoxemia first appear in submaximal exercise? … and why is there such marked heterogeneity in its occurrence among subjects of equal high fitness levels[15,74]?
- Heavy exercise-induced expiratory flow limitation with some degree of hyperinflation occurs at high ventilations in many young trained athletes and even at not so high ventilations in healthy fit elderly and in female athletes (see examples below under "Healthy Aging").This incurs a limitation to expiratory flow and to ventilation, causes high rates of inspiratory and expiratory muscle force generation (see Fig. 18-4, right) and high levels of expiratory ITP which compromises stroke volume and cardiac output. Increasing the maximal flow–volume loop via breathing low-density gases such as $He:O_2$ prevents this expiratory flow limitation and increases the ventilatory response to heavy exercise.[75]
- When cardiac output exceeds 25 L/min during exercise in endurance athletes mean pulmonary arterial pressures will often exceed 35 to 40 mm Hg because of the limited capability of the pulmonary vasculature (relative to the systemic vasculature) to reduce its vascular resistance.[69,76] Accordingly, a substantial stress is placed on the right ventricle wall which greatly exceeds that on the left ventricle.[77] With prolonged heavy intensity exercise this substantial vascular load results in reduced RV (but preserved LV) function as reported following a marathon or triathlon.[78]
- If the exercise is of very high intensity and sustained, significant fatigue occurs in the diaphragm and expiratory muscles thereby promoting increases in sympathetic vasoconstrictor activity and a reduction in limb vascular conductance and blood flow. Use of positive pressure mechanical ventilation during exercise to prevent respiratory muscle fatigue, also reduces the rate of limb muscle fatigue development and improves endurance performance.[79,80]

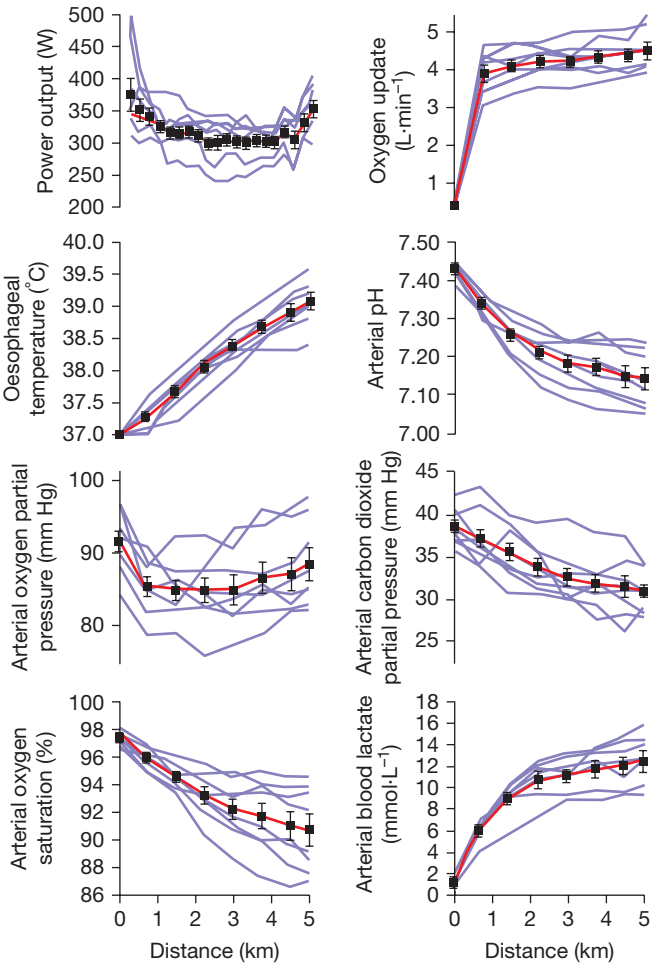

Figure 18-7 Effects of a 5-km time trial (cycle ergometer) in a normoxic environment on the physiological responses of trained cyclists. Thin lines are individual data ($n = 8$), with thick lines showing mean responses. Mean performance time was 483.4 ± 7.5 seconds (range, 437.5–478.4 seconds). Hemoglobin concentration was 14.4 ± 0.5 g L^{-1} and arterial oxygen content was 19.8 ± 0.8 mL O_2 100 mL^{-1} at rest and 16.4 ± 0.7 mL O_2 100 mL^{-1}/20.9 ± 1.0 mL O_2 100 mL^{-1} at 5 km. Note the progressive reduction in arterial hemoglobin O_2 saturation, due to a reduced Pa_{O_2} in the early stage of exercise, and thereafter to a progressive metabolic acidosis and increasing blood temperature. Also note the marked heterogeneity among subjects in their regulation of arterial P_{O_2}, Sa_{O_2}, and P_{CO_2}. (*Modified with permission from Amann M, Eldridge MW, Lovering AT, Stickland MK, Pegelow DF, Dempsey JA. Arterial oxygenation influences central motor output and exercise performance via effects on peripheral locomotor muscle fatigue in humans. J Physiol. 2006;575(Pt 3):937–952.)*

SPECIAL CASES OF RESPIRATORY SYSTEM LIMITATION TO EXERCISE PERFORMANCE

Healthy aging. Beginning in the second decade of life the healthy nonsmoking lung begins to lose elastic recoil (see Fig. 18-8A). This leads, during exercise, to expiratory flow limitation—with sequelae as described earlier such as ventilatory limitation, maldistribution of inspired ventilation, compromised stroke volume, and a significant prevalence of arterial hypoxemia (see Fig. 18-8B).[81] As mentioned earlier, expiratory flow limitation and its sequelae also occur during heavy/maximum exercise in the young highly trained athlete but with aging this occurs at much lower metabolic rates and ventilations than in the young (see Fig. 18-8B and contrast to Fig. 18-4 in younger athletes). Loss of elastic recoil also influences ventilation distribution in the lung resulting in a high V_D/V_T in the elderly. The V_D/V_T undergoes the normal decline during exercise but at a higher absolute V_D/V_T. This means that the healthy elderly must increase their $\dot{V}_E$ not only in proportion to the rising $\dot{V}_{CO_2}$ but also to accommodate the raised V_D. Remarkably this "extra" hyperpnea does indeed occur and Pa_{CO_2} is regulated at resting levels, but this homeostatic regulation also means greater ventilatory work and higher flow rates thereby increasing the probability of flow limitation—especially in the highly fit older subject during heavy intensity exercise.

Gender differences. Exercise-induced expiratory flow limitation is more prevalent in young healthy females versus males and occurs at lower levels of metabolic and ventilatory demand.[82] The explanation for this gender difference appears – as based on CT scan evidence – to be one of airway structure limitation, that is, the so-called airway dysanapsis wherein the diameter of intralobar airways is narrowed for any given lung volume in the female.[83] This gender difference blunts the ventilatory response to heavy exercise[82] and may also lead to maldistribution of inspired ventilation which may explain at least

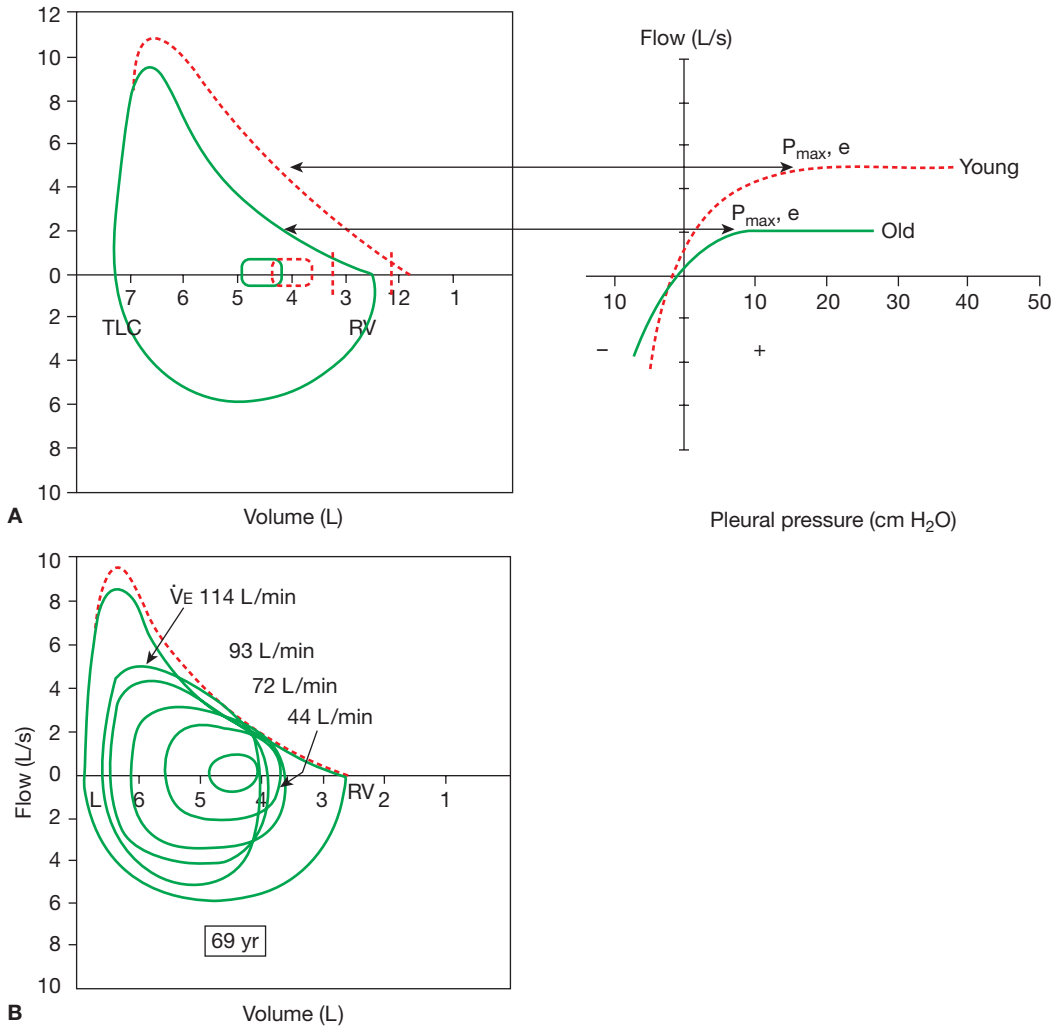

Figure 18-8 **A.** Maximum flow:volume loops and the isovolume pressure:flow relationships in the 30-year-old *(dashed line)* and 70-year-old nonsmoking male *(solid line)*. Note in the older subject the "scooping" in the expiratory limb of the maximum flow:volume loop indicating that airways are narrowing thereby reducing flow rate at any given lung volume during most of a forced expiration. The diagram on the right hand side shows that expiratory flow increases with increasing expiratory effort up to the critical closing pressure (P_{max}, e), at which point, despite additional expiratory effort, airways narrow and close and no increase in flow rate is achieved. Note the much lower P_{max}, e in the older subjects. Also note in the left hand figure that the end-expiratory lung volume is higher in the aged as is the airway closing volume *(solid line)*. These changes in the flow:volume loop and in airway closing volume and in the critical closing airway pressure occur with aging because of reduced lung elastic recoil. **B.** Flow:volume relationships at increasing levels of ventilation during steady-state exercise in the highly fit 69-year-old person. Contrast these with Figure 18-4 in the younger subject. The largest flow:volume envelope shown is that achieved via maximum volitional effort at rest, preexercise *(solid line)* and postexercise *(dashed line)* and the flow:volume loops within this maximal loop are from tidal breaths at rest and during increasing exercise intensities. In older subjects significant expiratory flow limitation begins at exercise ventilations (70 L/min or less) that are much lower than in the younger subject (>100 L/min.) Also note in the older subject that with the onset of the intersection of the tidal with the maximum expiratory flow–volume loop, end-expiratory lung volume increases back to and even in excess of resting levels. *(Reproduced with permission from Johnson BD, Reddan WG, Seow KC, Dempsey JA. Mechanical constraints on exercise hyperpnea in a fit aging population. Am Rev Respir Dis. 1991;143(5 Pt 1):968–977.)*

some of the occurrence of the widened A-aDO_2 and hypoxemia at lower work rates in female- versus male-trained athletes.

Athletic species differences. The thoroughbred horse with a $\dot{V}_{O_2max}$ >160 mL/kg/min or more than twice that of the highest fit humans are the epitome of respiratory system limitations as shown by substantial arterial hypoxemia and CO_2 retention, pulmonary hypertension, and alveolar–capillary barrier disruption developed by these equine athletes during exercise.[84] Thus the lung appears to be truly "under built" in these amazing athletes in terms of its capability for accepting the very high cardiac outputs and ventilations required by their large cardiovascular and locomotor muscle driven metabolic requirements. This respiratory system limitation to exercise contrasts sharply with other highly aerobic animals such as the prong-horned antelope whose $\dot{V}_{O_2max}$ is almost double that of the thoroughbred horse but has substantial upregulation of its lung alveolar–capillary surface area that is capable of accommodating their high metabolic requirements.[85]

Extrathoracic, upper airway flow limitation. A growing number of reports demonstrate that some athletes undergo sudden onset, paradoxical narrowing of the glottic aperture (vocal cord dysfunction or VCD) during exercise of severe intensity demanding high rates of airflow. This event immediately precipitates flow limitation, CO_2 retention, hypoxemia, and dyspnea. Evidence is accumulating to suggest that a highly significant portion of these VCD cases are wrongly diagnosed as asthma and therefore improperly treated—often with high doses of inhaled corticosteroids over many years.[86–88] Exercise-induced VCD seems to be especially prevalent in the highly competitive young adult or adolescent endurance athlete of both sexes. In a

large group of elite endurance athletes about 5% experienced symptoms of inspiratory stridor during heavy exercise and about one-half of these cases showed both VCD and exercise-induced asthma.[89]

The key to detecting exercise-induced VCD is to understand that this problem involves extrathoracic airway narrowing in both inspiration and expiration and that it most commonly occurs only *during* heavy intensity exercise with sudden onset when flow rates are high. Immediately following cessation of exercise, as air flow rate falls precipitously, the extrathoracic airway diameter is usually no longer compromised. Therefore, an appropriate (noninvasive) test to detect VCD is to examine the characteristics of the breath-by-breath, tidal flow:volume envelope *during* exercise—because the usual means of examining forced maximum expiratory maneuvers, pre- and/or postexercise, will most often miss the event.[88] Accompanying sudden increases in end-tidal P_{CO_2} and reductions in Sa_{O_2} are also helpful markers of VCD. For diagnostic purposes, it is especially important that heavy intensity exercise demanding high flow rates be employed.

Perhaps the starting point here is for the clinician to recognize that not all symptoms of exercise-induced shortness of breath in the competitive athlete are attributable to the intrathoracic airway. Furthermore, the failure of routine spirometry or acute bronchodilator or airway provocation tests to detect significant asthma may not just be due solely to the high intra and inter individual variability in these tests. Please consider the upper airway.

Training effects on the respiratory system – an enigma. The examples of the respiratory system limitations in the equine and human athletes cited earlier raise the question of why the respiratory system has not – apparently – adapted to meet the increased maximum metabolic requirements in the highly trained. After all, there is ample evidence of alveolar and capillary growth in response to chronic hypoxia in the maturing human and canine lung.[90,91] Even caloric restriction with refeeding and partial pneumonectomy elicit substantial compensatory growth in the lung's diffusion surface of rodents.[92] In contrast, there is substantial evidence that chronic physical training does not enhance structure or function of the lungs airways, diffusion surface, or pulmonary vasculature.[93–95] Even the normal age-dependent loss of lung elastic recoil and diffusion capacity and the occurrence of exercise-induced expiratory flow limitation were unaltered by chronic habitual physical training, as demonstrated via longitudinal study of long-distance runners in their sixth and seventh decades of life.[96] To the contrary, evidence is now accumulating to show that reactive, asthmatic airways are highly prevalent in elite endurance-trained athletes. Further, longitudinal training studies – including the use of repeated airway biopsies in elite cross-country skiers – revealed that much of this hypersensitivity may result from hyperpnea-induced epithelial airway injury and subsequent airway repair and remodeling (see Fig. 18-9). Airway dehydration and shear stress along with increased transmural pressure gradients occurring repeatedly with sustained heavy exercise may be the cause of epithelial injury.[97–99] These negative effects on the airway of high-intensity physical training stand in contrast to evidence showing an alleviation of airway hyperresponsiveness in mildly asthmatic children achieved via moderate intensity level training.[100] One potential mechanism accounting for these training-induced reductions in airway responsiveness may be a reduced tone of airway smooth muscle secondary to hyperpnea-induced repeated stretching of the airway. This positive training effect on the airways has also been observed in nonasthmatic sedentary children.[101]

In contrast to the lung, the inspiratory muscles of the chest wall do undergo substantial changes in strength and aerobic capacity with intense training as induced by either whole-body training or specific respiratory muscle training.[102] This training effect on the respiratory muscles might improve exercise performance in health and disease.[103,104] One such mechanism for this improvement

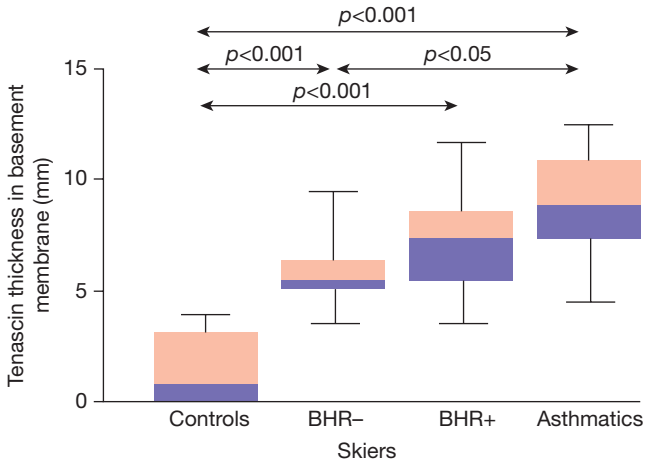

Figure 18-9 Thickness of tenascin immunoreactive band in subepithelial basement membrane zone in controls, in cross-country skiers with (+) and without (–) bronchial hyperresponsiveness (BHR), and in asthmatic subjects. Horizontal bar = median value. The basement membrane thickness is increased in all skiers relative to control subjects, indicating airway remodeling from chronic exercise training. In addition, skiers with asthma-like airway hyperresponsiveness tended to have a greater degree of remodeling. *(Reproduced with permission from Karjalainen EM, Laitinen A, Sue-Chu M, Altraja A, Bjermer L, Laitinen LA. Evidence of airway inflammation and remodeling in ski athletes with and without bronchial hyperresponsiveness to methacholine. Am J Respir Crit Care Med. 2000;161:2086–2091.)*

may involve a delay in diaphragm fatigue during prolonged heavy exercise, which would be expected to reduce metaboreflex effects on sympathetic, vasoconstrictor outflow and prevent reductions in blood flow and oxygen transport to limb locomotor muscles. This hypothesis has not yet been tested during whole-body exercise.

Hypoxic environments. Even mild elevations in altitude, that is, to only 1000 m or so have significant detrimental effects on $\dot{V}_{O_{2max}}$ and endurance performance. This is especially true in the highly trained athlete who may experience or be very close to significant arterial O_2 desaturation even at sea level and will undergo diffusion limitation and severe O_2 desaturation during exercise at even mild elevations in altitude (see Fig. 18-10).[58] Three major factors come into play as limiting factors to exercise performance at altitude in both acute and long-term hypoxic exposures. First, exercise-induced arterial O_2 desaturation and reduced O_2 transport will exacerbate fatigue of limb locomotor muscles, which in turn feeds back via limb afferents to inhibit cortical motor output, that is, "peripheral" leading to "central" fatigue.[105] Second, the marked hyperventilatory response to exercise in hypoxia is critically important to minimizing arterial O_2 desaturation – but at the same time comes at the cost of increasing respiratory muscle work. This increased respiratory muscle work hastens the onset of diaphragm fatigue, activation of the respiratory muscle metaboreflex triggering sympathetically mediated vasoconstriction of the locomotor muscle vasculature. Thus, a greater share of the cardiac output will be devoted to respiratory locomotor muscle blood flow and limb fatigue is exacerbated.[106] Third, CNS hypoxia, per se, depresses brain neurotransmitter turnover and inhibits motor output to locomotor muscles, that is, the so-called "central fatigue."[107]

Thus, in hypoxic environments both exercise-induced arterial O_2 desaturation and excessive blood flow requirements of the respiratory muscles would contribute significantly to exercise performance limitations by compromising O_2 transport to locomotor muscle ("peripheral" fatigue) and to the brain ("central" fatigue). CNS hypoxia, per se, appears to increase its relative contributions to exercise limitation as the severity of hypoxemia intensifies.

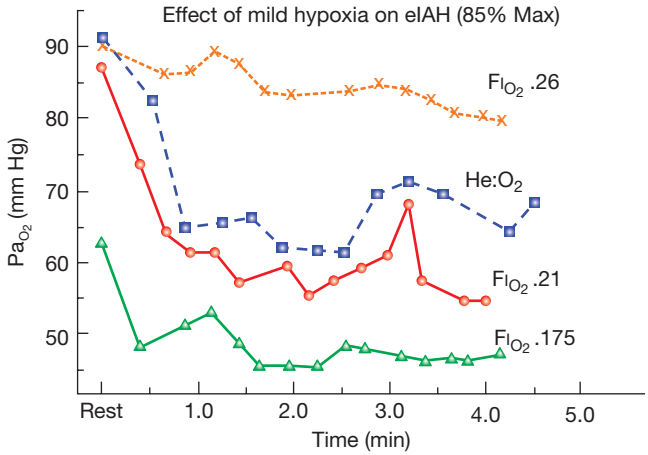

Figure 18-10 Effects of varying $F_{I_{O_2}}$ and of normoxic helium breathing on Pa_{O_2} during constant treadmill running at 15 mph (0% grade) i.e., 4 min. mile pace, in one fit subject ($\dot{V}_{O_2}$ = 4.54 L/min, or 97% $\dot{V}_{O_{2\,max}}$) ×, 0.26 O_2:N_2; o, 0.209 O_2:N_2; Δ, 0.175 O_2:N_2; □, 0.21 O_2:He; (b) the increase in Pa_{O_2} with He:O_2 breathing (vs. air) reflects the higher ventilation because the low air density gas decreased airway resistance and expanded the maximum flow:volume envelope, thereby reducing expiratory flow limitation during exercise; and (c) the prevention of arterial hypoxemia during exercise with mild inspired hyperoxia (0.26 $F_{I_{O_2}}$), indicating that the hypoxemia was not secondary to an extrapulmonary shunt. Note the marked arterial hypoxemia during exercise which accompanied the exposure to mild acute hypoxia (0.175 $F_{I_{O_2}}$). *(Modified with permission from Dempsey JA, Hanson PG, Henderson KS. Exercise-induced arterial hypoxaemia in healthy human subjects at sea level. J Physiol. 1984;355:161–175.)*

SUMMARY

With few exceptions it is safe to generalize that the healthy respiratory system – especially in youth and at sea level – is truly "overbuilt" to efficiently meet the considerable gas transport demands imposed by exercise. The key responses of the respiratory system insuring this homeostatic response include prevention of arterial O_2 desaturation and minimizing the work and therefore metabolic and circulatory costs of breathing. In turn these appropriate respiratory responses are insured by both the very special anatomical structure of the airways, lung parenchyma, pulmonary vasculature, and respiratory musculature as well as the precision with which ventilation is matched to metabolic requirements by the multifaceted autonomic control system. Among highly trained endurance athletes with near-normal respiratory system capacities but supernormal cardiovascular and locomotor capacities, the high demands for systemic O_2 transport do – in rare instances – exceed the lung's gas-exchange capabilities. More often in the highly trained, the high ventilatory requirements demand excessive respiratory muscle work and blood flow. So in these instances, the respiratory system will contribute significantly to exercise limitation. However, even in these cases cardiovascular system limitations remain the major "weak link" in O_2 delivery. Finally, there are instances where inadequacies within the healthy respiratory system impose more significant limitations to locomotor muscle O_2 transport and to exercise performance, including normal aging and gender effects on lung elastic recoil and/or airway resistance and upper airway patency during heavy intensity exercise. Again, the highly trained are more susceptible to these severe respiratory limitations because of their high demand for O_2 transport. Finally, the hypoxic environment through its effects on pulmonary diffusion limitation and ventilatory requirements greatly enhances the contribution of the respiratory system to O_2 transport and exercise performance limitations.

CHAPTER 19

Aging of the Respiratory System

Edward J. Campbell

The fastest growing segment of the US population consists of individuals of age 65 and older. In the 2010 census, this segment comprised 16% of the population. Since the 1950s, the median age of the US population has increased by 20 years.

The largest decrements in age-adjusted death rates have been occurring in older patients. With the increasing longevity of human population, it is necessary to understand the effects of aging on the respiratory system in healthy people. Perhaps more importantly, because the age-related decrements in respiratory system function can be unmasked by disease, it is critically important to point out that the aged: (1) have an enhanced predisposition to lung disease; (2) have a decreasing reserve of respiratory system function that decreases their ability to cope with the stresses of illness, injury, and surgery; and (3) may have differing responses to therapy when compared with their younger counterparts.

Even in individuals who enjoy apparently good health, there are measurable decrements in function of the respiratory system with age. These changes occur progressively as a healthy individual grows older and are most marked beyond 60 years of age. Cross-sectional studies show clear differences between elderly and young persons with regard to the structure and function of the components of the respiratory system (Table 19-1). As we will see, however, caution must be exercised in ascribing observed changes to age alone. It is also necessary to be aware that longitudinal studies of "healthy" individuals followed to old age are essentially not available. Where appropriate, methodologic problems in the available cross-sectional studies are described.

Although age-associated changes can be measured easily by objective testing, it is important to note that the routine activities of healthy elderly persons are not limited by the decreasing respiratory system function. However, whereas youthful persons have a marked excess of functional capacity over the amount required to meet metabolic needs at rest or with stress (physiologic reserve), the respiratory system draws on this reserve as its function declines with age. Thus, the physiologic reserve, especially for alveolar gas exchange, is reduced with aging. This leaves elderly individuals vulnerable to stresses, diseases, and injuries that are weathered much more easily in the young.

ARE CHANGES IN THE RESPIRATORY SYSTEM CAUSED BY AGING OR RELATED TO AGE IN OTHER WAYS?

For decades, the phenomena explained purely by aging have been required to satisfy specific principles. Roughly according to Hayflick,[1] the changes must be (1) intrinsic (as opposed to environmentally mediated); (2) universal; (3) progressive; and (4) usually detrimental to the organism. Developing an understanding of changes to the lung over time is complicated by the fact that the lung is an open system that is exposed to environment. As such, it is assaulted by respiratory infections and by a constant barrage of particulates and other air pollutants. In addition, the lungs are commonly exposed to tobacco smoke, to occupational dusts and fumes, and to effects of aspiration. At times, environmental influences are inextricably involved in the changes that are observed in the respiratory system over time. However, it is important to draw a distinction between alterations

TABLE 19-1 Respiratory System: Functional Divisions and Changes with Aging

Functional Division	Components	Function	Change(s) with Aging
Conducting airways	All airways not involved in gas exchange (mouth to terminal bronchioles)	Gas movement between environment and alveolar space	Slight changes in size; calcification; glandular hypertrophy
Lung parenchyma	Gas-exchanging airways and vessels; connective tissue framework	Gas exchange between alveolar space and capillary blood	Enlarged terminal airspaces; ventilation/perfusion mismatching
Bellows apparatus	Chest wall and muscles of respiration	Provide mechanical forces for ventilation	Increased rigidity of chest wall; decreased respiratory muscle strength
Ventilatory control	Respiratory control center (pons and medulla); carotid and aortic bodies	Maintaining homeostasis by altering ventilation to match metabolic needs	Markedly decreased responses to hypercapnia and hypoxemia
Cardiovascular system	Heart and systemic vasculature	Blood transport and tissue exchange of respiratory gases	Decreased maximal heart rate and cardiac output; decreased responsiveness to hypoxemia

purely related to aging and those associated with older individuals. Purely age-related changes are biologic phenomena and irreversible. Other alterations associated with increasing age have the potential to be preventable, treatable, and/or reversible.

CHANGES IN THE UPPER AIRWAY

There is a clearly increased risk of aspiration in the elderly that is thought to be a consequence of a number of age-related factors, including comorbid illnesses and debility, medications, and the aging process itself. With regard to purely age-related changes, attention has been focused upon the cough and swallowing reflexes, both of which are protective against aspiration. In the past, these reflexes have been thought to be controlled primarily by the brainstem, but there is now evidence that cortical and subcortical structures play critical roles in their control.[2] By their nature, reflexive cough and swallowing activate both sensory and motor areas in the cortex. The sensory component, including the sensory cortex in reflexive circuits, seems to be more vulnerable to aging than the motor component, including the motor cortex. Therefore, strategies to restore effective cough and swallowing reflexes should be focused upon compensations of sensory components.

Variable amounts of aspiration of both oropharyngeal contents (food particles, saliva, and oropharyngeal organisms), and also gastric contents (food particles and gastric secretions including gastric acid), are increasingly common with aging. Aspiration is particularly common in the very old. Because of the sensory alterations discussed earlier, aspiration in elderly individuals can be associated with few, or no, symptoms.[3]

A potentially important contributor to aspiration is gastroesophageal reflux. In accordance with the earlier discussion of sensory impairments, reflux esophagitis severity increases with age while heartburn severity decreases with age.[4] Consequences of gastroesophageal reflux may be exacerbated by esophageal motor abnormalities associated with aging. Recurrent aspiration of gastric contents in the elderly can lead to airway inflammation, bronchiectasis, and pneumonia.

STRUCTURAL CHANGES IN THE LUNG

Studies of the aging lung have shown changes in shape, with increase in anteroposterior diameter that lead to a "rounding" shape of the lung. These changes are presumably secondary to changes in the shape of the surrounding thoracic cage that are very common after the age of 75. In a study of 100 chest radiographs from individuals ranging in age from 75 to 93 years, 25% had severe kyphosis (>50 degrees) and 43% had moderate kyphosis (35–50 degrees) from vertebral fractures.[5]

CONDUCTING AIRWAYS

The conducting airways consist of the air passages from mouth to the level of respiratory bronchioles. Their volume comprises the anatomic dead space, and their geometry is a primary determinant of airway resistance. The larger cartilaginous airways show a modest increase in size with age, resulting in slight but probably functionally insignificant increase in anatomic dead space. Although calcification of cartilage in the walls of the central airways and hypertrophy of bronchial mucus glands is seen in advanced age, these changes in the extraparenchymal conducting airways appear to have little or no physiologic significance.

Ciliary motility is significantly decreased in subjects over the age of 60, which likely further increases the risk of lower respiratory infection and inflammation.[6]

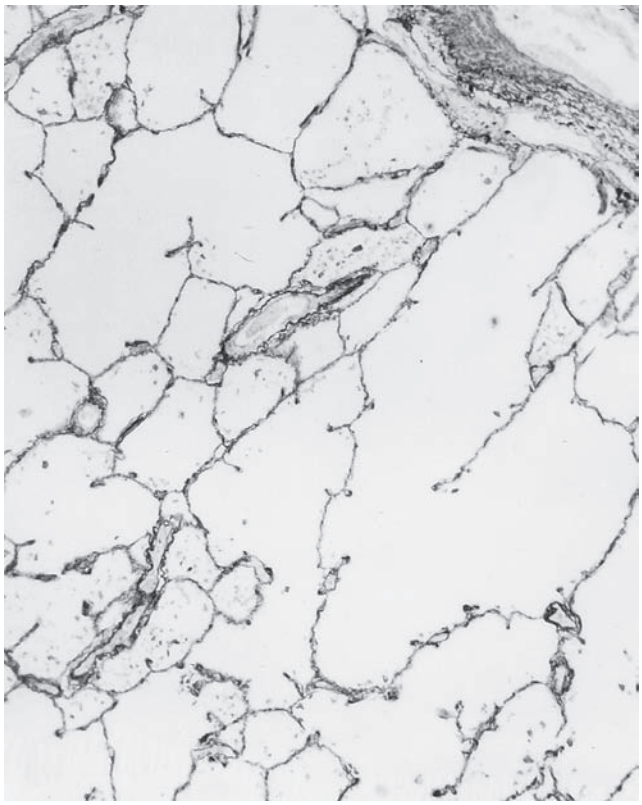
LUNG PARENCHYMA

After the age of 30 or 40, the respiratory bronchioles and alveolar ducts undergo progressive enlargement (Fig. 19-1). This change has been termed "ductectasia" because of the prominent finding of enlargement of alveolar ducts.[7] The proportion of the lung made up of alveolar ducts increases, and alveolar septa become shortened, leading to a "flattened" appearance of the alveoli. With the change in geometry, the distance between alveolar walls (known to morphologists as the mean linear intercept, or MLI) increases, while the surface-to-volume ratio of the lung decreases.[8] The age-related enlargement of the terminal respiratory units also produces a decrease in the percentage of parenchymal air contained within the alveoli.[9] The net result of these structural changes is that the alveolar surface area decreases by approximately 15% by age 70.

Pulmonary emphysema is also characterized by an increase in the size of terminal airspaces, an increase in MLI, and a decrease in surface area; however, destruction of alveolar septa with fusion of terminal airspaces is a defining characteristic of emphysema. There have been some reports of emphysematous lesions in aged lungs, but it is not certain that smokers were excluded from these studies. Since the fate of individual alveolar septa during the aging process has been somewhat controversial, some have referred to the histologic changes in aged lungs as "senile emphysema." A National Heart, Lung, and Blood Institute Workshop on the definition of emphysema[10] weighed the available evidence, and decided not to include age-related changes in the lung parenchyma under the definition of *emphysema*. To simplify terms and avoid confusion, they recommended use of the term *aging lung* to apply to the uniform airspace enlargement that develops with increasing age. Despite the continued use of "senile emphysema," this term should be avoided.

Computed tomography of the chest in individuals over 75 years of age has shown a surprising prevalence (60%) of a subpleural

A



B

Figure 19-1 Histologic changes in the aging lung. **A.** Normal lung of a 36-year-old woman. **B.** Lung of a 93-year-old woman. In (**B**), the alveolar ducts are dilated, and shortening of inter-alveolar septa is observed. *(Used with permission of the Mayo Foundation; photomicrographs used with permission of Charles Kuhn III, MD.)*

basilar reticular pattern that was absent from images from a control population that was less than 55 years old. Lung cysts were seen in 25% of the elderly subjects, but none of the controls.[11] These findings are usually associated with interstitial lung disease, but in the elderly they seem not to reflect a clinically relevant disease process. Caution must be exercised to avoid overreacting to similar image findings in older patients.

CHANGES IN MECHANICAL PROPERTIES OF THE LUNGS

Both the Lungs and chest wall are elastic. The resting volume of excised lungs is smaller than that contained within an intact thoracic cage, because the lungs are held at an increased volume by the outward recoil forces of the chest wall. Thus, in the intact thoracic cage, the lungs exert an inward recoil force. The retractile force of the lungs, or the "elastic recoil," can be measured during life by estimating the pleural pressure with an esophageal balloon at progressively decreasing lung volumes from total lung capacity to functional residual capacity (FRC), when the airways are open and there is no air flow. The negative pleural pressure is generated by the lungs' elastic recoil forces.

The pressure measurements may be displayed on a pressure–volume diagram (Fig. 19-2). Figure 19-2 compares, at the same volume, the elastic recoil pressures of a young man, a normal elderly adult, and a patient with emphysema. The normal elderly individual and the patient with emphysema, both have a greater decrease in elastic recoil pressure than does a young person.[12] This is reflected in the leftward shift of their pressure–volume curves.[13–16] This loss of elastic recoil is the physiologic hallmark of emphysema. However, emphysema is characterized by a much greater loss of elastic recoil than is caused by aging alone.

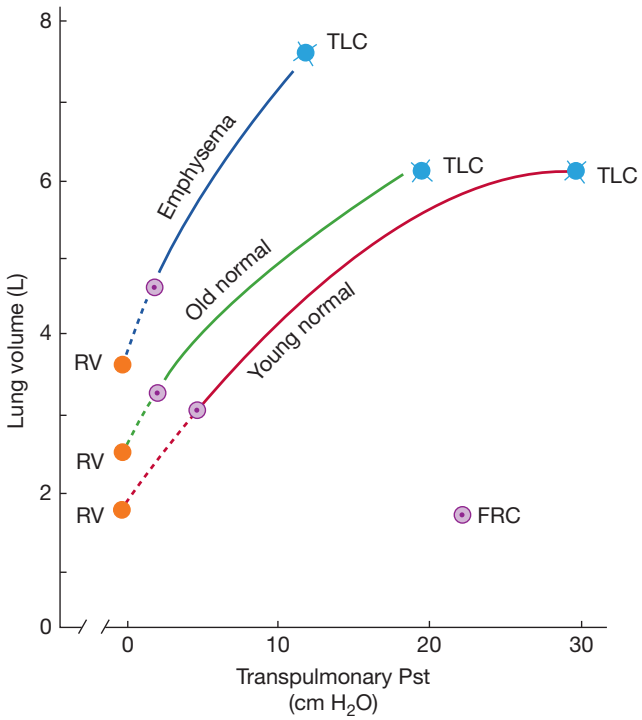


Figure 19-2 Static pressure–volume curves of the lungs. Static recoil pressure, expressed as transpulmonary pressure measured at various lung volumes, is plotted against lung volume on the ordinate. Note that at any lung volume, the recoil pressure is less in the aged individual than in the young, normal control, resulting in a pressure–volume curve that is shifted upward and to the left. For comparison, a curve for a patient with emphysema is shown. In emphysema, recoil pressures are reduced much more, and lung compliance (the slope of the pressure–volume relationship) is clearly abnormal. *(Reproduced with permission from Pride NB. Pulmonary distensibility in age and disease. Bull Physiopathol Respir. 1974;10(1):103–108.)*

There has been some disagreement regarding the effects of aging on lung compliance (Δ volume/Δ pressure; that is , the slope of the pressure–volume relationship Fig. 19-2). The question is whether there is a parallel leftward shift of the pressure–volume curve with aging (no change in compliance), or, instead, a steeper slope in addition to a shift (indicating an increase in compliance), as seen in emphysema. In aged individuals, the static pressure–volume curve is slightly steeper and is more concave in relation to the pressure axis. However, there is a general agreement that changes in lung compliance with aging are not physiologically significant.

Two forces in the lung parenchyma are responsible for producing the elastic recoil of the lungs. The greatest part of the elastic recoil forces is provided by the surface tension at the curved air–fluid interface of the small airways and alveoli. The second retractive force is that produced when the fibrous skeleton of the lung (primarily the elastic fibers) is stretched.

CHANGES IN SURFACE FORCES

Most of the loss in lung recoil with age is likely to be related to the decrease in lung surface area with age The loss of surface area that accompanies aging can be expected to reduce the area of gas–liquid interface, resulting in a decrease in the surface tension forces and, ultimately, a decrease in the total elastic recoil of the lung. Whether it is due to loss of air–liquid interface or to changes in lung structural macromolecules the reduced elastic recoil has important consequences for the function of the intraparenchymal airways and, ultimately, on alveolar gas exchange and forced expiratory flow (see "Pulmonary Function Tests").

CHANGES IN STRUCTURAL MACROMOLECULES

Weibel has produced elegant studies of the "integral fiber continuum" that extends from the hila to the pleura. This consists of axial fibers extending to the alveolar septae, and septal fibers extending to the pleura.[17] Although most proteins in the lung turn over relatively rapidly, the structural proteins, elastin and collagen, in the lung fibrous network provide a very stable, long-lived skeletal structure for the lung.

Elastic fibers consist in large part of an extremely hydrophobic, highly cross-linked, and very elastic macromolecule (elastin). These fibers are thought to contribute substantially to lung elasticity. Analysis of whole lungs has revealed that the elastin content actually increases (rather than decreases) with age. More recent evidence indicates that the increase in lung elastin with age is accounted for by an increase in pleural elastin; parenchymal elastin does not change.

Careful studies of the elastic fibers in the lung parenchyma have shown that they are remarkably stable following postnatal lung growth. Certain biochemical changes in very long-lived proteins (change of amino acids into their mirror-image structures, or racemization) provide a type of "biological clock" that permits an estimate of the time that has elapsed since the proteins were synthesized. Because of the constraints of the protein synthetic mechanisms, only L-amino acids are incorporated into newly synthesized proteins. With the passage of years at body temperature, however, there is a readily measurable accumulation of D-aspartic acid. When all of the lung proteins are examined together, minimal D-aspartic acid is found. In purified lung elastin, however, there is an age-related accumulation of D-aspartic acid,[18] indicating that lung elastin is turning over very slowly if at all (Fig. 19-3). It has also been possible to estimate lung elastin turnover by measurement of the incorporation into elastic fibers of carbon 14 (^{14}C) from atmospheric nuclear weapons testing. For example, individuals who completed their postnatal lung growth prior to the nuclear age show no excess ^{14}C in their lung elastin, indicating absence of new elastin synthesis. In contrast, an appropriate excess of ^{14}C is found in the lung elastin of individuals whose lungs were growing in the post–weapons testing era. Modeling of the radiocarbon data indicates that the "mean carbon residence time" in elastin is 74 years.[18]

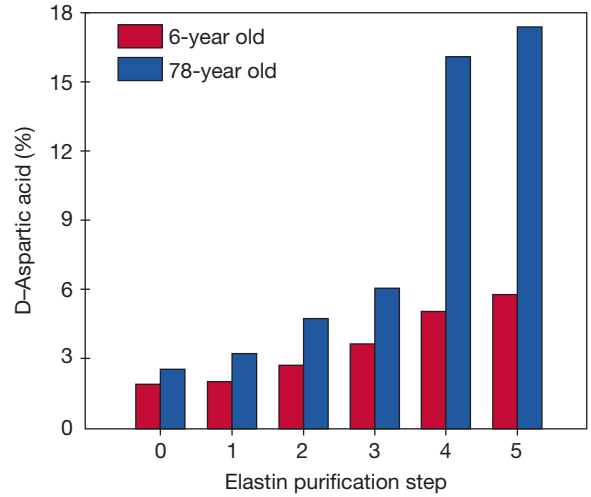

Figure 19-3 Longevity of human lung parenchymal elastin, as evidenced by in vivo racemization of aspartic acid. Each pair of bars shows results from two individuals with greatly differing ages at time of death. Step 0 of elastin purification represents whole lung parenchyma, while step 5 is purified elastin. D-aspartic acid detected in the 6-year-old specimen can be attributed to racemization that occurs during the analytical procedures, whereas, the difference in prevalence of D-aspartic acid between the young and old individual has resulted from racemization in vivo. Note that results from whole-lung hydrolysates (step 0) are similar for both specimens, reflecting their composition of proteins, having predominantly rapid turnover. However, purified elastin from the oldest specimen has racemized extensively in vivo, indicating that it was synthesized many decades before death. These data for elastin agree well with results for other very long–lived proteins. *(Reproduced with permission from Shapiro SD, Endicott SK, Province MA, et al. Marked longevity of human lung parenchymal elastic fibers deduced from prevalence of D-aspartate and nuclear weapons–related radiocarbon. J Clin Invest. 1991;87(5):1828–1834.)*

Taken together, the amino acid racemization and radiocarbon data indicate that lung parenchymal elastin is stable over the human life span, and it appears that the elastin content of the lung parenchyma not only does not change with age, but the individual fibers persist for at least many decades.

Other studies of lung elastic fibers have shown changes in the location and orientation of individual fibers with age as well as changes in the cross-linking of elastin. Thus, some authors have suggested that remodeling of the lung architecture may occur without replacement of elastic fibers. In any case, at the present time, the age-related changes in connective tissue do not provide a sufficient explanation for the decrease in elastic recoil forces observed in the elderly.

Studies of collagen in alveolar walls of humans, as measured by hydroxyproline, have failed to show a consistent change in its quantity during aging.[19] Although human studies have not been done, studies in rodents and birds suggest that lung collagen fibers, like elastic fibers, are very long-lived.[20] Finally, although some qualitative changes in collagen during aging have been described (decreases in solubility and increases in intermolecular cross-links), these appear to have no relationship to changes in lung elastic recoil.

Although convincing evidence for very slow compensatory human lung growth (over many years) has been provided following pneumonectomy,[21] under more ordinary circumstances it appears that the lung adapts to changing dimensions of thorax by realignment of its fibrous skeleton rather than by molecular remodeling.

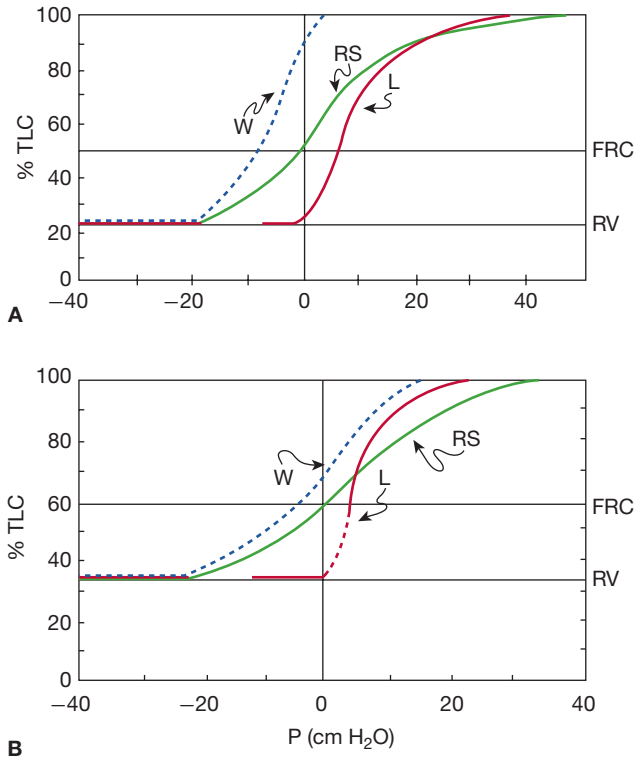

Figure 19-4 Static compliance relationships of the components of the respiratory system. (L, lungs; W, chest wall; RS, total respiratory system.) **A.** A 20-year-old man. **B.** A 60-year-old man. Note that the static compliance of the chest wall is substantially decreased (reduced slope) in the older individual, while functional residual capacity (the resting volume of the respiratory system, or the point at which the pressure gradient across the respiratory system is zero) increases. As in Figure 18-2, it is also apparent that the static recoil pressure of the lungs is reduced in the older subject. *(Data from Mittman C, Edelman NH, Norris AH, et al. Relationship between chest wall and pulmonary compliance and age. J Appl Physiol. 1965;20:1211–1216; and Turner JM, Mead J, Wohl ME. Elasticity of human lungs in relation to age. J Appl Physiol. 1968;25:664–671.)*

■ CHANGES IN CHEST WALL

There is good evidence that the chest wall becomes more rigid with advancing age.[22] As may be seen in Figure 19-4, the static pressure–volume curve of the chest wall is shifted to the right and is less steep with increasing age. The articulations of the ribs with the sternum and the spinal column may become calcified, and the compliance of the rib articulations decreases. The changes in rib articulations may be compounded by the development of kyphosis due to osteoporosis. The decreasing compliance of the chest wall demands greater work from the respiratory muscles. For example, in a 70-year-old person, approximately 70% of the total elastic work of breathing is expended on the chest wall, whereas this value is 40% in a 20-year-old person.

Figure 19-4 also demonstrates that the compliance of the total respiratory system decreases with age because the decrease in lung elastic recoil is outweighed by the changes in the mechanical properties of the chest wall.

CHANGES IN MUSCLES OF RESPIRATION

Age-related changes in nonrespiratory skeletal muscle include decreased work capacity due to alterations in the efficiency of muscle energy, metabolism, atrophy of motor units, and electromyographic abnormalities. Based upon lessons learned with other skeletal muscles, it appeared likely that age-related abnormalities in respiratory muscles also would be found.

An early study by Black and Hyatt appeared to confirm age-related decrements in respiratory muscle function by measuring maximal inspiratory pressure ($P_{I_{max}}$) and maximal expiratory pressure ($P_{E_{max}}$) in 120 normal individuals (both smokers and nonsmokers) between the ages of 20 and 70.[23] Maximal respiratory pressures in females were 65% to 70% of those in males. No significant age-related changes were observed in individuals under the age of 55. Trends toward reduced maximal respiratory pressures with age were seen in both genders and with both $P_{I_{max}}$ and $P_{E_{max}}$. With the number of males studied, the change with age in $P_{I_{max}}$ was not statistically significant for male gender.

More recently, McElvaney and coworkers came to a different conclusion in a similar study of 104 healthy individuals over the age of 55.[24] They found a large variation in maximal respiratory pressures from individual to individual (as by Black and Hyatt), but no significant correlation with age. In contrast, in a third population of 160 healthy individuals who ranged in age from 16 to 75 years, Chen and Kuo found significant gender differences in maximal respiratory pressures as well as trends toward decrements with age for $P_{I_{max}}$ and $P_{E_{max}}$ in both genders. The age-related change in $P_{E_{max}}$ in males was not statistically significant with the sample size studied. When the 40 individuals of both genders in the youngest age group (16–30 years) were compared with the 40 individuals in the oldest group (61–75 years), the decrement in $P_{I_{max}}$ was 32% to 36%, while the decrement in $P_{E_{max}}$ was 13% to 23%.[25] Representative findings for maximal respiratory pressures in women are illustrated in Figure 19-5.

Chen and Kuo also measured inspiratory muscle endurance against a resistive load, and found significant decrements with age. Physically active men had greater inspiratory muscle endurance than sedentary men.

In summary, it appears that when populations of healthy individuals of widely differing ages are studied, moderate age-related decrements in respiratory muscle strength and endurance can be

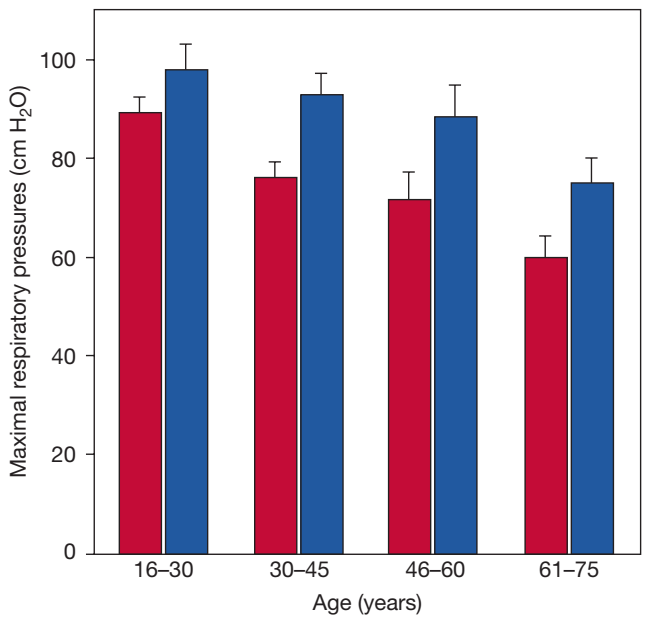

Figure 19-5 Representative variations in maximal respiratory pressures with age among women. Inspiratory and expiratory measurements were made at residual volume and total lung capacity, respectively. Maximal inspiratory pressure *(open bars)* and maximal expiratory pressure *(hatched bars)*. Error bars are standard errors of the mean. Although quantitatively moderate, variations with age were statistically significant for both measurements. *(Data from Chen H-S, Kuo C-S. Relationship between respiratory muscle function and age, sex, and other factors. J Appl Physiol. 1989;66(2):943–948.)*

found. These studies usually define *healthy* only by the absence of disease and do not control for physical activity. They are complicated by marked interindividual variability, and longitudinal studies have not been reported. Continuous respiratory muscle activity may have a training effect that leads to better preservation of respiratory muscle function when compared with other skeletal muscles. Finally, physical activity may have an additional training effect that enhances inspiratory muscle endurance in all age groups.

CONTROL OF BREATHING

In young individuals, minute ventilation is matched with metabolic demands. As a result, arterial blood gas values remain stable throughout a wide range of activities from rest to strenuous exertion, while oxygen consumption and carbon dioxide production are varying widely. Similarly, when the efficiency of gas exchange is diminished by lung disease or congestive heart failure, appropriate increases in minute ventilation minimize the resulting hypercapnia and/or hypoxemia in healthy young individuals. The ventilatory control system is described in detail in Chapter 11.

Ventilatory control mechanisms are typically tested by stressing the respiratory system, by inducing either hypoxemia or hypercapnia while monitoring ventilatory parameters (and often cardiac parameters as well). Such tests have shown striking differences between young and elderly individuals in both ventilatory and cardiac responses.

DIMINISHED VENTILATORY RESPONSE TO HYPERCAPNIA

Kronenberg and Drage compared the ventilatory responses to hypercapnia in eight young (mean age, 25.6 years) and eight elderly (mean age, 69.6 years) individuals.[26] During the tests, the subjects were asked to rebreathe 5% CO_2, while their $P_{A_{O_2}}$ was held above 200 mm Hg by supplemental oxygen to eliminate hypoxic ventilatory drive. Measurements were made while $P_{A_{C_2}}$ was allowed to rise to 65 mm Hg. Although there was considerable individual variation and some overlap between the groups, the elderly individuals had a significantly diminished ventilatory response to hypercapnia, measured as the slope of the relationship between ventilation and $P_{A_{C_2}}$.

DIMINISHED VENTILATORY RESPONSE TO HYPOXIA

When Kronenberg and Drage measured the ventilatory response to hypoxia at constant CO_2, they found even more striking differences between the young and elderly subjects (Fig. 19-6). For example, the ventilatory response to a $P_{A_{O_2}}$ of 40 mm Hg was uniformly smaller in the older subjects, and there was no overlapping between the groups.[26] The mean minute ventilation at a $P_{A_{O_2}}$ of 40 mm Hg was 40.1 and 10.2 L/min in the young and old groups, respectively.

DIMINISHED OCCLUSION PRESSURE RESPONSES

Peterson et al. confirmed the previously discussed observations and have shown that the differences in responses of elderly subjects to both hypercapnia and hypoxia are due to a lesser increase in tidal volume while the ventilatory rate increases normally. Since this observation could be caused by differences in respiratory muscle strength or increases in chest wall stiffness, the authors also measured airway occlusion pressures, which are valuable indices of respiratory drive that are not affected by respiratory muscle strength or respiratory mechanics.[27] The measurement (P_{100}) is the negative pressure at the mouth, measured 100 ms after the start of inspiration against an occluded airway. The occlusion pressure responses to both hypoxia and hypercapnia (Fig. 19-7) were significantly reduced in the 10 elderly subjects studied by Peterson (mean age, 73.3 years) when compared to nine young control subjects (mean age, 24.4 years). Although the elderly individuals had reduced respiratory muscle strength (mean, 24% lower maximal static inspiratory pressure), the differences in occlusion pressure persisted when normalized for these differences.

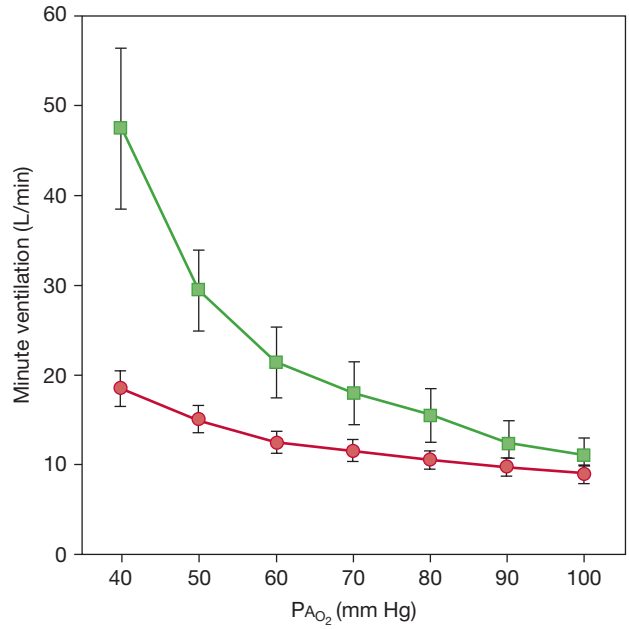

Figure 19-6 Variations with age in ventilatory responses to hypoxia. Eight normal men aged 64 to 73 *(circles)* and eight controls aged 22 to 30 *(squares)* were subjected to isocapnic progressive hypoxia by a rebreathing method. Data values are means, with standard errors of the mean shown by the error bars. Note that the ventilatory responses differ strikingly between the elderly individuals and the controls. *(Reproduced with permission from Kronenberg RS, Drage CW. Attenuation of the ventilatory and heart rate responses to hypoxia and hypercapnia with aging in normal men. J Clin Invest. 1973;52(8):1812–1819.)*

The previously mentioned seminal studies of ventilatory control have been discussed in some detail out of respect for their groundbreaking conceptual importance. Subsequent studies have created some confusion that appears likely to be due to methodologic differences, ages of subjects, and small sample sizes. However, in 14 of 16

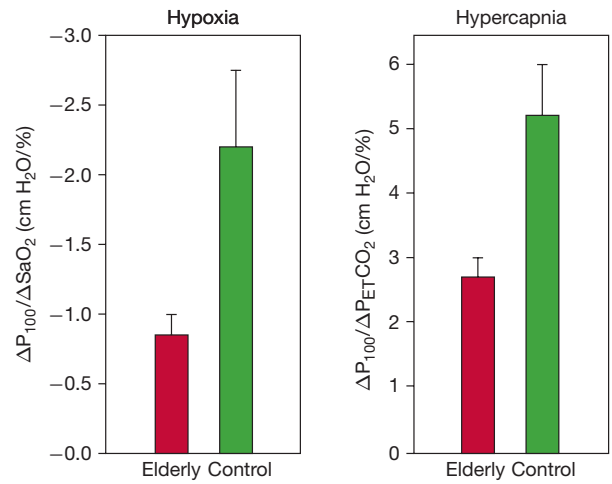

Figure 19-7 Variations with age in occlusion pressure responses to hypoxia and hypercapnia. Data shown are slopes of relationships between occlusion pressure responses and either Sa_{O_2} or end-tidal P_{CO_2}; error bars are standard errors of the mean. Elderly individuals had significantly diminished occlusion pressures in response to both hypoxia and hypercapnia. Both differences were significant, with $p < 0.01$. *(Reproduced with permission from Peterson DD, Pack AI, Silage DA, et al. Effects of aging on the ventilatory and occlusion pressure responses to hypoxia and hypercapnia. Am Rev Respir Dis. 1981;124(4):387–391.)*

studies reviewed by Lalley, ventilatory responses in the elderly were found to be abnormal.[28]

In summary, the reduced responsiveness in tidal volume to either hypoxemia or hypercapnia with age is apparently due to a reduced responsiveness of ventilatory drive or neural output from the respiratory center. It has not been determined whether the diminished ventilatory drive results from altered chemoreceptor function or from altered function of the respiratory center. Kronenberg and Drage favored altered receptor function based on their observation that elderly subjects responded to an alveolar oxygen tension of 40 torr with only an 11% increase in heart rate, whereas the young subjects responded with a 34% increase.

■ RESPIRATORY LOAD COMPENSATION AND DYSPNEA

Reflex compensation for a change in respiratory mechanical load (as in lung disease, changes in posture, and mouth versus nose breathing) normally serves to maintain ventilation constant during the change. Akiyama et al. measured responses to inspiratory flow-resistive loading in young and elderly individuals and found significant differences.[29] In the young control group, inspiratory loading resulted in an increase in P_{100} at each level of induced hypercapnia, such that inspiratory loading did not change the ventilatory response to hypercapnia when compared with unloaded responses. In marked contrast, the P_{100} in the elderly group did not change when an inspiratory load was applied. In the absence of a compensatory change in ventilatory drive, ventilatory responses to hypercapnia were reduced during inspiratory loading in the elderly group.

At each level of P_{CO_2}, the intensity of perceived dyspnea in response to inspiratory loading was greater in the elderly than in the control group. Thus, the sensation of dyspnea was intact or enhanced in the elderly subjects, while their compensatory responses were reduced. This suggests the possibility that, elderly individuals may complain of a greater dyspnea than younger individuals with similar pathophysiologic deterioration.

■ SENSITIVITY TO RESPIRATORY DEPRESSION BY OPIOIDS AND SEDATIVES

Older individuals are substantially more sensitive to respiratory depression by opioids and sedatives. This phenomenon demands extra vigilance when these medications are prescribed in nonintubated elderly patients. The enhanced drug effect has been shown to be multifactorial, and the various mechanisms involved are beyond the scope of this chapter.[30–32] However, the dangers associated with higher levels and more prolonged effects of these drugs are real and potentially catastrophic.

PULMONARY CIRCULATION

Invasive physiologic studies of pulmonary artery catheterization have typically been biased by including only subsets of patients whose signs and symptoms led to referral for heart catheterization and who, therefore, may not be representative of a "healthy" cohort. Further, age-related changes in the pulmonary circulation are difficult or impossible to separate from changes due to heart disease or age-related changes in cardiac function.

Ehrsam et al. reported a retrospective analysis of right heart catheterization studies performed in 125 asymptomatic subjects who ranged from 14 to 68 years of age.[33] Small increases in right atrial, pulmonary artery, and pulmonary artery wedge pressures observed in the highest age group disappeared when values were adjusted for sex, weight, and height. No significant age-related changes were found in cardiac output, stroke volume, or oxygen uptake. Age explained 10% or less of the total variation in the hemodynamic and pressure variables when assessed by multiple regressions. During supine exercise with a bicycle ergometer, however, pulmonary artery and wedge pressures increased with age, particularly in subjects over the age of 45. The changes were highly significant with age accounting for 12% to 30% of the total variation when assessed by multiple regressions. Finally, pulmonary artery resistance showed a highly significant increase with age, whether measured at rest or during exercise, with age contributing 12% to 27% to the total variation in pulmonary artery resistance. Although the cohort studied were all asymptomatic and ambulatory, it is possible that silent coronary artery disease was present in some of the subjects, and the prevalence of coronary artery disease can be expected to increase with age. Moreover, younger patients tended to be referred for evaluation of a heart murmur, whereas the older patients were referred for "pulmonary investigation" that included coin lesions, hilar lymphadenopathy, "previous pulmonary infiltrates," and smoke inhalation. Cigarette smoking history was not discussed. Thus, it is not certain that the younger and older patients were strictly comparable.

More recently, Davidson and Fee reported the results of right-heart catheterization at rest in 47 normal subjects who were free of coronary disease and had normal left ventricular systolic function.[34] Smokers were included. The investigators found highly significant but quantitatively modest age-related increases in mean pulmonary artery pressure, pulmonary vascular resistance, and pulmonary/systemic vascular resistance ratio, but they found no age-related differences in pulmonary artery wedge pressure. The authors felt that the most likely explanation for the age-related changes in pulmonary artery pressure and pulmonary vascular resistance was a primary abnormality of the pulmonary vascular bed, but they could not exclude the effects of subtle abnormalities in left ventricular function.

In summary, studies of pulmonary hemodynamics with aging are limited by retrospective design, bias in patient selection, and potential effects of smoking. Minor increases in pulmonary vascular resistance and age-related increases in pulmonary artery wedge pressure during exercise have been reported. These age-related changes may not be physiologically significant.

PULMONARY FUNCTION TESTS

Lung function and exercise capacity decline with age in concert with numerous other physiologic, morphologic, and biochemical changes. Descriptions of "normal" age-related changes are confounded by an increasing prevalence of disease, chronic illness, medication use, and an increasingly sedentary lifestyle. Further, chronologic age only approximates physiologic age; the two often differ significantly. Chronologic age is, therefore, an imperfect measure for indexing changes with senescence. While it would be desirable to isolate the effects of biologic aging (aging in the absence of disease), it is essentially impossible to do so. The best studies to do so are longitudinal, tracing change with time, because they avoid the obvious biases of cross-sectional studies. Longitudinal studies, however, have methodologic problems and biases of their own, the most obvious being that the healthy elderly represent a healthy survival population. If, as a group, they have better than average lung function, they would not represent the general population of elderly people well.

■ LUNG VOLUMES

Figure 19-8 illustrates typical lung volume changes with aging based on cross-sectional studies. With the exception of vital capacity, the effect of aging on lung volumes is based on cross-sectional rather than longitudinal data because there are almost no longitudinal studies of static lung volumes. Total lung capacity (TLC), the volume of air in the lungs at the end of a maximal inspiration, is marked by the point at which the recoil pressure exerted by the respiratory system is exactly counterbalanced by the maximal inspiratory pressure generated by the respiratory muscles. Since both the compliance of respiratory system (lung and chest wall combined) and maximum inspiratory pressure fall with aging, TLC might also be expected to fall. However, in seven cross-sectional studies of TLC summarized

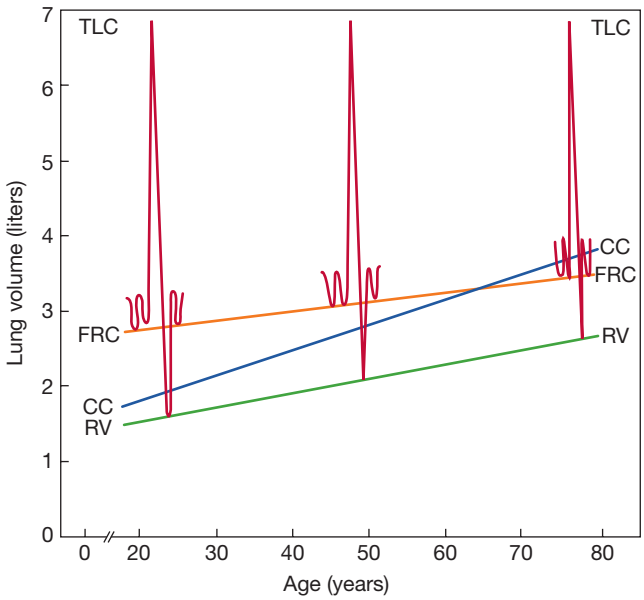

Figure 19-8 Schematic illustration of lung volume changes with age based on cross-sectional studies in seated individuals. (TLC, total lung capacity; FRC, functional residual capacity; RV, residual volume; CC, closing capacity.) Although not labeled, vital capacity (VC) is TLC minus RV. The most consistent changes are an increase in RV and a decrease in VC. *(Reproduced with permission from Peterson DD, Fish-man AP. Aging of the respiratory system, in Fishman AP (ed). Update: Pulmonary Diseases and Disorders. New York, McGraw-Hill, 1992, pp 1–17.)*

by the European Coal and Steel Community, four of the studies in men and three of those in women did not find a significant age coefficient.[35] The remaining studies found only small declines in TLC with age, on the order of −8 to −19 mL/yr. When these study results were combined into average equations, no significant age coefficients were reported for either men or women. McClaran et al. measured lung volumes twice in 18 healthy, fit men.[36] The first measurement was at a mean age of 67 and the second was 6 years later. Although average TLC fell 25 mL/yr, the change was not statistically significant. The study was small and the interval was short.

In summary, current cross-sectional studies suggest that TLC either does not decline with age or declines very slowly. It is interesting to speculate on the possibility that cross-sectional studies of TLC might be confounded because they typically index TLC to both age and height. Height declines with aging, and maximum height during a life span appears to increase with successive generations. The author believes that longitudinal studies of TLC with age are likely to show small but significant declines with age.

Both slow and forced vital capacity (FVC) decline with age, more rapidly in men than women. Average decrements in vital capacity per year vary considerably; in cross-sectional studies, declines range from 21 to 33 mL/yr in men and 18 to 29 mL/yr in women. Theoretically, longitudinal studies should provide better estimates of the effect of aging on lung function. Ware et al., in a study containing both longitudinal and cross-sectional computations, found cross-sectional falls in FVC for men and women to be −34 and −27.8 mL/yr, respectively.[37] The longitudinal estimates were −40 mL and −31.3 mL/yr, respectively. This study contradicts the generally held concept that longitudinal studies show smaller declines in FVC than cross-sectional studies. Currently, it is not certain whether longitudinal studies are all that much different from cross-sectional studies in describing declines in FVC and forced expiratory volume in 1s (FEV_1). Longitudinal studies tend to show an acceleration in the rate of loss in FVC and FEV_1 as age advances.

Cross-sectional studies of residual volume (RV) and the RV/TLC ratio consistently show increases with age. In the young, RV, the volume of air in the lungs at the end of a maximal expiration, is the volume at which the outward static recoil pressure of the respiratory system is counterbalanced by the maximal pressure exerted by the expiratory muscles. In older subjects, expiratory flow never completely reaches zero and the determination of RV is made partly by the length of time an individual can maintain expiratory effort.[38] Other factors leading to an increased RV with aging include loss of lung recoil, decreased chest wall compliance, decreased expiratory muscle force, and increased small airway closure (air trapping) in dependent lung zones. Time of exhalation and increase in air trapping are probably more important than changes in lung and chest wall compliance in explaining the increase in RV with aging.

FRC is also determined by the balance of the elastic recoil forces of the lung and chest wall; but, in this instance, the equilibrium occurs at the end of a quiet (unforced) exhalation. Since lung recoil falls and the chest wall stiffens with age, one would expect FRC to increase. Cross-sectional studies, however, show inconsistent results, with most showing no change in FRC with aging. Studies that find an increase in FRC with aging show a small positive age coefficient on the order of 7 to 16 mL/yr. McClaran's longitudinal study found FRC to increase 40 mL/yr, but again, the change was not significant.[36] Despite the conflicting data, it is generally believed that FRC increases with aging.

Loss of lung recoil also changes the volume at which airway closure occurs. When adults exhale fully, small airways close in the region of the terminal bronchioles in dependent lung zones. The lung volume at which this closure begins is measured as closing volume or, if it is added to RV, closing capacity. Closing volume increases linearly with age from about 5% to 10% of TLC at age 20 to about 30% of TLC at age 70.[39] The loss of lung elastic recoil, a possible decrease in the recoil of the intrapulmonic airways, and decreases in small airway diameter probably explain most of the changes in CV.

Closing volume encroaches on tidal volume by about age 44 when subjects are supine and about age 65 when they are seated (Fig. 19-8). Airway closure during tidal breathing explains most of the decrease in arterial oxygen tension (PA_{O_2}) observed with aging[40,41] and may contribute to an aging-related increased frequency dependency of compliance.

AIRFLOW

While essentially all expiratory flows measured during a maximum expiratory maneuver decrease with age, the declines are most evident at lower lung volumes (Fig. 19-9). Nunn and Gregg, in a study of 225 male and 228 healthy female nonsmokers,[42] reported a modest, nonlinear decrease in peak expiratory flow (PEF) with aging (Fig. 19-10), which reached a high point at age 30 to 35; a decline became evident at about age 45. After age 50, the average decline was about 4 L/min per year in men, about 2.5 L/min per year in women.

Figure 19-11, from Paoletti et al.,[43] illustrates changes in FEV_1 during growth, maturation, and senescence. Changes in FVC are similar. In one model of aging, FVC and FEV_1 increase progressively during the growth phase until about age 12. In the maturation phase (during adolescence), there is an acceleration of these increases. Increases in FVC and FEV_1 are seen up to about 20 years in women and about 25 years in men; increases in lung volumes occur even after somatic growth ceases. There appears to be a plateau phase where there is little or no change in FVC or FEV_1 prior to the onset of a decline. However, Robbins et al. demonstrated that, while the plateau correctly represents average data, lung function is often increasing or decreasing in individuals (Fig. 19-12). Their study confirms the suspicion that the "plateau" phase represents the merging of slower maturation-related increases in FVC and FEV_1 in some subjects, with subtle decreases in others.[44] In the decline phase, there appears to be acceleration in the rate of loss of FVC and FEV_1 as age progresses.

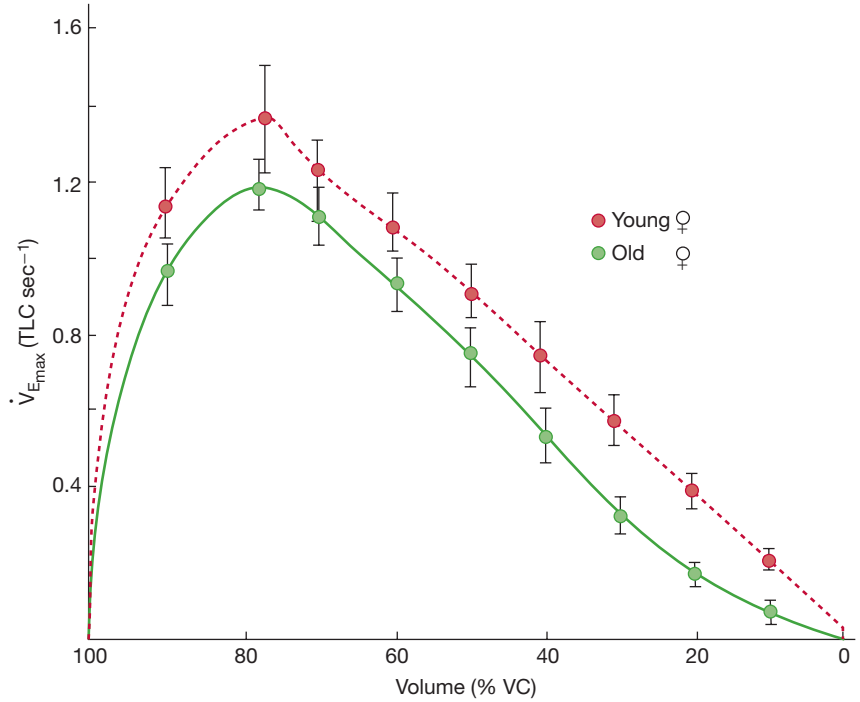

Figure 19-9 Illustrative maximal flow–volume curves for healthy "elderly" women (mean age, 63 years) and healthy young women (mean age, 25 years). Although all flows tend to be reduced with aging, the reduction in flow is most evident at lower lung volumes, where the flow–volume curve is clearly concave to the volume axis. *(Reproduced with permission from Peterson DD, Fish-man AP. Aging of the respiratory system, in Fishman AP (ed). Update: Pulmonary Diseases and Disorders. New York, McGraw-Hill; 1992:1–18.)*

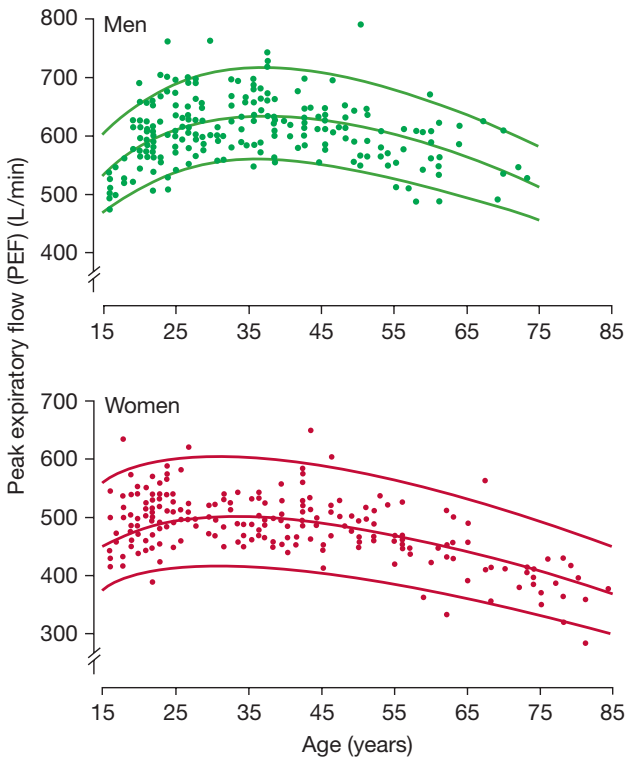

Figure 19-10 Changes in peak expiratory flow in 225 males and 228 females who were healthy nonsmokers. The *center line* is a regression curve representing mean data and the boundaries are 90% confidence intervals. *(Reproduced with permission from Nunn AJ, Gregg I. New regression equations for predicting peak expiratory flow in adults. Br Med J. 1989;298(6680):1068–1070.)*

An accelerated rate loss at older ages is, however, not found in all studies. The rate of decline in FVC and FEV_1 with age tends to be greater: (1) in men; (2) in taller individuals; (3) in individuals with larger baseline values; and (4) in individuals with increased airway reactivity.

AIRWAYS RESISTANCE

Total airway resistance measured at FRC does not change with aging. Since upper airways increase and smaller airways decrease in size with aging, it is likely that peripheral airway resistance increases and central airway resistance decreases. That total airway resistance does not change with aging may be a function of the counterbalancing of these two opposite changes. However, since about 90% of total airway resistance resides in the upper airways, significant changes in peripheral airway resistance might not be readily reflected in total airway resistance. Significant increases in peripheral airway resistance with age also would be consistent with the more dramatic decreases in maximum flow observed at low lung volumes.

GAS EXCHANGE

The carbon monoxide diffusing capacity (D_{LCO}), also known as transfer factor (T_{LCO}), declines with age. Earlier cross-sectional studies report a linear decline in D_{LCO} of about −0.2 mL CO/min per mm Hg per year for men and −0.15 mL CO/min per mm Hg per year for women. These declines are roughly 0.5% per year. In a large representative sample of US adult men, Neas and Schwartz found an almost linear fall in D_{LCO}.[45] In women, however, they found a nonlinear, quadratic decline in D_{LCO} with age. After age 47, the nonlinear component was not significant and the decline in D_{LCO} was identical to that in the earlier studies. The decline in D_{LCO} with age did not vary with race.

The decline in D_{LCO} with age is not explained by increased nonhomogeneity of gas distribution. Measured D_{LCO} falls as alveolar P_{O_2} increases, and venous hemoglobin concentration falls. Neither alveolar P_{O_2} nor hemoglobin concentration varies enough with age to explain the aging decline in D_{LCO}. The magnitude of the decline in D_{LCO} corresponds fairly well to the magnitude of the known aging-related decrease in the internal surface area of the lung.

The components of D_{LCO} are membrane diffusing capacity (Dm) and pulmonary capillary blood volume (Vc). Both Dm and Vc decrease with age. In a cross-sectional reference value study of 54 male and 36 female healthy nonsmokers, the decline in Dm and Vc with age were found to be linear.[46] Membrane diffusing capacity fell at about 0.6% per year in both men and women. Pulmonary capillary blood volume fell at about 0.3% per year.

Although alveolar oxygen pressure ($P_{A_{O_2}}$) remains constant with age, arterial P_{O_2} (Pa_{O_2}) decreases and the alveolar–arterial oxygen tension gradient ($P_A - a_{O_2}$ increases with aging (Fig. 19-13).[47] The decline in Pa_{O_2} with aging is more pronounced when subjects are studied in a recumbent as contrasted with an upright position. The most likely explanation for the decline in Pa_{O_2} with aging is increased mismatching of ventilation to blood flow ($\dot{V}_E/\dot{Q}$) as airway closure begins to occur during tidal breathing. Increased ($\dot{V}_E/\dot{Q}$) mismatching with aging is also associated with an increase in physiologic dead space.[48,49] Hypoventilation does not contribute to the age-related fall in Pa_{O_2}, since Pa_{CO_2} and pH do not change with age (Fig. 19-13).

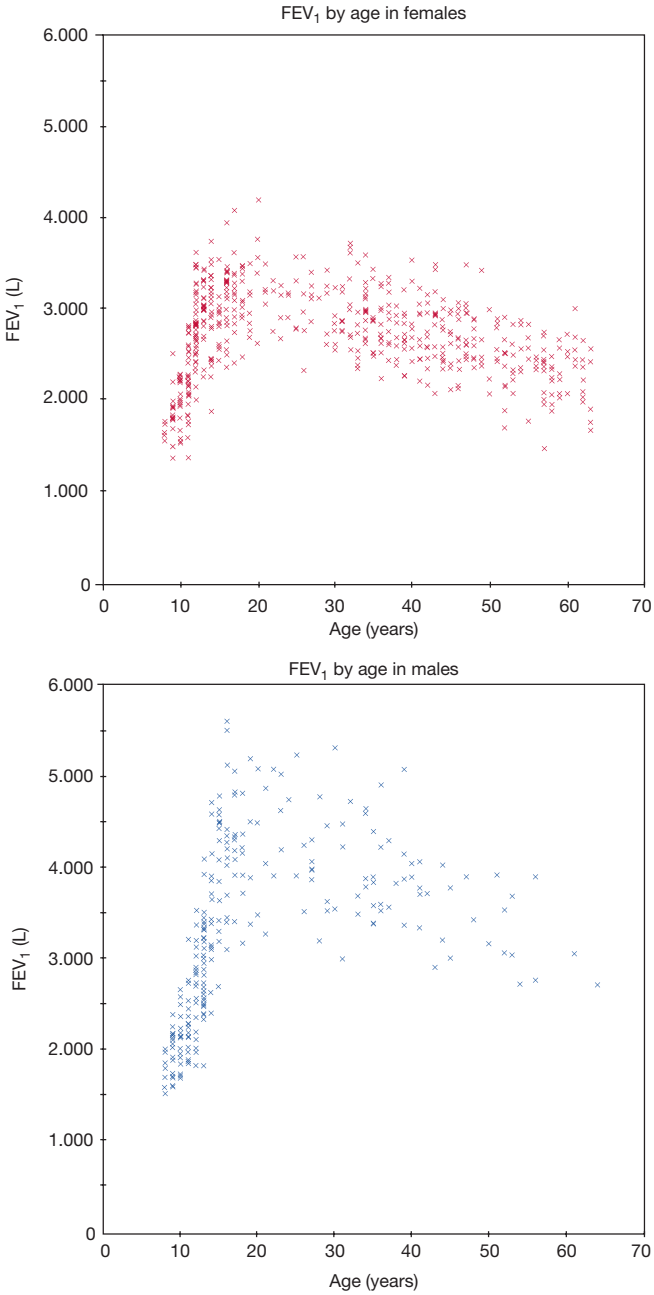

Figure 19-11 Change in FEV_1 with age from a cross-sectional study of 538 females and 263 males selected as "normal" from a larger study of 3289 subjects. Changes in FVC are similar. *(Reproduced with permission from Paoletti P, Pistelli G, Fazzi P, et al. Reference values for vital capacity and flow-volume curves from a general population study. Bull Eur Physiopathol Respir. 1986;22(5):451–459.)*

EXERCISE CAPACITY

Peak $\dot{V}_{O_2}$ ($\dot{V}_{O_2\,peak}$) and maximum work capacity decrease with aging in both sedentary and active individuals.[50] $\dot{V}_{O_2\,peak}$ (L/min) increases until about age 20. Declines are evident at about age 25 in both men and women and continue at about 1% per year (Fig. 19-14). If one expresses $\dot{V}_{O_2\,peak}$ as a function of body weight (L/kg per min), the decline is evident much earlier, perhaps in the first decade of life. The magnitude of the decline in $\dot{V}_{O_2\,peak}$ tends to be greater in longitudinal than in cross-sectional studies and occurs roughly twice as fast in sedentary than in physically active persons. Most, but not all, studies report linear declines in $\dot{V}_{O_2\,peak}$ with age, even though a nonlinear decline would be expected based on the number and type of variables that affect exercise capacity.

The decline in exercise capacity with age occurs as a result of normal aging but is accelerated by lifestyle issues. Aging is associated with significant changes in body configuration. Specifically, there is an increase in total body weight, primarily representing an increase in fat mass, since fat-free mass (mostly muscle mass) decreases with aging. The changes are most pronounced in sedentary persons. Muscle mass decreases, with a preferential atrophy of type II muscle fibers, and is associated with a decrease in muscle capillarization and oxidative activity. Muscle strength decreases on the order of 2%/yr from ages 20 to 70. Variables associated with loss of exercise capacity with aging are listed in Table 19-2.

While exercise capacity declines with aging, it is also clear that the ability to respond to exercise conditioning is well maintained even at very advanced ages. Elderly individuals respond to both endurance and resistive training with improvements similar in magnitude to those seen in the young.[50–52] There are equivalent increases in $\dot{V}_{O_2\,peak}$, muscle mass, capillarization of muscle tissue, muscle oxidative activity, and general muscle strength.

LUNG AND AIRWAY INFLAMMATION

In recent years, there has been considerable interest in the presence and control of lung inflammation in elderly individuals, and this has become a confusing subject. A variety of quantitative abnormalities in mediators of inflammation have been described in elderly individuals that have mostly been in the direction of increased lung parenchymal and airway inflammation. However, these differences from younger subjects must be viewed in the context that elderly individuals have impaired cough, increased evidence of gastroesophageal reflux, and decreased effectiveness of the ciliary escalator. All of these abnormalities can be expected to lead to an increased load of particulates and microorganisms in the lower respiratory tract, and/or recurrent episodes of aspiration. As a striking example of studies of airway inflammation, the mean quantity and percentage of neutrophils in broncho-alveolar lavage fluid have been found to be increased in elderly individuals, but many of the studied elderly subjects were indistinguishable from young normals.[53] The increased mean values in the elderly were strongly influenced by outlying high values in a subpopulation, and thus presumably did not result from a direct effect of aging.

SLEEP

Sleep complaints from elderly patients present a difficult problem for the clinician, who must determine whether the complaints are related to the normal aging process, sleep hygiene issues, or the presence of pathology.[54,55] Problems with sleep are widespread among elderly persons, with 25% to 40% complaining about sleep difficulties. There is no evidence to confirm the widely held belief that the need for sleep declines with age. However, sleep quality decreases, and the frequency of various primary sleep disorders increases. The most common age-related change in sleep pattern is a striking increase in the number of nocturnal awakenings, resulting in lower total sleep time and lower sleep efficiency (total sleep time/time in bed). Whether or not sleep latency changes with aging is equivocal. The amount of time spent in stage 1 nonrapid eye movement (NREM or light) sleep tends to increase with age. The decrease in total sleep time at night is associated with an increase in unwanted daytime naps. Disrupted sleep in the elderly is, in large part, explained by medical and psychological issues and the lack of structured physical and social activity during the day. Chronic illnesses, nocturia, medication and alcohol use, periodic leg movements, bereavement, and depression also play a role. Not surprisingly, the elderly are more likely to use sedatives or hypnotics; their use is more frequent in elderly women than in elderly men. While

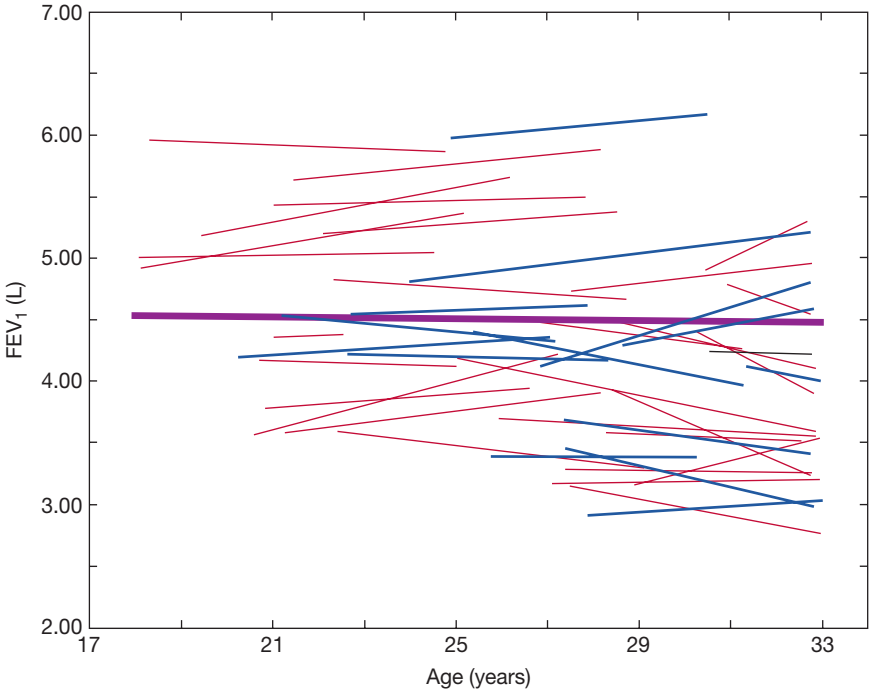

Figure 19-12 Predicted FEV_1 trajectories from 44 men based on linear regressions of longitudinal data. Nonsmokers *(fine lines)* and smokers *(dashed lines)*. The heavy line is based on the entire group's data. While the group's data show no change with age, data for individuals show both increases and declines with age during this time period, when a plateau in lung function was theorized to occur. *(Reproduced with permission from Robbins DR, Enright PL, Sherrill DL. Lung function development in young adults: Is there a plateau phase? Eur Respir J. 1995;8(5):768–772.)*

hypnotics and sedatives are occasionally necessary, their chronic use may contribute to sleep disruption and aggravate certain sleep disturbances, such as sleep apnea. Increased autonomic activity, increased sensitivity to external stimuli (which may increase arousals as a result of environmental factors), decreased exposure to outdoor light, inactivity, and daytime napping also play a role in sleep disruptions in the elderly. Alterations in endogenous circadian rhythms for variables like temperature and cortisol or thyroid-stimulating hormone (TSH) levels may also contribute to sleep disruption in the elderly.

The neural system that regulates sleep is, like most other systems, subject to the aging process, and sleep disruption occurs in the elderly in the absence of any pathologic process. The amount of stages 3 and 4 sleep (slow- or delta-wave sleep) declines with aging, although some argue that the aging decline is mostly a technical issue related to how delta-wave amplitude is defined. Changes in slow-wave sleep appear to be evident early, perhaps by 20 years of age. Arguments have been made both for and against declines in the amount of REM sleep with age. The persistent controversy about REM sleep and aging suggests that if REM sleep does change with aging, the magnitude of decline is so small that it does not overwhelm the confounding factors in studies.

Sleep disorders such as sleep apnea and restless limb syndrome, with periodic limb movements, appear to be more prevalent in older persons, and they are also marked more among nursing home residents than the independent elderly. For example, using an apnea index of five per hour as a threshold, one study found evidence of sleep apnea in 42% of elderly nursing home residents, in contrast to 24% of the independent elderly. A community-based study of individuals aged 71 to 87, showed a 55% prevalence of sleep-disordered breathing that was documented by polysomnography, including 38% obstructive sleep apnea and 17% central sleep apnea.[56] However, longitudinal follow-up of these individuals did not show an independent correlation with either cardiovascular disease or mortality.

INTERPRETING PULMONARY FUNCTION TESTS IN THE ELDERLY

Several issues complicate the interpretation of lung function tests in the elderly, as reviewed by Vaz Fragoso and Gill.[57] The elderly are not well represented in most reference value reports; the number of subjects usually falls off significantly after age 60. The number of

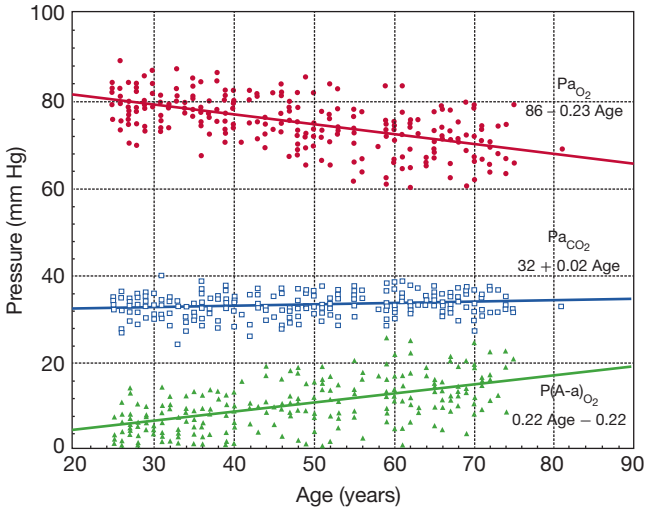

Figure 19-13 Change in Pa_{O_2}, Pa_{CO_2} and A-a gradient $P(A\text{-}a)_{O_2}$ with age. Data were obtained from 200 healthy men and women living in Salt Lake City, UT (altitude = 1400 m). Sea-level data would be similar, with a small upward shift in Pa_{O_2} and Pa_{CO_2}.

Variable	Comment
Decreased muscle mass	These changes especially affect $\dot{V}_{O_2}$ calculated per kg of body weight
Increased fat mass	
Decreased tissue oxygen delivery Decreased maximal heart rate Decreased stroke volume Decreased maximal $C(a-\bar{v})_{O_2}$ difference	As a result of the decreased cardiac output and maximal $C(a-\bar{v})_{O_2}$, delivery and extraction are reduced; decreased cardiac output is a major contributor to the age–related decline in exercise capacity
Maximum voluntary ventilation	
Increased ventilation at each workload	At each workload, older individuals breathe more and work harder for each breath than younger persons; however, the effect is small and contributes little to the decline in exercise capacity with aging
Increased oxygen cost of breathing	
Sedentary lifestyle	Lifestyle issues play a large role in the rate at which exercise capacity is lost with age; the good news is that, like other deconditioned groups, the elderly respond very well to exercise training
Decreased training intensity in active persons	
Decreased willingness to work to maximal level during tests	

subjects over age 80 is usually so small that mean values calculated from regression equations are essentially an extrapolation of the data for younger persons. This means that the average or "predicted" value may not be as representative for the elderly as it is for middle-aged persons. The fall in sample size with aging likely reflects the reduced total number of candidates for participation and the larger number of individuals who fail screening criteria. In reference value studies, individuals are screened so as to be free of symptoms and illnesses that alter lung function. These selection criteria may eliminate more older than younger candidates because of their increased prevalence of illness. Also, test quality is carefully standardized. Cognitive impairment may compromise test quality. As a result, older individuals may have more difficulty meeting test quality criteria, increasing their likelihood of exclusion and potentially increasing the variability of reference data for the elderly. In summary, the selection processes may make the older individuals who participate in reference studies less representative of the individuals who present for clinical lung function testing.

These same issues also affect the limits applied to determine whether a tested individual is within the "normal" range. Limits are often defined assuming that the distribution of data is Gaussian. Although tests of this assumption are sparse, there is reason to suspect that it is more likely to fail in the elderly. Even when the "normal" range is defined using methods that avoid assumptions about data distribution, data from the elderly are often lumped with those of the younger subjects. The result may be an erroneous "normal" range. All these reference value issues suggest that increased caution should be used in interpreting lung function tests in the elderly. This caution is especially important for those over age 80 and in any elderly person whose data lie near the limits of a "normal" range.

CHAPTER 20

Innate and Adaptive Immunity in the Lung

Charles S. Dela Cruz
Jonathan L. Koff

The lung is constantly exposed to foreign agents. As a result it is faced with the challenge of distinguishing nonpathogenic moieties in ambient air from potentially pathogenic antigens derived from microorganisms. Here, we use the term "pathogens" to refer to infectious agents, allergens, toxins, and other inhaled antigens unless stated otherwise. The lung protects itself using local tissue structures such as the mucus layer, ciliary ladder, and smooth muscles. It also employs complex immune defenses that are both innate and adaptive.[1,2] The immune responses need to be able to recognize and to react to a wide variety of stimuli. They must be able to recognize and to eliminate unwanted pathogens to keep pulmonary structures free of infection. On the other hand, they must not overreact to inhaled stimuli to avoid potential excessive inflammation and lung injury. This need to control the intensity and duration of such responses is required to preserve normal lung structure, especially the highly vascularized and fragile alveolar epithelial surface that is required for gas exchange. Alterations of these lung protective mechanisms lead to many of the pulmonary diseases physicians face in their patients. Therefore, understanding the innate and adaptive immune responses in the lung is important in our attempts to understand the pathophysiology and to improve the management of many pulmonary diseases. The anatomic and immune defenses will be reviewed in this chapter.

ANATOMIC MECHANISMS

Given the lungs' large surface area, it is exposed to many inhaled environmental challenges, because the air we breathe contains infectious agents, toxic gases, and fine particulate matter (Fig. 20-1). The alveolar and capillary membrane barriers are important for gas exchange, and need to be defended from the injurious effects of incoming toxic and infectious pathogens. If the consequences of these exposures are not controlled, this can lead to excessive inflammation, lung edema, as well as propagation of infectious agents. This can, in turn, lead to alveolar destruction, abnormal fibrotic repair, and compromised gas exchange. Air is inhaled through the nose or the mouth into the extrathoracic portion of the trachea before it enters the thorax. The nose filters and conditions the inhaled air for humidity and body temperature as it flows through the nasal turbinates. Nasal hairs also provide a barrier that traps larger particulates. The nasal secretions lining the airway mucosa contain many substances such as lysozyme, immunoglobulins (such as secretory immunoglobulin A [sIgA]), and antimicrobial peptides that bind to, and inactivate invading microbes. For example, sIgA accounts for 15% of the total protein in upper airway secretions and plays a significant role in neutralizing and preventing epithelial attachment of invading viruses and bacteria.[3] The conducting airway mucosa is also coated with acidic viscous fluid and mucus secreted by Clara cells, goblet cells, and bronchial glands (Fig. 20-1). This fluid makes up an important airway surface lining that coats the bronchial epithelium and forms a barrier between the outside world and the lung parenchyma.

INNATE IMMUNITY IN THE LUNG

The innate immune response is an evolutionarily conserved system of host defense evident in all multicellular organisms. In the constant battle between host and pathogens, the purpose of the innate immune system is to provide a rapid response, in contrast to the adaptive immune system, which provides a more specific response but takes longer to respond (see Section "Adaptive Immune Responses in the Lung"). Because humans breathe approximately 10 L of air per day (12 to 15 breaths/min × 500 mL tidal volume), we are constantly exposed to pathogens (e.g., viruses, bacteria, and fungi), allergens (e.g., house dust mites, dander), and toxins (e.g., cigarette smoke and pollutants). The innate immune system allows humans to respond to these stimuli even if they have not been exposed to them previously.

Because of the constant exposure to the environment, similar to other mucosal surfaces (e.g., gut and skin), the innate immune system must maintain a balanced response. Ideally, this should include (1) pathogen recognition, (2) initiation of an appropriate response, which is typically manifested by inflammation, and (3) resolution of inflammation. An inappropriately regulated innate response contributes to the pathogenesis of lung diseases as diverse as asthma, emphysema, and interstitial lung disease.

The most important property of the innate immune system is its response to pathogens regardless if there has been a prior exposure. Thus, an acquired immunologic memory against the pathogen is not required. The anatomic and antimicrobial structures that prevent infection and injury noted earlier can be thought of as part of the innate response. Therefore, one of the most important roles of the lung innate immune system is its function as a barrier to inhaled pathogens.[4] The epithelial surface of the lung creates a barrier with tight junctions between neighboring cells that prevent pathogen entry (Fig. 20-1). In addition to this barrier function, the epithelium has a coordinated system for the removal of inhaled pathogens. Goblet cells and secretory glands produce mucus that engulfs pathogens. A coordinated system of ciliated cells moves mucus up the mucociliary "ladder" to be expectorated during coughing. A disturbance in this essential function leads to significant pathology. In primary ciliary dyskinesia (PCD), cilia function is impaired and individuals develop bronchiectasis with recurrent bacterial infection.[5] In cystic fibrosis (CF), an abnormality in epithelial chloride channel function causes changes in the airway surface liquid that prevents effective mucus clearance, which also leads to chronic inflammation, bronchiectasis, and recurrent bacterial infections.[6,7] The mucociliary "ladder" is particularly effective for large molecules, but smaller molecules (<5 μM) are able to directly descend to the distal alveolar epithelium. Here, instead of mucociliary clearance, particles encounter secreted surfactant proteins (specifically SP-A and SP-D; also known as pulmonary collectins) that act as opsonins, and assist resident macrophage in phagocytosis.[8] Finally, the epithelium also produces a variety of innate immune antimicrobial molecules that activate alveolar macrophages (AMs) to kill pathogens.[9]

PATHOGEN RECOGNITION

The innate immune response allows the host to respond to a wide array of pathogens. However, the mechanism(s) that the host uses to recognize these pathogens was poorly understood until the 1980s. At that time, a seminal advance in our understanding of the immune system occurred when it was proposed that the host detects, and responds to these

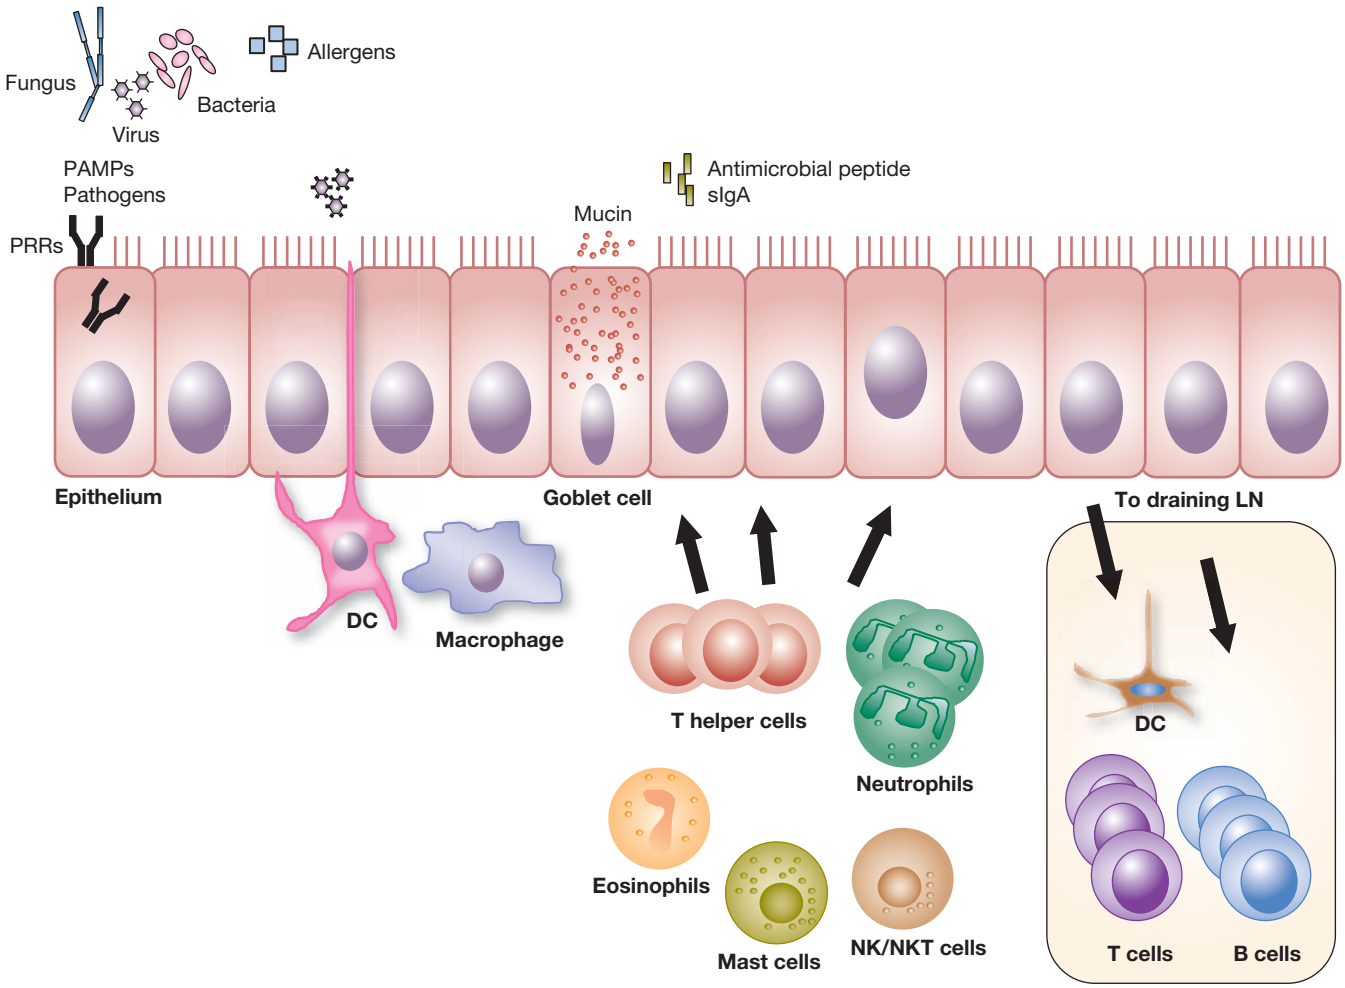

Figure 20-1 Innate recognition of pathogen or PAMPs on airway epithelium. Pathogens such as fungus, virus, or bacteria (or their associated pattern-associated molecular proteins [PAMPs]) and environmental allergens are first detected by membrane bound, cytosolic and/or endosomal innate sensors or pattern recognition receptors (PRRs). The respiratory epithelial cells provide a physical barrier between the airway luminal antigens and the underlying respiratory tissues in their control of immune defense and tolerance. Specialized epithelial cells can have cilia, produce a mucus layer and secrete antimicrobial proteins and secretory IgA (sIgA) that limit pathogen exposure to the epithelial cells. Dendritic cells (DCs) interdigitating between and lying near the epithelium, as well as tissue macrophages, are well positioned to sample and ingest incoming antigen. Recognition of the antigen by the innate immune receptors leads to production of pro-inflammatory cytokines and chemokines which recruits immune cells such as neutrophils, T cells, NK cells, NKT cells, eosinophils, or mast cells. Activated DCs that have taken up the inhaled antigen migrate to nearby draining lymph nodes. In the lymph nodes, the DCs help integrate the signals from the inhaled substance and the innate immune response into signals that direct cells of the adaptive immune system. The DCs encounter appropriate naïve $CD4^+$ T cells where factors such as the phenotype of the antigen-presenting cells (APCs) and cytokine milieu modulate differentiation of $CD4^+$ T cell subsets with their characteristic cytokine and functional profiles. These immune cell functions and cytokine production determine whether an activating or a tolerant response will develop.

pathogens via a cadre of receptors that recognize conserved sequences called pathogen-associated molecular patterns (PAMPs), which exist in pathogens, and are not present in the host (Fig. 20-2).[10,11] Experiments in *Drosophila* (fruit flies) in 1996 identified pattern recognition receptors (PRRs) that recognized PAMPs and supported the concept of innate receptors.[12] Subsequently, PRRs were identified in humans,[13] and more recently, additional PRRs have been shown to recognize endogenous molecules released from damaged cells, which are referred to as damage-associated molecular patterns (DAMPs).[14,15] The major types of PRRs are described in sections "Toll-Like Receptors", "RIG-I-Like Receptors", "Nod-Like Receptors" and "C-Type Lectin Receptors".

Toll-Like Receptors

The mammalian Toll-like receptor (TLR) family received its name from the *Drosophila* Toll gene. Early studies that involved the genetic manipulation of Toll resulted in dramatic defects in innate immune responses (Table 20-1; Fig. 20-2).[12,16] Since this discovery, the TLRs are appreciated to be the prototypical PRR molecules.[13,17] It is now known that some TLRs are present on the cell surface, and others are in endosomes (intracellular vesicles). As a group, they are characterized by N-terminal leucine-rich repeats that recognize pathogens, a transmembrane region, and a cytoplasmic domain that is highly homologous to the interleukin (IL)-1 receptor and the IL-18 receptor.[18] To date, 11 TLRs have been identified in humans, with different TLRs recognizing distinct PAMPs.[19] In general terms, TLR recognition of PAMPs is based upon cellular compartmentalization. Recognition of viral RNA and DNA occurs in endosomes by TLR3, TLR7, and TLR9, while TLR2 and TLR4 have been shown to recognize viral proteins. The remaining TLRs recognize bacteria, parasite, and host

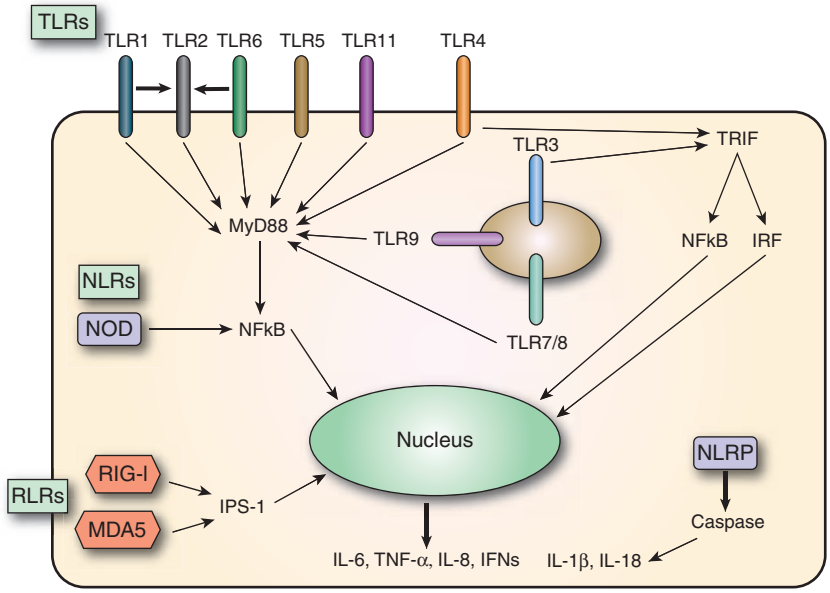

Figure 20-2 Pattern recognition receptors (PRRs). Classes of PRRs include Toll-like receptors (TLRs), retinoic acid–inducible gene-I–like receptors (RLRs) and nucleotide oligomerization domain–like receptors (NLRs). Not shown are C-type lectin receptors (CLRs). TLRs, RLRs (e.g., RIG-I, MDA5, and other sensors), and NLRs (e.g., NOD1, NOD2, NLRP3, etc.) are innate immune sensors that recognize danger signals derived from pathogens (PAMPs), damaged cells (DAMPs), or associated nucleic acids at the cell surface, in endolysosomes or in the cytoplasm. Signaling by these sensors promotes, either the activation and nuclear translocation of transcription factors (IRFs, NFκB and AP-1) that drive expression of cytokines (IFN-α/β, TNF, and pro-IL-1β), or the assembly of the caspase-1 inflammasome and subsequent maturation of IL-1β from pro-IL-1β. IFN, interferon; IL, interleukin; IRFs, interferon regulatory factors; MDA5, melanoma differentiation–associated gene-5; NFκB, nuclear factor κB; NLRP, NLR with a pyrin domain; NOD, nucleotide oligomerization domain; RIG-I, retinoic acid–inducible gene-I; TNF, tumor necrosis factor; TRIF, TIR-domain–containing adapter-inducing interferon-β.

proteins (e.g., DAMPs), while TLR7 and TLR9 recognize DNA from bacteria or protozoa.

TLR Signaling Pathways

TLR recognition of PAMPs stimulates signaling pathways that ultimately lead to activation of gene transcription and protein production. The responses that are elicited can be cell type specific. They also utilize two distinct pathways based on which of two adaptor molecules they employ: (1) myeloid differentiation primary response gene 88 (MyD88) and (2) TIR-domain–containing adapter-inducing interferon-β (TRIF). With the exception of TLR3, and one of the pathways downstream from TLR4, MyD88 is required for the downstream signaling of TLRs. MyD88 interacts with the IL-1R–associated kinase (IRAK)-4, and other IRAK family members, before they dissociate from MyD88 and interact with TNFR-associated factor 6 (TRAF6). IκB kinase (IKK)-β and MAP kinases are activated, leading to another complex of IKK molecules that are degraded and release nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB). NF-κB is a critical transcription factor for TLR-induced genes in inflammation. In addition, activation of the MAP kinase cascade leads to another transcription factor, AP-1, which is associated with activation of cytokines. TRIF-dependent signaling was found to be responsible for TLR3 signaling and, more recently, TRIF was implicated in TLR4 signaling.[20] TRIF interacts with TRAF3 and TRAF6, and leads to TNF receptor (R)-associated death domain protein (TRADD), ultimately leading to activation of NF-κB. Interestingly, TLR4 was found to activate MyD88 at the surface of the plasma membrane, while TRIF activation occurred when TLR4 was in endosomes.[20] Downstream from TRIF is activation of interferon regulatory factors (IRFs), which lead to interferon production and activation of interferon-dependent genes.

TABLE 20-1 Toll-Like Receptors

TLRs	PAMP	Cellular Location
TLR1	Lipoprotein (bacteria)	Plasma membrane
TLR2	Lipoprotein (e.g., bacteria, viruses, parasites, host damage)	Plasma membrane
TLR3	dsRNA	Endosome
TLR4	LPS (bacteria, virus, host damage)	Plasma membrane
TLR5	Flagellin (bacteria)	Plasma membrane
TLR6	Lipoprotein (bacteria, virus)	Plasma membrane
TLR7 (human TLR8)	ssRNA (virus, bacteria, host damage)	Endosome
TLR9	CpG-DNA (virus, bacteria, protozoa, host damage)	Endosome
TLR10	Unknown	Endosome
TLR11	Profilin-like molecule (protozoa)	Plasma membrane

RIG-I–Like Receptors

The RIG-I–like receptor (RLR) family presently includes three members: retinoic acid–inducible gene-I (RIG-I), melanoma differentiation–associated gene 5 (MDA5), and laboratory of genetics and physiology 2 (LGP2) (Table 20-2).[21] RLRs are expressed at a basal level by all nucleated cells, suggesting a central role in innate immune recognition and response to viral infection. A measure of their importance can be seen in the evolution of viral mechanisms to evade or suppress RLRs.[22] In the 1950s, interferons were discovered to be a critical antiviral innate immune response to viral infection produced by infected cells, and important in the recruitment and activation of natural killer (NK) cells and lymphocytes that recognize and kill virus-infected cells.[23] While the presence of an intracellular TLR receptor for dsRNA was hypothesized in 1969,[24] and subsequently identified, the discovery of RLRs introduced a second family of PRRs that are cytoplasmic sensors of viral nucleic acids that contribute to antiviral host defense by inducing interferon production. RIG-I was initially discovered in 1997 as a gene induced in acute promyelocytic leukemia cells after stimulation

TABLE 20-2 RIG-I-Like Receptors

RLRs	PAMP	Cellular Location
RIG-I	Short dsRNA	Cytoplasm
MDA5	Long dsRNA	Cytoplasm
LGP2	Unknown	Cytoplasm

with retinoic acid.[25,26] Several years later, RIG-I was found to be activated by interferon.[27] Similarly, MDA5 was identified in 1999,[28] and was later found to be induced by interferon.[29] LGP2 was suggested to function as a RIG-I inhibitor, exerting a regulatory role on antiviral innate immune responses,[30] but recent experiments suggest that LGP2 may modify viral RNA to assist RIG-I and MDA5 recognition of dsRNA.[19] Three genes encode RLRs in mice and humans, and all share a conserved helicase domain. Briefly, RIG-I and MDA5 are composed of two N-terminal caspase recruitment domains (CARDs), a central DEAD box helicase/ATPase domain, and a C-terminal regulatory domain.[31] LGP2 retains the helicase domain but lacks the CARD domain.[31] Their cytoplasmic location allows for recognition of dsRNA viruses and dsRNA intermediates generated during ssRNA viral replication. In addition, there is evidence that ssRNA is detected from viruses that do not produce significant amounts of dsRNA.[19] Importantly, eukaryotic cells avoid self-activation of RLRs by RNA in mitochondria, and RNA released into the cytosol is packaged to avoid RLR recognition.[22]

In the human lung, RLRs have been found to respond to a range of respiratory viruses, from rhinovirus (common cold virus) to influenza virus. In response to viruses, activation of intracellular signaling ultimately leads to interferon production and the activation of interferon-dependent genes. RLR signaling is dependent on CARDs, which interact with the interferon-β–promoter stimulator 1 (IPS-1, also known as MAVS, CARDIF, or VISA). IPS-1 is localized on the mitochondrial membrane. IPS-1 activates TRAF3 and TRADD, which are common molecules for IFN-inducible gene expression.[19] In addition, NF-κB signaling has been implicated.[32]

NOD-Like Receptors

Nucleotide oligomerization domain (NOD)-like receptors (NLRs) are another family of cytoplasmic pathogen sensors that were discovered in the 1990s (Table 20-3).[33] Briefly, the molecular structure of NLRs includes a central nucleotide-binding domain and C-terminal leucine-rich repeats. The N-terminal portions of most NLRs contain protein-binding motifs (e.g., CARDs, a pyrin domain, and a baculovirus inhibitor of apoptosis protein repeat [BIR] domain).[19] NLRs activate important signaling pathways mediated by NF-κB and MAP kinases, and activate caspases. The result is activation of diverse signaling pathways that induce innate immune responses.[34]

NOD1 and NOD2 identify bacterial PAMPs by recognition of peptidoglycan from gram-negative bacteria, gram-positive bacteria, and mycobacteria. The importance of NLRs was highlighted by the evidence that NOD polymorphisms are associated with increased severity of atopy, eczema, and asthma,[35] as well as other inflammatory diseases (e.g., Crohn disease,[36] tuberculosis,[37] and lung cancer[38]). This suggests that a defect in bacterial clearance may influence the host microbiome and subsequent pathophysiology of disease. Distinct from NOD1 and NOD2 are a group of NLRs that activate caspases, such as caspase-1. Caspase-1 is the prototypical caspase that has been shown to be required for cleavage and processing of inflammatory cytokines (IL-1β, IL-18) into their active forms. This signaling pathway is now commonly referred to as the "inflammasome," and has been shown to be critical for effective innate immune responses against a wide range of microbial pathogens, cancer, and inflammatory, metabolic, and autoimmune diseases.[39] Specific to the lung, the inflammasome is critical for responses to important pathogens such as influenza A virus,[40,41] *Streptococcus,*[42,43] *Pseudomonas aeruginosa,*[44] and *Mycobacterium tuberculosis.*[45] In addition, activation of the inflammasome has been suggested to contribute to the pathogenesis of asthma,[46] chronic obstructive pulmonary disease (COPD),[47] and pulmonary fibrosis.[48]

TABLE 20-3 NOD-Like Receptors

NLRs	PAMP	Cellular Location
NOD1	Gram-negative > Gram-positive bacteria	Cytoplasm
NOD2	Gram-negative, Gram-positive bacteria, mycobacteria	Cytoplasm
NLRP 1–14	Viruses, bacteria, mycobacteria	Cytoplasm

C-Type Lectin Receptors

The C-type lectin receptors (CLRs) were identified in the early 1900s, and represent a diverse family that includes over one thousand members.[49] The CLRs were initially characterized as Ca^{2+}-dependent (C-type) carbohydrate-binding (lectin) proteins[49] but, subsequently, some CLRs were found to not bind carbohydrate ligands or require Ca^{2+}-dependent signaling.[50] Currently, CLRs have been classified into 17 groups.[50] Structurally, CLRs are characterized by a carbohydrate-recognition domain (CRD) that is highly conserved.[49] Despite this conserved CRD structure, CLRs are involved in cell functions as diverse as adhesion, repair, endocytosis, and phagocytosis, as well as innate immune pathogen recognition. CLRs recognize carbohydrates on a wide variety of pathogens including viruses, bacteria, and fungi. Several of the canonical CLRs include dectins, mannose-binding lectin (MBL) receptors, and surfactant protein (SP). Dectin-1 and Dectin-2 are important PRRs for recognition of fungi.[51] Upon recognition of fungal PAMPs, intracellular signaling pathways involve activation of NF-κB and MAP kinases.[52] MBL receptors function as PRRs by recognition of carbohydrate motifs on pathogens, which leads to complement activation.[18] MBL recognizes diverse pathogens that include gram-positive and gram-negative bacteria, yeast, parasites, mycobacteria, and viruses.[53] SP was first identified as a critical phospholipid for maintaining alveolar compliance to prevent atelectasis.[54] However, in the 1980s after the discovery of MBLs, sequencing of SP revealed significant structural similarities.[55] In accord with these similarities, SP-A and SP-D, secreted by alveolar epithelium, have been shown to function as agglutinins, opsonins, and inflammatory modulators[8] in response to viruses, bacteria, mycobacteria, and fungi.[56]

PATHOGEN-INDUCED INNATE IMMUNE RESPONSES

Inhaled pathogens may circumvent the mucociliary "ladder" on airway epithelium, which is typically the first responder to pathogens by virtue of its location and distribution. Antigen-presenting cells (APCs) such as dendritic cells (DCs) provide a critical role for pathogen recognition by extending projections into the airway between epithelial cells to sample the environment. On both airway epithelium and DCs, there is a wide repertoire of PRRs that recognize pathogens.[57] Upon recognition of PAMPs, PRRs activate signaling pathways that lead to subsequent inflammatory responses. An important component of this inflammatory response is the production of chemokines to recruit hematopoietic cells (e.g., neutrophils, eosinophils, macrophages, and lymphocytes including NK, and NKT cells) that are critical effector cells for the initiation and resolution of inflammation. In addition to chemokine production, PRR activation stimulates the production of a variety of cytokines (e.g., tumor necrosis factor (TNF)-α, IL-1β, IL-6, TGF-β, IL-10) that activate effector cells and contribute to the regulation of innate and adaptive responses in the lung.[57] PRR activation influences the balance of oxidation and proteases present in the lung. Importantly, dysregulation of oxidation has been shown to contribute to the pathogenesis of COPD,[58] while defective antiproteases, best exemplified by α1-antitrypsin deficiency, is a significant risk factor for the development of asthma, bronchiectasis, and emphysema.[59] Antimicrobial peptides are also produced by epithelial cells, as well as recruited hematopoietic cells, in response to PRR activation

(Fig. 20-1).[60] In humans, two significant groups of antimicrobial peptides are the cathelicidins[61] and defensins.[60] These small cationic peptides have antimicrobial activity against gram-negative and gram-positive bacteria, fungi, parasites, and viruses.[62] Epithelial and hematopoietic cells (e.g., neutrophils) produce both cathelicidins and defensins, and in addition to their antimicrobial properties, these peptides have been implicated in the induction of inflammation, influencing adaptive immune responses and wound repair.[61,62] Therefore, antimicrobial peptides are an excellent example of an innate immune response, initiated by PRR recognition of pathogens or PAMPs, which results in a protective response, regulates inflammation, and bridges innate and adaptive immunity. Recently a group of innate immune cells, known as innate lymphoid cells (ILCs), have been identified that lack specific antigen receptors but can produce an array of effector cytokines.[63,64] These ILCs have morphologic characteristics of lymphoid cells and can respond to a variety of signals and play an important role in immunity against microorganisms, tissue homeostasis, and repair of damaged tissues. Currently, there are three subsets of ILCs identified: ILC1s include IL-15–dependent NK cells; ILC2s are characterized by their production of T helper (Th) 2 cytokines (IL-5 and IL-13); and ILC3s express the nuclear hormone receptor retinoic acid receptor–related receptor (ROR)γt and produce cytokines IL-17 and IL-22.[63,65] These cells are important in innate immunity and very likely will be discovered to contribute to the development of effective adaptive responses.

CELLULAR RESPONSES IN THE LUNG

When pathogens bypass the initial lung mucosal barriers, the host's immune system responds in an orchestrated defense that involves a number of specialized cells that target the threat, neutralize it, and cleanup remnants to prevent the tissue injury. Macrophages function as phagocytes to engulf pathogens (viable and nonviable microorganisms), as well as apoptotic and necrotic cells that have undergone physiologic and pathologic cell death.[66] Ultimately, the lung must perform these tasks in a selective manner to avoid unnecessary inflammation that can cause continued tissue destruction. The innate immune system, as described earlier, is made up of a humoral arm (lactoferrins, lysozyme, sIgA, SPs, MBLs, and defensins) as well as a cellular arm (AMs, DCs, neutrophils, ILCs, etc.) that express numerous PRRs and or phagocytic receptors important for their diverse functions.

MACROPHAGES

Macrophages, initially described in the 1880s, are large mononuclear phagocytic cells. They play an important role in host defense based on their ability to phagocytize inhaled moieties, maintain tissue homeostasis, and function as APCs which are important in adaptive humoral and cell-mediated responses.[67] Macrophage precursors arise from committed hematopoietic stem cells in the bone marrow and are released into the circulation as monocytes before they differentiate into macrophages and DCs as they migrate into the lung. Tissue-resident macrophages form a specialized population based on their local anatomic location. Once called dust cells for their ability to engulf particulates, AMs, named for their presence in the pulmonary alveolus, frequently contain granules of various exogenous materials.[68] One example is particulate matter such as the black carbonaceous granules seen in lungs from smokers and long-term city dwellers. Routine bronchoalveolar lavage will identify these resident airway and AMs. However, pulmonary interstitial macrophages from lung tissue can only be collected by tissue dispersion techniques.[69] Of note, AMs are inferior APCs when compared to DCs.[70]

AMs secrete numerous products (e.g., cytokines, chemokines, and peptides) and directly interact with other cells and molecules through the expression of a variety of surface receptors.[71] AMs have multiple functions that include phagocytosis of cells undergoing apoptosis and necrosis, clearance of ingested pathogens or particulates, routine clearance of surfactant, and suppressing inappropriate inflammation and immune responses to harmless inhaled antigens. Macrophages ingest and phagocytose microbial or environmental particulate matter, which is then enclosed in intracellular vesicular phagosomes that undergo fusion with primary or secondary lysosomes to form phagolysosomes. In these AMs vacuoles, intracellular killing takes place through mechanisms that include antimicrobial proteins, degradative enzymes, oxidation, reactive oxygen intermediate generation, and "respiratory burst" known as nicotinamide adenine dinucleotide phosphate (NADPH) oxidase degradation. Macrophages facilitate many innate recognition functions because they express diverse PRRs (e.g., TLRs, NLRs, and CLRs) to assist host defense in combating invading pathogens. The recognition and clearance of invading pathogens can also occur via opsonin-mediated phagocytosis through the Fcγ receptors. These receptors allow macrophages to be selective in their response to phagocytosed antigen, minimize damaging effects on normal cells, and limit responses to harmless moieties that can be frequently encountered in the airway.

While AMs have greater respiratory burst capacity than other phagocytes,[72] there are certain organisms that have evolved to evade AMs to improve their growth and survival. For example, mycobacteria prevent the fusion of phagosomes and lysosomes, escaping the harmful effects of the lysosomal hydrolases, and thus are resistant to the effects of macrophages. Some inhaled pathogens such as *M. tuberculosis* and environmental particulates such as silica are resistant to AM function and remain in intracellular lysosomal vacuoles for the duration of the macrophage life span. Macrophages also produce inflammatory cytokines and chemokines to recruit other specialized cells to assist in PRR recognition and host defense, in turn, helping to shape the adaptive immune response that follows.

Lung resident AMs are continuously encountering inhaled substances because of their unique position in the alveolar lumen (Fig. 20-1). Because of this location and the potential to cause harm to surrounding delicate and sensitive lung structures (e.g., alveolar epithelium), AMs are normally kept in a quiescent state to limit unnecessary inflammation and injury to nearby structural type I and surfactant producing type II pneumocytes when they encounter harmless antigens. Compared to AMs, DCs are less capable phagocytes with lower levels of expression of phagocytic receptors such as CD11b. In contrast, AMs produce lower levels of pro-inflammatory cytokines and suppress adaptive immune responses through their effects on neighboring DCs and T cells. It has been shown that depletion of AMs can lead to exuberant lung inflammation in response to otherwise innocuous antigens.[73] These AMs, when mixed with DCs in vitro, can suppress T cell function through the release of factors such as nitric oxide, IL-10, TGF-β, and various prostaglandins.[74]

DENDRITIC CELLS

If the relatively nonspecific mechanisms of the innate immune system fail, there is a highly developed network of DCs that is responsible for mobilizing the adaptive immune response, especially against invading pathogens and unwanted antigens.[70,75] DCs are also important phagocytic cells and, in general, are better APC than macrophages.[70] DCs are critical at bridging innate and adaptive immunity because of their extensive interdigitating physical extensions that reach between cells to provide a tight surveillance network within intraepithelial and subepithelial structures of the respiratory tract. Via this network, DCs continuously sample what the lung encounters. Because of their distribution, they are ideally positioned to participate in determining whether an inhaled moiety results in pulmonary immunity or tolerance. DCs express MHC and accessory molecules such as CD80, CD86, and CD40 making them excellent professional APCs to incoming naïve T cells.[76,77]

They also express a number of innate immune receptors including TLRs, NLRs, and CLRs for the recognition of various patterned motifs from inhaled antigen and pathogens. Lung DCs also express prostaglandin receptors that affect migratory behavior and cell maturation. They also express inflammatory receptors that detect DAMP proteins such as uric acid, ATP, and high-mobility group box (HMGB)-1. Their ability to sense, take up, process incoming molecules, and migrate to nearby draining lymph nodes for antigen presentation, allows DCs to bridge innate and adaptive immunity in the lung. In the lymph nodes, DCs present MHC peptide antigen complexes to T cell receptors (TCRs) on naïve T cells and in the appropriate context of costimulatory molecules on their cell surface and cytokines in the local microenvironment, naïve T cells are activated and proliferate. In the absence of appropriate costimulation or cytokines, DC and T cell interaction can lead to tolerance to an antigen, a mechanism that likely helps to avoid harmful immunologic response to harmless inhaled antigens.

DCs have been divided into several subsets based on their cell surface protein expression, origin, location, and specialized function.[78] In mice, three major subsets of DCs have been described: resident conventional DCs (cDCs), plasmacytoid DCs (pDCs), and inflammatory DCs. The resident cDCs expresses CD11c markers and have been divided into those that express CD11b, and those that are CD11b negative. At baseline, cDCs expressing MHC and CD11c line the conducting airways and are able to extend their dendrites into the airway lumen between tight junctions. In murine models, these cDCs can also express langerin and the mucosal integrin CD103. cDCs have good antigen presentation function. A migratory cDCs subset migrates to nearby lymph nodes after capturing inhaled antigen in the airway lumen, while lymphoid tissue resident cDCs reside in the lymph nodes and spleen and respond to antigen delivered via the draining lymphatics. pDCs are characterized by the expression of the surface marker Siglec-H (a bone marrow stromal antigen-1) and abundance of endosomal innate receptors TLR7 and TLR9, which make pDCs particularly important antiviral effectors because of their type I interferon production in response to viruses and bacterial DNA. Residing in the alveolar space are alveolar DCs, which classically express MHC class II and CD11c, and can have CD103 subsets. These alveolar DCs have been described to resemble human Langerhans cells.[79]

In response to innate and inflammatory stimuli, DCs are able to increase their numbers with rapid recruitment. These DCs have similar abilities to undergo antigen processing, to migrate to draining lymph nodes, and to modulate naïve T cells for either activation or tolerance. The inflammatory cDCs are normally not present in the lung. However, in the setting of inflammation and/or infection, circulating monocyte–derived $CD11b^+$ DCs upregulate CD11c, retain Ly6C, and can rapidly be recruited to the lung as inflammatory cDCs to respond to the stimulus. Comparable subsets of DCs in human lungs have been described such as myeloid type of DC that express both blood dendritic cell antigen (BDCA)1 or BDCA3 and HLA-DR and pDCs that express BDCA2 and CD123.[80–82]

Overall, DCs rely on neighboring structural cells, such as the airway epithelial cells, to influence the type of antigen-specific immune response. This epithelial–DC interaction in the lung plays an important role in immune homeostasis as well as the initiation and transition of innate immunity toward antigen-specific adaptive immunity. Some have proposed that extracellular matrix surrounding epithelial cells and DCs produces certain chemokines that allow for the activation properties of DCs.[83] Antigen presentation by APCs such as AMs and DCs is a required priming event for T cell activation to occur.

NEUTROPHILS

Neutrophils are derived from the bone marrow and require granulocyte colony–stimulating factor (G-CSF) for their proliferation and differentiation into their mature form. In times of stress or infection, neutrophils are mobilized from the bone marrow into the blood stream and eventually to sites of inflammation such as the lungs.[84] During this process, neutrophils become activated, generate free radicals, release granule contents, and participate in phagocytosis and degradation of invading microbes. Neutrophils are one of the first phagocytes recruited to sites of acute lung diseases, but they have a limited life span after their release from the bone marrow and within hours they are cleared with the resolution of the inflammation or disease process. However, in chronic lung diseases, neutrophils can be persistently recruited to the lung. Recruited tissue neutrophils are thought to live substantially longer, up to several days, than circulating neutrophils.[85] These neutrophils, which are modulated by the local microenvironment, are important for antipathogen responses, but they can cause significant lung tissue damage when they accumulate over longer time periods and release granule contents that can be toxic when released in an uncontrolled manner.[86,87] Neutrophils are able to respond to a number of particulate and soluble stimuli. They also have the ability to be primed prior to exposure to stimuli.[88] For example, neutrophils can be primed, or pre-activated, by stimuli such as IL-8, granulocyte macrophage colony–stimulating factor, platelet activating factor, and reactive oxygen species. This process helps prepare neutrophils for subsequent contact with pathogens by extending their life span, upregulating cell surface integrins (such as CD11b), optimizing NADPH oxidase assembly, and prolonging neutrophil functional longevity.[89,90] Neutrophils play an important role in innate immune response to infection, as these phagocytic cells also possess an impressive array of microbicidal weapons against invading pathogens that include toxic oxygen radical species and proteolytic enzymes. Local infiltration and tissue accumulation of neutrophils are mediated by chemokines that are produced by inflamed tissues. At sites of inflammation, mediators such as IL-1 or TNF-α induce or augment the expression of adhesion molecules on endothelial cells and circulating granulocytes. Intravascular circulating neutrophils slow down, roll along, and then anchor on the endothelium allowing entry to the lung interstitium and subsequently the alveolar space. Ultimately, inflammation will cease and, with successful containment of pathogens, resolution of inflammation often follows. This resolution of inflammation requires wound healing and restoration of the lung's normal structure and function. Mechanisms for resolution of tissue inflammation are not as well established, but include substances such as sphingosine-1-phosphate for restoring endothelial barrier and vascular permeability after endotoxin injury or natural mediators derived from essential fatty acids such as ω-3 fatty acids with their anti-inflammatory and pro-resolving properties.[91] Cytokines such as IL-10, TGF-β, and IL-1 receptor antagonist have also been implicated as important mediators of inflammatory resolution. An inability to resolve inflammation can lead to chronic inflammation in the lung as seen in a number of pulmonary diseases.

ADAPTIVE IMMUNE RESPONSES IN THE LUNG

An essential prerequisite for a successful host immune response is the ability to discriminate between self and nonself.[92,93] Adaptive immune responses, which can also be described as acquired, refer to antigen-specific immunity that often takes several days to mature and to develop a targeted response to a specific antigen. Ultimately, the goal of this adaptive response is to react with, and subsequently remove, a specific antigen. This type of immunity is one that develops throughout life and is the premise behind vaccination for pulmonary infections caused by pathogens such as influenza virus and *Streptococcus pneumoniae*.[94,95] From an immunologic standpoint, an antigen is defined to be a substance that reacts to antibody molecules or antigen receptors on lymphocytes. For example, B cells recognize antigen through specific B cell receptor (BCR) (and in this case immunoglobulin [Ig]), while T cells recognize antigen through specific TCR.

This recognition is through specific epitopes on the antigen being recognized. For T cells to recognize antigenic epitopes through TCR, cells recognize peptide epitopes from antigen only when presented by APCs (e.g., DCs and macrophages) in the context of appropriate MHC molecules. Adaptive immune responses are often divided into two major branches: humoral immunity and cell-mediated immune responses. Humoral immune responses rely on the production of antibodies in response to encountered antigens and are mediated by B lymphocytes. Cell-mediated immune responses involve various immune cells such as T lymphocytes, cytotoxic T lymphocytes, activated macrophages, and/or activated NK cells. Activated macrophages and NK cells destroy intracellular pathogens and stimulate nearby structural cells to secrete cytokines that influence other cells of the immune system. Cytotoxic T lymphocytes (often $CD8^+$ cells) are capable of destroying host cells that display foreign antigens on the cell surface, such as cells infected with viruses or intracellular bacteria, or cancer cells that display tumor antigens.

The adaptive arm of the immune response relies on specific recognition of antigens by B and T lymphocytes. These cells are highly equipped to be specific because of their receptors, thus the immune system is capable of recognizing a large number of antigens. The functionality of adaptive immunity is based on specific gene rearrangement that results in the generation of over 10^{11} different species of antigen receptors on the cell surface of T and B cells.[96–98] In addition to adaptive immune responses, this defense system targets pathogens that have evolved mechanisms to evade or to counteract innate immune responses. Therefore, the adaptive immune response builds upon, is shaped by, and itself shapes innate immune responses resulting in a strong interplay between the innate and adaptive arms of our immune system.[99] Adaptive immunity helps protect the lungs not only against a range of pathogens, but environmental inhalants, such as cigarette smoke, dusts, as well as allergens. The adaptive immune response is quite versatile, relies on exquisite specificity, and takes advantage of robust memory. This is especially evident when it comes to countering airborne antigens. It is estimated that our human body has the ability to recognize 10^7 or more different epitopes and can make up to 10^9 different antibodies, each with different specificity. These epitopes are antigenic determinants that are part of the antigen that is recognized by the antibodies generated by B cells, or by receptors on B and T cells. To recognize the immense number of different epitopes, the human body produces 10^7 or more distinct clones of both B and T lymphocytes, each with their unique BCR or TCR, respectively.[85,100] Among the large variety of BCRs and TCRs, there is bound to be at least one that has the epitope-binding site capable to recognize any antigen the immune system eventually encounters. Thus, the body is able to recognize any conceivable antigen it may eventually encounter, allowing for an adaptive immune response. However, only a few B and or T cells can recognize any one epitope, and these cells require an appropriate stimulus to allow for rapid proliferation. This process typically takes several days to occur. During this time, to achieve an effective and mature adaptive immunity, the invading pathogen could cause considerable damage, which is why innate immune responses are important at the early stage of infection, unless the host has already encountered the antigen before and has developed a specific adaptive immune response against the antigen. In this situation, during a repeated encounter with an antigen, adaptive immunity, which already has an established memory response, will take a shorter period of time to mobilize the adaptive effector cells to counter the invading antigen.

A majority of T cells express TCR with αβ variable chains, which permits them to recognize short peptide epitope of an antigen. Typically, precursor αβ T cells are recruited out of the bone marrow to the thymus. In the thymus, they undergo the process of positive, then negative selection to assure that the resultant T cells appropriately respond to peptide in the context of self-MHC, but not strong enough to cause potentially damaging autoreactivity. It is also during this thymic maturation that the T cells acquire the expression of either CD4 (allowing it to recognize peptide in the context of class II MHC) or CD8 (allowing it to recognize peptide in the context of class I MHC). Of note, only a small fraction, <5% of all precursor T cells, complete this process of thymic education and maturation. These cells become naïve T cells that circulate throughout the host to encounter their specific antigen for antigenic stimulation. Thymus-independent T cells do exist and have been identified in the gut, but are less well understood in the lung. However, these cells are limited in their diversity and recirculatory capacity and cannot compensate for the lack of thymus-dependent T cells.[101]

T cell development occurs in the thymus where bone marrow–derived premature naïve T cell precursors congregate.[102–104] These T cells start off as double negative cells (CD4 and CD8 negative). Upon acquisition of successful rearrangement of α- and β-TCRs, as well as expression of both CD4 and CD8 (making them double positive cells), these developing T cells undergo positive and negative selection. Since TCRs recognize antigen only in the context of MHC molecules, T cells must be "educated" to first recognize host MHC. During positive selection, double positive T cells that can recognize self-MHCs are selected for proliferation, and those T cells that do not recognize self-MHCs are removed through apoptotic cell death pathways. Positive selection also assures that the appropriate TCR selection will associate with the appropriate CD4 or CD8. For example, TCRs specific for MHC class II need to retain CD4, and lose CD8. If the reverse occurs, they will die via apoptosis. The same is true for T cells that are specific for MHC class I, which need to retain CD8 and lose CD4. Single positive thymocytes (either $CD4^+$ or $CD8^+$) undergo negative selection to remove potential autoreactive cells. Those T cells that have high affinity for binding self-proteins presented on self-MHCs are induced to upregulate genes that drive apoptosis, eliminating them in the thymus. However, if they escape this elimination process, they may subsequently react against self-antigens, which can result in autoimmunity. Positive selection identifies T cells that react with self-MHC and self-antigen.[105] Negative selection eliminates those that react strongly with self-MHC and self-antigen. Therefore, a successful T cell differentiation selects for MHC restricted TCRs with low affinity for self-antigens.

The underlying premise of the adaptive immune response that allows the system to recognize an unlimited scope of antigens that the host ultimately can encounter is the generation of antigen receptor diversity through gene translocation and recombination processes.[106] This process helps shape each receptor (either TCRs on T cells or BCRs, or the Igs on B cells). The TCRs have α- and β-chains, where there are many different V and J genes that can make up the TCR α-chain, and many V, D, and J genes that can recombine to form the variable TCR β-chain. Similarly, BCR undergoes similar gene recombination, including junctional diversity and somatic hypermutation that help generate a wide scope of BCR diversity. In the end, each T or B cell will exhibit a unique receptor capable of recognizing its unique antigen. For B cells, the BCR (Ig) recognizes specific epitopes of the antigen. For T cells, $CD8^+$ or $CD4^+$ T cells will express unique cognate complementary shaped peptide that is bound to either MHC class I or MHC class II molecules, respectively.

GENERATION OF AN IMMUNE RESPONSE

Upon cognate recognition of T cells with antigen/peptide presented on MHC molecules on APCs, the activated lymphocytes rapidly proliferate to produce large clonal populations (Fig. 20-3). Circulating memory T cells have the capacity to persist in the host for a long time and become mobilized and reactivated during a repeat encounter with the same antigen. This subsequent exposure of antigen leads to a more rapid and persistent production of effector cells in a process called clonal expansion. This allows the limited

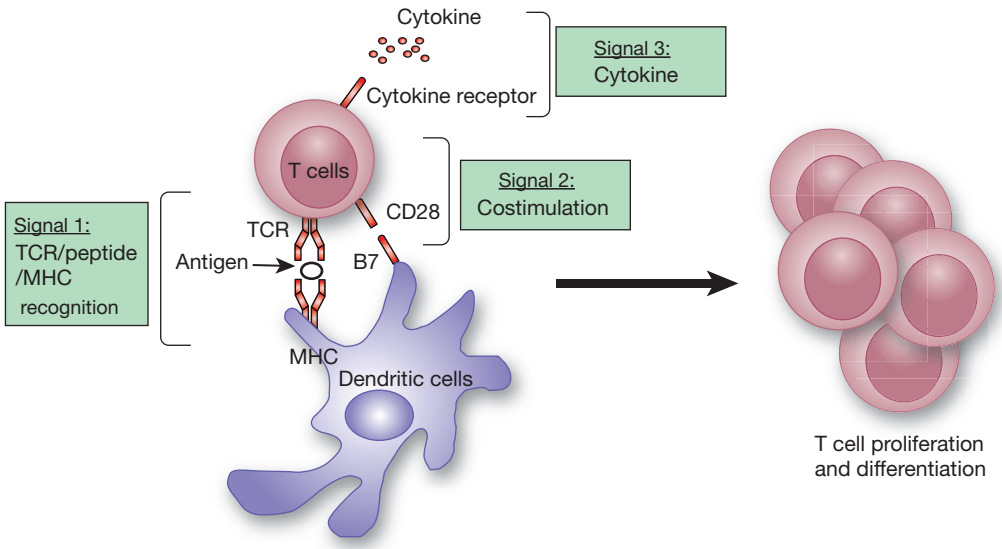

Figure 20-3 Generation of an immune response. Dendritic cells (DCs) and other antigen-presenting cells (such as macrophages) link the innate and adaptive immune response. DCs from the innate immune system present their antigen to naïve T cells at local draining lymph nodes; in the case of the respiratory tract, these are the mediastinal draining lymph nodes. T cell receptor (TCR) ligation to MHC molecules associated with peptides processed from antigen (e.g., pathogen, allergen, toxin) by DCs provide "signal 1." The binding of costimulatory molecule CD28 on lymphocyte to CD80 and CD86 expressed by DCs ("signal 2") leads to T cell activation and cell lineage differentiation. "Signal 3" is provided by the polarizing cytokine signals from nearby innate immune cells and local tissue environment. Depending on the type of antigen that is presented and the nature of cytokines in the microenvironment, innate DC cells direct the development of various T helper lymphocyte lineages that play crucial role in adaptive immune system.

T cell number, with the appropriate antigen recognition and specificity, to expand and proliferate when necessary. During adaptive immunity, pathogens encountered in the mucosal surfaces and, in the lung, the airway mucosa, are transported to draining lymphoid organs where antigen is recognized by naïve B and T lymphocytes, which leads to cell activation. These activated B and T cells proliferate and differentiate into effector cells.

Naïve T cells undergo development and maturation in the thymus and circulate out of the thymus to mucosal surfaces and lymph nodes to encounter antigens.[107,108] APCs, such as macrophages and DCs from the innate immune system, present endocytosed foreign antigen to naïve T cells at local draining lymph nodes. APCs present MHC class II–associated peptides processed from pathogens to $CD4^+$ T cells that express specific TCR against the particular antigen peptide/MHC complex. The TCR–CD3 complex binds to the antigen peptide MHC complex on APC, and this interaction triggers intracellular signaling pathways that provide the first signal, "signal 1," of T cell activation. Upon a subsequent encounter with the same antigen, memory T cells are reactivated using these same TCR pathways.[107] A second signal, "signal 2," is required to ensure that naïve T cells are responding to foreign antigen. This process involves binding of CD28 on lymphocytes to costimulatory molecules CD80 and CD86 that are expressed only by activated APCs. "Signal 2" leads to T cell lineage differentiation. Without "signal 2," during the initial antigen exposure, T cells become anergic and are unable to respond to subsequent antigen encounters, a process that avoids or minimizes production of autoreactive cells, and thus autoimmunity against self-antigens. Once T cells are activated by the two signals, only "signal 1" is required for subsequent future activation; an example of this is seen with memory T cells providing a faster immune response. After two-signal activation, Th cells proliferate and produce multiple cytokines, and this includes IL-2 production for autocrine activation by upregulation of the IL-2 receptor, CD25. "Signal 3" involves polarizing cytokine signaling from innate immune cells that allow for the development of specific types of immune responses.[109] Inflammatory cytokines such as IL-12 can act directly on naïve T cells to provide a third signal, along with antigen and IL-2, to optimally activate differentiation and clonal expansion. $CD4^+$ Th cells play an important role in mediating various types of immune responses through their cytokine release. There are also other CD4-expressing T cells that are not Th cells; these include some cytotoxic T cells, NKT cells, and regulatory T (Treg) cells.

■ ACTIVATION OF NAÏVE HELPER T CELLS

$CD4^+$ T cells play an important role in adaptive immune responses. Proliferating Th cells that develop into effector T cells can differentiate into one of several lineages (Fig. 20-4).[110] Depending on the type of antigen that is presented, the strength of the TCR signal, and the nature of cytokines in the microenvironment, innate APCs (typically DCs) direct the development of various Th lymphocyte lineages. The differentiation of each $CD4^+$ T cell subset is associated with the expression of specific transcription factors that lead to production of an array of cytokines that help orchestrate a specific host response. $CD4^+$ Th cells, based on their cytokine production, help dictate this type of response. The most studied and established Th subset is the dichotomy between type 1 and type 2 responses, often called T helper 1 (Th1) and T helper 2 (Th2) responses.

Th1 cells promote cell-mediated immune responses and are required for host defense against viral and intracellular bacterial pathogens. Th1 responses can be characterized by the secretion of IFN-γ, IL-12, IL-10, and TNF-α/β, and stimulation of classically activating macrophages to tackle intracellular pathogens.[111] These cytokines promote macrophage activation, nitric oxide production, and cytotoxic T lymphocyte proliferation, leading to phagocytosis and destruction of microbial pathogens. Th1 responses in the lung are important because AMs encounter antigens to activate these specific effector responses. IL-27 signaling in naïve $CD4^+$ T cells induces STAT1-dependent expression of the Th1-specific transcription factor, T-bet, which promotes expression of IFN-γ and IL-12 receptors. Subsequent activation stimulates STAT4-dependent

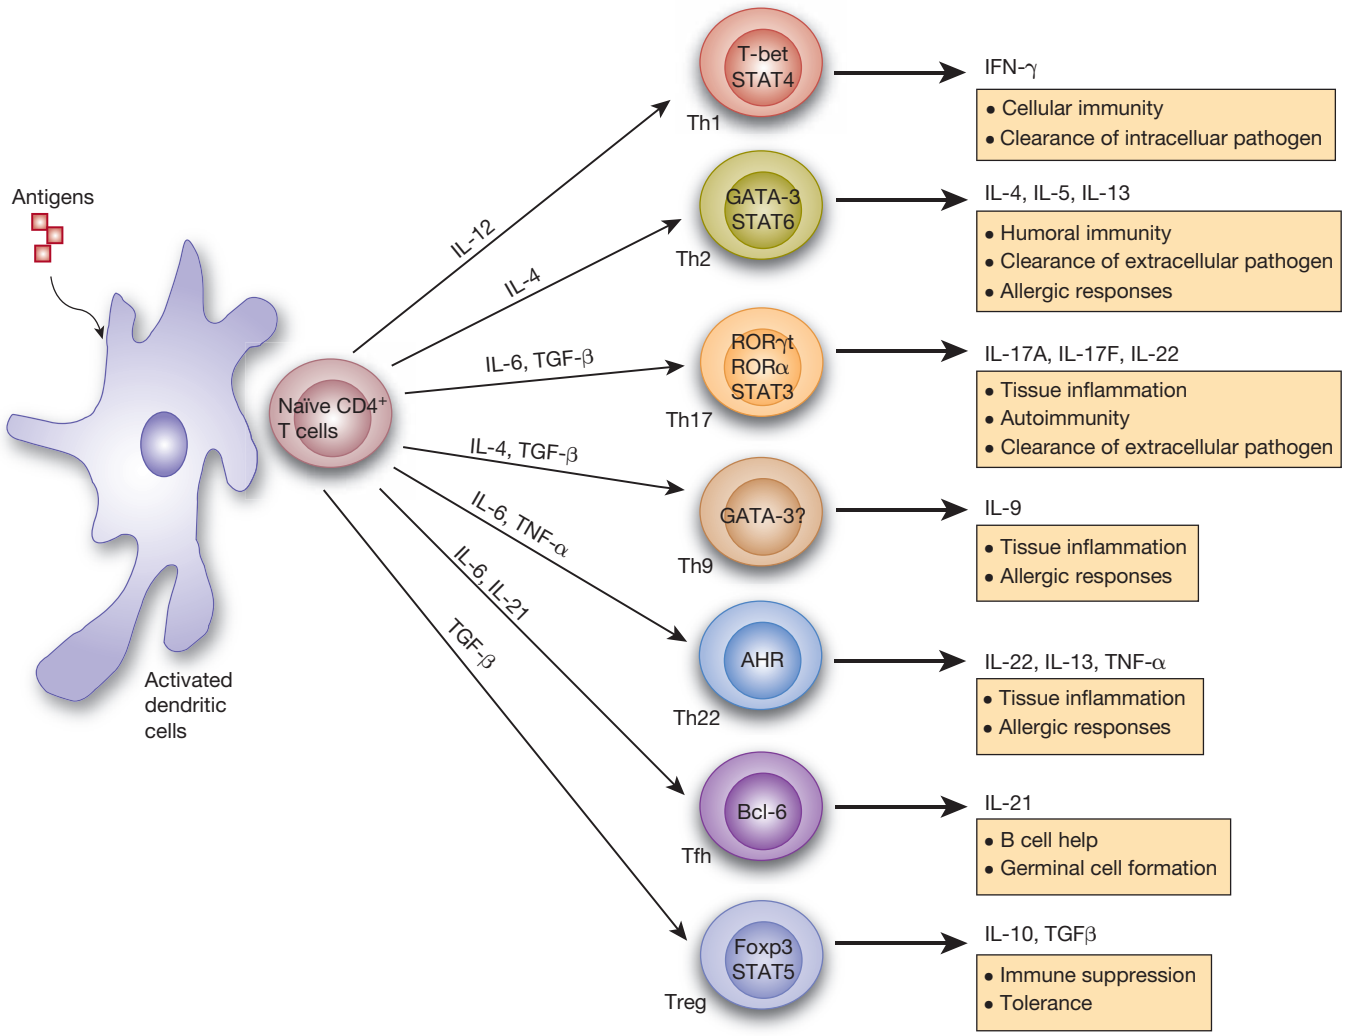

Figure 20-4 T cell differentiation. Naïve CD4$^+$ T cells differentiate into one of several T helper (Th) cell lineage based on signals from innate immune cells induced by antigenic and inflammatory stimuli as presented by activated DCs. The resultant products of differentiated T cells subsequently help tailor the immune response to various encountered antigen scenario. Th cell differentiation is classically regarded as a dichotomy between two main cell types, termed Th1 and Th2. Th1 cells produce IFN-γ as the signature cytokine and are predominantly involved in cell-mediated immunity against intracellular pathogens. In contrast, Th2 cells do not produce IFN-γ and instead produce IL-4, IL-5, and IL-13. Th2 cells are effective activators of B cell proliferation and antibody production, mediating humoral immunity essential for the eradication of extracellular pathogens as well as mediating allergic type of inflammation. Th17 cells have been described as a distinct Th subset characterized by the production of IL-17A, IL-17F, and IL-22, contributing to host defence against extracellular pathogens particularly on mucosal surfaces, as well as in the pathogenesis of autoimmune diseases. Recently, more Th cell subsets have been described such as Th9 and Th22 cells that participate in allergic type of immune responses. Other stimuli cause CD4$^+$ T cells to become regulatory T (Treg) cells that help dampen immune responses. Other stimuli allow CD4$^+$ T cells to reside in lymph nodes, differentiate into follicular helper T (Tfh) cells and provide help to B cells. The various Th subsets require activation of specific master regulator transcription factors such as T-bet, GATA-3, RORγt, Bcl-6, and Foxp3 as well as various STAT molecules for their differentiation as indicated in the diagram. Bcl-6, B cell lymphoma-6; Foxp3, forkhead box p3; ROR, retinoid-related orphan receptor; AHR, aryl hydrocarbon receptor; STAT, signal transducer and activation of transcription.

IFN-γ production and Th1 differentiation. While Th1 cells are critical for the clearance of intracellular pathogens, exaggerated Th1 responses can result in lung pathology (e.g., autoimmune disease, interstitial lung disease, and COPD). Th2 responses are characterized by production of IL-4, IL-5, IL-9, IL-13, and IL-25, and these cytokines favor antibody production and class switching to IgE and IgG. Th2 cells are required for humoral immunity and play an important role in coordinating immune responses to extracellular pathogens.[112] Th2 differentiation occurs in the presence of IL-4 and either IL-2, IL-7, or thymic stromal lymphopoietin (TSLP). IL-4 stimulates naïve CD4$^+$ T cells to induce STAT6-dependent expression of GATA-3, the transcriptional regulator of Th2 cells, which promotes IL-5 and IL-13 expression, and stimulates the expansion of Th2 cells, while suppressing the differentiation of other T cell subtypes. In addition to IL-4–induced activation of GATA-3, IL-2, IL-7, or TSLP is required during Th2 differentiation to activate STAT5, which cooperates with GATA-3 to promote T cell production of IL-4. IL-4 regulates clonal expansion of Th2 cells and, along with IL-13, promotes B cell production of IgE and alternative macrophage activation. Th2 cells also produce IL-5 to stimulate eosinophil activation and survival, or IL-9 to promote mast cell activation. Th2 responses are typically important host immune responses to

extracellular pathogens such as parasites or helminths. However, excessive Th2 signaling has been implicated in the development of chronic allergic inflammation and asthma.

T helper 17 (Th17) cells are involved in the immune response against specific fungi and extracellular bacteria.[113] Th17 cells develop from naïve $CD4^+$ T cells in the presence of TGF-β and IL-6, cytokines that induce STAT3-dependent expression of IL-21 and the transcription factor RORγt. IL-21 and IL-23 help establish, regulate, and develop (via clonal expansion) Th17 cells. RORγt-induced gene expression leads to the secretion of IL-17A, IL-17F, and IL-22. Cytokines secreted by Th17 cells stimulate chemokine secretion by resident cells, leading to the recruitment of neutrophils and macrophages to sites of inflammation. These cells produce additional cytokines and proteases that further augment immune responses. For human Th17 differentiation, Th17 polarization requires IL-1β, IL-6, IL-21, and IL-23, and is less dependent upon TGF-β. While Th17 cells play a central role in eliminating harmful microbes, persistent secretion of Th17 cytokines can promote chronic inflammation and has been implicated in lung diseases such as COPD, sarcoidosis, and granulomatous diseases. The role of cytokine polarization in lung diseases has been studied in transgenic animal modeling systems where specific cytokines are over-expressed, or cytokine receptors or transcriptional factors such as GATA-3 and T-bet are modified. These studies have helped to elucidate the effector function of individual cytokines and their pathophysiologic consequences in the lung.[114]

T helper 9 (Th9) cells secrete high levels of IL-9, CCL17, CCL22, and in mouse, IL-10. Th9 cell differentiation requires the presence of TGF-β and IL-4, which induce transcription factors PU.1/Spi-1 and IRF 4 that regulate IL-9.[115] Cytokines such as IL-1β, IL-6, IL-21, and type I interferons all enhance Th9 differentiation, and IL-2 and IL-25 promote IL-9 secretion. Different from Th2 cells, Th9 cells do not express IL-4, IL-5, or IL-13. Th9 cells are important for host defense against parasitic and helminthic infections, but they are also associated with the development of chronic allergic inflammation, airway remodeling, and autoimmune diseases.[115,116] T helper 22 (Th22) cells primarily secrete IL-22, IL-13, and TNF-α. Similar to Th17 cells, Th22 cells express IL-22, but in contrast, they express several fibroblast growth factors (FGFs) and do not express IL-17, IL-4 (Th2 marker), or IFN-γ (Th1 marker).[117] Th22 cells differentiate in the presence of IL-6 and TNF-α, and their differentiation is inhibited by TGF-β.[118] Th22 cells can be regulated by the aryl hydrocarbon receptor (AHR) transcription factor. IL-22 secreted by Th22 cells primarily affects epithelial and stromal cells rather than other hematopoietic cells, which lack a functional IL-22 receptor. Th22 cells contribute to allergic inflammation in the lung, but their role in skin immunity is better established.

Another subset of $CD4^+$ T helper cells are follicular helper T cells (Tfh) which regulate the development of antigen-specific B cell immunity.[119,120] These Tfh cells help B cells generate antibody-producing plasma cells and long-lived memory B cells. Tfh cells are identified by Bcl-6 (a transcriptional repressor) expression and IL-21 secretion. IL-6 and autocrine IL-21 signaling induce Th cells to express Bcl-6, which controls Tfh cell differentiation and suppresses differentiation of Th1, Th2, and Th17 cells. These Tfh cells have been implicated in several autoimmune diseases, including systemic lupus erythematosus and Sjögren syndrome. The actions of Th cells are balanced by Treg cells, a subpopulation of CD4-expressing cells that specializes in suppression of T cell–mediated immune responses.[121,122] Treg cells are identified by their expression of CD25 and the transcription factor Foxp3. Treg cells are capable of regulating and suppressing immune responses. They produce cytokines such as TGF-β and IL-10 that have immune suppressive activities. Of note, failure to activate an appropriate T cell response can lead to chronic infection, while exaggerated T cell responses can cause excessive tissue damage and are associated with inflammatory and autoimmune diseases. During lung infections, Th1 may mediate lung damage in response to infection. Thus, downregulation of such Th1 responses may help preserve lung integrity. Th2 responses are known to be important during the wound healing process, but if this response is prolonged and uncontrolled, it can worsen the injury and contribute to fibrosis.

Considering the diverse and important roles Th cells play in the immune system, it is not surprising that these cells influence the immune response in many pulmonary diseases. Th cells can make occasional mistakes or generate responses that would be considered harmful. In the worst-case scenario, Th cell responses may be disastrous and prove fatal to the host. Fortunately, this is a very rare occurrence. The adaptive immune system must achieve a balance of sensitivity to respond appropriately to foreign antigens, without responding to host antigens and damaging self. When the immune system responds to very low antigen levels that it should not respond to, a hypersensitivity response, such as seen in airway allergies and autoimmune lung diseases, ensues. There are four general types of hypersensitivity reactions that have been described: Type 1 reactions, such as in asthma and allergic lung diseases, involve IgE antibodies and a Th2 response; Type 2 and Type 3 hypersensitivity responses involve the role of autoimmune and low affinity antibodies (and, in some instances, it is felt that Th2 cytokines promote such disorders); and Type 4 reactions, also known as delayed-type hypersensitivity, are the result of chronic inflammation and activation of lymphocytes and macrophages, typically a Th1 cytokine response. Another T cell subtype more recently discovered and less well studied is the γδ T cell subset.[123,124] These T cells have TCR with γδ-chains, rather than the conventional TCR chains. They represent 1% to 5% of circulating lymphocytes and are often found in mucosal surfaces, such as the airways. γδ TCRs have more limited repertoire diversity, and are considered, at times, invariant because they are only able to recognize limited types of antigens. These γδ T cells have been shown to be important in maintaining normal airway responsiveness or tone, as well as in their immunoregulatory role in numerous infectious and noninfectious diseases in the lung.[123,125]

CONCLUSIONS

The lung is a vast organ composed of conducting airways, alveoli, and tissue parenchyma that is highly specialized to sample the diverse antigens that we breathe in. The lung is equipped with a well-orchestrated immune system to clear particulate debris and to eliminate inhaled pathogens and toxins to protect the delicate capillary–alveolar barrier system that is critical for gas exchange. The immune system in the lung has evolved complex and diverse innate and adaptive immune responses to accomplish these critical functions of host defense.

CHAPTER 21

Lymphocyte- and Macrophage-Mediated Inflammation in the Lung

Praveen Govender
Frederic F. Little
Kevin C. Wilson
David M. Center

INTRODUCTION

The lung receives a continual flow of foreign infectious and noninfectious antigens during respiration. Like the gut, genitourinary tract, and skin the lung is one of the interfaces of the sterile body with the environment. The lung's immune defense system and inflammatory mechanisms are poised to deal with this role. In this chapter we will consider the inflammatory and immune roles of two key cells of hematopoietic origin: the lung lymphocyte and the lung macrophage.

While these two cell types interact extensively and might even be considered co-dependent in many situations, they represent two very different arms of the inflammatory response. The macrophage, as a phagocytic cell, is of ancient phylogenetic lineage. It is a sentinel of the innate immune system. As such, it is not antigen specific but it is triggered by many inflammatory stimuli through both specific and pattern recognition receptors. Lymphocytes are present only in vertebrates and represent a significant refinement in the inflammatory response by the ability to recognize and adapt to specific antigens and discriminate between self and nonself. The functional distinction between these two arms of the immune system is blurring with the recent discovery of innate lymphoid-derived immune cells and the appreciation of multiple functions of macrophages in the inflammatory response.

Macrophages or dendritic cells (DCs) are required for optimal presentation of antigens to lymphocytes, and for optimal lymphocyte activation and cytokine production. Conversely macrophage microbicidal function and release of arachidonate and oxygen metabolites is influenced by cytokines produced by activated T lymphocytes and phagocytosis is markedly enhanced by antibodies produced by B lymphocytes. The cooperation between these two cell types represents a cornerstone of lung defense against noninfectious antigen challenge or microbial infection. Another chapter will deal with acute lung inflammation mediated by neutrophilic leukocytes. In this chapter we will present a brief overview of the macrophage and lymphocytes in the human lung, their function and interactions, and a synthesis of their role in lung inflammation and disease.

We will assume a basic knowledge of immunology. However, an explanation of the terminology used in this chapter is appropriate. Many surface receptors expressed by immunologic cells have had multiple names based on different functions. In the past 30 years these terms have been grouped together in a series of standardized "clusters of differentiation" (CD) for the purpose of standard nomenclature. A list of the CD markers referred to in this chapter, other names used for them, and their putative functions are included in Table 21-1.

TABLE 21-1 Cluster of Differentiation Antigens and Surface Molecules Discussed in this Chapter

Name/CD Designation	Function
CD1	Accessory molecule for antigen presentation on APCs
Sheep RBC receptor/CD2	Accessory molecule for T lymphocyte activation, adhesion receptor (ligand LFA-3)
CD3	Signaling subunit of TCR
αβ TCR	T-cell receptor for antigen
γδ TCR	Alternate form of the T-cell receptor for antigen
CD4	T-cell coreceptor (ligand MHC Class II); marker for helper/inducer cells
CD8	T-cell coreceptor (ligand MHC Class I); marker for cytotoxic cells
CD11a,b,c	α chains of the β2 integrin/CD18; CD11a (LFA-1); CD11b (Mac-1/CR3); CD11c (CR4)
CD14	Macrophage receptor for lipopolysaccharide
CD18	β2 integrin chain
CD25	p55 IL-2 receptor; T-cell activation antigen (TAC)
HLA-DR	Class II MHC; expressed on APCs; activation antigen for T cells
CD28	Stimulatory accessory molecule for T lymphocyte activation (ligands B7–1/CD80, B7–2/CD86)
CTLA-4/ CD152	Inhibitory accessory molecule for T lymphocyte activation (ligands B7–1/CD80, B7–2/CD86)
CD29	Common β chain of the β1 integrins
VLA-1–6/ CD49a–f	Adhesion molecules; α chains of the β1 integrins (ligands ECM proteins)
VLA-4/α4β1 integrin	Adhesion molecule (ligand VCAM-1 expressed on endothelium, fibronectin)
α4β7 integrin	Adhesion molecule (ligand VCAM-1, fibronectin)
HML-1/αEβ7 integrin	Adhesion molecule (ligand epithelial cell carbohydrate antigen)
ICAM-1/CD54	Cell adhesion molecule for cell–cell interaction (ligand LFA-1/CD11a/CD18)
B7–1/CD80, B7–2/CD86	Accessory molecules for T-cell activation; ligands CD28 (enhances) CTLA-4 (inhibits)
CD95/Fas	Receptor for Fas ligand, induction of apoptosis
VCAM-1/ CD106	Adhesion molecule expressed on activated endothelium (ligand α4 integrins)
CCR3	Chemokine receptor (CKR) for CCL11/eotaxin
CCR4	CKR for CCL17/TARC (thymus and activation-regulated chemokine)
CCR5	CKR for CCL4
CCR7	CKR for CCL21/SLC (secondary lymphoid-tissue chemokine)/TCA-4 (T-cell activation-4)

CD, cluster of differentiation; RBC, red blood cell; TCR, T-cell receptor; VLA, very late activation antigen; LFA, lymphocyte function–associated antigen; APC, antigen-presenting cells; MHC, major histocompatibility complex antigen; CR, complement receptor; ECM, extracellular matrix; ICAM, intercellular adhesion molecule; VCAM, vascular cell adhesion molecule; CCR, chemokine CC type receptor; CCL, chemokine CC type ligand.

LYMPHOCYTES IN THE LUNG

Lymphocytes are much more abundant in the lung than previously documented. Recent estimates from CD3+ stained cells in histologic sections of normal human lung approximate the resident T-cell pool to be 10 billion T cells, which is comparable to the number of T cells in human blood.[1] These resident T cells have been examined in detail (see[2]) and are primarily memory T cells with a resident effector phenotype (rTem). In the normal lung these lymphocytes are distributed in one of four compartments (Fig. 21-1). The compartments include lymphocytes at the epithelial surface (LES) including those in the bronchoalveolar space; lymphocytes associated with the epithelium in lymphoid aggregates (also known as bronchus-associated lymphoid tissue [BALT]); interstitial and intraepithelial lymphocytes (IELs); and an intravascular pool. Although the presence of BALT in normal human lung is controversial, it is clear that BALT is present in the setting of infection and possibly with chronic airway inflammation.[3,4] Each compartment has a distinct phenotypic and functional repertoire. It is not yet clear whether there is a sequential influx of lymphocytes from the blood/intravascular pool to interstitium or BALT and finally to the epithelial surface, or whether lymphocytes are destined to reside in one or another of these pools from the time of maturation and/or activation. The absence of afferent lymphatics to the lung dictates that the intravascular pool is the original source of lymphocytes destined to one of the pulmonary compartments. The exact nature of influx and turnover of normal lung lymphocyte populations is not clear. However, the identification of organ- and lung-specific homing chemotactic cytokines (chemokines) with selective distribution of their cognate receptors raises the possibility that the origins of the populations of each compartment are distinct and for intercompartmental trafficking to occur, there must be site-specific signals that alter the chemotactic receptor repertoire in situ.

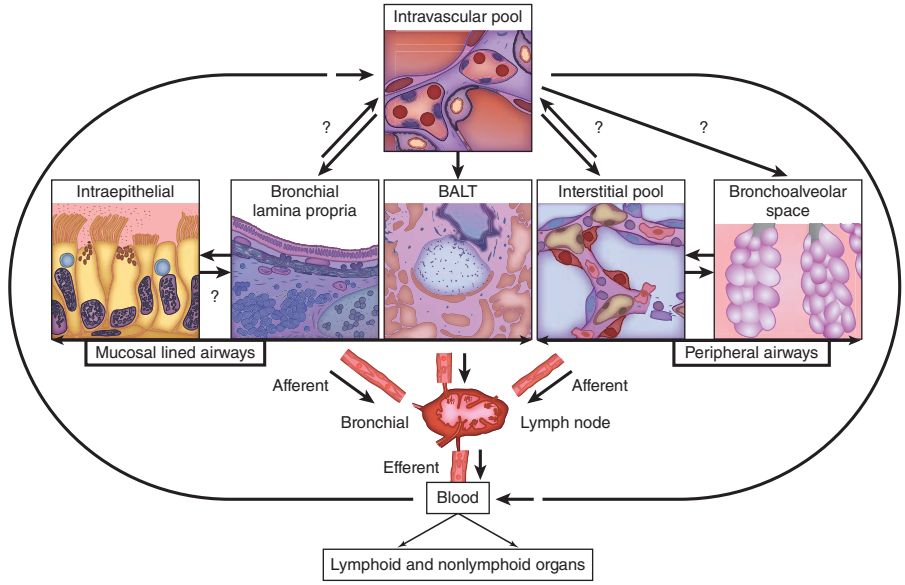

Figure 21-1 Lymphocytes are found in the lung in distinct sites. These include LES (including those at the bronchoalveolar surface); the interstitial and intraepithelial lymphocytes (IELs), bronchus-associated lymphoid tissue (BALT) which are centers of airway antibody production; and an intravascular pool. Lymphocytes travel from lymph nodes to blood and into lung via interaction with lung endothelial cells. Arrows indicate hypothesized trafficking from one pulmonary compartment to another. Some lymphocytes from these various compartments may be able to exit the lung back to lymph nodes, and others become effete and die. For further explanation see text. *(Reproduced with permission from Pabst R. IS BALAT a major component of the human lung immune system? Immunology Today. 1992;13(4):119–122.)*

LYMPHOCYTES AT THE EPITHELIAL SURFACE (LES)

LES and IELs are best studied as lymphocytes from the bronchoalveolar space, are easily recovered from the lung using bronchoalveolar lavage (BAL). Although in normal nonsmoking individuals lymphocytes make up only about 5% to 15% of the 10^5 cells found per milliliter of BAL fluid, lymphocyte numbers may increase dramatically during an inflammatory response.[5–7] LES differ markedly from blood lymphocytes suggesting either a selection bias or organ-specific maturation process that occurs between the blood and lung (Table 21-2). Approximately 70% of LES are T cells; the CD4/CD8 ratio of T cells is approximately the same as in the blood, though with a larger scatter among individuals.[8] Over 70% of BAL T cells are of the previously activated memory type as determined by expression of a low–molecular-weight form of the leukocyte common antigen CD45 (CD45RO),[9,10] and many have been chronically activated as shown by expression of the $\alpha 1\beta 1$ integrin. The balance of BAL T cells are naive, based on their expression of one of the chemokine receptors CCR7,[11] which primarily identifies T cells that have not come into contact with their cognate antigen. It is unclear what the T-cell representation in BAL is of IEL compared to LES. LES are more likely than blood T cells to express the activation antigen HLA-DR, and CD8+ (cytotoxic/suppressor) and LES are more likely to express markers associated with cytotoxic cell function.[5] An unusual population of memory cytotoxic cells which lack the accessory molecule CD28 has also been described in normal LES.[12] In the neonatal rodent lung the majority of T cells express the gamma-delta T-cell receptor, and account for about 20% of resident (whole lung) pulmonary T cells in adult mice—a percentage that is markedly upregulated with infection.[13] By contrast, the vast majority of human T cells at the epithelial surface are alpha-beta+. The function of the small population of gamma-delta LES T cells in humans remains unknown, but functional similarities to homologous mouse cells suggest that their primary role is to regulate the primary immune response.[14] There are a variable number of natural killer (NK) (including NK-T) cells in this compartment as might be expected in an area of microbial and antigen assault. However, the bulk of NK activity in the lung is found in the interstitial population.[15,16] B cells are also present in the LES population derived by BAL. They have been documented to produce antibodies of all types, with their primary role being to provide mucosal immunity through the secretion of IgA.[5] It is unknown whether there are selected B cell populations among LES.

The source and fate of these T and B cells are unknown. It seems reasonable to hypothesize that epithelial surface T cells (and other lung T cells) emerge from the circulation, perhaps proliferate locally and differentiate further while in the lung, and then die or recirculate.[17] The appearance of labeled blood T cells in LES have been found in the circulation. The predominant memory phenotype of epithelial surface and interstitial T cells strongly suggests that such differentiation occurs before entry into the lung. Once in the epithelial compartment it

TABLE 21-2 Characteristics of Lung Lymphocytes[a]

Location	Number	Cell Type	Comments
Epithelial surface	10^4/mL BAL; approx 10^8 total	CD4/CD8 ratio = blood 70% T cells >90% memory cells 40% express $\alpha_E\beta7$ integrin (70% of CD8+) Memory CTL NK phenotype present, decreased function	Specialized for interaction with epithelial cells. First line of defense?
BALT	? If present in normal (i.e., uninflamed) human lung	B cells in center T cells scattered in center and surrounding follicle	Local antigen sampling and antibody production
Interstitium	10^7/g lung tissue; approx 6×10^9 total	CD4/CD8 ratio < blood >90% memory T cells Bulk of NK activity	With intravascular, equal to total blood lymphocyte pool.
Intravascular	? Characteristics in human	?	Possible mobilizeable cells poised for lung entry

BAL, bronchoalveolar lavage; CD, cluster of differentiation; CTL, cytotoxic T lymphocyte; BALT, bronchus-associated lymphoid tissue.
[a]For a review, see Reference.[15]

appears that bronchial IEL T cells can be long lived potentially surviving within the epithelium for several months, in contrast to the short life span of lymphocytes in the lamina propria.[18,19]

Many LES adhere to and interact with airway epithelial cells through the expression of a unique adhesion molecule (HML-1/αeβ7 integrin).[20,21] This integrin is expressed on 40% of LES (60% of CD8+ cells are HML-1+ while fewer CD4+ cells express it) and on intestinal lymphocytes, but only rarely on blood or lung interstitial lymphocytes. It is likely that local influences, such as epithelial-derived cytokines like transforming growth factor beta-1 (TGFβ1), result in the expression of this molecule on LES.[22–24] Epithelial cells are directly stimulated by bacteria to release specific chemokines and cytokines (e.g., interleukin (IL)-8, MIP2α (CXCL2), MIP3α (CCL20), IL-7, IL-15) depending on the organism and pathogenicity.[25] These ligands can bind surface chemokine and cytokine receptors on adjacent LES, suggesting that these cells are not necessarily effete or dying cells, which are present in the airway only to be cleared by the mucociliary escalator and expectorated. Rather, they include a specialized lymphocyte population involved in the surveillance of the airway and interaction with epithelial cells. The possibility that LES re-enter the interstitium and lymphoid tissue has been confirmed experimentally in rats.[26] In addition to their interaction with airway epithelial cells, LES directly interact with mucosal DCs, whose phenotype directs further T-cell phenotype evolution (see Lymphocyte Activation in the Lung, below)

LES can be stimulated to proliferate, produce cytokines and antibodies, and to perform cytolytic functions. However, they are in general hyporeactive in proliferative or antibody responses to antigen or mitogens when compared to blood T cells or even when compared to memory T cells in lung interstitium. The reason for this is not known, but may relate to immunosuppressive influences in the airways, including alveolar macrophages (AMs),[27] local production of TGFβ1,[28] the immunosuppressive activity of pulmonary surfactant lipids or proteins,[29] and the possible presence of other immunomodulatory cytokines like IL-10 and IL-16.

■ BRONCHUS-ASSOCIATED LYMPHOID TISSUE (BALT)

BALT is the term applied to localized subepithelial collections of lymphocytes in the airways, and is a secondary lymphoid tissue analogous to other types of mucosa-associated lymphoid tissue (reviewed by Berman et al.,[6] in-depth review by Randall[30]). BALT is present in normal rodent airway and increases in amount with age. Current evidence suggests these structures are uncommon or absent in adult humans but are present in childhood and may appear and proliferate later in life in response to infection or chronic inflammation.[3,30–35] These data suggest that inflammation or infection induces the development of these lymphoid aggregates in humans, and are termed inducible BALT (iBALT) to distinguish them from the classically defined BALT observed in rodents, which is believed to be formed independent of antigen.[36]

Classically defined BALT is similar to gut-associated lymphoid tissue (GALT; e.g., Peyer's patches) in appearance, association with epithelium and a blood vessel, presence of specialized cuboidal or high endothelial venules characteristic of lymphoid tissues, and a specialized thinned overlying epithelium facilitating antigen entry from the bronchial lumen and exit of lymphocytes and lymphocyte products. Immunohistochemistry has revealed a preponderance of B cells staining with IgM, IgG, and IgA, with a scattering (approximately 20%) of T cells, especially CD4+ helper cells within and surrounding the aggregate. BALT lacks organized germinal centers found in other secondary lymphoid tissue. The resemblance of BALT to GALT, as well as the similarity of lymphocyte recirculation patterns from lung- and gut-associated lymphoid tissue has suggested to some authors that these structures represent a common mucosal immune system. In this paradigm, recirculating blood lymphocytes exit into these structures which provide an efficient exposure to antigens sampled from the environment. Activated memory cells are then a source of local antibody production, and they may disperse through the circulation to other mucosal sites to provide dissemination of immunologic memory.

Despite these observations that have been made in rodents, several issues continued to limit what we can infer about BALT function in humans. They include its near absence in normal human airways and limited presence in experimental animals which are primarily observed in pathogen-free colonies. In fact, the infrequent appearance of BALT in humans and mice has led some to doubt whether BALT is an important secondary lymphoid organ.[31] However, there is accumulating evidence that iBALT plays a role in the adaptive immune response to infection.[36] In this new paradigm, infection and inflammation trigger the development of these localized lymphoid tissues through recruitment and priming of naive lymphocytes thereby generating antigen-specific lymphocytes in situ. At the same time, infection and inflammation activate local antigen-presenting

cells, which migrate to conventional secondary lymphoid organs (i.e., lymph nodes) for priming and activation of effector cells. Thus, these local lymphoid tissues are capable of not only expanding effector cells that were primed in conventional secondary lymphoid organs but also initiating primary immune responses in situ. In support of this paradigm, splenectomized lymphotoxin-α-null mice that lack the ability to form any secondary lymphoid tissues are still able to develop iBALT[36] in response to infection suggesting distinct mechanisms govern over these lymphoid tissues.

The uniqueness of iBALT in humans and mice is highlighted by the structural difference compared to constitutive BALT in rodents. The iBALT can vary in organization from small clusters of B cells, T cells, and DCs to well-developed follicular aggregates and unlike constitutive BALT, which is found in the upper airway of rodents, iBALT is found in perivascular, peribronchial, and even interstitial areas in the lower airways of the lung.[36] In humans, the specialized overlying epithelium has not been characterized.[37] B-cell follicles, which are seen in iBALT, are centered around CD21-expressing follicular dendritic cells (FDCs)[36] and separated by interfollicular regions containing resident CD11c+ DCs and both CD4+ and CD8+ T cells.[38] The lymphocyte homing chemokines CXCL13 and CCL21 are required for recruitment of naive lymphocytes at HEVs, but unlike conventional lymphoid organs their secretion appears to be independent of LTα.[36] IL-17–producing T cells[33] and CCR7-dependent Tregs[39] have been shown to be important for development of iBALT.

Knowledge of the role of iBALT in the lung is still evolving. BALT development appears to be part of the normal immune response to infectious antigens. The role of BALT expansion in a wide variety of chronic lung diseases such as hypersensitivity pneumonitis, chronic obstructive pulmonary disease, and idiopathic pulmonary fibrosis is less clear.[40]

INTERSTITIAL LYMPHOCYTES

Lymphocytes are rarely seen in histologic sections of normal human lung, and there are no established techniques to study these cells as an exclusive, pure population. However, several investigators have prepared lymphocytes from human lungs extensively washed to remove airway surface cells using minced tissue and enzymatic digestion. The resulting population of pulmonary infiltrating lymphocytes in normal humans appears to be distinct from lymphocytes recovered from normal BAL.[41,42] Specifically, approximately 20×10^6 mononuclear cells were found per gram of wet lung tissue; of these 70% were lymphocytes, of which 90% were CD2+ T lymphocytes. There was enrichment for memory T cells similar to that seen in LES, but the CD4/CD8 ratio among IL T cells was lower than that seen in blood or LES. Memory T lymphocytes from the interstitial compartment can be stimulated to produce cytokines, and to proliferate in response to IL-2 despite a decreased proliferative response to mitogens.[43] Most, if not all NK activity in the lung has been localized to the interstitial compartment.[44] The exact origin, fate, and function of interstitial lymphocytes are not known.

INTRAVASCULAR LYMPHOCYTES

The presence of this lymphocyte pool has been convincingly shown in animals, especially the pig.[32] Experimental data includes lung perfusion studies showing the continued slow elution of lymphocytes from lung following elimination of red blood cells. The presence of an intravascular lymphocyte pool in humans has not been directly confirmed. However, labeled lymphocytes injected into humans are "held up" in the lung whether injected intravenously or intra-arterially (reviewed by Berman et al.[6]). These data confirm the more recently detected presence of homing receptors on the surface of lymphocytes that match cognate organ-specific chemokine expression.[45] Therefore, this phenomenon likely represents margination of lymphocytes in capillaries due to adhesion molecule interactions. Complete phenotypic characterization of this pool in the human is unknown, as is the size and role of this pool in populating interstitial or epithelial lymphocytes.

LYMPHOCYTE RECRUITMENT TO THE LUNG

Lymphocytes are recruited to extravascular sites through a complex process involving adhesion to endothelial cells (ECs), release from adhesion, transendothelial migration, interaction with cellular matrix, and response to locally produced chemoattractants.[6,46,47] This sequential process is characterized by an initial capture step that is mediated by selectins and integrins, followed by arrest/activation mediated by chemokine and cytokine receptors and other integrins.[45,48] The role of chemokines has emerged as central to the regulation of tissue-specific lymphocyte homing and retention. These are low–molecular-weight proteins that share a cysteine repeat motif (e.g., C-C or C-X-C), near the N-terminus. As a class, these proteins have cationic charge, and therefore bind heparin.[49] Chemokine function is mediated through cognate seven transmembrane-spanning receptors. There is significant promiscuity between chemokine receptors and their ligands, such that any specific chemokine may have several ligands and vice versa. Because of their physicochemical properties, the chemokines may bind to heparin-like regions of EC membrane receptors, preventing dilution of locally produced chemoattractant signal by blood flow and facilitating concentration gradients, a phenomenon known as haptotaxis. Chemokines have been shown to enhance both adhesion to ECs and endothelial transmigration of multiple leukocyte types including T-cell subsets and monocytes. Recently, chemokines have also been found to act as accessory growth factors for T-lymphocytes.[50] While CXCL15 (lungkine) appears to be selectively expressed in mouse lung, there does not appear to be a unique human lung–specific lymphocyte directed chemokine profile. However, certain chemokines (see below) are preferentially expressed in TH2 and TH1 type immune responses in the lung.

The interaction of adhesion molecules expressed on blood T cells with complementary adhesion molecules on EC is the critical first step to T-cell emigration from the blood. This step is closely regulated at the level of expression of adhesion molecules by T cells at different stages of development, and by transiently increased adhesion molecule function following T-cell activation. Similarly, expression of adhesion molecules by EC may be increased markedly by organ site and location, or by proinflammatory cytokines, especially tumor necrosis factor (TNF)-α, IL-1, and interferon-γ (IFN).[51–54] Treatment of EC with these cytokines markedly alters the adhesiveness of EC for leukocytes, including certain subsets of T cells. The result of such EC activation by local production of cytokines or other factors is that the exit of T cells from the blood is not random, but rather is restricted to sites such as lymphoid tissues, mucosal sites, or tissue sites of inflammation.

The specific events involved in T-cell transendothelial migration have been dissected at the cellular level, while their characterization in human lung is incomplete. T lymphocytes first appear to "roll" along the endothelium, an interaction which requires loose adhesion via T-cell α4β1 integrin/endothelial VCAM-1 and P-selectin/PSGL-1.[15] A signal is required to produce formal "capture" via other integrin molecules, particularly lymphocyte LFA-1 (αLβ2 integrin) interaction with ICAM-1 or other ligands on endothelium. This latter signal enhances the avidity of integrins for ligand, strengthening adhesion. Other interactions, including decay of integrin affinity, homotypic interaction of T cell and endothelial PECAM (CD31) at EC junctions, and release of matrix degrading enzymes, permit release of firm adhesion and T-cell migration into matrix.[47] Preliminary evidence in TH2-cell migration suggests that this step is mediated by T-cell CCR3/endothelial CCL11 and CCR4/CCL17, respectively.[16,55,56]

T cells are constantly recirculating from blood to tissue and back, with an average half-life in the blood of only about 18 hours.[57] In addition, the sites of migration in vivo appear to be quite different for naive/virgin cells, as opposed to previously activated memory cells. Due to a high level of CCR7 expression, naive cells preferentially traffic to lymphoid tissue where they are likely to encounter antigen,[58] while memory cells traffic to nonlymphoid tissues such as skin or lung.[53,59]

The normal lung vasculature may have unique properties that facilitate the retention of circulating lymphocytes. Whether injected intravenously or intra-arterially, labeled lymphocytes are held up in the lung disproportionately in comparison to other organs. Thus, this is not just a "first-pass" clearance effect from capillary passage.[6] Several investigators have found that antibodies to adhesion molecules, particularly lymphocyte function–associated antigen (LFA)-1, decrease lymphocyte retention in the lung. However, capillary size may determine trapping of activated cells since cytoskeletal changes occurring coincident with activation reduce cellular deformability; this has been shown to be a significant force in the lung trapping of activated neutrophils and monocytes. Lymphocytes also become larger, and lose deformability with activation, but the role of this process in lung retention of lymphocytes is not yet defined.

Lymphocyte chemoattractants represent another step in the regulation of the exit of adherent or trapped T cells from the capillary circulation. As noted earlier, varied T-cell chemoattractants have been described which are relevant to the lung, many of which also alter the growth and activation of T cells (reviewed in References[6,49,50,60]). A partial listing of known chemoattractants may be found in Table 21-3. In lung diseases multiple T-cell chemoattractants have been found in BAL or in tissue specimens, including the chemotactic growth factors IL-2,[29,61] IL-16,[62] IL-33,[63,64] insulin-like growth factor I[13], the C-X-C chemokine IL-8 (CXCL8), and the C-C chemokines macrophage chemotactic protein (MCP)-1 (CCL2), RANTES (CCL5), and macrophage inflammatory protein (MIP)-1α (CCL3).[62,65,66] These chemokines have multiple cellular origins, including macrophages, ECs, and epithelial cells. IL-2 is presumed to be of lymphocyte origin while IGF-1 and IL-16 have multiple potential cellular sources including T cells, eosinophils, and epithelial cells.[67,68] IL-33 is an epithelial-derived alarmin which in addition to being a chemoattractant to TH2 cells via ST2/IL1RAcP receptor also attracts ILC2, eosinophils, and mast cells. Its central role in TH2 immune deviation in asthma in response to epithelial cell necrosis to a variety of injuries is becoming increasingly appreciated.[69–72] It has also been noted that CXCL9, 10, and 11 appear to be important in TH1 responses in the lung, but their expression may relate more to induction by interferon-γ rather than a lung-related phenomena.

Recruitment of lymphocytes to the lung along chemotactic gradients is a complex phenomena involving multiple chemotactic factors, gradients, and responding cell receptors. The final complexion of the lymphocyte population in any compartment is therefore the sum of the responsiveness of each phenotype sequentially responding to and then releasing from chemotactic gradients to respond again. The hierarchy of responses involves regulation of expression of receptors and responsiveness, a phenomena termed chemotactic factor receptor cross desensitization. This can explain retention of T cells (lack of responsive chemotactic receptors) and relocation (sequential responsiveness to induced or constitutive chemotactic gradients). Examples of these modulatory steps are present in human[74–76] and mouse T cells of all phenotypes and likely this is one of the prime factors for accumulation of T cells in organized lymphoid tissues in the thorax and lung (e.g., lymphadenopathy) during infection and inflammation. Moreover, chemotactic gradients and receptor desensitization can be induced by exogenous chemotactic factors of infectious origin, which can in turn regulate responses to endogenous chemotactic factors. For example, HIV-1 gp120 can downregulate the responsiveness of thoracic lymph node lymphocytes to sphingosine-1-phosphate, resulting in lack of normal egress.[74,75,77]

TABLE 21-3 Lymphocyte Chemoattractants[a]

Interleukins	Activation Stimuli
IL-1	Antibody to T-cell receptor (T cells)
IL-2	Antisurface immunoglobulin (B cells)
IL-6	Phorbol esters
IL-10	
IL-15	
IL-16	
IL-33	
Chemokine Chemoattractants	**Growth Factors**
CXCL8/IL-8	Insulin
CCL5/RANTES	IGF-1
CCL3/MIP1-α, CCL4/MIP-1β	TGFβ1
CCL2/MCP-1, CCL8/MCP-2, CCL7/MCP-3	
CXCL10/IP-10	
CL11/eotaxin	
Matrix Proteins	**Miscellaneous Chemoattractants**
Laminin	Lysophosphatidylcholine
Fibronectin	fMLP, mycobacterial lipoarabinomannan
Amyloid protein AA	Casein/denatured protein
Sphingosine 1 phosphate	

[a]*Not a complete listing.*
IL-, interleukin; RANTES, regulated activated normal T cells expressed, secreted; MIP, macrophage inflammatory protein; MCP, monocyte chemotactic peptide; IGF, insulin-like growth factor; TGF, transforming growth factor. For reviews, see References.[11,52,73]

LYMPHOCYTE FUNCTION IN THE LUNG

Lymphocytes in the lung serve four major functions: (1) antibody production; (2) cytotoxic activity including lysis of virally infected cells, cells that have bound antibody, and tumor cells; (3) cytokine production; (4) immune tolerance. These functions are summarized in Table 21-4 and in a number of references cited.[5,49,78]

Antibody production in the lung by B lymphocytes serves to bind antigen and facilitate inactivation of bioactive material and phagocytosis by macrophages. Mucosal IgA is of particular interest in its active transepithelial transport to the bronchial lumen. Antibody production by lung B cells has been extensively studied in mouse lung. Following challenge, antigen is removed to regional lymph nodes by motile phagocytic cells (macrophages and DCs) where optimal activation of T and B cells occurs. Activated cells relocate into the circulation and migrate into the lung at areas of inflammation, and local antibody production results. Rechallenge with antigen results in a more rapid local response derived from resident memory cells.[5,6,79] While the duration of pulmonary memory lymphocytes is unknown, systemic B lymphocytes can persist for over 100 days in the absence of antigen,[80] as is the case with memory CD4+ and CD8+ T cells.[81]

The lung contains multiple types of cytotoxic cells, including NK cells (not antigen restricted), antigen-restricted cytotoxic cells, and cells exhibiting antibody-dependent cytotoxicity. One unusual aspect of lung cytotoxic cells is the pre-eminence of CD3+ cytotoxic T cells

TABLE 21-4 Function of Lung Lymphocyte Subpopulations[a]

Cell Type	Function	Secreted Products
TH1 cell	Intracellular microbes, (i.e., intracellular bacteria, antiviral and antifungal defense) granuloma formation, graft rejection	IL-2, IFN-γ, IL-3, IL-6, IL-12, IL-16, GM-CSF, TGFβ1
TH2 cell	Allergic inflammation, antiparasite (e.g., helmiths) defense	IL-2, IL-4, IL-5, IL-9, IL-10, IL-3, IL-13 IL-16, GM-CSF, TGFβ1
TH17 cell	Extracellular bacteria and certain fungi. Neutrophilic inflammation	IL-17 A(IL-17), IL-17 F, IL-21, IL-22, TNFα GMCSF, IL-26 (human TH17)
TCTL (CD8 cell)	Antigen-restricted lysis of viral- or mycobacteria-infected macrophages or epithelia; lysis of fungi, tumor cells	TH1 cytokines, perforin, IL-4
T REG cell	Peripheral tolerance (various phenotypes). Maintenance of immature DC	IL-10, TGF-β1, IL-35
NK cell	Nonantigen-restricted lysis of virally infected and tumor cells	Perforin, granzymes, α-defensins, IFNγ, TNFα/β, CCL3, CCL4, CCL5, also IL-17A, IL-22
NKT cell	Restricted αβTCR interacting With cells presenting glycolipids associated to CD1d	IFN-γ, IL-4, IL-13, IL-2
B cell	Antibody production	IgM, IgG subtypes 1–4, IgE, IgA, IL-10

[a]Not a complete listing. Listed are cytokines or other products produced under in vitro conditions or documented in lung disease.
TH1, T helper type 1; TH2, T helper type 2; CTL, cytotoxic T lymphocyte; NK, natural killer cell; IL-, interleukin-; CMI, cell-mediated immunity; GM-CSF, granulocyte macrophage colony–stimulating factor; TGFb1, transforming growth factor beta 1; DC, dendritic cell.
For reviews, see References.[15,55]

with NK activity (nonantigen-receptor–mediated killing of tumor cell targets). This is in contradistinction to the blood, where the majority of cells expressing NK activity are CD3–.[5] These natural killer T cells (NKT cells) make up less than 0.2% of human peripheral blood T cells and, contrary to an earlier report,[82] are low in number in bronchial tissue and BAL in health and disease. In asthmatics, it is approximated they account for, at most, 1.7% and 0.2% in bronchial tissue and BAL, respectively.[83] They have an invariant TCRα–receptor chain receptor (variable [V] and joining chain [J] Vα14 Jα18 in mice and Vα24 Jα18 in humans) combined with a limited, but not invariant TCRβ-chain repertoire (Vβ8.2, Vβ7, or Vβ2 in mice and Vβ11 in humans), and conventionally are referred to as iNKT or type 1 NKT cells. They recognize foreign and self-glycolipid antigens presented by MHC-class-I-like CD1d antigen-presenting molecule (reviewed by Godfrey, Stankovic, and Baxter[84]). While a role for iNKT cells in host defense to a variety of infectious antigens (e.g., Cryptococcus neoformans)[85] and in modulating the inflammatory response in asthma[86] has been suggested, details of their function have to be elucidated.

NK activity is found in the interstitial compartment of lung T cells and NK cells are present among LES accounting for approximately 10% of tissue lymphocytes. The majority (80%) are phenotypically the cytotoxic subset (CD56dimCD16high) in humans and resting pulmonary NK cells have been found to be functionally impotent.[44,87–89] The impairment of cytotoxic capacity of resting pulmonary NK cells in BAL and lung tissue is believed to be due to the suppressive effects of cytokines such as TGFβ and other mediators such as prostaglandins from AMs, pulmonary surfactant[90] and respiratory epithelial products such as IL-15.[91] The importance of this regulation of NK cells in the lung is exemplified in certain genetic deficiencies which result in either chronic activation of NK cells leading to granulomatous inflammation or recurrent viral and bacterial infections that can involve the upper and lower respiratory tract.[92–94]

Cytokine production by lung T helper cells (TH) has emerged as a major focus of investigation in lung inflammation. In contrast to antibody production by B cells, T cells produce cytokines. Broad ranges of cytokines have been documented to be produced by lung T cells in inflammatory disease (Table 21-4). In general, the complexion of the inflammatory response correlates with the cytokines produced by T cells, suggesting that T cells orchestrate many inflammatory responses.

Activated T-helper (TH) cells produce a distinct spectrum of cytokines.[95–97] The repertoire of a single T cell to produce cytokines appears to be limited and stereotyped, depending on the circumstances of activation. According to data accumulated in mice, naive T cells produce mainly IL-2 in response to activation. After proliferation and switch to memory cell phenotype, T cells differentiate and produce one of four major clusters of effector cytokines, the best characterized being TH1 (interferon-γ, IL-2), TH2 (IL-4, IL-5, IL-10, IL-13), TH17 (IL-17, 23, 25), and Treg (TGFβ, IL-10, PGE). These TH phenotypes share mutually exclusive transcriptional programs, regulated by the transcription factors T-bet (TH1) and GATA-3 (TH2), RORγ/STAT3 (TH17), and FoxP3 (Treg), respectively.[98–100]

Historically, the division between TH1 and TH2 phenotypes was derived by exclusion of the alternate type and led to confusion in the distinction between these phenotypes particularly in humans where the distinction is not as predictable as in the mouse.[95] These two major phenotypes roughly conform to polarized expressions of cell-mediated immune responses: granuloma formation with activation of mononuclear phagocytes and production of opsonizing IgG2 antibody (TH1); or optimal antibody response including IgE formation, often with associated eosinophilia (TH2).

Certain immune responses in the lung are dominated by either a TH1 or TH2 response, while others are mixed. For example, in human asthma T cells producing TH2 cytokines predominate,[101] but IFN-γ producing cells are found in the airways suggesting a mixed response.[102] In contrast, granulomas at sites of tuberculin reactions in skin show evidence for production of IFN-γ and IL-2 but not IL-4.[103] In leprosy or leishmaniasis an ineffective host reaction is associated with a TH2 response, and an effective granulomatous response is associated with a TH1 response. In addition, treatment of ineffective responses to leishmania with IFN-γ have been reported to increase the efficacy of chemotherapy.[96] In sarcoidosis, airway and granuloma cells, particularly activated CD4+ (HLA-DR+) T cells, have been found to produce both IL-2 and IFN-γ, suggesting the predominance of a TH1 response. There is considerable cross-regulation of TH1 and TH2 subsets even after commitment to production of these cytokines, leading to the general concept that the character of an immune response as well as its termination may depend on the sequential predominance of TH1 or TH2 responses. Indeed, the functional distinction between TH1 and TH2 cells is less distinct in humans as it is in the mouse. As a result of these earlier studies, it is now clear that other T-cell phenotypes participate in all these inflammatory events in the lung beyond traditional TH1 and TH2 dichotomy.

First, there is an important role of T cells (and T-regulatory cells in particular) in mediating mucosal tolerance and immune homeostasis.[104,105] This function in the mucosa is directly related to their interaction with mucosal DCs.[78,106,107] While the phenotypic classification of these cells is evolving, the peripheral pool of regulatory T cells (Tregs) is a mixture of natural thymus–derived Tregs (nTregs) and induced Tregs (iTregs), which originate from naive CD4+ T cells under conditions of low antigenic stimulation or by cytokines primarily transforming growth factor beta (TGFβ). While the relative contribution of each type of Treg to immune suppression and homeostasis is not clear, the fact that their TCR repertoire is different suggests a nonredundant complementary role.[108] There appear to be multiple phenotypes within the Treg population with overlapping mechanisms of action. However, the transcriptional factor forkhead box protein 3(Foxp3) appears essential for the suppressive function of this T-cell subset. Deletion of Foxp3 in mice (Scurfy) and humans (IPEX syndrome) results in a lethal condition of autoimmunity and inflammation emphasizing the critical role of Tregs in immune homeostasis and IL-2 in the growth and expansion of Treg. The majority of studies examining the regulatory potential of T cells in inflammatory lung disease, however, have been in *ex vivo* manipulation, depletion, and adoptive transfer experiments in the mouse.[109,110] The evidence for intraparenchymal (i.e., mucosal or interstitial) human Treg cells is not direct, but the requirement for maintenance of peripheral tolerance in the lung and systemic inducibility of tolerance to inhaled antigen[111] provides the basis for their speculated presence in the epithelium. In addition, intratracheal treatment of mice with the immunomodulatory cytokine IL-16[112,113] elicits an expansion of lung CD4+CD25+ T cells.[114]

TGFβ is required for the development of iTregs, but dual stimulation of TGFβ with either IL-4 or IL-6 (IL1β in humans) can alter the cytokine profile of peripheral T cells from suppressive Tregs to proinflammatory TH9 or TH17 cells, respectively. Similar to TH1 and TH2 development, TH9/TH17 and Treg cell development is cross-regulated at the transcription factor level, an important mechanism for maintaining immune homeostasis in the periphery.[115] At the functional level, this requirement of TGF-β for the induction of both Foxp3+ Tregs and TH17 cells provides a system for efficient balance between tolerance and immunity. In the steady state, TGFβ induces Foxp3 and Tregs, inhibits inflammation, and maintains self-tolerance, but once IL-6 is produced by innate immune cells in response to microbial triggers, Treg generation is prevented and the function of nTregs is suppressed while TH17 cells are induced to produce a strong proinflammatory response characterized by neutrophilia.[115]

While a distinct functional role of predominantly IL-9 secreting TH9 cells in the lung is unknown, the TH17 cell cytokine cluster (IL-17A, IL-17 F, IL-22, and IL-21) is understood to help protect the lung against extracellular bacteria and fungi.[116] However, the observed elevations of IL-17A and IL-17F in sputum and blood/BAL in asthma[117,118] indicate that TH17 cells contribute to chronic inflammatory disease as well. TH17 cells, like TH1 and TH2 cells, accomplish some of their role by recruiting cells of the granulocytic–monocytic lineage: TH1 cells recruit monocytes/macrophage, TH2 cells recruit eosinophils, basophils, and mast cells, and importantly TH17 cells recruit neutrophils. Given that up to 50% of asthmatics are nonatopic[116] and IL-17 mediates neutrophilic inflammation, there has been interest in understanding TH17 role in difficult to treat asthma. Interestingly, in vitro experiments have shown that the neutrophilic airway inflammation and bronchial hyperresponsiveness caused by TH17 cells was steroid resistant, consistent with the clinical phenotype.[119] While sarcoidosis is classically thought of as a TH1 disease, IL-17–producing cells are also elevated in peripheral blood and bronchoalveolar lung fluid of these patients.[120] Moreover, both single IL-17A+ and double IL-17/IFNγ+ cells have been reported in sarcoid granulomatous tissue.[121] Thus TH17 cytokine cluster helps understand the heterogeneity in classical TH1 and TH2 disease in the lung.

However, T cells are not the only source of IL-17, innate lymphoid cells (ILCs) such as NKT cells, NK cells and γδ T cells produce IL-17.[115] There is great interest in understanding the contribution of ILCs to immune homeostasis and pathology in the lung. Three features define ILCs: the absence of recombination-activating gene (RAG)-dependent rearranged antigen receptors; a lack of myeloid cell and DC phenotypic markers; and their lymphoid morphology. While the prototypical ILC population is NK cells (see previous section), several other distinct ILC populations have recently been described, all of which appear to originate from a common lymphoid (Id2+) progenitor cell and all, like conventional T cells, produce cytokines.

A particular source of confusion is the number of different names that have been used to characterize these different ILC populations. For example, ILCs that produce TH2-cell–associated cytokines have been variously called natural helper cells,[122] nuocytes,[123] and innate helper 2 (Ih2) cells[124] without clear evidence of uniqueness. A functional nomenclature system based on cytokines produced[125] has recently been proposed: Group 1 ILCs produce IFNγ, Group 2 produce type 2 cytokines (including IL-5 and IL-13), and Group 3 ILCs produce IL-17 and IL-22. ILCs are changing our view of how lymphocytes function in lung inflammation. For example, ILC2 have been shown to contribute IL-13 not IL-4 production in ovalbumin-induced lung inflammation mouse models[126,127] and in IL-13 –/– mice, which are resistant to allergic lung inflammation and virus-induced airway hyperresponsiveness transfer of IL-13 expressing ILC2 s was sufficient to restore airway hyperresponsiveness in both models[126,128] A human equivalent of ILCs have been found in patients with chronic rhinosinusitis.[129]

B-lymphocyte biology has also significantly advanced in recent years and now B cells are known to be comprised of different populations and proven to be pleiotropic in function (Ref.[130] summarizes the current understanding of B-cell lineages in the lung.) Briefly, in mice the majority of B cells are B2 B cells, which originate from the adult bone marrow precursor, traffic through peripheral lymphoid tissue, interact with cognate antigen, and after activation develop into either memory B cells or antibody-secreting plasma cells. In the human lung, the majority of B cells are these mature naive B2 B cells and they reside in BALT (see previous section) or draining lymph nodes. In mice, there is a family of innate-like B cells: marginal zone B cells, B1α and B1β B cells that contribute to rapid immune responses against pathogens and other stimuli. B1 B cells are a small self-renewing subset of B cells that originate from the fetal liver and secrete most, if not all, natural antibodies (IgM and IgA isotype) in the apparent absence of antigenic challenge. Natural antibodies are often polyreactive and bind to foreign antigens as well as to self-components (ex rheumatoid factor) and are important for early pathogen recognition and maintenance of tissue homeostasis.[131] B1 B cells constitute a minor fraction of the spleen and secondary lymphoid tissues but are enriched in the pleural and peritoneal cavities. It is not known whether B1 B cells residing in the pleural cavity migrate into the lung. Human B1 B cells do exist and are found to have marker profile of CD20+CD27+CD43+CD70– and could either be CD5+ or CD5–.[132]

The central role of B cells is the production of immunoglobulins, both within the parenchyma and for export to the mucosal surface of the airway, in the case of polymeric IgA and IgM. In addition, B cells are now known to function as antigen-presenting cells and producers of both inflammatory and regulatory cytokines (i.e., IL-10–producing B-regulatory cells [B-regs]). Very little is known about either of these functions in the lung by B cells. Much of disease

immunopathology in the lung is based on T-cell biology, but there is an expanding appreciation of B-cell contribution to diseases such as hypersensitivity pneumonitis, COPD, autoimmune connective tissue diseases, and idiopathic pulmonary fibrosis (see the review by Kato et al.[130] for details). But overall, all these diseases illustrate the potential for the lung to generate an exuberant B-cell response to antigen, either inhaled or self-antigen.

LYMPHOCYTE ACTIVATION IN THE LUNG

T lymphocytes are designed to require specific (antigenic) signals for activation, restricting their involvement in inflammation to situations where antigen overwhelms the mucociliary escalator and macrophage and neutrophil defenses. Lymphocytes are activated following engagement of an antigen receptor of remarkably fine specificity. This receptor is unique to a given lymphocyte clone, and is generated by recombination of gene segments in the antibody (for B cells) or T-cell–receptor genes. B-cell receptors consist of single membrane–spanning antibody molecules of the same specificity as the B cell, while T-cell receptors consist of a heterodimeric receptor (dimers of alpha and beta or gamma and delta chains). The T-cell receptor is highly antigen specific and has structural homology to the immunoglobulin molecule. Lymphocytes are activated by cross-linking of membrane antibody by antigen (B cells) or by engagement of the antigen receptor by antigen bound to major histocompatibility complex (MHC) molecules on the surface of so-called antigen presenting cells (APCs), also known as accessory cells. APCs provide many "accessories" for T-cell activation including: (1) a source of MHC molecules to which antigen can bind; (2) internalization and "processing" of antigen including protease digestion into antigenic fragments; (3) multiple cell adhesion molecules which bind to complementary adhesion molecules on T cells and serve to strengthen T-cell–accessory cell interactions and transduce activation signals required for optimal lymphocyte activation; and (4) production of cytokines that amplify activation including IL-1 (reviewed by Cruikshank et al.[112]).

APCs in the lung include pulmonary macrophages of all varieties, however, DCs and Langerhans cells are most efficient in this function (see below). These cells express important "accessory" cell adhesion molecules important to accessory cell function, including ICAM-1, LFA-2, LFA-3, and the CD28 ligands B7–1, B7–2, and CTLA-4.[68,133,134] Other cells, which may be induced to express Class II MHC molecules, may also act as weak accessory cells. Such cells include local B cells, epithelial cells, smooth muscle cells, and fibroblasts. Uncommitted naive T cells require intense accessory cell interaction to be activated by antigen, while previously activated (memory) T cells require less accessory cell input and might be influenced by interaction with such weak accessory cells. Due to naive CCR7+ T cells' inability to cross postcapillary venules, as mentioned earlier most lung T cells are memory cells, which suggests that the relatively weak lung accessory cells may indeed play a role in T-cell activation in the lung inflammatory response (Table 21-5).

As discussed earlier, the lung has proved to contain major immunosuppressive elements, which may serve to prevent inappropriate or excessive T-cell activation in an area of the body, characterized by constant antigen bombardment. These influences include surfactant lipids which have been shown to inhibit T-cell activation, proliferation, and cytokine production[136]; basal production (perhaps by epithelial cells) of the potent immunosuppressive cytokine TGF-β1[28]; and an inhibitory effect of AMs.[27] These inhibitory effects may be moderated, reduced, or increased in various disease states.[137] The role of DC phenotype and degree of maturation in directing activation versus tolerance in T cells is emerging as a key determining step in pulmonary T-cell differentiation. DCs can be broadly described as activating or tolerogenic, and this distinction appears to be related to the maturity of the DC and functionally to the presence of costimulatory molecules on the cell surface (e.g., CD80, CD86, CD40).[106,107] Typically, DCs process inhaled antigen and migrate to draining lymph nodes to present antigen to naive T cells. (The role of BALT in this process is unknown, see earlier discussion.) Thereafter, the nature and concentration of processed antigen determines the fate of cognate T cells: TH1, TH2, TH17, or Treg.[138,139] Presumably, TH cells that have encountered Ag in secondary lymphoid tissue acquire cell surface markers that direct homing and permit postcapillary emigration to lung interstitium and epithelium, either as regulatory or effector cells. There is evidence that the communication between DC and T cells is not exclusively toward T cells; differentiated T cells communicate with local DC via cytokines and cell surface markers to alter DC phenotype. This phenomenon has been described in a mouse diabetes model,[140] and proposed in murine allergic airway inflammation.[141] In light of the emerging central role of DCs in immunologic lung disease and growing knowledge of their plasticity, future directions will likely approach modulating DC phenotype and function as targets for therapy.

LYMPHOCYTE CLEARANCE AND DEATH IN THE LUNG

The means by which lymphocytes exit the lung or are cleared during homeostasis or following an inflammatory response is largely unknown. Certainly apoptosis and autophagy play a role in clearing of senescent cells, but signals unique to lung diseases in activating these pathways are less clear. It is not known how long memory T or B cells reside in the lung in any of the compartments, nor is the extent of lymphocyte exit from the lung via lymph to nodes or to the circulation. However, it is clear from studies in the mouse that programmed cell death, or apoptosis, is involved in the termination of antigen-induced inflammatory responses. In lymphocytes, this energy-requiring form of cell death leading to the fragmentation of the nucleus and DNA may result from one of three events: (1) "neglect" or absence of stimulation; (2) stimulation out of context, or without the appropriate second signals (such as CD28 or matrix interactions); or (3) signaling via Fas (CD95) engagement with Fas ligand. Such regulation of cell death appears to be critically important for the termination of an immune response once

antigen has been cleared, preventing the accumulation of activated lymphocytes.[142]

MACROPHAGES IN THE LUNG

Macrophages reside in many organs. However, they are especially prominent in the lung and perform many functions. Macrophages ingest inhaled particles or antigens and are then removed on the mucociliary escalator. They also serve as "professional" APCs, traveling to regional lymph nodes where they sensitize T and B lymphocytes. Lung macrophages release a variety of cytokines and biologically active arachidonate metabolites, which influence the function of nearby cells including T cells, B cells, ECs, and fibroblasts. Finally, macrophages ingest microorganisms and, when stimulated, kill them using a variety of means including toxic oxygen metabolites and nitric oxide.

Macrophages or macrophage-like cells are found in several lung compartments including the epithelial lining fluid, interstitium, epithelium, and intravascular compartment. These cells have varying functional repertoires and are typically categorized as AMs, interstitial macrophages (IMs), DCs, Langerhans cells, blood monocytes, or blood macrophages, respectively. Each of these cell types, their recruitment, and their activation will be discussed.

MACROPHAGE TYPES

Alveolar Macrophages (AMs)

Derivation of AMs from blood monocytes was initially suggested by an experiment in which the quantity of AM declined 20 to 30 days after bone marrow ablation despite in situ proliferation and increased cell stability.[143] Conversely, similar experiments, but with shielding of the chest during bone marrow ablation, have now found that even by 8 months bone marrow monocytes contribute little to the alveolar macrophage compartment during steady-state conditions.[144,145] It is now appreciated in mice at least that lung macrophages have a chimeric origin being derived from the fetal yolk sac and bone marrow–derived blood monocytes and certain subtypes may persist for the mouse lifetime.[146,147] The differentiation of AM derived from blood monocytes is regulated by the tissue microenvironment.[21,135,148,149] However, the molecular details of this differentiation remain largely unknown.[150]

If quantity implies importance, then one would surmise that AMs play an essential role in the lung's defense against foreign invaders. Found in air spaces throughout the lung, it is estimated that macrophages make up 90% of cells found in the alveolar spaces of both smokers and nonsmokers. The absolute quantity of AM, however, is approximately four-fold greater in smokers than nonsmokers.[148] The increased quantity of AMs in smokers is likely due to both recruitment of blood monocytes from the bone marrow and their differentiation into AMs. In one study, AMs were exposed to ambient particles and their supernatant collected. The supernatant promoted transit of monocytes through the bone marrow and their release into the circulation. Analysis of the supernatant revealed large amounts of inflammatory mediators including granulocyte macrophage colony–stimulating factor (GM-CSF), macrophage colony–stimulating factor (M-CSF), macrophage inflammatory protein (MIP)-1beta (CCL4), monocyte chemotactic protein (MCP)-1 (CCL2), IL-6, and ICAM-1.[151] Many of these mediators are known to increase monocyte turnover in the bone marrow and to enhance their recruitment into peripheral tissues.

AMs have a diverse repertoire of functions. Importantly, AMs are the first line of defense against inhaled antigens and pathogens. As such, they have well-developed phagocytic activity that is enhanced when activated by opsonization or inflammatory signals (e.g., IFN-γ).[6,51,152] Activated AMs release more inflammatory mediators and have superior microbial killing than their unstimulated counterparts.[143,150,151] It is impossible to accurately assess the phagocytic and microbicidal capabilities of AM compared to other lung macrophages because many of the accessible AMs may have been depleted of a portion of their functional capabilities due to previous activation. In general, smaller AMs are more efficient at phagocytosis and microbial killing than larger AMs. The smaller AM may represent younger, recently emigrated phagocytes and the larger AM may represent previously activated AM.[143]

TABLE 21-6 Cytokines and other Bioactive Substances Released from Lung Macrophages[a]

Arachidonate Metabolites	Cytokines	
Thromboxane A_2	IL-1[b]	IL-10[υ]

Metalloproteases	IL-8(CXCL8)[b]	
Elastase	IP-10 (CXCL10)[b]	
Procoagulant activity	CCL17, 18, 22[υ]	

[a]*Not a complete listing.*
PG, prostaglandin; LT, leukotriene; IL-, interleukin; HETE, hydroxy tetraenoic acid; TNF, tumor necrosis factor; ; IFN, interferon; MIF, macrophage migration inhibitory factor; TGF, transforming growth factor; CCL, chemokine (C-C motif) ligand; CXCL, chemokine (CXC-motif) ligand; IP-10, Interferon gamma-induced protein 10 kd; Ym1, Chitinase 3-like protein 3; Ym2, Chitinase 3-like protein 4.
[b]*Bioactive substances associated with classically activated macrophages υ bioactive substances associated with alternatively activated macrophages. See References.*[79,135,136,154]

AMs release a variety of inflammatory mediators including arachidonate products, cytokines, and enzymes (see Table 21-6). These mediators impact extracellular matrix, fibrin deposition, and the function of leukocytes and lung cells at sites of inflammation.[21,143,153] Many also play key roles in the pathogenesis of lung diseases. As an example, IFN-γ–inducible protein 10 (IP-10; CXCL10), monokine induced by IFN-γ (MIG; CXCL9), and IFN-inducible T-cell α chemoattractant (I-TAC; CXCL11) are released by AMs and stimulate the release of matrix metalloproteinases-9 and -12 in emphysema.[73]

A wide array of receptors are expressed by AMs, of which most mediate AM activation, migration, or phagocytosis. Perhaps most important are the toll-like receptors (TLRs) which are pattern recognition receptors for microbial cell wall lipids, DNA repeats, and other components of infectious agents. They provide the recognition function of the innate immune system that links to CD14 and subsequent inflammatory cytokine release (e.g., IL-1, IL-6, TNFα) secretion reviewed by Basu and Fenton[155]). These cytokines are essential in controlling infection with intracellular organisms like *Mycobacterium tuberculosis*. For example, AMs express TLR-2 which, when activated, induces killing of intracellular *Mycobacterium tuberculosis*.[156] MARCO is a scavenger receptor

TABLE 21-7 Ligands Recognized by Alveolar Macrophage Receptors[a]

Immunoglobulins (Fc Receptors)	Complement Receptors for:
IgG1, IgG2a (murine)	C3b, iC3b, C4b, C3d, C5a
IgG2b, IgG3 (murine)	
IgG1, IgG3 monomers (human)	
IgE, IgA (murine, human)	
Protein, Cytokine, and Matrix Receptors	**Lipoprotein Receptors for:**
Fibronectin R	Low-density lipoprotein
Fibrin R	Beta–very-low-density lipoprotein
Lactoferrin R, transferrin R	
GM-CSF R	
IFN-γR, IL-2R, IL-4R, IL-1R, IL-1RA	
Insulin	
Chemotactic factor receptors	
Other Receptors and Adhesion Molecules	**Lectin Receptors for:**
Class II MHC (HLA-DR, -DP, -DQ)	α-linked galactose residues
CD4	N-acetyl galactosamine residues
β2 Integrins (CD18; CD11a, b, c)	N-acetyl galactosamine residues
β1 Integrins (CD29; CD49a, b, c, e, f)	α-Linked fucose residues
CD54 (ICAM-1)	N-acetyl neuraminic acid residues
CD14 (Lipopolysaccharide receptor)	Mannose residues (mannose receptor)

[a]*Not a complete listing.*
Fc, complement binding fragment of immunoglobulin; Ig, immunoglobulin; R, receptor; GM-CSF, granulocyte macrophage colony–stimulating factor; IFN, interferon; IL, interleukin; RA receptor antagonist; MHC, major histocompatibility complex antigen; CD, cluster of differentiation.

Am Rev Respir Dis. 1983;128:634–638; Palecanda A, Paulauskis J, Al-Mutairi E, et al. Role of the scavenger receptor MARCO in alveolar macrophage binding of unopsonized environmental particles. J Exp Med. 1999;189:1497–1506.

expressed by AMs that facilitates phagocytosis of unopsonized particles.[157] In the absence of MARCO, pulmonary infection and inflammation is markedly increased.[158] Other receptors expressed by AMs include chemokine receptors, cytokine receptors, Fc receptors that recognize opsonizing antibodies, complement receptors that facilitate phagocytosis, lectin receptors, bacterial endotoxin (CD14) receptors, and mannose receptors (see Table 21-7).

Under certain circumstances, AMs function as APCs and facilitate memory T lymphocyte activation. This ability is enhanced in disease states such as HIV, transplant graft rejection, and sarcoidosis. In alternative situations, AM may impact the immunologic synapse to suppress T lymphocyte activation. This supposition is corroborated by one animal model in which AM depletion enhanced lymphocyte activation, suggesting that AMs can suppress T lymphocyte activation in normal lung homeostasis.[27]

Interstitial Macrophages (IMs)

IMs are a population of macrophages found in the interstitium of the lung instead of the airway lumen. They may be precursors of AMs in transit from the vasculature to the air spaces.[143] Little is known about human IMs because they are not readily accessible for study. In murine models, IMs have been shown to be functionally different from AMs and suggest IMs have a unique role in immune homeostasis in the lung by protecting against aberrant immune responses to nonpathogenic environmental antigens, even in the presence of proinflammatory stimuli.[159] To this end, IMs have been shown to be more immunoregulatory than microbiocidal in comparison with AMs and one mechanism postulated is by inhibition of maturation and migration of DCs.[159,160] Conversely, IMs can exert a supportive influence on pulmonary DC immune function by preprocessing particulate antigen into smaller peptides that are then loaded on the surface of neighboring DCs.[161]

DCs and Langerhans Cells

DCs are potent APCs that reside within airway epithelium and lung parenchyma. Like AMs, they likely originate in the bone marrow, travel via the blood (0.5% of blood mononuclear cells are DCs), then translocate into tissue. Although chemokines and other factors like IL-16 that are chemotactic for DCs have been identified, the precise stimulus for translocation of lung DCs is unknown.[143] DCs are most numerous in large airway epithelium and decrease in quantity as the airways become smaller.[133] Histologic sections along the long axis of airways have revealed a meshwork of DC processes ideal for antigen sampling and interaction with T cells. A similar meshwork is found in BALT in the mouse.[162] It is unknown whether DCs proliferate in the lung.

DCs are highly mobile and travel from the airway to regional lymph nodes where they interact with lymphocytes.[162] DCs are 10- to 100-fold more potent than monocytes at presenting antigens to naive T lymphocytes. DCs express cell surface proteins that are essential for antigen presentation and lymphocyte activation including MHC, cell–cell adhesion molecules (e.g., ICAM/CD54, LFA-3/CD58, β1 and β2 integrins), CD4, and the CD28 ligands.[134,162] Specialized DCs with distinctive invaginations of the plasma membrane called Langerhans cells also exist in the lung, especially those of smokers. Like DCs, Langerhans cells are potent APCs but are less efficient at phagocytosis, microbial killing, and cytokine secretion compared to macrophages.[133] In mouse lungs, it has been shown that langerin+ DCs are able to sample the content of the airway lumen while keeping the epithelium barrier function intact through expression of tight-junction proteins claudin-1, claudin-7, and zonula-2, which form tight junctions with the airway epithelial cells.[163]

The importance of DCs to the pathogenesis of lung diseases was highlighted by a murine model in which CD11c+ DC depletion during an allergen trial resulted in abrogation of the characteristics of an asthmatic response eosinophilic inflammation, goblet cell hyperplasia, and bronchial reactivity.[164] Their role with T-cell education in the lung is discussed earlier. For the interested reader, one is directed to a state-of-the-art review on DCs in the lung.[161]

Blood Monocytes and Intravascular Macrophages

As discussed earlier, blood monocytes are likely the precursors of both lung macrophages (alveolar and interstitial) and intravascular macrophages with differentiation being directed by the microenvironment. This is supported by the observation that blood monocytes can be induced in vitro to express receptors characteristic of AM over a period of days if cultured in the correct microenvironment. The average monocyte spends 1 to 3 days in the circulation and then exits the circulation to differentiate into a macrophage. During inflammation, translocation from blood to tissue increases.[165]

Intravascular macrophages are found within the vasculature of the lung. They are located in postcapillary venules, strongly adherent, and face the flow of blood. Like IMs, these cells are not readily accessible and, therefore, are difficult to study.[166] They are presumed to act as intravascular inflammatory sentinels, ingesting antigens in the form of microbes, erythrocytes, fibrin, cellular debris and immune cells,[167] and releasing mediators in response to inflammatory stimuli which reach the lung via the blood.[168]

RECRUITMENT OF MONOCYTES AND MACROPHAGES

Monocytes are motile cells that adhere to ECs and then migrate with extraordinary efficiency. Monocyte adherence to ECs is promoted by the monocyte "rolling" along vascular walls to increase the likelihood that its β2 integrins (αLβ2, αMβ2, and 4β1) will bind the EC selectins.[43,51,169] Following adhesion, translocation into the lung parenchyma occurs. Once the monocytes have entered the tissue, they differentiate into IMs and continue to migrate via their β1 integrins. Both differentiation and migration are influenced by local tissue-specific factors including chemokines, cytokines, matrix components, complement fragments, antigens, and interactions with other cells.[43,143,149,165]

Monocytes respond to a variety of chemotactic influences including complement fragments (e.g., C5 a), bacterial peptide f-MLP, leukotriene B4, and the chemokines CCL2, CCL3, CCL4, and CXCL8 ((IL-8).[143] The importance of chemokines for monocyte migration is illustrated by a study that investigated the impact of CCR2 (the receptor for CCL2; MCP-1) deletion in a murine model of pulmonary granulomatous inflammation.[170] Following deletion, there was marked decrease in granuloma size and a dramatic decrease in the level of interferon-γ in draining lymph nodes. These findings suggest that CCL2 is vital for monocyte/macrophage migration to sites of inflammation.

Motility of AMs and DCs has also been studied. When labeled DCs and AMs are introduced into the airways, DCs but not AMs are readily found in draining lymph nodes, suggesting that DCs are far more motile than AMs.[133,162] DC migration is likely chemokine mediated. In one set of experiments, IL-13 and IFNγ were administered intranasally, resulting in increased numbers of DCs accumulating in draining lymph nodes, similar to the experiment previously described.[171] Compared to untreated mice, the treated mice had more expression of chemokines including CCL5, CCL2, and CCL7 (MCP-3). In addition, chemokine receptor expression was increased including CCR2, CCR5, and CCR10.

ACTIVATION OF LUNG MACROPHAGES

A major feature of tissue macrophages is the ability to be "activated."[21,143,150] Activation of macrophages is a key event in the inflammatory cascade in the lung and defines a functional state characterized by extrusion of pseudopodia and an increase in cell size and membrane ruffling. Examples of stimuli that interact with receptors on the macrophage's surface to induce activation include antigen–antibody complexes (via the macrophage's Fc receptors), complement fragments (via the macrophage's complement receptors), and cytokines (e.g., interferon-γ) and TLR ligands (e.g., LPS lipopolysaccharide) When activated, macrophage phagocytosis, receptor expression, and production of toxic oxygen metabolites are markedly enhanced. The activated macrophage is a secretory cell, releasing cytokines, toxic oxygen metabolites, and enzymes. Finally, antigen presentation is optimized in activated macrophages but increased expression of Class II MHC.[150]

Using several surface markers ([154]), activated macrophages can be further characterized as exhibiting an M1 phenotype (classically activated macrophages, i.e., induced typically by IFNγ) or an M2 phenotype (alternatively activated macrophages, i.e., induced by IL-4/IL-13). M1 macrophages are generally associated with TH1 (and TH17) immune responses, the production of reactive oxygen intermediates, proinflammatory cytokines, and robust antimicrobial activity. M2 macrophages are associated with TH2 immune response, immune response to helminthes, tissue healing, collagen production, and fibrosis (see Table 21-6). However, this binary view of macrophage activation and its functional alignment with TH1 and TH2 lineages is an oversimplification; a third class of macrophages called "regulatory macrophages" has also been described. These macrophages can be activated by TLR agonists in the presence of immunoglobulin G (IgG) immune complexes, apoptotic cells, and prostaglandins, and are defined by production of the immunosuppressive cytokines IL-10 and TGF-β1.[172] These cells are poor antigen-presenting cells and have a propensity to induce TH2 and some believe T regulatory cell responses. Rather than discrete stable subpopulations, many studies have documented flexibility in macrophage programming, with macrophages readily switching from one functional phenotype to another in response to new microenvironmental signals.[172]

These signals result in activated macrophages playing a prominent role in many lung diseases. While it is unclear whether macrophage activation is a cause or result of lung disease, it is probably both. As an example, in emphysema, macrophage activation is initiated by cigarette smoke exposure and results in the release of inflammatory mediators and byproducts that are toxic to lung parenchyma. These inflammatory mediators, in turn, activate additional macrophages, establishing a vicious cycle of macrophage activation and parenchymal lung destruction.

LYMPHOCYTE–MACROPHAGE INTERACTIONS IN THE LUNG

The interactions between lymphocytes and macrophages, and their effects on lung inflammatory cells and on lung inflammation are summarized in Figure 21-2. Lung macrophages and lymphocytes each perform important functions and influence the differentiation and function of a large variety of cells. Lung macrophages and lymphocytes also interact via direct cell–cell contact during T-cell activation and are greatly codependent. The interaction between bronchial DCs, which are highly effective APCs and typically more effective at antigen presentation than macrophages, is not detailed herein as DC's primary action in regulating pulmonary inflammation, as noted earlier, is following migration to regional lymph nodes.

AM and related cells are the initial sentinels of the innate immune response, phagocytizing and eliminating invading antigens and microbes. After interaction with microbial invaders, and especially in conditions of overwhelming invasion, lung macrophage activation via TLRs and CD14 and other receptors (see Table 21-6) results in the release of inflammatory mediators which activate adhesion molecule expression on ECs, and promote the migration and activation of blood leukocytes including polymorphonuclear leukocytes (PMNs), monocytes, lymphocytes, and eosinophils (*left half* of Fig. 21-2). Rapid induction of selectin molecules stored in Weibel–Palade bodies of endothelium results in the rolling adhesion of neutrophils and monocytes. Migration of these leukocytes may be rapidly modulated by rapid release of arachidonate products such as LTB4, bacterial products themselves like the peptide f-MLP, complement fragments, and chemokines. More time is required for optimal expression of adhesion molecules, which enhance lymphocyte entry, especially VCAM and expression of the chemokine chemoattractant cytokines. One exception is the release within hours of IL-16 from epithelium or resident T cells in response to mast cell–derived histamine.[62]

Interaction of resident or infiltrating T cells with APCs (mainly DC, Langerhans cells and monocytes) results in optimal T-cell activation with resultant production of cytokines, which act upon a variety of cytokine-receptor bearing cells (*right half* of Fig. 21-2). This results in the activation of endothelium, optimal B-cell production of antibody, generation of cytotoxic effector T cells, and depending on the nature of the cytokines produced a delayed-type hypersensitivity or granulomatous (type 1 cytokines), allergic (type 2 cytokines), or other T-cell immune response including neutrophilic TH17 inflammation. Fibrosis or repair may also be influenced by the production of neutral proteases by AM,[151,173] or by the elaboration of the fibrogenic cytokine TGFβ1 by T cells or other

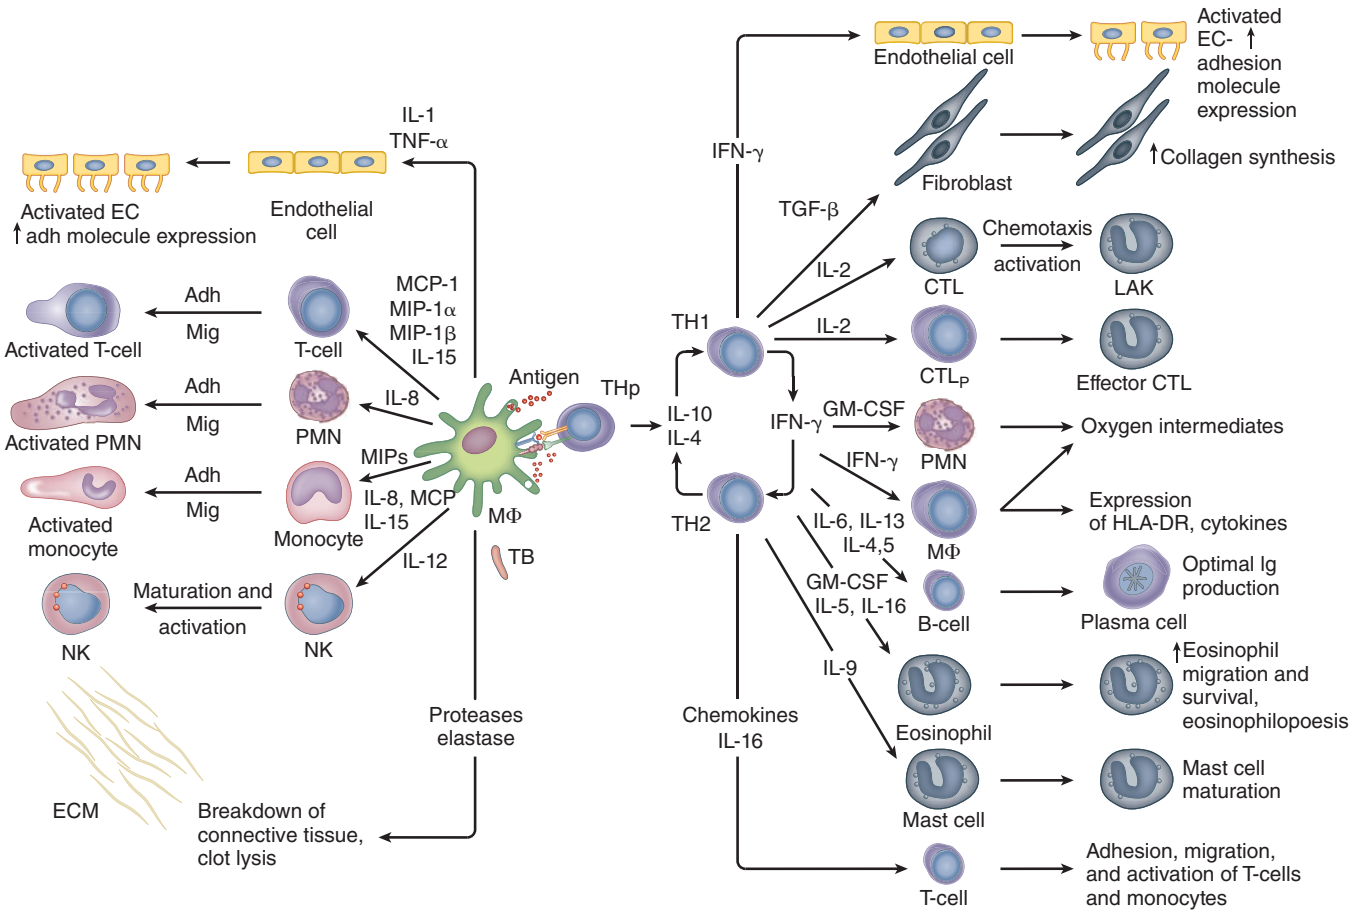

Figure 21-2 Lymphocyte and macrophage interactions in lung inflammation. Lymphocytes and macrophages interact directly and indirectly to influence lung inflammation. These interactions are complex, as illustrated in this diagram, which contains a necessarily incomplete sampling of these processes. Lymphocytes and macrophages interact directly in the process of lymphocyte activation; macrophages also are immunosuppressive in some circumstances. Activated T lymphocytes express a broad range of cytokines, which interact with a variety of effector cells; B lymphocytes produce antibodies. T lymphocytes also may interact with infected epithelial or phagocytic cells or with tumor cells to effect cell lysis. Macrophages similarly produce a large number of cytokines, which alter the functions of a variety of cells. Macrophages also release arachidonate metabolites, reactive oxygen species, nitric oxides, and a large number of proteases, which alter the function of surrounding cells, kill invading microorganisms and degrade matrix proteins. See text for further explanation. *(Adapted with permission from Agostini C, Chilosi M, Zambello R, Trentin L, Semenzato G. Pulmonary immune cells in health and disease: lymphocytes. Eur Respir J. 1993; 6(9):1378–1401.)*

cells depending upon the TH skewing. Of particular interest for the future are the ways the lung macrophage–lymphocyte inflammatory access is "turned off." The networks responsible for control and/or resolution of inflammation to prevent lung damage are likely to be as complex as those that initiate the inflammatory responses in infectious and noninfectious lung diseases.

Overall, the mammalian lung is uniquely poised to protect the environment of the lower respiratory tract and its essential gas exchange units though the presence of a complex network of monocyte/macrophage and lymphocytes selectively sequestered in various anatomical compartments. Together, they coordinate early innate responses to microbial infection and subsequent specific acquired immune responses (e.g., to viruses) that have evolved to protect the organ. Of particular interest in certain noninfectious or autoimmune lung diseases is the similarity of inflammatory responses to those in response to infections where the consequences are deleterious rather than beneficial. Thus, understanding ways to control lung innate and acquired immune responses will be essential in developing appropriate therapies for inflammatory lung diseases. Unfortunately, the converse is also true. Individuals treated with antibodies to TNFα to control the inflammation of rheumatoid arthritis or inflammatory bowel disease are at risk for reactivating latent *Mycobacterium tuberculosis* infections, an infectious disease clearly controlled by early innate and late acquired immunity. More detailed understanding of these processes, how to regulate them quantitatively and how to replace essential elements, is clearly needed to adjust the balance in individuals whose immune systems are compromised or in those whose immune systems are overwhelmed by infection or self-antigens.

CHAPTER 22

Mast Cells and Eosinophils

Edward S. Schulman
Peter H. S. Sporn

INTRODUCTION

For more than a century physicians have noted a clear connection between mast cell (MC) activation and the subsequent appearance of eosinophils both within the circulation and in tissues. Only recently, however, have basic insights been gained into the mechanisms of this cellular collusion. In keeping with this association, human MCs and eosinophils are considered together in this chapter.

MCs and eosinophils were discovered in the 1870s by the same observer, Paul Ehrlich. He noted that some cells stained in a peculiar fashion when incubated with standard aniline dyes such as toluidine blue and alcian blue. He used the term metachromasie or metachromasia to describe the peculiar color modifications that occurred and the term Mastzellen, meaning "well fed" or "fattened" in German, to describe what we now call MC. Interestingly, this latter term is now known to be a misnomer, since MC cytoplasmic granules are not phagocytosized but rather synthesized during cell growth and again during regranulation. Ehrlich also noted that some cells stained intensely when incubated with the acidic dye eosin. As a result, these cells were called eosinophils. Studies of these two cell types, over the ensuing years, have provided great insight into their roles in biology. They have also highlighted the differences that exist in these cells among different species and their heterogeneity even within a single species and even within single organs.

MAST CELLS

The capacity of strategically localized human MC to rapidly release a panoply of powerful chemical mediators makes this cell a unique member of the body's immune response network. Although most frequently discussed in the context of hypersensitivity immune responses, MCs are also known to participate in normal physiological processes including gastric acid secretion,[1] angiogenesis,[2,3] and lipid clearance.[4–8] Increasing evidence supports a role in the innate immune response, especially serving bacterial defense.[9] MCs also participate in nonallergic pathophysiological processes such as inflammatory bowel disease,[10,11] arthritis,[12] scleroderma,[13,14] tumors, interstitial pulmonary fibrosis,[15–18] envenomation,[3,19–22] and atherosclerosis.[4,5,23,24] Over the years, basophils have been confused with MC in a number of contexts.[25] This confusion is due, in part, to a number of similarities between the cells, including the shared expression of FcRI (high-affinity receptor for Fc fragment of IgE), release of preformed histamine, and metachromatic staining. However, MCs are mononuclear cells and are almost exclusively localized to tissues. In contrast, basophils are circulating polymorphonuclear cells that are found occasionally in tissue reactions, including the late-phase allergic response. In addition, significant differences in the two-cell populations exist in cell lineage, ultrastructure, mediator release biochemistry, mediator profiles, pharmacology, and surface antigenicity.

ANATOMIC LOCALIZATION

MCs are present in all organs but are particularly abundant in the nose, skin, gastrointestinal tract, and lung. They reside primarily near blood vessels, within the adventitia of arteries, and also near lymph vessels and nerves.[26–28] Estimated concentrations of human lung MCs (HLMCs) range from 500 to 4000 mm^{-3}. In nonasthmatics, HLMCs localize to submucosal connective tissues and not epithelium or smooth muscle. Though data in asthmatics are conflicting as to whether numbers are increased versus nonasthmatics, MCs localize to three critical sites: bronchial epithelium,[29] airway mucus glands,[30] and within smooth muscle.[31–34] Mediator release from the small numbers of HLMCs within the epithelium may subserve initial antigen recognition and also be strategically placed to respond to nonantigenic signals, including hyperosmolarity,[35] as well as "endogenous" mediators, including extracellular adenosine and adenosine 5′ monophosphate (ATP).[36–38] In the case of aeroallergens, permeabilization resulting from epithelial MC mediators enhances further antigen penetration to deeper airway smooth muscles and mucus glands, which in turn, promotes bronchoconstriction and mucus secretion, respectively. The finding of HLMC within the smooth muscle layer appears to be a common and critical finding in asthmatics. It is an uncommon finding in nonasthmatics and in patients with eosinophilic bronchitis. Other than MC localization to ASM, the latter condition has virtually identical

structural remodeling changes to asthma but is not associated with obstruction or airway hyperresponsiveness (AHR).[31,39] In the lung periphery, abundant MCs reside within small airways and in the alveolar septa, within a few microns of the alveolar lumen.[37] The small numbers of MC in bronchoalveolar lavage (BAL) fluid (≤0.1% of all cells) likely result from epithelial shedding.[27,40]

■ ORIGINS OF MAST CELLS

MCs are believed to be derived from pleuripotent hematopoietic stem cells.[41] Tryptase-negative MC-colony–forming cells leave the marrow and circulate with a surface phenotype that is CD (cluster of differentiation) 34+, c-kit (CD117)+, LY–, CD14–, and CD17–. The progenitors home in a tissue-specific manner where they undergo differentiation, maturation, and synthesis of granule proteases in response to microenvironmental factors, including the matrix and chemokines from fibroblasts, endothelial cells, airway smooth muscle cells, and possibly T cells. The microenvironmental factor most critical in chemotaxis, differentiation, adhesion, proliferation, maturation and survival is stem cell factor (SCF or c-kit ligand), the ligand for the c-kit tyrosine kinase receptor. This receptor is expressed on the MC surface throughout its life span.[42,43]

■ MAST CELL HETEROGENEITY

Striking differences in the morphology, T cell dependence, resident proteoglycans, and responsiveness to secretagogues and drugs have been described in human MC.[44–51] The ontogeny of this heterogeneity, as well as the differing roles these MC play in physiology and disease remain speculative.

The most commonly recognized system for classifying human MC is based on the expression of protease profiles as determined by immunohistochemical staining using monoclonal antibodies. According to this system, the serine proteinase tryptase (T) is expressed in virtually all human MC, and a subset, predominantly in the submucosa of the gut and in the skin and within asthmatic airway smooth muscle also express chymase (C) and multiple other proteases including carboxypeptidase A and cathepsin G. Those that express tryptase alone are classified as the MC_T type, and those with additional proteases, as the MC_{TC} type.[52–54] Because significant numbers of both types can be found in the same organ (e.g., lung), tissue location alone cannot dictate the protease type. In the lung, only 8% to 35% of MCs are MC_{TC}, 1% is MC_C, and the remainder are MC_T. The protease system does follow some rules of distribution and function. MC_T are preferentially localized in bronchi, bronchioles, at mucosal surfaces, alveolar parenchyma, lamnia propia, in areas of T-cell infiltration and are reduced in immunodeficiency syndromes. The MC_{TC} phenotype does not appear immune related and more prevalent in pulmonary vessels and pleura. As detected by immunohistochemical staining, the subtype more selectively expresses interleukin (IL)-4 (85% MC_{TC} vs. 15% MC_{TC}). IL-5 and IL-6 are almost exclusively restricted to the MC_T subtype. Within human lung different compartments appear to show site-specific expression of FcεRIα, IL-9 receptor, histidine decarboxylase (higher in MC_T of bronchi than MC_T of alveoli), 5-lipoxygenase, leukotriene C_4 (LTC_4) synthase, vascular endothelial growth factor (VEGF), basic fibroblast growth factor (FGF)[55] and renin.

HLMC diameters vary between 8 and 18 μm with the majority being 12 to 15 μm. Histamine contents of 2.5 to 10.0 pg/MC vary directly with cell diameter. HLMC densities vary from 1.053 to 1.123 g/mL with the majority (67%) between 1.077 g/mL and 1.088 g/mL. These diameter and density-based subtypes also are distinct with respect to mediator content and function. MC location also subserves function: Airway and parenchymal MC differ in their releasibility. At the ultrastructural level, marked heterogeneity has been described (see Morphology below). Finally, at least two types of proteoglycans are present in HLMC: chondroitin sulfates, predominantly chondroitin sulfate E, and heparin. HLMCs are both positive and negative for the heparin-sensitive dye berberine sulfate, whereas stomach MCs synthesize exclusively chondroitin sulfate E and not heparin.[56,57]

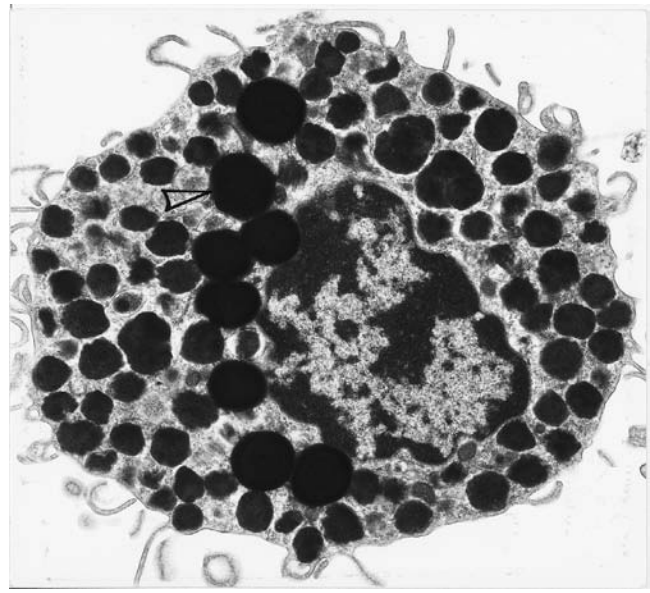

Figure 22-1 Ultrastructure of the human lung mast cell after purification. The mast cell is a mononuclear cell packed with multiple dense cytoplasmic granules that vary in size and shape. Eight electron-dense lipid bodies *(open arrow)* are bunched near the nucleus (×15,000). *(Reproduced with permission from Dvorak AM. Recovery of human lung mast cells from anaphylactic degranulation utilizes a mixture of conservation and synthetic mechanisms, in Galli SJ, Austen KF (eds). Mast Cell and Basophil Differentiation and Function in Health and Disease. New York: Raven; 1989.)*

■ MORPHOLOGY

All MCs are mononuclear cells with heterogeneous cytoplasmic granules (Fig. 22-1). A variety of granule-filling patterns occur within individual cells: scrolls, crystals, particles (the least seen in pure form), and combinations (mixed). The appearance of individual patterns can be influenced by cross section. Granules are outlined by a perigranular membrane. Cell membranes are outlined by short, narrow surface folds.[58–62]

■ MORPHOLOGY OF DEGRANULATION AND REGRANULATION

Following IgE-mediated (anaphylactic) activation of HLMC, granules swell and their perigranular membranes fuse to form canaliculi that open through multiple pores to the cell exterior. Within 20 minutes of activation, granular matrix materials solubilize within these intracytoplasmic channels and empty. In HLMC, only rarely is extrusion of nonsolubilized granules observed. Lipid bodies, which are electron-dense nonmembrane-bound organelles,[63–66] remain adjacent to these channels. They appear to serve as repositories of arachidonic acid and occasionally release lipid into the degranulation channels. In vivo, a process termed "piecemeal degranulation" is more frequently observed than anaphylactic degranulation.[67] This process involves the budding of small vesicles from granule membranes and their movement to the cell surface. Piecemeal degranulation may be more typical of the ongoing MC release observed in chronic asthma.

Depending on the extent to which an individual cell has degranulated, one of two predominant types of regranulation are observed individually or in combination. In partially degranulated cells, the channel (formerly perigranular) membranes are reutilized, and regranulation events resemble degranulation in reverse. In cells with

more complete degranulation, the channel membranes are placed in continuity with the plasma membrane and externalized. This results in the appearance of elongated, activated cell surface folds. These excessive folds can be internalized or shed. Shedding results in cells that are initially small (7 μm), but then enter a rapidly expanding recovery cycle to produce a fully mature cell.[62]

■ ACTIVATION

Immunological activation of MC is the mechanism most studied.[68] It results from antigen cross-linking of antigen-specific cell surface IgE molecules and subsequent aggregation of the high-affinity receptors (FcεRI) to which they are attached.[69,70] Receptor dimerization is the minimum cross-linkage requirement for IgE-mediated activation. In vitro, immunological activation can be achieved using antibodies directed against human IgE or the FcεRI-receptor itself. The mechanism(s) involved in chronic HLMC activation characteristic of asthma are not known but likely may reflect low-level allergen activation. Recent evidence contends that monomeric IgE alone, in the absence of antigen, can also induce prolonged mediator release, a mechanism that may be operative within the asthmatic airway.[71]

Non–IgE-mediated release triggers of MC are also well characterized. In general, the profile of agents that degranulate MC from human intestine and synovium is similar to that of HLMC but different from skin MC.[62,72,73] These non–IgE-mediated secretagogues include ionophores, hyperosmolar stimuli, and "histamine-releasing activities" derived from human alveolar macrophages and other cells.[74–77] The purified anaphylatoxin C5a, an active trigger of human basophils and dermal MC, is generally inactive in HLMC,[78,79] although CD88, the receptor for C5, has been reported in the MC_{TC}.[80] Consistent degranulators of dermal but not HLMC include substance P, morphine, polyamines such as 48/80, and SCF. Even within lung compartments, responsiveness to triggers may vary. Compound 48/80 is reported to degranulate BAL MC, whereas those from lung parenchyma are minimally responsive. To date, neuropeptides have been shown to be inactive in degranulating HLMC. Bee venom phospholipase (PL) A_2 and antigens from dust mites, cockroaches, pollens and fungal spores contain phospholipases and proteases, which can lead to MC release through the protease-activated receptor (PAR) 2.[81,82] Finally, expression in both mouse MC and human progenitor–derived MC of several innate pattern recognition receptors, including the Toll-like receptor-2 (TLR-2) and TLR-4, has been reported.[83,84] The expression of TLR and effects on activation of HLMC are as yet poorly defined. Human peripheral blood–derived cultured MCs are reported to produce type I IFNs following exposure to double-stranded RNA and/or virus, the former implicating TLR-3 expression.[83]

■ MODULATORS OF ACTIVATION

Although not acting as direct release triggers, a number of endogenous chemicals in the MC microenvironment can influence activation. Extracellular ATP and its breakdown product, adenosine, are potent modulators of HLMC degranulation, although neither directly activates HLMC in vitro.[36–38,85] In asthmatics, aerosolized adenosine induces bronchoconstriction, an effect not observed in other groups of pulmonary patients or normals.[86] The ability of antihistamines to inhibit this response has directly implicated activation of allergically primed airway MC by adenosine.[87,88] Components of the local connective tissue matrix such as fibronectin also modulate MC reactivity.[89]

■ BIOCHEMICAL ANALYSIS OF HLMC ACTIVATION

Elegant studies defining the biochemical events following IgE-mediated activation have been performed in rodent MCs or cell lines.[90,91] Evaluations of similarities and differences in HLMC activation await future investigations. Two receptors for IgE have been identified. The high-affinity IgE receptor (FcεRI) on MC and basophils is expressed in a tetrameric form ($\alpha\beta\gamma2$) and on antigen-presenting cells is present in a trimeric form ($\alpha\gamma2$). The Fc fragment of IgE binds to the α-chain of FcεRI. Expression of the β-chain amplifies signaling. A low-affinity IgE receptor (FcεRII; CD23) is present on B cells but not on MC or basophils.[92] Serum IgE levels correlate with basophil expression of FcεRI, likely indicating a role for IgE in stabilizing the FcεRI on the cell surface. As noted earlier, receptor dimerization is the minimum cross-linkage requirement for antigen-mediated allergen activation through the FcεRI. Following receptor aggregation, multiple signal transduction pathways are activated. Since FcεRI possesses no inherent tyrosine kinase activity, critical to the sequential activation are two tyrosine kinases, lyn which is associated with the β chain and syk. Lyn binds to the β-chain–associated immunoreceptor tyrosine-based activation motifs (ITAMs), which are phosphorylated after FcεRI aggregation. For degranulation to proceed, syk then binds to the γ-chain–linked ITAM, which are also phosphorylated after receptor aggregation. The lynsyk-driven pathway directly or indirectly stimulates tyrosine phosphorylation of several adapter proteins, including the transmembrane adaptor molecule linker for activation of T cells (LAT) among others. These events lead to the generation of inositol triphosphate (IP_3) which induces Ca^{2+} mobilization from intracellular rough endoplasmic reticulum (RER) stores. Also activated are phospholipase C-γ1 and PLC-γ2.[93–101] In this context, at 2 minutes following FcεRI aggregation, extracellular calcium influx occurs through CRACM channels (Ca^{2+} release–activated Ca^{2+} [CRAC] modulator 1),[102,103] which is a prerequisite for degranulation to proceed over the next 5 to 20 minutes. Other "early-phase" granule-associated and lipid mediators (e.g., arachidonate metabolites) are also released over 20 minutes. Over the ensuing 1 to 24 hours, mRNAs for select cytokines are generated followed by their protein synthesis and release.

■ CHEMICAL MEDIATORS

The clinical expression of MC-mediated responses may reflect the individual mediators or in certain instances, the interplay of the multiple mediators these cells release (Table 22-1). The temporal sequence of their release appears critical to the development of both the early- and late-phase responses after antigen challenge (Fig. 22-2). Certain mediators are virtually unique to MC (e.g., tryptase, chymase, heparin), and others are shared with one or more other cells (e.g., histamine, LTC_4, and IL-5).

Mediators released within minutes after activation are divided into preformed, or secretory, granule-associated mediators (e.g., histamine) and nonpreformed, or newly synthesized mediators (e.g., lipids). It is now known that tumor necrosis factor alpha (TNFα) may be both preformed and newly synthesized. Other cytokine mediators, including IL-5 and IL-13, are only detected over hours and may be critical to the evolution of the "late-phase" response.

■ PREFORMED MEDIATORS

Mast cells contain a number of preformed mediators. Each is discussed below.

Histamine

Histamine measurements have served as a classic marker of MC-mediated events. The pleiotrophic effects of histamine are mediated through the differential expression, regulation, and distinct intracellular signals evoked by four distinct receptors, H1, H2, H3, and H4. The actual role of histamine in asthma remains less clear, although levels in BAL fluid are many-fold higher in asthmatics, and plasma levels rise three- to fivefold following airway antigen challenge. Most histamine-induced allergic respiratory reactions are mediated via the H1 histamine receptor subclass, producing enhancement of vascular permeability, mucus production, initiation of neurogenic reflexes, and bronchial smooth muscle contraction. The reasons for the marginal value of the H1 receptor-blocking drugs in asthma may be due to high local tissue concentrations of histamine that exceed the inhibitory

TABLE 22-1 Human Mast Cell and Eosinophil Mediators

	Mast Cells	Eosinophils
Granule-associated (preformed) mediators	Histamine	MBP
	Heparin	ECP
	Chondroitin-sulfate E	EDN
	TNFα	EPO
		CLC protein
Enzymes	Tryptase	EPO
	Chymase	ECP, EDN
	Cathepsin G	Collagenase
	Elastase	MMP-9
	Carboxypeptidase-A	Indoleamine 2,3-dioxygenase
Acid hydrolases	β-hexosaminidase	β-glucuronidase

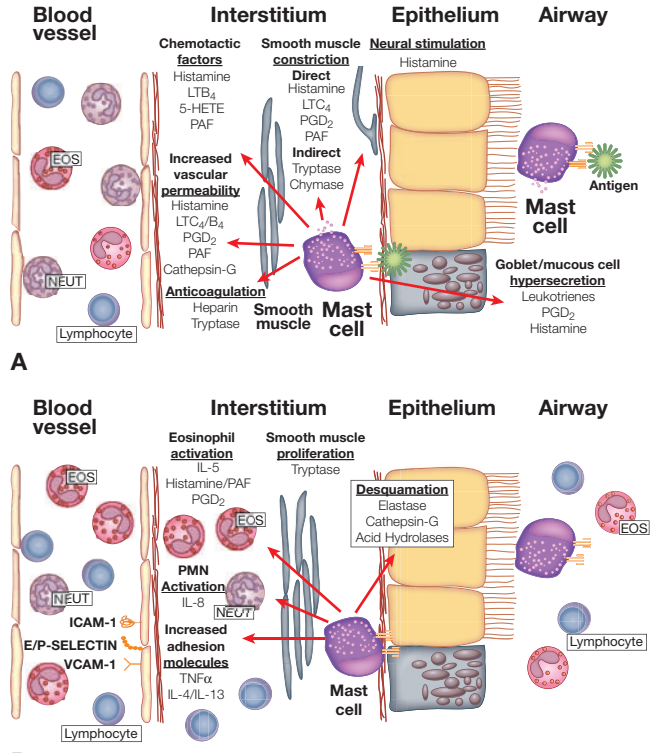

Figure 22-2 Effects of mast cell mediators in the early- and late-phase responses following airway allergen challenge. **A.** Early phase: Mediators are released within minutes following antigen cross-linking of allergen-specific IgE on the cell surface. Mechanisms of the initial airflow obstruction that persists for 30 to 60 minutes include smooth muscle constriction, edema formation due to increased vascular permeability, nerve stimulation, and mucus hypersecretion from both goblet cells and submucosal glands. **B.** Late phase. Within hours, the effects of newly synthesized and released cytokine mediators along with delayed effects of early-phase mediators produce recurrent airway obstruction. Mast cell mediators and cytokines can increase the expression of adhesion molecules on endothelial cells, both recruit and activate leukocytes (particularly eosinophils), contribute to epithelial desquamation, and stimulate smooth muscle proliferation.

capacity of these agents and/or the redundancy of histamine actions with the multiple other mediators that are released.

Proteoglycans

MC proteoglycans serve as the major determinant for the metachromatic tinctorial properties of the cell and form the granule backbone to which other preformed mediators, including histamine and neutral proteases, are bound. HLMCs synthesize heparin and chondroitin sulfate E proteoglycans in roughly a 2:1 ratio.[56] In humans, heparin appears to be unique to MC. In addition to anticoagulant activity, heparin possesses both anti-inflammatory and immunoregulatory properties.[104–106] Heparin may limit allergic responses in the skin, nose and lung and exert protective effects on exercise-induced asthma (EIA). The inhibitory effects may be related to the extracellular binding and inhibition of multiple mediators, including histamine and cytokines.

Chemotactic Factors

Within hours of MC activation, airway inflammation (the late-phase response) at the tissue level is characterized by the infiltration of leukocytes. This response is principally eosinophilic but also contains neutrophils and, over time, lymphocytes. Chemotactic mediators may be derived directly from MC and/or other cells through secondary stimulation. Early-phase MC-derived eosinophilic chemotactic activities include leukotriene B_4 (LTB_4), platelet-activating factor (PAF), and histamine.[107] HLMCs robustly express IL-8, which along with LTB_4, attracts neutrophils. MCs are responsive to chemokines released from other cells. Airway smooth muscle secretes a number of chemotactic factors including CXCL8, -10, -11, and -12. It appears that the CXCR3/CXCL10 axis predominately mediates the HLMC migration into the airway smooth muscle observed in asthmatic airways.[108,109]

Proteases

Large quantities of neutral proteases are contained within MC and constitute the predominant protein component of the secretory

granule. The proteases include tryptase, chymase, cathepsin G, carboxypeptidase A, and elastase.[52–54,110]

Tryptase is the predominant neutral protease of the MC granule. It is a tetramer that is stabilized by its association with proteoglycan. The concentration of tryptase in pulmonary MC is 11 pg/MC. Since the concentrations of tryptase in circulating basophils (α tryptase, see below) are negligible, responses characterized by the presence of histamine but not tryptase at the reaction site or in the circulation implicate mediation by basophils and not MC. Two forms of tryptase (α and β) have been identified. The α tryptase is constitutively secreted in an inactive form and reflects systemic MC burden. The active β form is packaged in the secretory granule and acutely rises in anaphylactic reactions. Postulated roles for tryptase in pathophysiology remain to be established. Described actions include the degradation of the neuropeptide vasoactive intestinal peptide (VIP), mitogenic effects on smooth muscle and epithelial cells, and inactivation of procoagulant proteins.

Chymase is associated with heparin in a manner similar to tryptase. The role of chymase in asthma and other disorders is not clearly defined. Chymase may play a role in tissue remodeling. Substrates include angiotensin I, converting it to the angiotensin II, VIP (inactivates), substance P, bradykinin, and kallidin (inactivates). Other activities include activation of matrix metalloprotease and stimulation of tissue neutrophilia and eosinophilia.

Cathepsin G is a neutral protease with chymotryptic specificities. The concentration of cathepsin G in HLMC is roughly 100 to 700 ng/10^6 cells. An elastase released from HLMC appears to be identical to human neutrophil elastase. A measurement of 40 to 170 ng/10^6 cells assumes all HLMCs contain this enzyme, although it may be localized to an HLMC subset. Among carboxypeptidases, the MC carboxypeptidase A, a metalloexopeptidase, is unique. Granule-associated acid hydrolases include β-hexosaminidase, β-glucuronidase, and arylsulfatase.

NONPREFORMED MEDIATORS

Arachidonic acid metabolites are generated within minutes of MC activation and play a crucial role in the early phases of the asthmatic response. Cyclooxygenase metabolism in MC generates large quantities of prostaglandin (PG) D_2 and a small quantity of thromboxane A_2.[37,111] PGD_2 is the most potent bronchoconstrictor of the cyclooxygenase metabolites. Additional actions of PGD_2 include induction of chemotaxis in eosinophils, basophils, and Th2 cells; increase in capillary permeability and vasodilation. Although all tissue MCs generate PGD_2, not all generate significant quantities of 5-lipoxygenase products (e.g., lung > skin). The major 5-lipoxygenase pathway products of HLMC are LTC_4, and LTB_4, with lesser quantities of 5-HETE. In IgE-mediated human lung challenges, MCs constitute the major source of released LTC_4.[112]

PAF is an early-phase phospholipid bronchoconstrictor that consists of a family of molecules. In contrast to the other lipid mediators, MCs appear to retain PAF intracellularly or demonstrate rapid reuptake of any that may be released.

HLMCs synthesize and release TH2-type cytokines, including IL-5, and -13, which are felt to be central to the evolution of the late-phase response.[113,114] Additional multifunctional cytokines, including IL-3, -6, -8, transforming growth factor beta (TGFβ), basic fibroblast growth factor (bFGF) and TNFα, are also synthesized by HLMC. In general, cytokine protein products are released over a 1- to 24-hour period following allergic activation. IL-4, a cytokine that virtually defines Th2 immunity, is immunolocalized to HLMC, which are rich in surface IL-4 receptors. However, generation of IL-4 mRNA and protein release has been reported by some, but not all, investigators.[113,115] TNFα, stored preformed within MC granules is in a unique position to exert diverse host defense effects in allergy and innate immunity.[116] Recent studies suggest that increased expression of TNFα within HLMC may play a role in asthmatic airway inflammation and correlates with asthma severity.[117,118]

Amphiregulin, a member of the epidermal growth factor family, is secreted following FcεRI-mediated activation. Its effects include increasing mucin gene expression, which may contribute to the epithelial cell metaplasia and mucus hypersecretion of asthma.[119]

PHARMACOLOGIC MODULATION OF MAST CELL FUNCTION

Only a limited number of pharmacologic agents have been tested in vitro on HLMC activation–secretion. In general, these agents have been tested on human parenchymal MC rather than those in bronchi or resident in BAL.[36,37,120] Moreover, inhibitory potency has been evaluated with anaphylactic degranulation rather than piecemeal degranulation, the latter being more characteristic of asthma.[121,122] Several receptors that inhibit MC activation contain immunoreceptor tyrosine-based inhibition motifs (ITIMs). Following inhibitory receptor activation these regions are phosphorylated, and then recruit phosphatases that dephosphorylate key-signaling molecules.[123] The common classes of antiallergic and/or antiasthmatic drugs used in clinical practice have received most evaluation. To date, the β-agonist pharmacologic agents, as typified by fenoterol and salmeterol, are reported to be among the most potent global inhibitors of HLMC mediator release with concentrations that inhibit histamine release by 50% (IC_{50}) of $\leq 10^{-8}$ M. Less effective inhibitors include the theophylline-like phosphodiesterase inhibitor isobutylmethylxanthine (IC_{50} = 0.5 mM) and PGE_2 ($IC_{50} = 10^{-5}$ M). Although widely touted as "MC stabilizers," disodium cromoglycate and nedocromil sodium, which recently have been shown as agonists at G-protein–coupled receptor 35 (GPR35)[124] poorly inhibit purified HLMC histamine release.[47,125] Inhibition of BAL MC activation by these agents is reportedly more striking.[126]

The effects of glucocorticosteroids on MC are diverse, including both stimulatory and inhibitory effects on the transcription of select genes. Release of early-phase mediators (e.g., histamine, LTC_4) in vitro and acute airway responses in vivo are unaffected by short pretreatment (up to 24 hours) with these drugs. In contrast, IgE-mediated generation of TH2-type late-phase cytokine mRNA and protein (e.g., IL-5, -13) are suppressed ($IC_{50} = 10^{-8}$–10^{-9} M).[127]

FK-506, a macrolide that binds to a specific binding protein, inhibits HLMC mediator release at low concentrations (0.1–300 nM). Cyclosporin A, which binds to cyclophilin, and auranofin, an orally absorbable gold compound, both inhibit HLMC mediator release.

Specific inhibitors of leukotriene generation include direct 5-lipoxygenase enzyme inhibitors, such as A-60477 (Zileuton), and indirect inhibitors, such as MK-886, which bind to a protein termed 5-lipoxygenase–activating protein (FLAP). Interestingly, PGD_2 release is markedly enhanced by FLAP inhibiton. This phenomenon has been termed a reverse shunt effect. Generally, 5-lipoxygenase pathway inhibitors do not affect HLMC histamine release. Cyclooxygenase-1 inhibition plays a critical role in a certain subset of "aspirin-sensitive" asthmatic patients (see below). Agents such as indomethacin potently inhibit HLMC PGD_2 generation ($IC_{50} = 5.5 \times 10^{-10}$ M) while producing significant enhancement of LTC_4 release.

MAST CELLS IN PULMONARY DISEASE

MCs have been implicated in a variety of pulmonary disorders based, to a great extent, on their presence in increased numbers and/or percentages in diseased tissues and the recovery of increased concentrations of MC-derived mediators, particularly histamine, in BAL fluid. Implicated pulmonary disorders include asthma, idiopathic pulmonary fibrosis, sarcoidosis, extrinsic allergic alveolitis, and chronic bronchitis.[51,128–131]

Asthma

MCs within airway epithelium are in an ideal sentinel position to be exposed to inhaled inciting stimuli. Intraepithelial MCs (IEMCs) express tryptase but seldom chymase except in severe asthma[27,29] and were traditionally thought to represent the classic MC_T phenotype. Recent reports assert that intraepithelial MC_T in "Th2-high" asthma also expresses carboxypepeptidase A3 (CPA3), which had previously been identified only in association with MC_{TC}. At baseline, even very mild asthmatics show evidence of continuous MC degranulation in bronchial mucosa and increased histamine content in BAL. Analysis of BAL in allergen-challenged atopic subjects and asthmatics demonstrates increased release of histamine, tryptase, and PGD_2. Increased numbers of lumenal MC are also noted and correlate with mediator content, airflow obstruction, eosinophil numbers, and bronchial hyperresponsiveness. In general, asthmatic MCs exhibit ultrastructural evidence of degranulation. In nonfatal asthma, there is a significant increase of MC within airway smooth muscle and mucosal gland stroma.[30] Multiple redundant MC mediators likely contribute to increased mucus gland secretion and smooth muscle constriction. Following chronic corticosteroid treatment, allergic reactions are diminished in association with depletion of MC in both the epithelium and submucosa.

Although much attention has been given to IgE-mediated mechanisms of asthmatic airway activation, it is likely that multiple other MC-triggering mechanisms operate under a variety of immunologic, occupational, and environmental conditions. One mechanism proposed for EIA relates to airway cooling and the generation of hyperosmolarity on the dried airway surface leading to MC degranulation.

Up to 10% of asthmatics are intolerant of aspirin and other nonstructurally related nonsteroidal anti-inflammatory drugs (NSAIDs). In vitro pretreatment of human airway tissues with indomethacin results in increased LTC_4 generation following IgE-mediated stimulation. MCs are the principal cells expressing LTC_4 synthase in the airways of aspirin-exacerbated asthmatics[132] and these patients have increased Cox-2 expressing bronchial MC numbers.[133]

Fibrosis

The cellular composition of diffuse fibrotic reactions includes striking increases in MC numbers. MCs synthesize and release important mediators of fibrosis, including TGFβ and hFGF.[15–18,134] The hypothesis that MCs and their mediators are critical to the development of fibrotic reactions is supported by animal models in which MC hyperplasia has been a constant finding in pulmonary fibrosis induced by bleomycin, ionizing radiation, and asbestos. Bronchial remodeling with subepithelial fibrosis is also a prominent feature of the asthmatic airway. It is not clear whether MC proliferation and activation drive and/or are secondary to the fibrotic process. The latter mechanism could be effected through fibroblast generation of SCF, producing MC proliferation, chemotaxis, and inhibition of apoptosis.

EOSINOPHILS

While eosinophils are considered leukocytes, like MC, they in fact reside primarily in the tissues. Indeed, the ratio of tissue to blood eosinophils is estimated to be 100:1 or greater. Under normal circumstances, the major resident population of eosinophils is in the lamina propria of the gastrointestinal tract. Eosinophils are also present in the thymus, as well as the uterus and developing mammary gland in females. In the absence of disease, very few eosinophils are found in the lung. On the other hand, large numbers of eosinophils traffic to the lungs and other tissues in the setting of allergic diseases, helminthic parasite infections and certain other pathological states.

■ EOSINOPHIL DEVELOPMENT

Eosinophils develop in the bone marrow from hematopoietic stem cell precursors. The immediate eosinophil precursor is a common eosinophil–basophil progenitor. Specific differentiation to the eosinophil lineage involves coordinated expression of the transcription factors, GATA-1, PU.1, and C/EBP. Among these, GATA-1 plays a central role, since mice with deletion of a high-affinity GATA-binding site in the GATA-1 promoter (ΔdblGATA1 mice) completely lack eosinophils, without loss of other hematopoietic lineages.[135] The cytokines, IL-3, granulocyte-macrophage/colony-stimulating factor (GM-CSF) and IL-5 stimulate growth and differentiation of eosinophils in the bone marrow. IL-5, the only one of these that is eosinophil specific, plays an essential role in stimulating bone marrow production of eosinophils and triggering their release into the circulation.[136] IL-5 is produced by lymphocytes and endothelial cells in the bone marrow, as well as by lymphocytes and parenchymal cells in the lung and other tissues. The importance of IL-5 in eosinophil production is demonstrated by the fact that transgenic mice overexpressing IL-5 develop profound blood and tissue eosinophilia.[137] On the other hand, IL-5 knockout mice have markedly reduced numbers of eosinophils at baseline, and fail to develop eosinophilia in response to allergen sensitization and challenge.[138] These and other findings have provided the impetus for development of IL-5 and IL-5 receptor–targeted monoclonal antibodies, which are under study for therapy of asthma and other eosinophilic diseases, as discussed below.

■ MORPHOLOGY AND STRUCTURE

The mature human eosinophil has a diameter of 12 to 17 μm, slightly larger than the neutrophil. The nucleus is usually bilobed, and the cytoplasm contains characteristic granules that stain yellow-pink with eosin. The distinctive features of eosinophil granules can be seen clearly by electron microscopy (Fig. 22-3). Primary granules, which appear during the promyelocytic stage of development, are round, membrane-limited structures that contain Charcot–Leyden crystal (CLC) protein.[139] Secondary (also termed specific or cytoplasmic crystalloid) granules appear later during eosinophil differentiation.[140] These are more numerous and appear as oval or elongated membrane-bound structures with a dense crystalline core and less dense matrix. The secondary granule core contains major basic protein (MBP), while other granule proteins are in the matrix. Lipid bodies are non-membrane-bound, lipid-rich organelles that localize arachidonic acid-metabolizing enzymes and serve as sites of eicosanoid synthesis.[141]

■ GRANULE PROTEINS

Eosinophils contain a number of cationic granule proteins that have toxic effects on parasitic helminths and RNA viruses, as well as on host cells. In addition, a variety of other proteins, including enzymes and cytokines, are stored in and released from eosinophil granules. MBP, a highly basic protein that accounts for more than half of eosinophil granule protein mass, is found in the crystalline core of specific granules.[142] MBP is synthesized as a preproprotein, which is cleaved to a 13.8-kD highly cationic molecule during eosinophil maturation. The pro-peptide, which is anionic, is thought to protect the developing eosinophil from the toxic effects of the highly cationic mature MBP. Low levels of MBP are expressed in basophils, consistent with their close lineage relationship to eosinophils. MBP is directly toxic to larvae of Schistosoma mansoni, Trichinella spiralis, and other helminths, supporting a role in host defense against parasites.[143] Several lines of evidence have suggested that MBP could be an important mediator of asthma. MBP inhibits ciliary function and is toxic to respiratory epithelial cells.[144,145] When administered to the airways of monkeys, MBP caused transient bronchoconstriction followed by persistent bronchial hyperresponsiveness.[146] In addition, MBP was shown to bind to and inhibit M2 muscarinic receptors, increasing vagally mediated bronchoconstriction in guinea pigs.[147] On the other hand, mice deficient in MPB showed no attenuation of airway histopathological changes or airway hyperreactivity in an allergen-induced asthma model,[148] suggesting that

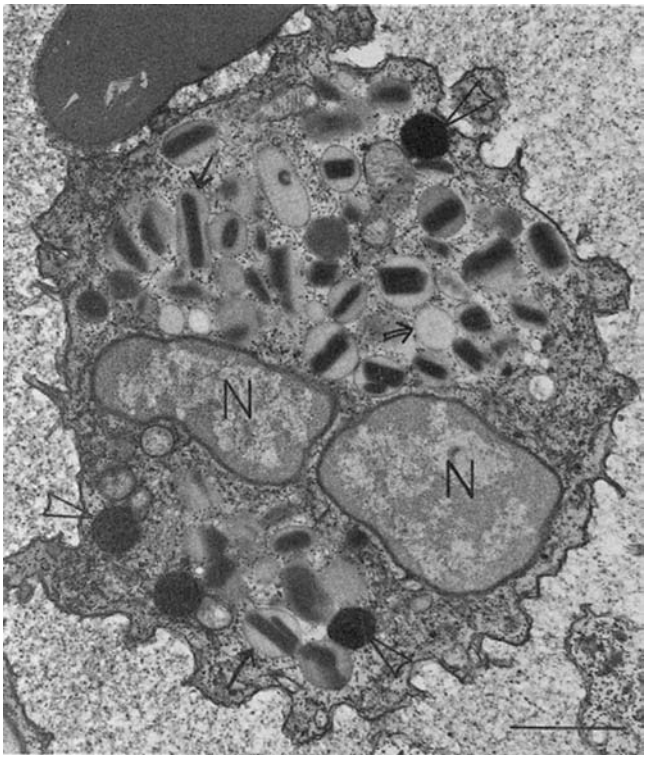

Figure 22-3 Ultrastructure of a mature human blood eosinophil. The bilobed nucleus (N), specific granules *(closed arrows)*, primary granules *(open arrow)*, lipid bodies *(open arrowheads)*, mitochondria, and irregular surface processes are seen. Dark cytoplasmic particles represent glycogen. *(Reproduced with permission from Dvorak AM, Ackerman SJ, Weller PF. Subcellular morphology and biochemistry of eosinophils, in Harris JR (ed). Megakaryocytes, Platelets, Macrophages, and Eosinophils, vol 2. New York: Plenum Press; 1991.)*

MBP does not play an essential role in allergic airway disease, at least in the mouse.

Eosinophil cationic protein (ECP) and eosinophil-derived neurotoxin (EDN) are both highly basic proteins found in the matrix of specific granules. ECP and EDN are homologous proteins (67% amino acid sequence identity), the result of gene duplication, that are also similar to human pancreatic ribonuclease (RNase) A.[143] Indeed, both ECP and EDN are active RNases, with the ability to inactivate RNA viruses, such as respiratory syncytial virus (RSV).[143] EDN was initially described as a neurotoxin that causes severe damage to myelinated neurons, a property possessed by ECP, as well. This activity may account for the neurological abnormalities seen in patients with hypereosinophilic syndrome (HES) and CSF eosinophilia. Like MBP, ECP and EDN are both helminthotoxic.[143] Levels of ECP are elevated in blood, BAL fluid, and sputum in patients with asthma, and have been found to correlate with disease activity.[149] For this reason, ECP levels in blood or sputum are often monitored in asthma clinical trials as a means of assessing response to treatment.

Eosinophil peroxidase (EPO) is another highly basic protein found in the matrix of specific granules. EPO is a unique peroxidase, expressed only in eosinophils. In the presence of H_2O_2, EPO oxidizes halide ions to form highly reactive hypohalous acids. Bromide is the preferred substrate, leading to hypobromous acid (HOBr), an extremely potent oxidant that damages DNA and other critical cellular targets. EPO plus H_2O_2 and halide ions can kill multiple parasites, bacteria, mycobacteria, and also MC and tumor cells.[150] The potential role of EPO in allergic airway disease has been explored in mice with targeted deletion of the EPO gene. In this study, despite a marked reduction in bromo-oxidation of lung proteins, EPO deficiency did not result in any attenuation of allergen-induced airway inflammation or bronchial hyperresponsiveness,[151] indicating that EPO is not essential for development of allergic pulmonary pathology in the mouse.

CLC protein localizes to the primary eosinophil granule, and is also expressed in basophils. The protein readily crystalizes to form bipyramidal CLCs, often seen in affected tissues and considered a hallmark of eosinophil-associated diseases. Previously thought to possess lysophospholipase activity, CLC protein has been shown to belong to the galactose-binding lectin family (galectins) and to avidly bind the sugar mannose.[152] Despite the long-recognized association of CLCs with eosinophil infiltration of tissues, the role of CLC protein in eosinophil-related pathology is unknown.

Eosinophils also contain within their granules various other enzymes, including β-glucuronidase, arylsulfatase B, and matrix metalloproteinase-9 (MMP-9), as well as preformed cytokines and chemokines, which can be released in regulated fashion, as discussed further below.

CHEMICAL MEDIATORS

Eosinophils may produce a number of important chemical mediators, each of which is discussed below.

Lipid Mediators

Upon stimulation, eosinophils produce large quantities of the 5-lipoxygenase–derived eicosanoid, LTC_4. Synthesis of LTC_4 in eosinophils occurs at the nuclear membrane.[153,154] and in cytoplasmic lipid bodies.[155] Following secretion, LTC_4 is converted extracellularly to LTD_4 and LTE_4. These cysteinyl leukotrienes act through $cysLT_1$ and $cysLT_2$ receptors to cause bronchoconstriction, stimulate mucus secretion, promote synthesis of Th2 cytokines, and contribute to airway remodeling.[156] The ability to block these effects underlies the beneficial actions of cysLT receptor antagonists and leukotriene synthesis inhibitors in asthma. Other biologically active lipids produced in substantial quantities by eosinophils include 15-HETE, 5-oxo-ETE, and PAF. However, the roles of these products in asthma and other eosinophil-associated diseases remain unclear.

Cytokines and Chemokines

Classically, eosinophils were considered terminal effector cells of inflammatory responses, acting by secretion of granule proteins and the acute release of other mediators. However, it is now recognized that eosinophils synthesize a wide array of cytokines and chemokines, equipping them to participate in the regulation of immune and inflammatory responses. The major cytokines and chemokines expressed in eosinophils are listed in Table 22-1. Interestingly, a number of these factors have autocrine or paracrine effects on eosinophils themselves. Most notably, IL-3, GM-CSF, and IL-5, which are produced by activated T lymphocytes and other cells, including MCs and eosinophils themselves, enhance eosinophil survival and activate eosinophil function in vitro and in vivo.[154,157–164] In another example, IL-16, a product of eosinophils and other cells, triggers rapid eosinophil release of CCL5 (RANTES), which generates autocrine signals that augment release of LTC_4 and IL-4.[165] A number of cytokines and chemokines synthesized by eosinophils are stored within granules. When cells are stimulated, these preformed cytokines are released by a regulated process involving piecemeal degranulation, which is described further below.

Eosinophil-derived cytokines likely contribute to regulation of inflammatory responses in eosinophil-associated diseases and drive specific pathophysiological responses. For example, elaboration of Th2 cytokines amplifies allergic responses, and is likely important in host defense against parasites and in pulmonary fibrosis. TGFα released by eosinophils is a potent stimulus for synthesis of mucins by airway epithelial cells,[166] which contributes to asthma and other eosinophilic airway diseases. Also, accumulating evidence implicates eosinophil-derived TGFβ as a driver of airway remodeling in asthma,[167] and suggests a link to pulmonary fibrosis, as well.[168] A clearer understanding

of the roles of eosinophil cytokines in human diseases will emerge as therapeutic agents designed to target specific cytokines, their receptors and downstream signaling pathways are tested in clinical trials.

Reactive Oxygen Metabolites

Like neutrophils, eosinophils synthesize superoxide anion ($\bullet O_2^-$) and H_2O_2 through the action of NADPH oxidase. Notably, NADPH oxidase components are more highly expressed and more readily activated in eosinophils than neutrophils, endowing stimulated eosinophils with a greater capacity to produce $\bullet O_2^-$ and H_2O_2.[169] As discussed previously, eosinophils produce HOBr through the action of EPO on bromide and H_2O_2.[150] In a reaction involving HOCl and $\bullet O_2^-$, EPO also catalyzes formation of hydroxyl radical (•OH), the most reactive of all oxygen metabolites. As noted, EPO-derived oxidants kill parasites and other microorganisms, and thus may be important for host defense. By contrast, EPO appears not to play a key role in allergic airway disease in mice.[148,151] The importance of eosinophil-derived oxidants in human health and disease is at present uncertain, and requires further study.

Eosinophil Recruitment

Current knowledge about the mechanisms of eosinophil recruitment into tissues is based largely on studies of asthma and allergic diseases, but these mechanisms may operate in other eosinophilic disorders as well. The initial step in eosinophil recruitment involves priming, which converts the resting cell to an adhesive, migratory and activation-sensitive phenotype. Priming likely results from exposure to IL-3, IL-5, GM-CSF and chemokines such as CCL11 (eotaxin-1), particularly in allergic individuals, in whom these factors are elevated in the circulation.[170–173] TNFα, leukotrienes, and other inflammatory mediators may prime eosinophils as well. Once primed, eosinophils make contact with the blood vessel wall and undergo rolling, mediated by E- and P-selectins on endothelial cells, which can be upregulated by IL-1 and TNFα, and L-selectin that is constitutively expressed on the eosinophil.[174–177] Rolling activates eosinophil integrins, which mediate tight adhesion through high-affinity binding to endothelial cell adhesion molecules. The eosinophil integrins, VLA-4 (α4β1 or CD49d/CD29) and CD11b/CD18, and their respective endothelial counterligands VCAM-1 and ICAM-1, comprise the most important binding pairs responsible for firm adhesion to the vessel wall. IL-4 and IL-13 increase VCAM-1 expression on endothelial cells.[178,179] Because VLA-4, the binding partner for VCAM-1, is highly expressed on eosinophils, but not neutrophils, this represents a mechanism for selective eosinophil recruitment to sites of allergic inflammation.[175,180] Integrin-mediated firm adhesion is followed by diapedesis, or transmigration across the endothelium. Eosinophils are further activated by endothelial transmigration, which also increases their ability to survive.[181] Based on in vitro studies, eosinophils can probably survive in tissues for 2 weeks or longer.

Upon entering tissue, eosinophils shift from β_1- to β_2-integrin–dominated interactions under the influence of chemokines such as CCL24 (eotaxin-2),[182] and migrate along chemoattractant gradients. Multiple factors are known to be chemotactic for eosinophils, including PAF, LTB_4, complement factors C3a and C5a, GM-CSF, IL-3, IL-5, IL-16, and the chemokines CCL3 (MIP-1α), CCL5, CCL7 (MCP-3), CCL11, CCL24, CCL26 (eotaxin-3), and CXCL8 (IL-8). Among these, IL-5 and the eotaxins (CCL11, CCL24, and CCL26) are the most highly selective for eosinophils, making them attractive as potential therapeutic targets. Indeed, clinical trials of agents directed against IL-5, CCL11, and their receptors in patients with asthma have recently been reported or are underway. The results of some of these studies are discussed at the end of this chapter.

Eosinophil Activation and Degranulation

The priming process required for eosinophil recruitment also represents the initial phase of eosinophil activation. IL-5 is the most important cytokine for priming of eosinophils in vivo.[170,171,183] IL-5 binds to heterodimeric receptors on the eosinophil surface, consisting of a ligand-specific α chain and common β chain that is also used in the receptors for IL-3 and GM-CSF. Binding of IL-5 to its receptor triggers a variety of intracellular signaling cascades, which enhance multiple eosinophil functions, including the response to chemotactic factors, integrin-mediated adhesion, agonist-stimulated LTC_4 and superoxide generation, phagocytosis, and helminthotoxic activity.[154,158,160,171,173,184] IL-3 and GM-CSF are capable of enhancing these functions, as well. As noted earlier, IL-5, IL-3, and GM-CSF also enhance eosinophil survival. The effects of all three cytokines are antagonized by glucocorticoids, which also induce eosinophil apoptosis.[185,186]

Priming of eosinophils in the circulation is enhanced in patients with asthma and hypereosinophilic states, resulting in greater functional responses when blood eosinophils from such individuals are studied in vitro, in comparison to cells from normal controls.[171] In vivo priming has also been demonstrated in eosinophils obtained by BAL following antigen instillation into the lungs of allergic subjects (segmental allergen challenge).[164]

Eosinophils express a panoply of surface receptors that can mediate cell activation. These include receptors for immunoglobulins (IgA, IgG, and IgE), complement components (C3a and C5a), eicosanoids (LTB_4, cysteinyl leukotrienes, and PGD_2) and PAF, and numerous cytokines and chemokines. Priming can upregulate cell surface expression and/or activation of specific receptors,[187] and may induce new expression of receptors not normally present on resting eosinophils, such as the high-affinity IgE receptor FcεRI.[188] Ligand binding to many of these receptors triggers responses that include degranulation, lipid mediator synthesis, and generation of reactive oxygen species. Various ligands activate distinct signaling cascades within the cell, resulting in stimulus-specific differential activation of eosinophil effector functions.

As in MC, the principal mode by which granule-associated proteins are released from human eosinophils is piecemeal degranulation.[140,189–191] This process involves secretion of specific granule contents in discrete packets, without granule-to-granule or granule-to-plasma membrane fusion. An eosinophil undergoing piecemeal degranulation in vitro is illustrated in Figure 22-4. Electron microscopic studies reveal that piecemeal degranulation is associated with the development of complex vesiculotubular networks within emptying granules.[190,191] Interestingly, it has been shown that intracellular cytokine receptors within granules and secretory vesicles play a key role in transporting and guiding selective secretion of their cognate cytokines, allowing for stimulus-specific, selective and sequential release of cationic granule proteins and stored cytokines and chemokines.[192] In addition, receptors for cysteinyl leukotrienes have been demonstrated on eosinophil granule membranes, where they may mediate secretion of granule contents from intact cells in response to endogenously generated LTC_4 or secretion from cell-free granules triggered by extracellular LTD_4.[193]

Besides piecemeal degranulation, the secretion of whole granules, referred to as compound exocytosis, has been described, although this process is not usually observed in vivo. Compound exocytosis involves SNARE family transport docking and vesicle fusion proteins.[194] Finally, cytolytic degranulation is a term used to account for the presence of cell-free eosinophil granules seen in tissue in certain eosinophilic diseases.[140] Whether this is a regulated process or the result of eosinophil necrosis at sites of inflammation is not known.

■ MAST CELL–EOSINOPHIL INTERACTIONS

Since shortly after their discovery, it has been recognized that MC and eosinophils home to many of the same tissues, particularly in the setting of allergic and other inflammatory conditions. Not surprisingly, therefore, researchers have identified a variety of cooperative interactions between the two cell types. For example, the eosinophil granule proteins MBP and ECP can trigger histamine, PGD_2, and cytokine

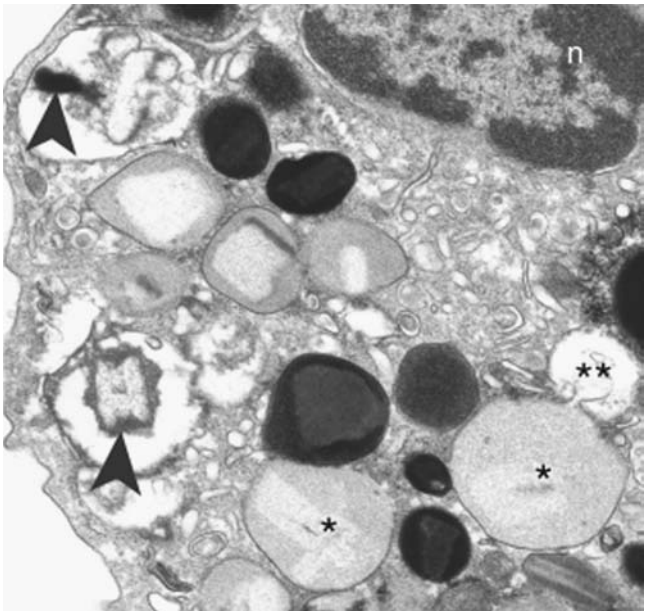

Figure 22-4 Ultrastructure of a human blood eosinophil activated in vitro with CCL11 (eotaxin). Specific granules undergoing piecemeal degranulation exhibit lucent areas in their cores, matrices, or both. Granules with residual cores *(arrowheads)*, reduced internal electron density (*) and membrane empty chambers (**) are shown. *(Reproduced with permission from Melo RCN, Perez SAC, Spencer LA, et al. Intragranular vesiculotubular compartments are involved in piecemeal degranulation by activated human eosinophils. Traffic. 2005;6(10):866–879.)*

release from human MC.[195,196] Eosinophils also produce important MC survival and activation factors, such as SCF and nerve growth factor (NGF).[197] Conversely, MC-derived TNFα induces eosinophil GM-CSF release and autocrine survival enhancement,[198] and MC tryptase induces eosinophil IL-6 and IL-8 secretion.[199] Also, the MC mediators histamine and PGD_2 have been shown to augment synthesis of LTC_4 in human eosinophils.[200] In addition, MC chymase suppresses eosinophil apoptosis and increases adhesion molecule expression, chemokinesis, and cytokine and chemokine release by human eosinophils.[201] Not all MC–eosinophil interactions are proinflammatory, however, as it has been shown that MC tryptase can cleave and inactivate the eosinophil chemokines CCL5 and CCL11.[202] Thus, MCs and eosinophils communicate bidirectionally in complex ways that may amplify or potentially modulate the inflammatory response.

EOSINOPHILS AND HOST DEFENSE

Many years ago, histopathological evidence of eosinophils surrounding dying helminths in tissue biopsy specimens led to the hypothesis that eosinophils play a role in the immune response to multicellular parasites. Subsequently, it was demonstrated that, in the presence of antibodies or complement, eosinophils can kill parasites in vitro, as can purified eosinophil granule proteins.[203] Further support of a role for eosinophils in host defense against helminths came from epidemiological studies that correlated high eosinophil counts with resistance to posttreatment reinfection with Schistosoma spp. in humans.[204] Moreover, studies of experimental helminth infections in mice depleted of eosinophils by IL-5 neutralization or gene targeting have indicated that IL-5 and eosinophils are important for protective innate immunity against a variety of parasites,[205–207] although the results are not all consistent.[208] Other studies of mice deficient in CCL11 or treated with a monoclonal antibody targeting CCR3 (the receptor for CCL11 and other eosinophil-active chemokines) have also demonstrated that eosinophils are important for clearance of parasites in vivo.[209,210] A recent study using mice made eosinophil-deficient by expressing the diphtheria toxin A gene under control of the EPO promoter (*PHIL* mice),[211] as well as mice lacking either MBP or EPO, showed that eosinophils kill parasite larvae during primary *Strongyloides stercoralis* infection by a mechanism dependent on MBP.[212] A consistent finding in a number of these studies is that eosinophils play an important role in host defense during primary parasite infection, whereas they appear not to be essential for adaptive responses leading to protective secondary immunity.[207,209,210,212] Interestingly, other recent studies showed that survival of *Trichinella spiralis* was actually reduced in mice genetically ablated of eosinophils, and that parasite growth and survival were restored when the mutant mice were reconstituted with eosinophils by intravenous transfer; in this model, eosinophils enhanced parasite survival by promoting accumulation of Th2 lymphocytes and preventing induction of inducible NO synthase in macrophages and neutrophils at sites of disease.[213,214] Thus, while substantial evidence indicates that eosinophils are protective in the innate immune response to many parasites, the roles they play in helminthic infections are complex and depend on interactions with other immune cells.

As noted earlier, human ECP and EDN are both RNases, and can inactivate RSV in vitro.[143] Mouse eosinophils express a diverse array of eosinophil-associated RNases (EARs) with the ability to inactivate pneumonia virus of mice (PVM),[215] a major pathogen in rodents that is closely related to RSV. More recently, it has been demonstrated that hypereosinophilic IL-5 transgenic mice exhibit enhanced virus clearance when infected with RSV,[216] and that activated eosinophils recruited to the lung in a model of allergen-induced airway disease are profoundly antiviral and promote survival in an otherwise lethal PVM infection.[217] Thus, while they contribute to the pathophysiology of allergic airway disease in the mouse, in the same context activated eosinophils have the capacity to mediate effective antiviral host defense. Further studies are needed to define the role of eosinophils in the immune response to viral infection in humans.

Human MBP and ECP also possess bacteriocidal activity, and various bacteria can induce degranulation of human eosinophils in vitro.[143] In addition, human eosinophils are able to kill *Escherichia coli* in vitro by a mechanism involving NADPH oxidase- and EPO-generated oxidants.[143] Despite these observations, few data exist to implicate a role for eosinophils in host defense against bacterial infections in vivo.

IMMUNOREGULATORY CAPACITY OF EOSINOPHILS

Recent investigations have demonstrated that human and mouse eosinophils can process antigen, express major histocompatibility complex II (MHC-II) and co-stimulatory molecules, and function as "professional" antigen-presenting cells.[218,219] In mice, eosinophils within the airway lumen can migrate to regional lymph nodes where they stimulate antigen-specific T-cell proliferation.[220] In addition, eosinophils synthesize, store, and secrete Th2 cytokines and chemokines, endowing them with the capacity to initiate Th2 differentiation of CD4+ T cells as well as recruit Th2 cells to sites of infection or allergen deposition, as demonstrated in several mouse models of allergen-induced airway disease and parasitic infection.[221] Thus, there is now substantial evidence, largely from murine models, that eosinophils play a central role in directing the Th2 immune response. These findings emphasize that, beyond their cytotoxic and destructive potential, eosinophils contribute in complex ways to host defense and the pathophystiology of allergic disease.

EOSINOPHIL–DISEASE ASSOCIATIONS

Peripheral blood eosinophilia and eosinophilic lung inflammation are common in a variety of pulmonary conditions, including those listed in Table 22-2. The clinical manifestations and treatment of these disorders are discussed in detail elsewhere in this textbook.

TABLE 22-2 Eosinophilic Lung Diseases

Asthma
Allergic bronchopulmonary aspergillosis/mycosis
Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome)
Simple pulmonary eosinophilia
Chronic eosinophilic pneumonia
Acute eosinophilic pneumonia
Helminthic infections
Drug hypersensitivity reactions
Hypereosinophilic syndrome

Among eosinophilic lung diseases, asthma is by far the most common and most well studied. Over the years, much evidence has accumulated supporting a key role for eosinophils in the pathogenesis of asthma. Among the numerous animal studies addressing this question, most compelling are those involving genetically eosinophil-deficient (ΔdblGATA1 and *PHIL*) mice, which are protected against allergen-induced airway hyperresponsiveness, allergic airway inflammation, mucus hypersecretion, and peribronchiolar collagen deposition.[135,211,222,223] In humans with asthma, eosinophils and their specific products (e.g., ECP) increase in the airway lumen and airway wall during spontaneous exacerbations and following experimental allergen challenge.[149,224,225] Sputum eosinophil numbers and ECP levels also correlate with asthma severity.[149] When asthma improves, either spontaneously or in response to treatment, eosinophils and their products decline.[226,227] Corticosteroids, the most effective therapy for asthma, have potent anti-eosinophil effects.[228] Also, an inhaled corticosteroid treatment strategy directed specifically at reducing sputum eosinophils resulted in significantly better asthma control than treatment based on standard asthma guidelines.[229] Finally, as discussed in the next section, specific eosinophil-targeted therapy with an IL-5–neutralizing monoclonal antibody has been shown to reduce exacerbations and facilitate steroid tapering in patients with severe, oral corticosteroid-dependent asthma with high eosinophils.[230,231]

HES is a rare disorder characterized by persistent marked blood eosinophilia (>1500/μL) or prominent tissue eosinophilia and eosinophil-induced organ damage or dysfunction, in which secondary causes of eosinophilia, such as parasitic or viral infections, allergic diseases, drugs, and hypoadrenalism have been excluded.[232] Pulmonary involvement is seen in 50% of cases. HES is classified as either myeloproliferative or lymphocytic, based on pathophysiology. The myeloproliferative form, exemplified by patients bearing the FIP1L1-PGDFRA fusion gene, which produces a constitutively active tyrosine kinase that drives eosinophil hyperproliferation, represents a type of myeloproliferative neoplasm. The tyrosine kinase inhibitor, imatinib mesylate, is useful in treatment of these patients. In lymphocytic HES, eosinophil proliferation is driven by T-cell overproduction of IL-5 and/or other eosinophil hematopoietins. Corticosteroids are the first line of treatment for these patients. The anti–IL-5 monoclonal antibody, mepolizumab, has also been shown to be effective in steroid-requiring lymphocytic HES.[233]

In addition to the disorders listed in Table 22-2, eosinophils may play a role in the pathogenesis of several pulmonary diseases not normally thought of as eosinophilic in origin. Among these is idiopathic pulmonary fibrosis, in which elevated numbers of eosinophils in BAL fluid have in some studies been associated with a poor prognosis.[234] This is consistent with in vitro and animal data demonstrating the ability of eosinophils to promote tissue fibrosis. Another example is cystic fibrosis, in which increased levels of cationic eosinophil granule proteins correlate with worse pulmonary function, presumably due to toxic effects of these proteins on lung cells.[235]

PHARMACOLOGIC MODULATION OF EOSINOPHILS

Corticosteroids have been the mainstay of pharmacotherapy for eosinophilic disorders for many years. Corticosteroids induce apoptosis of eosinophils, both directly and by inhibiting formation of the prosurvival cytokines, IL-5, IL-3, and GM-CSF.[185,186,228] This leads to rapid reductions of circulating and tissue eosinophils and clinical improvement in the majority of treated patients. Leukotriene receptor antagonists and the anti-IgE monoclonal antibody omalizumab are two other classes of drugs used to treat asthma and allergic diseases that have been shown to reduce circulating eosinophil counts and cause eosinophil apoptosis.[226,236] Of course, these classes of drugs are not specific for eosinophils, so the degree to which their anti-eosinophil activities contribute to their beneficial effects is uncertain.

More recently, highly selective anti-eosinophil therapeutics have been developed and tested in clinical trials. To date, the best studied of these new agents has been the anti–IL-5 monoclonal antibody, mepolizumab, which is highly effective in reducing circulating eosinophil levels in asthma. Although it did not improve clinical endpoints in mild to moderate asthma,[237] mepolizumab has been shown to reduce exacerbation rates, facilitate corticosteroid tapering and improve asthma-related quality of life in patients with severe, oral steroid-dependent asthma and increased sputum eosinophils.[230,231,238] As noted earlier, mepolizumab also led to clinical improvement and facilitated steroid tapering in a randomized trial of patients lymphocytic HES.[233] Similar benefits were seen in an open-label trial of mepolizumab in eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome).[239] Other eosinophil-selective therapies in earlier phases of clinical development include monoclonal antibodies, antisense oligonucleotides or small molecule inhibitors targeting the IL-5 receptor, CCL11, CCR3, IL-13, and the IL-4 receptor α chain.[240] An intriguing anti-eosinophil strategy in preclinical development involves targeting Siglec-8, a sialic acid–binding immunoglobulin-like lectin expressed on the surface of human eosinophils and MCs. Engagement of Siglec-8 with cross-linking antibody or glycan ligands triggers selective apoptosis of eosinophils and inhibits inflammatory mediator synthesis and release by MCs (without affecting their survival), suggesting the possibility that activators of Siglec-8 signaling might be particularly effective therapeutic agents by virtue of their ability to target two major cell types that drive allergic respiratory disease.[241]

Ongoing and future investigations involving the novel eosinophil–targeted therapies listed earlier, as well as others yet to be devised, will hopefully lead to safe, new treatments for eosinophilic respiratory disorders. Such studies will also almost certainly yield new and unexpected insights into the complex roles eosinophils play in human health and disease.

CHAPTER 23

Leukocyte Accumulation in Pulmonary Disease

Nicholas W. Lukacs
Peter A. Ward

INTRODUCTION

Mediators produced during inflammatory/immune responses dictate the severity and intensity of pulmonary disease. The profile of inflammatory leukocyte populations accumulating in inflamed tissues is initiated by cytokine-induced expression of adhesion molecules on the vascular endothelium. Endothelial adhesion molecules include intracellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), as well as E- and P-selectins that initiate, and in some cases, mediate the migration of leukocytes into tissues. Subsequently, leukocyte adherence to the endothelium is followed by leukocyte migration into the inflamed tissue, directed by chemotactic molecules at the site of the inflammatory/immune response. Upregulation of these early response mediators is crucial for the initiation of early events that regulate the inciting agent, whether it is infectious or noninfectious in nature. However, the continuous over-production of these mediators can lead to destructive, pathologic consequences due to the continued recruitment and activation of disease-specific leukocyte populations. In human lung, inflammation-induced damage can be observed in numerous inflammatory diseases, including both acute and chronic disease settings. In this chapter, we will examine the mediators that promote inflammatory diseases in lung and outline how specific leukocyte populations can contribute to pulmonary pathology.

LEUKOCYTE ADHESION AND MIGRATION INTO THE LUNG

Important considerations in the biology of leukocyte adhesion and migration into the lung are discussed below.

SELECTIN AND ADHESION MOLECULES IN LUNG INFLAMMATION

The release of early response mediators leads to the upregulation of selectins (E and P) and other adhesion molecules (ICAM-1, VCAM-1, etc.) on surfaces of vascular endothelial cells within the site of inflammation.[1–7] Initially, selectin molecules (P and E) are quickly upregulated on the vascular endothelium and initiate "rolling" of leukocytes on activated endothelium through Ca^{2+}-dependent recognition of cell surface carbohydrates of the *sialyl Lewis X* family and related oligosaccharides. Initial and rapid expression of selectin molecules results in a slowing of leukocyte velocities in the circulatory flow, allowing additional interactions to proceed.[8–11] However, such interactions are required to ultimately allow firm adhesion of leukocytes to endothelial cells. Once the leukocytes have begun the selectin-mediated rolling process, they must next go through a series of activation events to allow them to firmly adhere to other adhesion molecules. Leukocytes ultimately bind firmly to the vascular endothelium via β-integrin receptors on leukocyte surfaces, resulting in a very rapid increase in binding affinity, and engagement of other molecules that are upregulated during inflammatory responses on the vascular endothelium. A number of β-integrin adhesion molecules play a role in the migration process, and they are differentially expressed on subsets of leukocytes.[12–14] The β1α4 integrins (VLA-4), expressed primarily on mononuclear cells and eosinophils, have been shown to bind to vascular cell adhesion molecule-1 (VCAM-1), while β2-integrins (CD11/CD18) are expressed on all leukocytes and bind varyingly to intracellular adhesion molecules-1,2,3 (ICAM-1,2,3), the first of which is highly expressed on endothelial cells. These families of adhesion molecules are able to facilitate leukocyte binding to the activated endothelium and can further dictate the type of leukocytes that bind and extravasate into the inflamed tissue. For example, while neutrophils rely on CD11/CD18 binding to ICAM-1, eosinophils depend upon VLA-4/VCAM-1 interactions to firmly adhere to the endothelial cell surface. Once firmly adherent, leukocytes then enter the tissue following chemotactic gradients through a series of detachment/readherence events typified by the polar expression of integrins specific for the adhesion molecules contained on surfaces of mesenchymal-derived cells.

Cell-to-cell communication during inflammatory events is mediated by cytokines that initiate, maintain, and regulate the inflammatory responses, dictating the intensity of the inflammatory response. The early response cytokines, IL-1 and TNF appear to play a pivotal role in the induction of inflammatory responses through the initiation of cytokine cascades.[15–19] The exuberant production of IL-1 and TNF may lead to multisystem injury and systemic complications, as exemplified in septic shock syndromes. As indicated earlier, IL-1 and TNF initially upregulate selectin (E-selectin) and other adhesion molecules (ICAM-1, VCAM-1) needed for the first step of leukocyte extravasation into tissues. In addition, IL-1 and TNF upregulate other inflammatory cytokines (e.g., IL-6) involved in the chemotactic responses of leukocytes into inflamed tissues. Interestingly, the type of cytokine expressed can dictate the nature of the inflammatory response based upon the adhesion molecule that it induces. For example, while TNF and IL-1 are critical for upregulation of ICAM-1 that facilitates neutrophil and monocyte adhesion, IL-4 produced during allergic responses preferentially upregulates VCAM-1. This adhesion molecule mediates eosinophil adhesion. Thus, the inflammatory/immune cytokine environment in lung can tailor the initiation and adhesion interactions for a particular leukocyte recruitment profile. The production of one of a number of classes of chemotactic factors is required for the movement of leukocytes from the vascular compartment to the extravascular compartment of the lung. We will next describe and characterize the function of chemotactic mediators that are expressed in the lung during specific disease conditions.

CHEMOKINES AND GPCR SIGNALING IN LEUKOCYTE ADHESION

The rapid change in affinity of the β-integrins rely on two events: (1) Initial binding to selectin molecules that activates Syk and MAPK, allowing β-integrin to reach an intermediate affinity state; and (2) activation of leukocyte expressed G-protein coupled receptors (GPCR) on the surface of leukocytes.[20–27] The GPCR ligands, usually chemokines bound to the endothelium via glycosaminoglycans (GAGs), initiate rapid Ca^{2+}-dependent β-integrin activation.[28,29] The β-integrin activation results in a conformational change in its extracellular domain, allowing the active binding site for the putative adhesion molecule to be accessible. If the adhesion molecule is also upregulated and expressed on the activated vascular endothelium, the leukocyte rapidly and firmly adheres and spreads along the endothelial surface due to additional actin polymerization, which is also induced during chemokine-GPCR activation events. Thus, the leukocyte very rapidly transitions from a rolling leukocyte to a cell that is firmly adherent, resulting subsequently in transmigration into the tissue. In addition to the GPCR signal, it also appears that the shear stress experienced by leukocytes also plays a role in development in firm adhesion events. These interactions are described in Figure 23-1.

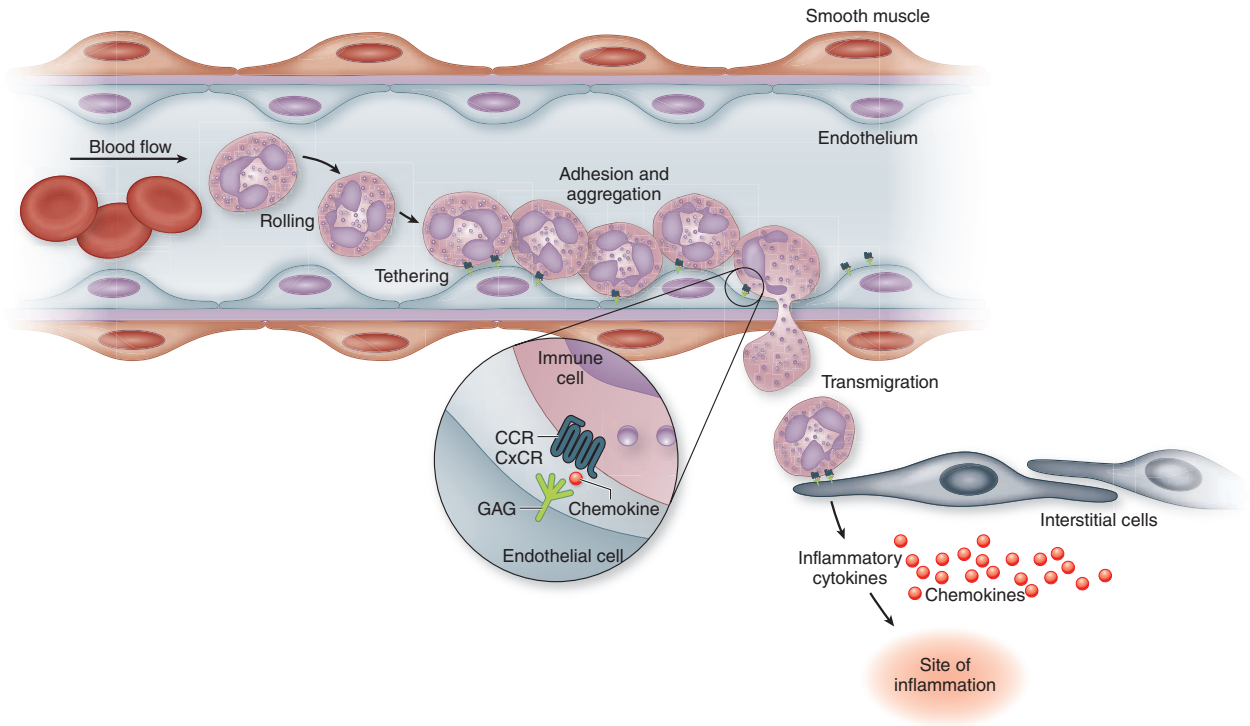

Figure 23-1 Leukocyte migration requires coordinated interactions between adhesion molecules and chemotactic molecules.

A significant amount of research has occurred in recent years, defining critical signaling events that occur during the early stages of leukocyte migration, including selectin-mediated rolling, GPCR-mediated integrin binding, actin polymerization, and leukocyte polarization. One of the most critical events in the transition of leukocytes from rolling to firm adhesion and extravasation is engagement of endothelial bound chemokine ligands with appropriate GPCRs. Chemokine binding activates the Gi-coupled protein-mediated phospholipase C (PLC), which results in inositol-1,4,5 triphosphate (IP_3) formation as well as diacylglycerol (DAG), triggering intracellular Ca^{2+} increases due to translocation from the ER.[30–32] This signaling cascade initiates the activation of Rho GTPases, Rap-1 and Talin1, subsequently mediating integrin affinity increase for their adhesion molecule ligands and allowing clustering following binding. Blockade of events at any stage along this activation pathway can inhibit the β-integrin–mediated adhesion, and interrupting firm adhesion to the activated endothelium.

■ CHEMOATTRACTANTS AND MIGRATION INTO THE LUNG

Below is discussed the role of various chemoattractants in the immune response against pathogens, including complement, arachidonic acid and its derivatives, and chemokines.

Complement

The complement activation cascade plays a significant role in the innate immune response against pathogens, but continual or excessive activation during inflammatory or infectious responses can lead to severe tissue injury. The initiation of the complement cascade can be accomplished via multiple mechanisms, including antibody–antigen complexes, bacterial products, toxins, and lectins (Fig. 23-2). Of the complement activation products, fragments from C3 and C5 have the most profound effects on the inflammatory response. The split products of C3, C3a and C3b, are generated by C3 convertase (other products of C3 cleavage [iC3b, C3d, C3g]) have significant activating roles in the inflammatory pathway. C3a is an anaphylatoxin that induces the activation of mast cells/basophils resulting in mediator release, all of which appear to have direct and indirect effects on vascular permeability.[33–35] C3b acts as a potent opsonizing component, binding to bacteria and allowing accelerated phagocytosis and clearance of pathogens via the C3b receptor on neutrophils and macrophages (Mac-1 [CD11b/CD18]). The split products of C5, C5a and C5b, can subsequently be induced through the sequential participation of C3b and C5 convertase. Similar to C3a, but much more potent, C5a is an anaphylatoxin that interacts with its two receptors (C5aR, C5L2), causing mast cell and basophil degranulation and activation of neutrophils, which collectively induces immediate changes in vascular permeability.[34,36–40] In addition, C5a stimulates vascular smooth muscle contraction and has neutrophil chemotactic and activating characteristics that promote directed migration of these leukocytes toward a concentration gradient.[41,42] C5a can also stimulate neutrophil oxidative metabolism, granule discharge, adhesiveness to vascular endothelium, and assembly on the neutrophil surface of NADPH oxidase (NOX2). C5a can directly stimulate endothelial cells in a G-protein receptor-dependent fashion to cause signal transduction events resulting in increased intracellular Ca^{2+}, induction of superoxide (O_2^-), and expression of P-selectin.[43–45] C3a lacks these activities. Altogether, the functions of C3 and C5 split products indicate that they are potent inflammatory mediators.

Elevated complement component levels in plasma have been described with several pulmonary diseases, including sarcoidosis, idiopathic pulmonary fibrosis (IPF), acute respiratory distress syndrome (ARDS), and chronic obstructive pulmonary disease (COPD).[46,47] Not only can complement initiate GPCR-mediated leukocyte migration but it appears complement activation products can direct the development of immune responses. This can be accomplished via several pathways during initiation of immune responses by regulating IL-12 production.[48] Specifically, C3a appears to drive IL-12 production that then favors type 1 immune responses,[49] while C5a downregulates IL-12 and allows IL-4–mediated type 2 immune responses to be induced.[50] Interestingly, recent studies in $C3^{-/-}$ mice have shown that Th17 responses are also regulated by complement.[51] In contrast, another study suggested that, when C5aR was blocked, there was an exacerbated allergic response that

Leukocyte population	Chemokine receptor
Neutrophil	CxCR1 (human only) CxCR2 CCR1
Monocyte	CxCR2 (inflammatory) Cx3CR1 (homeostatic) CCR1 CCR5
Dendritic cell	CCR1 CCR2 CCR6 (resting) CCR7 (activated/mature) CxCR4
Basophil	CCR2 CCR3
Eosinophil	CCR1 CCR3
Th1 cell	CCR1 CCR5 CxCR3
Th2 cell	CCR3 CCR4 CCR8
Th17 cell	CCR6
Treg cell	CCR4 CCR8

Figure 23-2 Preferential expression of chemokine receptors on leukocyte subsets can lead to preferential recruitment during pulmonary disease.

also was dependent upon increased IL-17,[52,53] suggesting that the previous study with $C3^{-/-}$ mice was due to inhibition of downstream C5a activation. Thus, while early complement-induced response is critical for containment of infectious organisms, it may be especially important during sensitization to various antigens in determining the phenotype of the pulmonary immune response that will govern the severity of disease outcomes.

The receptors for C3a and C5a have been a source of intense research over the past several years and have led to the resurgence of interest in potentially blocking specific responses during pulmonary disease. The distribution of these receptors depicts their broad role in innate and acquired immune responses. Both C3aR and C5aR are present on alveolar macrophages, DCs, and mast cells, and are also present on sentinel cell populations in the lung that provide important cues for the immediate and prolonged determination of effective immune responses.[54] In particular, activation of these cell populations have been assessed for the differential activation consequences of C3a and C5a. At the same time the expression of C5aR on neutrophils allows an immediate and efficient migration into the lung and activation at the site of inflammation. C5aR is also displayed on cells involved in chronic immune responses, such eosinophils recruited during allergic responses. Thus, activation of the complement system can have potent effects on both acute inflammatory responses as well as chronic inflammation, both of which can lead to long-term pulmonary dysfunction. Interestingly, a second C5a receptor, C5L2, binds C5a and C5a *des arg* extremely efficiently, but C5L2 has no linkage to G proteins.[55] Research examining the possible implications of this second receptor for modulating C5a-mediated responses by competitively binding up C5a during inflammatory responses is the subject of focus from several laboratories. While the function of this second C5a receptor has been controversial, C5L2 appears to mediate several pathologic events, including events in sepsis and perhaps diabetes.[56–60]

Role of Arachidonic Acid and its Products in Lung Responses

The production of arachidonic acid (AA) followed by its enzymatic processing produces a number of lipid mediators that have long been known to be associated with acute and chronic inflammatory responses in the lung.[61–63] Phospholipase A2 degradation of AA leads to its breakdown into platelet activation factor (PAF) that can be immediately processed by 5-LO into 5-HPETE and further processed by 5-LO into leukotriene A4 (Fig. 23-3). 5-HPETE can alternatively be processed into 5-HETE by peroxidases. Leukotriene A4 can be further processed into LTB4 by LTA4 hydrolase or LTC4 by LTC4 hydrolase, followed by continued processing of LTC4 into LTD4, and finally, LTE4. These latter metabolites, C4, D4, and E4 are known as the cysteinyl leukotrienes that are best known to cause airway contractility, causing decreased lung function during large airways disease, such as asthma. Targeting the cysteinyl leukotrienes for blockade has provided significant relief to particular subsets of asthmatic patients.[64]

Of the AA metabolites, PAF and LTB4 have been characterized for their chemotactic activity, promoting migration of leukocytes into sites of inflammation. These mediators were originally identified as potent neutrophil chemoattractants and were associated with acute inflammation-induced airway damage. PAF has a broad range of specificity in its ability to induce leukocyte chemotaxis, since it induces the recruitment of not only neutrophils, but also of monocytes, lymphocytes, and eosinophils.[65,66] During allergic diseases, PAF may have a role in augmentation of eosinophil responses.[67] The actions of PAF on endothelial cells indicate that PAF has a direct role in upregulation of selectin and adhesion molecules and can induce the release of superoxide anion (O_2^-). Instillation of PAF into human, monkey, or guinea pig airways induced an immediate LTC4-independent

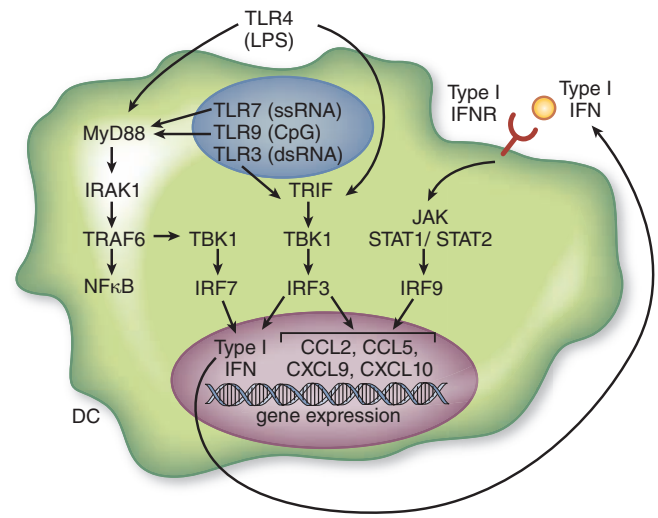

Figure 23-3 Inflammatory gene activation by TLR and type I IFN leads to enhanced leukocyte recruitment.

bronchoconstrictor response, suggesting a possible role in development of pathophysiology in asthmatic responses. Overall, these studies indicate that the signals provided by PAF are not only chemotactic but can also participate in the augmentation of immune/inflammatory pathways in lung. However, over the years several PAF specific inhibitors have been developed, but they have failed to demonstrate effective blocking or attenuating inflammatory responses in human lung.

While leukotrienes in general have broad effects on inflammatory responses, LTB4 is one of the most potent neutrophil chemotactic molecules known and induces O_2^- production. LTB4 can also act to recruit other leukocyte populations, such as monocytes and eosinophils.[68,69] In eosinophil chemotactic assays, LTB4 is more potent than PAF in the activation and degranulation of eosinophils. LTB4 has been found in many disease states, including psoriasis, bacterial peritonitis, inflammatory bowel disease and asthma.[70] LTB4 is rapidly expressed by phagocytic cells (PMNs and macrophages) following stimulation with bacterial LPS or fMLP. More recently, the LTB4 receptor, BLT1, has been implicated in preferential recruitment of Th2 type T lymphocytes during allergic pulmonary responses.[71–73] This receptor has also been implicated in recruitment of T lymphocytes that mediate lung allograft rejection and development of obliterative bronchiolitis in lung allographs in rodents.[74] Thus, LTB4 and BLT1 are now being considered as targets for therapy in chronic immune responses in the lung, in contrast to their traditional roles as potent neutrophil and mononuclear cell chemoattractant in acute lung injury.

Chemokines and Immune Cell Migration

Chemokines (discussed in chapter 26) have been divided into two main families based upon their sequence homology and the position of the first two cysteine residues, C-x-C (alpha) and C-C (beta).[75,76] There are two minor families described each with a single member, the C and Cx3C families. Much of our understanding of chemokines has centered upon their role in mediating leukocyte recruitment to the site of inflammation in lung or specifically directing recirculation of leukocytes during homeostasis. Interestingly, results have indicated that many of these family members also have diverse roles in the activation and differentiation of various immune and nonimmune cell populations. While the chemokine family members' function is diverse, the promiscuous binding relationship between multiple members with a single receptor as well as a specific receptor being able to bind multiple chemokines underscores our relative lack of understanding of the biology of the chemokine family. In particular, it is often difficult to understand how such a vast number of chemotactic molecules, several being produced simultaneously, could coordinate inflammatory responses. Recent studies demonstrate that it may be the overall profile of chemokines being produced that dictates the inflammatory cell response resulting in leukocyte accumulates at a site of injury or infection. This latter aspect can be best displayed during acute inflammatory responses, such as in bacterial infections, when the cellular infiltrate is primarily neutrophilic.[77] Chemokines that bind to CxCR1 and CxCR2 mediates this process. Likewise, when more insidious pathogens are present and acute inflammatory mechanisms cannot effectively control the infectious process, immune cytokines, such as IFN and IL-4, tend to drive the production of chemokines that allow the mononuclear cells, macrophages, and lymphocytes to accumulate at sites of infection, resulting in a more effective immune response for enhanced clearance of the pathogen. Thus, although there are numerous chemokines being produced during any single inflammatory response, the overall profile of the response may be directed to recruitment of cells that are most appropriate to deal with particular stimuli. These "fine tuned" responses mediated by chemokines also depend upon the chemokine receptor profile of the transmigrating leukocyte (Fig. 23-2). For example, while many leukocytes such as PMNs and macrophages tend to have a fairly fixed chemokine receptor expression (CxCR2 for PMNS and CCR2 for inflammatory macrophages),[78–80] T cell subsets (Th1, Th2, Th17, Treg cells) express a differential profile of chemokine receptors that may preferentially allow recruitment to specific types of inflammatory/immune responses.[81–84] Those aspects will be discussed in later sections.

LEUKOCYTE ACCUMULATION AND LUNG PATHOLOGY

A variety of leukocytes may accumulate with the lung. Each is discussed below.

■ NEUTROPHILS

The accumulation of neutrophils (PMNs) in the lung is the first line of defense against infectious organisms. There are significant numbers of PMNs circulating normally, and they can be quickly mobilized from the bone marrow during inflammatory responses or during acute lung injury. Once activated at the site of inflammation, PMNs preform phagocytic and bacterial/fungal killing functions that promote clearance of bacterial and fungal pathogens. They also can quickly release a number of enzymes, (proteases, etc.), that can have detrimental effects on the local lung tissue and cause physiologic dysfunction and severe damage if not tightly regulated. Individuals with one of many abnormalities in PMN formation, recruitment, or activation defects often develop recurrent, severe infections, both bacterial and fungal.[85,86] As described earlier, PMNs enter the lung via an initial adhesion event that progresses via a selectin-mediated rolling and subsequently through a β_2-integrin (CD11b/CD18)/ICAM-1–induced firm adhesion. While controversial evidence using animals exists, it appears that entry into the lung via the alveolar vasculature may not require the entire adhesion progression since there is low shear stress, allowing leukocytes to migrate into the airspace with less resistance.[87–90] This is because the diameter of the neutrophil and the capillary is nearly the same, which would not allow rolling. Nevertheless, in the alveolar vasculature the adhesion molecules described in section II are still present, functional, and are required for ultimate PMN transmigration. Not surprisingly, numerous chemotactic factors can quickly mobilize and mediate PMN migration into inflamed tissues. These factors include bacterial products such as fMLP, an N-formylated 3 amino acid peptide that is produced by numerous bacteria. fMLP binds to a GPCR (fMLPR). Other chemotactic factors expressed by the host early during pathogen responses include C3a and C5a, as well as the primary lipid mediator, LTB4, all interacting with specific GPCR signaling on the surface of PMNs. Usually, the early migration of PMNs to the lung is likely due to the latter mediators that are quickly cleaved or stored in cells (such as in mast cell granules) and are readily activated or released upon pathogenic or injurious stimuli. Subsequently, the prolonged activation of the pulmonary environment beyond immediate responses (>4 hours) results in cytokine cascades leading to additional and numerous more efficient chemokine protein mediators of migration, including CxCL1 (GROα), CxCL5 (ENA-78), and CxCL8 (IL-8). The CxC family chemokines are produced by both immune and nonimmune cell populations and provide relative specificity for PMN accumulation during lung inflammatory disease via their cognate receptors, CxCR1 and CxCR2, predominantly found on PMNs. Increased numbers of PMNs are often found in severe inflammatory diseases of the lung and likely provide nonspecific damage that may result in lung dysfunction. Several strategies for blocking adhesion as well as chemotactic receptors are currently under development by numerous pharmaceutical companies.

■ EOSINOPHILS

The role of eosinophils evolutionarily has been linked to chronic parasitic diseases, in which they perform a protective killing response linked to parasite clearance.[91,92] However, as the parasitic burden in humans has been greatly reduced, the immune responses, especially at mucosal surfaces, have led to detrimental chronic responses to

inert parasitic antigens. This has led to a number of allergic inflammatory diseases, especially allergic asthma in the lung. Eosinophils are derived in the bone marrow, primarily in the presence of a Th2 type response that provides systemic IL-5 levels that feedback to the bone marrow, directing the maturation and release of eosinophils into circulation. The migration of eosinophils into the lung and other tissues rely on a different subset of adhesion and chemotactic factors for entry into the tissue compartments.[93–99] While the migratory adhesion pathway has not been as thoroughly defined, it appears that it also relies on an initial combination of selectin and β-integrin–mediated adhesion events prior to responding to chemotactic mediators in the lung. While eosinophils are able to utilize CD11b/CD18-ICAM-1–mediated migration pathways, it appears that more efficient and preferential migration is VLA-4 β-integrin–mediated VCAM-1 adhesion. Since VCAM-1 is highly upregulated in the lung during Th2 cytokine–mediated responses, as in asthma, such responses may relate to the inflammatory cytokine environment that stimulates maturation of eosinophils in the bone marrow (IL-5 mediated). Subsequent to adhesion of eosinophils to endothelial cells, eosinophil migration and accumulation in lung can also be regulated by the chemotactic factors that appear to preferentially recruit eosinophils. While C5a and the lipid mediators, LTB4 and PAF, can each provide a stimulus for such migration, it appears that chemokines are the primary stimuli for migration of eosinophils. In particular, CCR3 ligands are the most potent, including CCL5 (RANTES), CCL11 (eotaxin-1), CCL24 (eotaxin-2), and CCL26 (eotaxin-3). CCR3 is the characteristic chemokine receptor expressed on eosinophils and although they also appear to express CCR1, it appears to have only a minor role in the recruitment during chronic disease. Similar to the PMN, eosinophils can induce local damage in lung after their degranulation and release of proteases and enzymes. In addition, eosinophils have been implicated in progression of remodeling diseases, linked to their interaction with fibroblasts.[100,101] Eosinophils have the ability to transform normal fibroblasts into matrix-producing myofibroblasts. Eosinophils have been identified as a significant source of TGFβ, FGF, as well as other pro-fibrotic factors and have been implicated in severe remodeling in chronic allergic and inflammatory diseases.[102,103] Thus, significant effort continues to be made to target eosinophil migration during chronic pulmonary diseases, especially asthma.

MONOCYTES/MACROPHAGES

Resident macrophage populations play an important role in the lung, providing initial protection against pathogenic and noxious damage. The alveolar and interstitial macrophages that reside in and around airways appear to be ideally suited, having optimal ability to phagocytize and kill microorganisms as well as producing regulated levels of inflammatory cytokines. Macrophages also function for uptake of inhaled particles. Phagocytosis requires an intact cytoskeleton and is most efficient when phagocytosis is mediated by Fc receptors. Complement and scavenger receptors such as MARCO are also important mechanisms for mediating clearance of microorganisms.[104–107] During responses to infectious and inflammatory stimuli, the migration of monocytes from the blood can also play an important role in the clearance of the inciting agents. In humans, there appear to be two distinct subsets of circulating monocytes, CD14+ monocytes with high CCR1, CCR2 and CxCR2 expression, and low Cx3CR1 expression as well as a distinct CD16+ population of monocytes with high levels of Cx3CR1 and low levels of CCR2 expression.[108–110] Similar subsets exist in mice and, while not exact, this allows characterization of their different roles in disease once recruited to the site of inflammation allowing extrapolation to human disease. Mice lacking inflammatory, CCR2+ monocytes are highly susceptible to *Listeria monocytogenes* and *Mycobacterium tuberculosis* infections, demonstrating that infiltrating monocytes are important effector cells for the clearance of intracellular bacteria.[111,112] In a similar fashion the inhibition of inflammatory macrophage infiltration into the lung during *Aspergillus fumigatus* and *Cryptococcus* infections can lead to prolonged and detrimental infection by these organisms.[113,114]

The circulating CCR2+ monocyte population also appears to be the progenitor to inflammatory dendritic cells (DC), which express CD11b/CD11c. DC have a different developmental program and upregulate CCR6 on their surfaces for localization to airway epithelium where its ligand, CCL20, is expressed. This distinct subset of DC appears to be crucial for proper T cell activation to infections pathogens mediating Th1 type responses (IFNg producing) for the clearance of *M. tuberculosis*, *Toxoplasmosis gondii*, and *Cryptococcus neoformans* infections in animal models. In contrast, however, inflammatory DC recruitment to the lung (via CCR2) during chronic allergic disease may result in development of Th2 cytokine associated disease. Thus, the role of the inflammatory monocyte accumulation may depend on whether the inciting agent is an intracellular pathogen or a noninfectious stimulus that should optimally be ignored (immunologically tolerated), such as an allergen. Thus, attempts to regulate chronic inflammatory disease by targeting CCR2, its ligands or inflammatory monocytes themselves may cause deviations in lung inflammatory responses that are harmful.

INNATE LYMPHOID CELLS

A new classification of cytokine-producing cells has recently been named for their ability to respond to an inflamed environment in the absence of an antigenic specific stimulus. Innate lymphoid cells (ILC) have been further classified into three types, ILC1 (IFNγ-producing cells), ILC2 (IL-5/IL-13–producing Nuocytes), and ILC3 (IL-17/IL-22–producing cells).[115–117] These subsets are present in relatively low numbers in the lung and respond to innate cytokine signals and information of their accumulation during disease is only now beginning to be explored. ILC1 respond directly to IL-12 and express t-bet, similar to NK and Th1 cells, and have been recently shown to reside at much higher numbers in inflamed intestines of Crohn's disease patients. ILC1 cells appear to be distinct from NK cells, since they do not express granzyme B and other NK cell markers.

ILC2 (a.k.a. Nuocytes) or innate helper cells, respond to epithelial-cell–derived IL-33 and IL-25, express the GATA3 transcription factor, and contain Sca1+, c-kit+, Lin–, and ST2+ (IL-33R) surface markers.[118,119] ILC2 have been clearly implicated in parasite clearance in the intestine, but more recently have been identified in playing a role in models of asthma and influenza-induced disease.[120,121] The ILC2 have been the most extensively characterized and, although there appears to be only a few thousand residing in the mouse lung at baseline, they can produce high levels of Th2 type cytokines, (IL-5 and IL-13), in response to cytokine stimuli, especially IL-33.[122,123] Recent data has suggested that circulatory pools of ILC2 exist in human asthma patients, but further studies need to be explored to determine their relevance in human pulmonary diseases. Early studies suggested that ILC2 (nuocytes) express CCR2 and CCR3, but further study will be required to determine if these receptors mediate accumulation of the cells in the lung.

CD4+ T LYMPHOCYTE SUBSETS

The severity and chronicity of lung disease is dictated by multiple factors including the persistence of stimuli, pathogen or antigenic challenge, as well as the phenotype of the immune response. As discussed earlier and in other chapters, the mediators produced during pulmonary disease may be the most critical in determining the type of inflammation that develops. The discovery of several subsets of CD4+ lymphocytes that are defined by the profile of cytokines produced is critical for selectively responding to various infectious organisms and/or different phase of immune responses.[124,125]

The trafficking of naive lymphocytes from the blood to lymph nodes is pivotal to the maintenance of effective immune surveillance.

However, deciphering the mechanisms involved in lymphocyte recruitment during inflammation may be more pharmaceutically attractive in order to therapeutically regulate chronic debilitating inflammatory diseases. Functional diversity of T cells has been demonstrated by the observation that naive T lymphocytes are activated and differentiate into Th0 type cells that produce different combinations of cytokines. Subsequently, these cells can further differentiate into either Th1 type cells (IL-2 and IFN), Th2 type cells (IL-4, IL-5, and IL-13), Th17 cells (IL-17 and IL-22), or Th9 cells (IL-9) depending upon the cytokine environment that the Th0 cells are exposed. It has become clear that certain diseases are characterized by the Th cytokine phenotype that is produced. For example, allergy and asthma responses have been identified as a largely Th2 type disease, with IL-4, IL-5, and IL-13 promoting the pathogenic phenotype. However, these traditional points of view have begun to break down as we begin to understand that, when we look at an exacerbated disease phenotype, such as a virus or bacterial infection, there appears to be a complex mix of Th cytokine phenotypes.[126–131] In particular, both bacterial- and viral-induced exacerbations appear to enhance the pathology by promoting IL-17 production that, while responding to the pathogenic assault, can also create chronic disease, examples of which are remodeling and mucus hypersecretion responses.[132,133]

Although numerous chemotactic mediators have been implicated in lymphocyte migration, the chemokine mediators appear to preferentially attract specific lymphocyte subsets, both based upon differential receptor display as well as chemokine ligands that are produced in the lung during a particular disease.[125,134,135] For example, IFN and TNF that are produced during Th1 type responses induce CCL3 and CCL5 that bind to CCR1 and CCR5 that are found on Th1 type cells. Other Th1 associated chemokines CxCL9, 10, and 11 all bind specifically to CxCR3 that is also highly expressed on Th1 type cells along with expression on $CD8^+$ cytotoxic T cells. Thus, these profiles of chemokine production are most appropriate for viral and intracellular bacterial infections. Likewise, there are CC chemokines that are preferentially upregulated by Th2 cytokines (IL-4 and IL-13), but not Th1 type cytokines including CCL1, CCL11, CCL17, and CCL22. These chemokine mediators bind to CCRs preferentially found on Th2 cells, including CCR8, CCR3, and CCR4, respectively. Thus, the cytokine environment can reinforce itself by recruiting additional T cells capable of producing chemokines associated with the allergic/asthmatic responses.[136–139] Recent data has also identified other chemokine receptor phenotypes, including CCR6/CCL20 receptor system that appears to be associated with Th17 cell migration.[140,141] Interestingly, CCL20 (LARC) is produced at significant levels by bronchial epithelial cells and attract both inflammatory DC and Th17 type cells that have increased expression of CCR6. Thus, effort continues to be made to identify compounds that might inhibit specific chemokine receptor GPCRs that can be used in specific chronic disease responses.

BACTERIAL INFECTION AND SEPSIS

The early response to infectious organisms is most important when dealing with bacterial infections that can be reversed by preventing colonization and by quickly eliminating the inciting agents. Bacteria, once established, can proliferate at an exponential rate that outpaces the ability to clear bacteria. These events can quickly overwhelm the local sentinel defenses provided by lung macrophage populations. A critical step in early bacterial clearance is the efficient and early recruitment of phagocytic cells (PMNs and monocytes) from the blood. The first response initiated in this case is activation of the complement system quickly resulting in the generation of C3a and C5a.[142] This initiates an early wave of infiltrating leukocytes that may be sufficient for removal of the invading pathogens. In a parallel process of de novo synthesis, continued persistence of the bacteria quickly leads to release of LTB4 from granulocytes, mast cell degranulation, and production of LTB4 from macrophages. LTB4 release effectively maintains the inflammatory influx of PMNs to cope with the presence of bacteria.[143] Subsequently, macrophage populations produce activating cytokines, (IL-1 and TNF), that mediate both adhesion molecule expression on endothelial cells and chemokine production, such as IL-8 and MCP-1, that promote continued influx of phagocytic cells.[144–146] A critical mechanism associated with bacteria-induced inflammatory responses has been shown to be inflammasome activation that induces a caspase-mediated process that cleaves pro-IL-1 to active IL-1 and activates NFkB pathways leading to induction of chemotactic responses that exacerbates inflammation.[147–149] Targeting inflammasome activation and especially IL-1 can significantly attenuate inflammatory diseases.[150–152] Recent evidence suggests that these activation pathways are central to the numerous inflammatory diseases, such as IBD,[153] with recent evidence indicating that pulmonary diseases may also be affected by inflammasome activation.[154–156] Thus, a well-coordinated and multifaceted series of chemoattractants are produced to promote acute inflammatory responses to control the bacterial infection. In addition to bringing about leukocyte migration, these chemoattractants activate PMNs and macrophages to promote enhanced phagocytosis and killing.

One of the harmful consequences of a vigorous and sustained recruitment of PMNs and macrophages, however, is the release of substances that cause tissue damage and necrosis of epithelial cells. Phagocytic cells, in response to the bacterial stimuli and phagocytic action, release proteolytic enzymes, reactive oxygen metabolites, and additional activating cytokines that cause injury to vascular and stromal cells in small and large airways. In particular, elastase release from PMNs may have a devastating effect on tissue.[157] Reports have suggested that the level of PMN-derived elastase in the airway reflects the intensity of PMN accumulation and correlates to the incidence of ARDS development.[158,159] There are numerous causes of PMN activation, including trauma, hemorrhage, burn, etc., all of which can lead to the development of life-threatening ARDS.

ARDS is a common disorder encountered in the ICU and involving septic patients, whether related to bacterial-induced disease or "sterile" inflammatory syndromes. Bacterial infections release danger associated molecules patterns (DAMPs), such as lipopolysaccharide or lipoteichoic acid, which interact with TLRs.[160] Sterile inflammation is a situation in which there is no bacterial inciting agent. This response leads to release of a variety of endogenous products generically referred to as "alarmins." These products interact with NOD receptors the result sometimes being a cytokine storm, multiorgan failure, and death.[160,161] ARDS is an overwhelming inflammatory response ("cytokine storm"), control of which is not possible at this time. These uncontrollable hyperinflammatory responses have been linked to PMN-associated inflammation. Thus, much of the current therapeutic effort has been focused upon attempts to reduce the ongoing influx and activation of PMNs. A number of investigations have examined the potential role of blocking PMN accumulation by blocking CD18 (Mac-1) with antibodies. These studies were largely unsuccessful, emphasizing our inadequate knowledge of lung inflammatory responses.

Given the lack of requirement in some models for adhesion molecule-dependent PMN accumulation, the role of chemotactic molecules has been more widely studied. In animal models of acute lung injury, blockade of C5a and/or its receptor, C5aR, attenuates lung injury, preserving vital lung function.[33,89,162,163] There has been interest in developing new therapies around blocking complement activation cascades as well as development of therapeutic antibodies designed to inhibit the acute inflammatory response. However, since complement and LTB4 mediators are primarily thought to be involved during the initial stages of inflammation and may only constitute a portion of the chemotactic environment, other more stable mediators have been targeted, especially the chemokines. A

large body of literature has characterized the significant levels of PMN-associated chemokines, in the CxC family.[164] They have been identified in the airways of ALI and ARDS patients, with the mediators' presence correlating with the severity of the inflammatory response. Numerous animal model studies have demonstrated that, by targeting the CxCR2 or its ligands, or using functionally inert CxCL8 (IL-8) homologs, a reduction in inflammation severity can be achieved. This has led to numerous pharmaceutical attempts for development of efficacious and safe compounds and biologics directed against chemokine ligands and their receptor, CxCR2. The CxCR2 antagonists may not only be useful in ALI or ARDS but in numerous other pulmonary diseases that appear to have PMN infiltration, including COPD, severe asthma, and even cystic fibrosis. Thus, controlling PMN infiltration and activation may be at the core of preserving lung function.

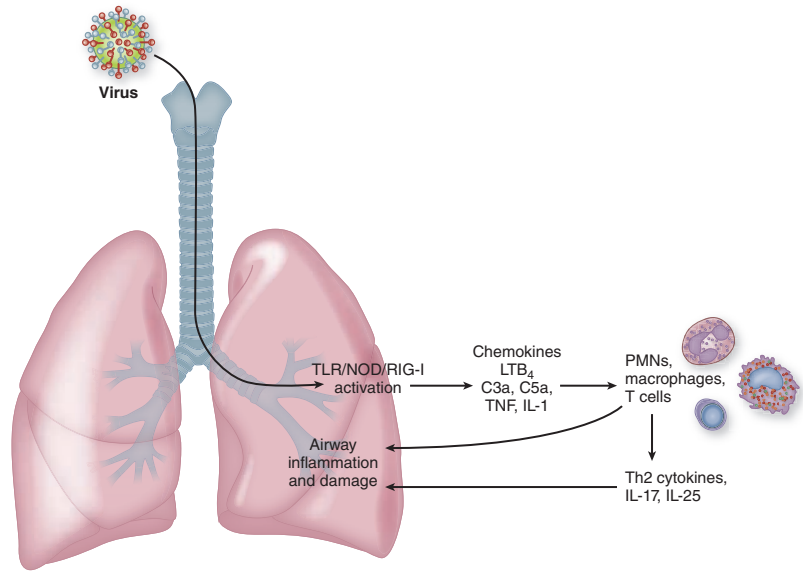

Figure 23-4 Viral exacerbation in pulmonary disease enhances chemotactic and inflammatory cytokine production leading to increased disease severity.

VIRAL EXACERBATION OF LUNG DISEASE

Many causes have been identified to explain exacerbation in patients with underlying lung disease, especially asthma and COPD. Viral infections appear to be the most common cause, such as with influenza, rhinovirus (RV), adenovirus, and respiratory syncytial virus (RSV). While there may be common pathways involved in the exacerbation of pulmonary diseases, activation of chemokines by viral pathogens may be the most prevalent mechanism.[165–168]

Approximately 10% of adults and up to 30% of children are affected by asthmatic disease, making it the most prevalent chronic respiratory disease, whereas COPD is an induced disease most clearly associated with smoking and occurs predominantly in older adults. The mechanism for viral exacerbation of the chronic lung response is unclear, but evidence points to a key role for increased leukocyte recruitment, inflammatory cell activation, and T cell differentiation. The asthmatic condition includes increases in mucus production and epithelial damage along with possible increases in airway remodeling and smooth muscle cell hyperplasia. While many viruses may be causative of asthma and COPD exacerbations, the most common viruses, RV, RSV, and influenza, all appear to function through many common pathways.[169–172] During infections, the upregulation of CxCL8 is significantly increased in sputum samples. CxCL8 is the mediator most frequently associated with exacerbation. Its presence correlates with the number of neutrophils and is productive of the severity of the exacerbation. PMN accumulation and activation lead to the local release of a number of proteases and MPO, with elastase having a significant effect on potentiating mucus production in the airway. In addition, other inflammatory mediators have also been detected during viral-induced exacerbations, including IL-6, LTB4, LTC4/D4, and histamine. Other chemokines that appear include CCL11 (eotaxin) and CCL5 (RANTES). Both have the ability to recruit eosinophils, further intensifying the inflammatory environment in lung.

The commonality of responses between these different RNA viruses likely stems from activation of Toll-like receptors (TLRs).[173,174] Virus-infected epithelial cells and innate immune cells quickly respond to the viral nucleic acid by TLR3 and TLR7/8 activation via dsRNA and ssRNA, respectively.[175,176] The activation of these TLR pathways activate several important mediator pathways including the TRIF adapter pathway leading to IRF3 and MyD88 adapter pathways that lead to NFkB for TLR3 and TLR7 (Fig. 23-3). The NFkB pathway mediates the production of a number of activating and chemotactic proteins, whereas the TRIF pathway primarily upregulates type I IFN and associated chemokine such as RANTES. Interestingly, however, there are differences in the ability of the different viruses to induce different levels of mediators, especially type I IFN. Influenza virus is known to promote high levels of type I IFN, described in animal models, often accompanied by secondary bacterial infection.[177,178] In contrast, RSV promotes comparatively low type I IFN due to specific inhibition of the activation pathways by nonstructural (NS) proteins produced by the virus.[179–182] Since type I IFN can induce additional chemokines together with the lytic nature of influenza, this may explain the intensity of the inflammatory responses that accompany influenza versus RV and RSV infections. Other pathogen recognition pathways, including the helicase (RIG-I) and NOD/inflammasome pathways have also been identified in these responses and contribute significantly to the inflammatory outcome of the responses.[183,184]

In addition to increased chemokines, it appears that other important mediators may also be preferentially expressed during viral exacerbation of asthma and COPD. Both IL-17 A and/or IL-25 (IL-17E) are induced during viral infections. The addition of these two IL-17 family members, both of which share a common receptor chain (IL-17RA), may contribute significantly to the pathogenic environment. Both types of infection induce a steroid-resistant response.[185,186] In the case of IL-17, a neutrophilic inflammation is induced through activation of CxC family chemokines, whereas IL-25 appears to induce an eosinophil accumulation and Th2 cytokine responses that on its own promotes a mucus-rich pathogenic environment. Thus, the addition of these two cytokines may be very important targets during these chronic airway responses where patients often develop steroid resistance in the most severe cases. As depicted in Figure 23-4, the ability of viruses to exacerbate pulmonary disease severity is a consequence of increasing the overall inflammatory response through the activation of several chemotactic mediators via PAMP-mediated pathways, as well as the activation of additional cytokine responses. Similar responses are operative during bacterial-induced disease exacerbation. While this section has outlined several of the critical mediators, other pathways are also important for the overall disease phenotype.

CHAPTER 24

Antibody-Mediated Lung Defenses and Humoral Immunodeficiency

Homer L. Twigg III

Antibody-mediated, or humoral, immunity is essential for host defense against respiratory pathogens. Defects in humoral immunity are common and frequently underappreciated. From a respiratory perspective, patients with impaired humoral immunity are susceptible to recurrent bacterial sinopulmonary infections and bronchiectasis. Antibody responses are also the principal mechanism behind the efficacy of vaccination against respiratory pathogens. This chapter focuses on our understanding of the normal B cell environment in the lung, generation of appropriate antibody responses after antigenic challenge, disease states associated with impaired lung humoral immunity, and the pulmonary response to vaccination.

OVERVIEW OF B CELL DEVELOPMENT (ONTOGENY)

The primary cell responsible for generating humoral immunity is the B lymphocyte. There are two phases in the development of antibody responses. The first phase is antigen independent and is called lymphopoiesis. As with the generation of other immune cells, the process begins with a multipotent stem cell in the bone marrow, which undergoes multiple maturation steps leading to mature but antigen naïve B lymphocytes (Fig. 24-1), which express IgM and IgD on the cell surface.[1] This process occurs entirely within the bone marrow (or liver during fetal development). Important cytokines in this process include interleukin (IL)-7,[2] *ckit*-ligand (stem cell factor),[3] and IL-11.[4] Mature B cells express the surface receptors CD19, CD20, CD21, and CD72.[5,6] CD20 is especially relevant as it is the target of the monoclonal antibody rituximab, which is used to deplete B lymphocytes in B cell lymphoproliferative disorders[7] and autoimmune disorders characterized by the production of pathogenic autoantibodies.[8]

At the completion of lymphopoiesis IgM expressing B cells traffic to various lymphoid organs, including lymph nodes in the lung, to await antigenic challenge and enter immunopoiesis.[9,10] Thus, unlike

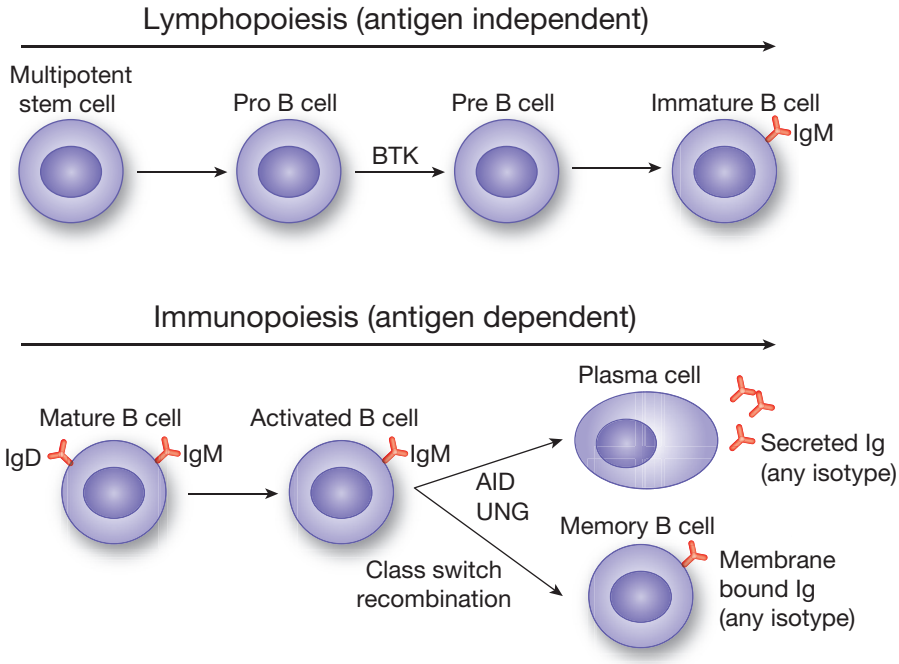

Figure 24-1 Overview of B cell ontogeny. Lymphopoiesis, which occurs in the bone marrow or fetal liver, is an antigen independent process, which begins with a multipotent stem cell and ends with an IgM expressing immature B cell, which will migrate to lymphoid tissues. Immunopoiesis begins with antigen stimulation (hence antigen dependent) and results in antibody secreting plasma cells and antibody expressing memory B cells. Class switch recombination leads to the generation of different immunoglobulin subtypes (IgG, IgA, IgE) from activated IgM expressing B cells. BTK, Bruton's tyrosine kinase, AID, activation-induced cytidine deaminase, UNG, uracil-N-glycosylase.

lymphopoiesis, immunopoiesis is antigen-dependent. The end result of immunopoiesis is the generation of antibody secreting plasma cells[1] and long lived memory B cells, which secrete immunoglobulin only upon re-exposure to antigen.[11] During immunopoiesis class switch recombination and somatic hypermutation occur resulting in the generation of IgA and IgG secreting cells out of IgM precursors and will be discussed in detail below. Immunopoiesis is most efficient in the presence of antigen activated T cells that provide "help" to B cells in the form of cytokines and cell surface activation signals. The most critical latter signal is the interaction between CD40 on B cells and CD40L on activated T cells. In the absence of such signaling (i.e., due to genetic mutations in CD40 or CD40L) class switching fails to occur, resulting in the accumulation of IgM secreting cells and the hyperimmunoglobulin M syndromes, discussed later in this chapter.

IMMUNOGLOBULIN DEVELOPMENT AND STRUCTURE

Below are discussed the basic structure of immunoglobulins and important characteristics of those immunoglobulins found in the lung.

BASIC STRUCTURE

Immunoglobulin (Ig) molecules are made up of two identical protein heavy chains and two identical kappa (κ) or lambda (λ) light chains.[12] Immunoglobulin heavy-chain genes reside on chromosome 14 and immunoglobulin light chains are derived from either the Igκ locus on chromosome 2 or the Igλ locus on chromosome 22. Immunoglobulin heavy chains contain both a variable region that will ultimately contribute to antigen binding and a constant region that binds to cell Fc receptors and complement. Mature immunoglobulin light chains also contain variable and constant regions. Within each variable region, there are hypervariable regions that represent the actual antigen binding site and less variable regions which make up the *framework region*.

The variable domain of the heavy chain is encoded by three sets of genes, the variable (V), diversity (D), and junctional (J) genes, which must be physically rearranged to result in expression of immunoglobulin heavy-chain protein.[13] Similarly, the variable region of the immunoglobulin light-chain protein is encoded by two sets of genes, the V and J genes, which are likewise rearranged to allow transcription of functional protein.[13] The rearrangement of DNA to join V, D, and J heavy-chain genes and V and J light-chain genes also results in elimination of unused V, D, and J sequences and noncoding stretches of DNA or introns. The many possible variable regions resulting from these random rearrangements confer a broad range of potential antigen specificities to the mature immunoglobulin molecules.

CLASS SWITCHING

Once immunopoiesis is initiated B cells alter the isotype of antibody that is produced via *isotype switching*.[13,14] This occurs in *switch regions* on immunoglobulin heavy chains through a process called *class switch recombination*. By translocation of the IgM variable region to *switch regions* adjacent to one of the constant regions coding for IgG, IgA, or IgE, the B cell is able to maintain antigen specificity and at the same time generate different immunoglobulin subtypes with different functional capabilities. Class switch recombination requires an enzyme called activation-induced cytidine deaminase (AID). AID also is critical for *somatic hypermutation*, a process where rapidly proliferating activated B cells have a high rate of point mutations in genes encoding the variable region leading to production of antibodies with different antigen binding affinities.[15] This results in a greatly expanded repertoire of B cells expressing surface IgG of different affinities for the triggering antigen. B cells expressing high affinity antibody on their surface (and thus bind greater amount of antigen) have a survival benefit over B cells coated with weaker affinity to antigen, where less signaling through antigen recognition results in B cell apoptosis. In this way the antibody response moves toward production of higher affinity and more specific immunoglobulin. The importance of AID is reflected in the development of one of the hyperimmunoglobulin M syndromes in patients with defects in this enzyme.[16] The structure of the various immunoglobulin classes is shown in Figure 24-2.

LUNG IMMUNOGLOBULINS

In the lung immunoglobulins comprise the second largest class of proteins present in bronchoalveolar lavage (BAL) fluid after albumin.[17] IgG is the major immunoglobulin in the lower respiratory tract[18] In contrast, IgA is the most abundant immunoglobulin in secretions from the upper respiratory tract, exceeding the concentration of IgG by a ratio of 2.5:1. Smaller amounts of IgE are consistently found in the BAL fluid of normal subjects.[17]

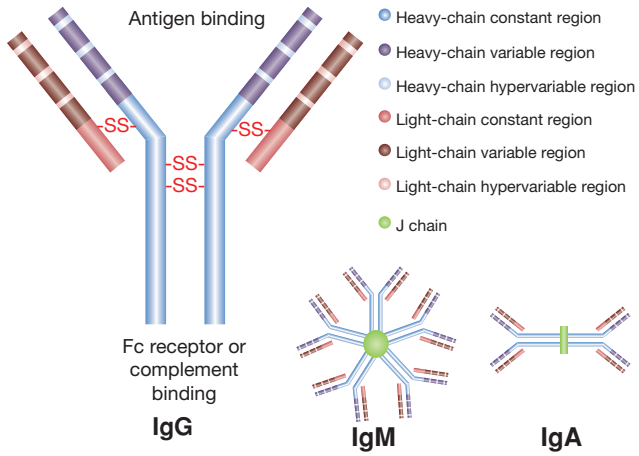

Figure 24-2 Basic immunoglobulin structure. Immunoglobulin molecules consist of two identical protein heavy chains and two identical light chains joined by disulfide bonds. Both heavy and light chains contain a constant and a variable region. Within each variable region there are hypervariable regions that represent actual antigen binding sites. IgM typically exists as a pentamer and IgA as a dimer.

IgG

IgG is the major circulating immunoglobulin found in the vascular compartment. In normal subjects, the amount of IgG measured in BAL (usually expressed as an immunoglobulin/albumin ratio) is in the same proportion as serum, suggesting that under resting conditions most IgG in the lung represents transudation from the vascular compartment.[17,19] This is further supported by the relatively small size of IgG (150,000 D). There are four IgG subclasses found in BAL fluid in approximately the same proportions as found in serum. IgG1 represents approximately 60% to 70% of the IgG present in BAL fluid, IgG2 20% to 25%, and IgG3 and IgG4 are present only in small amounts (<5%).[18] Responses to protein antigens predominantly reside in the IgG1 and IgG3 subclasses while polysaccharide antigens predominantly give rise to IgG2 antibodies.[20,21]

The major function of IgG is to opsonize pathogens and target them for clearance either through uptake by phagocytic cells or by fixing complement. In this regard IgG1 and IgG3 fix complement more avidly than IgG2.[22] Antibody also binds to Fc receptors on phagocytic cells to facilitate uptake. The three primary Fc receptors are FcRI, FcRII, and FcRIII. IgG1 and IgG3 bind FcRIII receptors on phagocytic cells equally well and more potently than IgG2.[23] IgG1 binds to the other Fc receptors more avidly than the other IgG subclasses. Binding of antigen–antibody complexes to Fc receptors is potentially a double-edged sword. On the one hand, not only is uptake of opsonized pathogens through Fc receptors more efficient, so is the intracellular digestion of organisms in phagolysosomes. For example, uptake of opsonized Mycobacterium tuberculosis through the Fc receptor results in intracellular killing of the organism, while uptake through other receptors (i.e., the mannose receptor) allows the organism to escape digestion.[24] On the other hand, uptake of opsonized pathogens through Fc receptors represents an "inflammatory clearance" mechanism that is associated with release of potentially harmful inflammatory mediators into the lung environment.[25]

IgA

In contrast to IgG, IgA is likely locally produced based on an elevated IgA/albumin ratio in BAL compared to serum.[26] IgA can exist as monomeric and polymeric proteins. The latter is usually found as dimeric IgA, characterized by two monomers connected by a J chain.[27] Most IgA in the lung is in dimeric form, with features of secretory IgA (sIgA) characterized by the presence of a J chain and secretory component (SC).[28] The large size of dimeric IgA (385,000 D) also argues against simple transudation of IgA from the vascular compartment into the lung. Finally, the presence of secretory component in BAL is another argument for the local production of IgA in the lung.[29]

IgA has two subclasses: IgA1 and IgA2.[27] IgA1 comprises nearly 80% of serum IgA. In contrast, IgA2 appears to be important in mucosal immunity and nearly half of the IgA present in secretions is IgA2. IgA exerts its protective effect through three mechanisms.[30] First, it serves as an immunologic barrier, inhibiting binding of organisms to mucosal surfaces. Second, the normal movement of IgA from the basilar to apical region of epithelial cells suggests that it may be effective in neutralizing intracellular pathogens. Finally, pathogens bound to IgA may be taken up by airway macrophages through the phagocytic process.

IgM

IgM is present only in very low amounts in respiratory secretions from normal subjects.[17] It exists as a pentamer and the resulting very large size (900,000 D) limit transudation into the lung under normal conditions. Nevertheless, IgM in BAL is greater than would be expected for simple diffusion suggesting some local production.[31] Furthermore, in some disorders characterized by lower respiratory tract inflammation IgM can be detected. However, in this setting it is almost certainly largely derived from serum transudation as part of the inflammatory process.

IgE

Under normal conditions the amount of IgE in BAL is lower than IgG, IgA, or IgM.[31] When present the IgE/albumin ratio suggests local production.[31] IgE–antigen complexes bind the high affinity receptor for IgE (FcRI) on mast cells, basophils, and eosinophils leading to immediate hypersensitivity responses.[32,33] IgE is important for host defense against parasites mediated by eosinophils.[34] However, in developed countries the main role of IgE in pulmonary immunity is in the pathogenesis of allergic and asthmatic disease.[35,36] The severity of disease is correlated with serum IgE in asthma and allergic patients. The importance of this molecule in the pathogenesis of asthma has led to the development of anti-IgE antibodies for patients with resistant IgE-mediated disease.[37] Interestingly, when IgE binds to the low affinity FcRII receptor it inhibits IgE synthesis and reduces inflammation.[38] Thus IgE may also have a role in downregulating the immune response.

CELLULAR INTERACTIONS LEADING TO ANTIBODY SECRETING CELLS

A number of important cellular interactions take place that eventuate in antibody secretion by cells.

B1 AND B2 CELLS

B lymphocytes comprise 1% to 10% of the lung lymphocyte population and can be separated into two main classes. Plasma cells constitutively secrete IgG and other immunoglobulin subclasses.[1,11] In contrast, memory B cells produce immunoglobulin only in response to re-exposure to particular antigens.[11] B cells can be further classified into B1 and B2 cells. B1 cells were first described in the gastrointestinal tract. These cells are IgM+, CD5+ cells that do not require T cell help for development.[39] In the lamina propria B1 cells undergo class switching to an IgA secretory cell. B1 cells home to peritoneal and pleural cavities, respond to common bacterial antigens, and are felt to be very important in the production of IgM and IgA against bacterial pathogens at mucosal sites.[40] As such, they are thought to be important in innate immunity against conserved bacterial antigens. Because of their autonomous ability to secrete antibody, they are also felt to contribute to autoimmune diseases. These cells are difficult to demonstrate in normal lung. As stated earlier, T cells are not necessary for B1 cells to produce antibody, though the presence of T cells appears to augment the immune response.[40–44]

In contrast to B1 cells, B2 cells require T cell help, mainly through secretion of the cytokines interleukin IL-4, IL-5, IL-6, and IL-10, as well as ligation between CD40 on B cells and CD40L on T cells.[45] T cell dependent antibody responses begin with uptake of antigen by accessory cells (AC) and presentation to T cells. AC function can be carried out by mononuclear phagocytes (monocytes, macrophages) or dendritic cells. Submucosal dendritic cells are likely the principal accessory cell in the lung.[46] B cells themselves can also serve as the accessory cell leading to T cell activation.[47] B cells in the lung express surface IgG and IgM. Crosslinking of surface IgG or IgM by antigen results in partial activation of B cells leading to expression of IL-2 receptors and MHC class II molecules,[1] which allows them to serve as accessory cells in T cell activation. With appropriate T cell help activated B cells eventually differentiate into short lived antibody producing plasma cells or memory B cells, the latter characterized by the coexpression of CD20 and CD27.[48] Other surface markers indicating B cell activation and differentiation include CD69, CD80, and CD86.[1] The latter two interact with CD28 and CTLA4 on T cells, respectively, thereby enhancing proliferation of helper T cells. Activation results in production of CD38+ CD138+ plasma cells that secrete IgM (primary response) or other immunoglobulin isotypes (secondary immune responses).[49]

COGNATE VERSUS NONCOGNATE RESPONSES

Activated T cells can provide cognate and noncognate B cell help. Cognate B cell help is antigen and MHC restricted and occurs after helper T cells have been activated through T cell receptor (TCR)–MHC class II/antigen complex mechanisms. It was initially thought that B cells were the obligate accessory cells for cognate responses since B cell–T cell contact was occurring through MHC class II/antigen complexes on activated B cells and the TCR on T cells. In contrast, when T cells are stimulated by accessory cells other than B cells or activated in an accessory cell independent manner (i.e., with immobilized anti-CD3), T cells can induce immunoglobulin production in many B cells in a non-MHC or antigen (noncognate) restricted manner. This latter phenomenon results in stimulation of both antigen specific as well as "bystander" B cells leading to a polyclonal antibody response. Subsequent work has shown that this bystander response is only important when the T cells providing B cell help are highly activated and/or differentiated, such as after exposure to IL-4 and IL-6.[49] This latter observation may explain the link between increased IL-6 secretion and nonspecific hypergammaglobulinemia in diseases such as HIV infection.[50] Additional work has shown that this bystander effect is mediated through LFA-1 (CD11a/CD18) on B cells and ICAM-1 (CD54) on activated T cells.[51,52]

CYTOKINE SECRETION

Resting T cells provide poor B cell help. T cells that have been stimulated by antigen can be loosely divided into Th1 and Th2 cells based on the cytokine profile they secrete.[53] Th1 cells secrete predominantly interferon-γ (IFN-γ) and interleukin (IL)-2 and are involved primarily in cellular immunity. Th2 cells secrete IL-4, IL-5, and IL-10 and drive humoral immunity. Th2 cells that provide B cell help are called "effector" cells. Signals from T cells to B cells are in two forms: direct cell to cell contact and cytokine secretion. While direct B cell–T cell contact is required for induction of antibody production, both Th1 and Th2 cell membranes can provide this signal.[54] What differentiates these two T cell populations is the cytokine profile they secrete. In particular, IL-4 seems to be an early competence factor that increases the number of B cells responsive to T cell help.[54,55] In contrast, IL-6 is a late factor[55] that promotes continued B cell proliferation and immunoglobulin secretion. IFN-γ downregulates most immunoglobulin secretion.[56] Thus Th2 cells secrete a more favorable cytokine pattern for immunoglobulin production. The one exception is IgG2, which is dependent on IFN-γ secretion.[56]

SPECIFIC B CELL AND T CELL RECEPTOR INTERACTIONS AND DOWNREGULATION OF B CELL RESPONSES

Tight regulation of antibody production and secretion is necessary to turn off the response when it is no longer needed and to prevent production of unwanted autoantibodies (Fig. 24-3). This control is mediated through a combination of signaling pathways between T cells and B cells. CD40L is an activation-induced molecule on CD4 T cells that delivers signals to B cells through its counterreceptor CD40, which is constitutively expressed on B cells. Highly activated T cells express increased CD40L. CD40 on B cells in turn downregulates CD40L on activated T cells.[57] These cells are subsequently unable to stimulate resting B cells. Thus this may represent an attempt to downregulate noncognate immunoglobulin production. However, CD40 ligation is still critically important for cognate interactions. Crosslinking of surface immunoglobulin on B cells results in apoptosis of the B cell unless simultaneous binding of CD40 by CD40L occurs.[58] Interestingly, CD40 binding alone induces Fas expression on B cells, an effect that is not inhibited even in the presence of B cell tropic factors such as IL-2, IL-4, and IL-10.[59] Thus ligation of CD40 acts to costimulate B cells that have been activated by binding of specific antigen while simultaneously increasing sensitivity to apoptosis in B cells not crosslinked by antigen. This drives an antigen-specific antibody response.[58]

The role of Fas/FasL interactions in modulating immune responses is well established. Activation of T cells upregulates expression of both Fas and FasL. This is seen as a mechanism to control chronic T cell activation.[60] Fas/FasL interactions are also important in modulating B cell responses.[61] As stated earlier, B cells stimulated through CD40 increase expression of Fas. Thus, these cells are susceptible to apoptosis mediated by FasL expressed by activated T cells. B cell apoptosis induced by FasL is blocked if there is simultaneous crosslinking of surface immunoglobulin by antigen, thereby preserving secretion of protective antibody in the presence of persistent pathogen exposure.

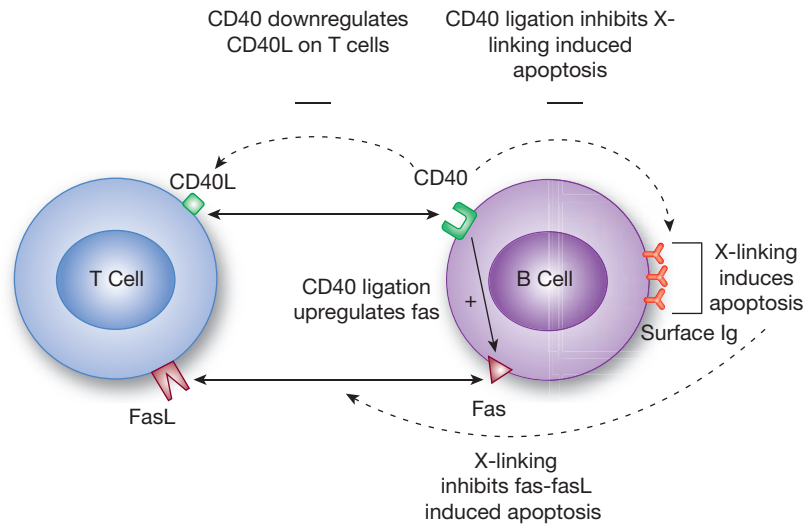

Figure 24-3 Interaction between T cells and B cells during the generation of a humoral response. Multiple signals occur between T cells and B cells. Depending on the presence or absence of crosslinking of surface immunoglobulin on B cells, T cells can either promote B cell growth or induce apoptosis.

PULMONARY ANTIBODY PRODUCTION IN RESPONSE TO ANTIGEN EXPOSURE

Pulmonary immunity to pathogens can be divided into innate and acquired responses. Most pathogens gaining access to the alveolar space are handled by phagocytosis by alveolar macrophages, the principal form of innate immunity. If phagocytosis of pathogens occurs in the absence of opsonizing antibody this usually results in "noninflammatory clearance," with minimal release of inflammatory mediators and preservation of lung structure and function.[62] If phagocytosis is overwhelmed, a specific acquired immune response occurs. This involves the interaction of B and T lymphocytes to produce an antigen-specific cellular and humoral immune response. In the lung, the acquired response has three distinct phases (Fig. 24-4)—afferent antigen processing and transport to regional lymph nodes,[63] presentation to naïve lymphocytes, and efferent migration of activated T lymphocytes and mature B cells back to the site of initial antigen challenge in the lung.[64] This results in the presence of antigen-specific immunoglobulin in the lung lining fluid and consequent increased effectiveness of professional phagocytes such as alveolar macrophages and neutrophils.[65]

This general pathway is similar for IgG and IgA production, though the length of the "circuit" is likely much less for IgA. Rather than having antigen travel to regional lymph nodes, in mucosal immunity IgA can be generated in specialized lymphoid tissue just beneath the mucosal surface, called mucosal-associated lymphoid tissue (MALT), suggesting that IgA secreting plasma cells are produced locally and IgA can readily diffuse back into the airspaces. Such submucosal lymphoid tissue in the upper airway, called nasal-associated lymphoid tissue (NALT), is seen in most animal species, including humans.[66] In contrast, in the lower respiratory tract bronchus-associated lymphoid tissue, or BALT, is readily demonstrable in mice[66] but has been more difficult to find in normal human airways.[67] Prior studies claiming that humans have BALT have generally been in subjects with an inflammatory pulmonary process.[68] Recent investigations may be shedding some light on this controversy, introducing the concept of inducible bronchus-associated lymphoid tissue, or iBALT. In mice lacking secondary lymphoid tissues (spleen, lymph nodes) a robust protective primary pulmonary B and T cell response was demonstrated after influenza infection.[69] This response was associated with induction of B cell follicles centered around follicular dendritic cells in submucosal tissues. Thus collections of antigen presenting cells, B cells, and T cells in the submucosa, which are thought to collectively represent BALT, may only be readily detectable during times of antigenic challenge.

Once antibody producing B cells are formed in secondary lymphoid tissue or MALT, they must traffic back to the original point of entry of the pathogen. This trafficking of lymphocytes back to mucosal sites has been intensely studied, giving rise to a four-step model. The first step is tethering. L-selectin on lymphocytes interacts with addressins on endothelial cells to slow down the movement of lymphocytes through capillaries. In NALT, the responsible endothelial receptor is PNAd[70] while in the lung adhesion is mediated by ICAM-1.[71] Tethering leads to lymphocyte activation mediated by chemokines and their receptors and subsequent firm adhesion to the endothelium. The latter is mediated by LFA-1 binding to ICAM-1 and $\alpha_4\beta_7$ integrin binding to MADCAM-1.[72] Finally, diapedesis through the mucosa occurs, a process that probably involves all the above receptor–counterreceptor interactions.

The end result of this process is the accumulation of antibody secreting plasma cells at the site of initial challenge. Once the invading pathogen has been cleared, plasma cells disappear and are replaced by memory B cells. The great majority of B cells in the normal lung are mature memory B cells. This mirrors the predominance of memory T cells in the lung,[73] suggesting that the lung is primed to respond quickly to antigenic challenges. IgG-, IgM-, and IgA-secreting B cells are present in normal subjects; however, poor correlations exist between the numbers of Ig producing BAL cells and the levels of Ig in BAL fluids.[17,74] In BAL fluid from nonsmokers IgG is present in the same proportion as in serum, leading to speculation that most IgG enters via transudation from the plasma compartments.[17,19] These two observations fit in well with the primary presence of memory B cells in the lung, suggesting that under resting conditions very little local antibody is made. Only after antigenic challenge is local production increased. In support of this is the finding of increased ratios of specific to total antibody in BAL fluid after pneumococcal infection suggesting that local antibody production can be increased after relevant exposures.[75]

DISORDERS OF HUMORAL IMMUNITY AND LUNG DISEASE

Either quantitative or qualitative defects may be associated with disorders of humoral immunity and resultant lung disease. In addition, lung disease has been noted in conjunction with development of autoantibodies. These topics are presented below.

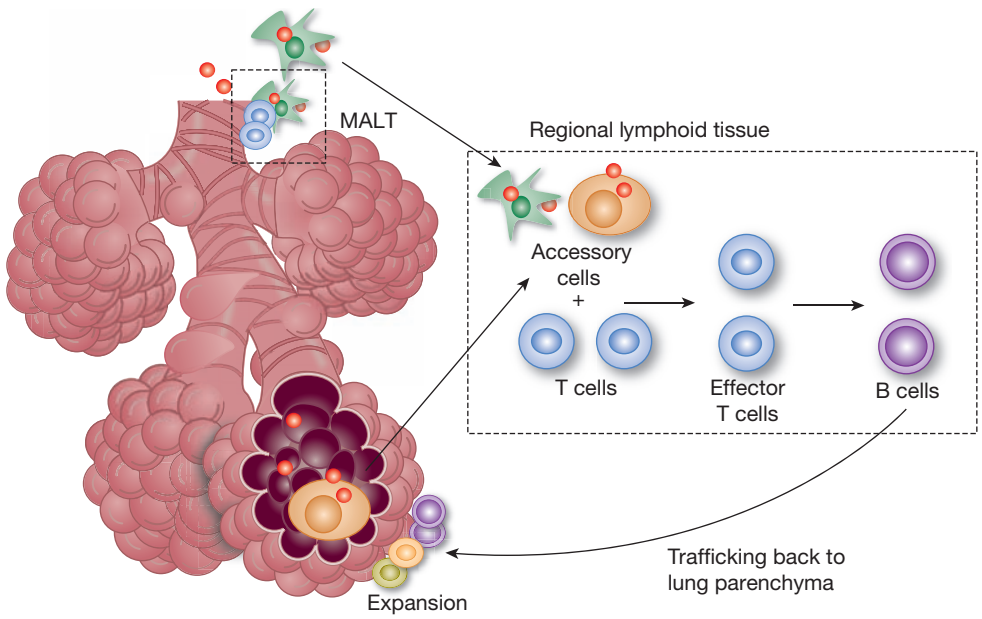

Figure 24-4 Pathway for generation of antigen-specific immune responses in the lung. Foreign antigen is taken up by antigen presenting cells and transported to regional lymph nodes where the primary cellular and humoral immune response is generated. Effector cells then traffic back to the lung to the site of initial antigen challenge. B cells will become antibody secreting plasma cells while others will become memory B cells. This circuit is significantly shorter in the presence of mucosal-associated lymphoid tissue (MALT).

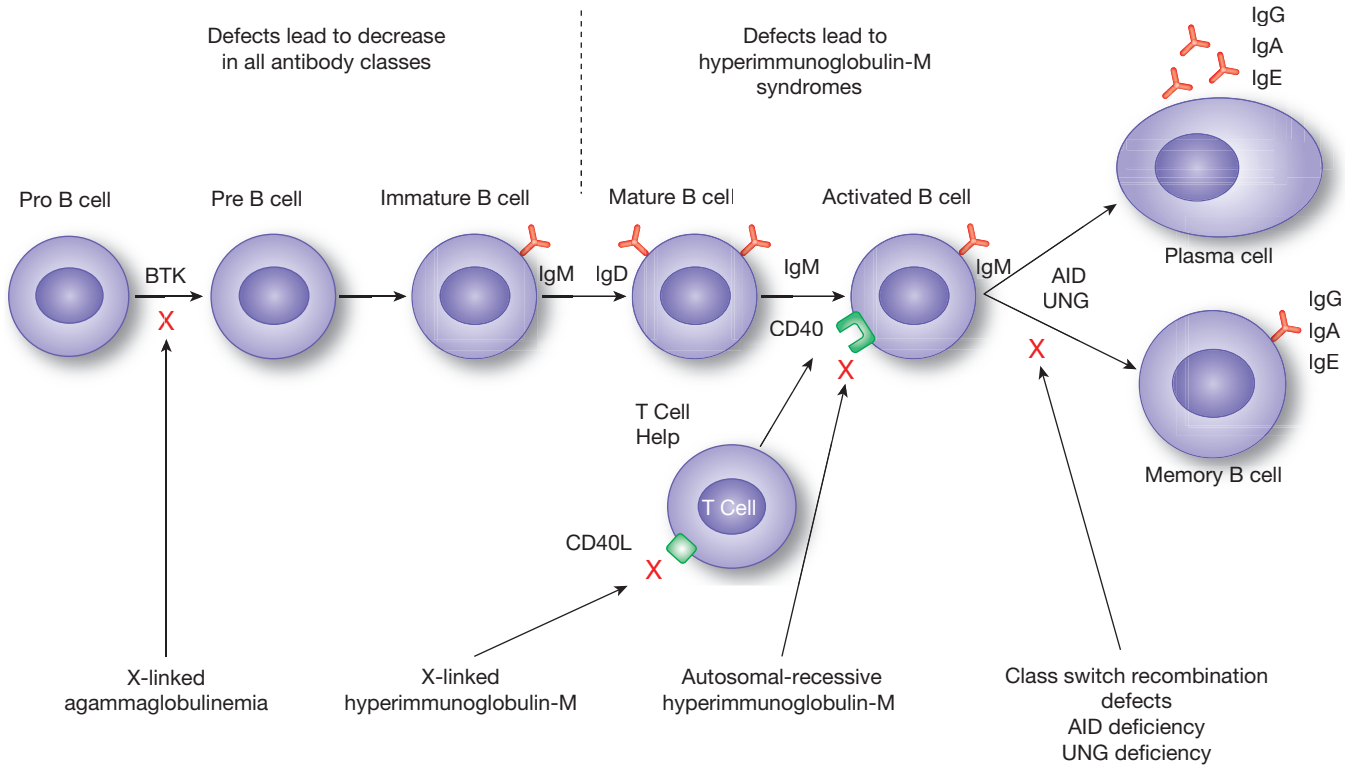

Figure 24-5 Known sites of molecular defects leading to immunoglobulin deficiency. Note defects that occur past the mature B cell stage tend to lead to hyperimmunoglobulin-M syndromes while defects prior to this stage lead to loss of all immunoglobulin classes. BTK, Bruton's tyrosine kinase, AID, activation-induced cytidine deaminase, UNG, uracil-N-glycosylase.

INTRODUCTION

In general, defects in humoral immunity result in an increased susceptibility to bacterial infections, including recurrent sinusitis, bronchitis, pneumonia, otitis media, and even meningitis. In particular, the patients are susceptible to infection with encapsulated organisms such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Neisseria* species. Chronic diseases such as bronchiectasis and obstructive lung disease can occur as a result of recurrent infection. Antibody defects can be either quantitative (an absolute decrease or loss of antibody) or qualitative (poor antigenic specificity and/or poor opsonic function). In addition, the presence of antibodies against host antigens can lead to autoimmune lung disease. Figure 24-5 shows some of the known molecular defects causing immunoglobulin deficiency. The cause of most of the selective immunoglobulin deficiencies described below is unknown.

QUANTITATIVE DEFECTS

Isolated *IgA deficiency* is the most common primary immunodeficiency in humans, occurring in roughly 1 in 500 individuals.[76] The presence of IgA deficiency is defined by a serum IgA level of less than 5 mg/dL and normal levels of other immunoglobulins. Asthma, IgE-mediated allergic disease, and autoimmune diseases are more common in patients with IgA deficiency.[77] Only about a third of patients with IgA deficiency develop recurrent sinus, pulmonary, and gastrointestinal tract infections, usually with encapsulated bacteria. In the absence of an associated IgG subclass deficiency the development of structural lung disease is rare. These patients almost never require immunoglobulin replacement therapy. However, the coexistence of IgA and IgG subclass deficiency is extremely important to document since the latter may require immunoglobulin infusions. IgA deficient patients are at increased risk for anaphylactic reactions after blood product infusions, including immunoglobulin preparations, because of the presence of IgG anti-IgA antibodies in up to 60% of individuals.[78,79] As such, when the decision is made to give immunoglobulin infusions to an IgG deficient patient with a coexisting low IgA level, immunoglobulin preparations low in IgA must be used.

In contrast to IgA deficiency, patients with *IgG subclass deficiencies* frequently exhibit recurrent sinus and respiratory tract infections with encapsulated organisms regardless of whether it is associated with IgA deficiency.[80] IgG1 deficiency is the most common and it is frequently linked with deficiency of IgG2 and IgG3 as well. Unlike patients with IgA deficiency, the recurrent infections in IgG subclass deficiency can lead to chronic bronchiectasis, and assessment of immunoglobulin deficiency should be part of the standard evaluation of patients with unexplained recurrent infections with destructive lung disease. Patients with IgG2 subclass deficiency have an impaired ability to respond to polysaccharides.[20] As such, their response to the standard polysaccharide pneumococcal vaccine is poor. When IgG subclass deficiency is combined with IgA deficiency the resultant lung disease is more severe than with either deficiency alone.

More severe disease occurs when there are multiple immunoglobulin defects. Perhaps the most common immunodeficiency in this group is *common variable immunodeficiency (CVID)*. Present in 1 in 25,000 individuals, this disease is characterized by hypogammaglobulinemia, decreased antigen-specific antibody responses, and recurrent sinopulmonary infections, frequently leading to chronic lung disease.[81] IgG levels are usually below 300 mg/dL and are accompanied by low IgA and IgM levels as well. Specific antibody responses to common antigens such as tetanus toxoid and pneumococcus are usually very low. Cellular immune defects, primarily lymphopenia with a normal or decreased CD4:CD8 ratio, may also be present. Thus, patients may present with infections typically associated with T cell defects (fungi, mycobacteria) in addition to infections caused

by encapsulated bacteria. Proliferation of B cells and T cells in response to strong mitogens is impaired as well. Thus CVID is felt to result from a failure of B cells to terminally differentiate, either due to poor T cell help or an intrinsic B cell defect. The impairment in immunity and immunosurveillance probably contributes to the increased incidence of autoimmune disease, malignancies, and gastrointestinal malabsorption in patients with CVID.[82–84]

Patients with *X-linked agammaglobulinemia (Bruton's agammaglobulinemia)* demonstrate a generalized defect in the ability to make all immunoglobulin classes. This is due to a deficiency of Bruton's tyrosine kinase (BTK), which is essential for early lymphopoiesis.[85] These individuals present in early childhood with recurrent middle ear, sinus, pulmonary, joint, bone, and CNS infections. They almost always develop chronic lung disease, including bronchiectasis, pulmonary fibrosis, and pulmonary hypertension.[86–88] IgG levels are below 200 mg/dL and the other Ig subclasses may be absent. In contrast to patients with CVID, lymphoid tissue is hypoplastic in these patients.

Hyperimmunoglobulin M syndrome refers to several diseases characterized by low concentrations of IgG, IgA, and IgE and a normal or elevated IgM level. As might be expected based on our understanding of normal B cell development, these syndromes result from failure of IgM secreting B cells to undergo class switching. The most common disorder is X-linked hyperimmunoglobulin M syndrome, which arises from a deficiency in the important T cell costimulatory molecule CD40L.[89] Deficiency in the B cell CD40 molecule has also been described, though this is rare.[90] Patients with either of these disorders have severely impaired T cell dependent antibody production. Other hyperimmunoglobulin M disorders are caused by genetic mutations in the enzymes required for class switching, such as AID[91] and uracil nucleoside glycosylase.[92]

Immunoglobulin replacement therapy can prevent recurrent infection and ameliorate some of the long term sequelae of IgG deficiency.[93,94] However, it is important to base treatment decisions on the inability to make specific antibody, not just on an isolated low IgG (or IgG subclass) level. Typically when immunoglobulin deficiency is suspected total IgG, IgA, IgM, and IgG subclass concentrations are checked. A lymphocyte phenotype panel should also be obtained to look for low T and B cell numbers. If low antibody titers are detected, then one should measure common specific antibody titers. Usually tetanus toxoid and pneumococcal antibody titers are assessed because this assesses both the ability to respond to protein (tetanus) and polysaccharide (pneumococcal) antigens. If specific antibody titers are low the patient should be given the tetanus or pneumococcal vaccine and repeat antibody titers obtained 4 weeks later. Failure to increase antibody titers into a "protective" range is indicative of immunoglobulin deficiency and warrants consideration of immunoglobulin replacement therapy. There are several immunoglobulin preparations available. As mentioned earlier, if IgA deficiency is present, a preparation that contains very low IgA should be used to minimize the risk of anaphylaxis.[78] A typical dose of immunoglobulin is 400 mg/kg given once a month, with a goal trough serum immunoglobulin level immediately before the next infusion of 500 mg/dL.

■ QUALITATIVE DEFECTS

Once antibody is produced in the lung, it must be effective in promoting clearance of the offending pathogen. Just having a vigorous antibody response is insufficient. There are several diseases characterized by poor functioning antibody.

Selective antibody deficiency with normal immunoglobulins (SADNI) was first recognized in the 1980s. The disease is characterized by poor antibody responses to polysaccharide antigens despite normal IgG, IgG subclass, IgM, and IgA concentrations.[95] While many of the primary immunodeficiency diseases described earlier are associated with poor responses to polysaccharide antigens, SADNI should be reserved for patients with only this specific defect. SADNI is one of the most common immunodeficiencies occurring in 5% to 10% of older children and adults presenting with recurrent sinopulmonary infections.[96,97] As with other immunoglobulin deficiencies, these patients also have an increased incidence of atopic disease. Since SADNI is a diagnosis of exclusion, normal IgG, IgG subclass, IgM, and IgA levels must be demonstrated. To demonstrate polysaccharide unresponsiveness, baseline pneumococcal titers are measured and then the 23-valent polysaccharide pneumococcal vaccine is administered.[98] Four weeks later pneumococcal titers are repeated. An appropriate response is indicated by an antibody titer of 1.3 μg/mL or greater in 70% of the serotypes tested.[98] Some patients have an appropriate response to vaccination, but this is followed by a rapid loss of antibody titers over 6 months. These patients fall within the spectrum of patients with SADNI. One of the main reasons for establishing the diagnosis of SADNI versus other immunodeficiencies is the differences in treatment. Patients with SADNI should be administered the 13-valent conjugated pneumococcal vaccine, which is more immunogenic due to the presence of a protein carrier attached to polysaccharide antigens that acts as a hapten.[99] Unlike in more severe humoral immunodeficiencies, immunoglobulin replacement therapy is needed only in a minority of patients with SADNI.

While *HIV infection* is most notably characterized by profound defects in cell-mediated immunity, antibody defects are also present. In fact, the occurrence of two bacterial pneumonias in a year is an AIDS defining illness.[100] HIV infection is characterized by an increased amount of total and pneumococcal-specific antibody in the alveolar space,[75,101] yet invasive pneumococcal disease is prevalent in this population. For example, in HIV-infected Malawians, a population with a high incidence of invasive pneumococcal infection, BAL contains four times the amount of pneumococcal-specific IgG compared to non-HIV-infected subjects. Capsule-specific IgG levels were highest in a group of HIV-infected patients with recent invasive pneumococcal disease, suggesting that despite polyclonal IgG responses in HIV-infected adults, appropriate responses to infection were also present.[75] However, the ability of highly purified BAL IgG from HIV-infected subjects to bind pneumococci is impaired compared to BAL IgG from non-HIV-infected subjects.[102] This parallels the work of other investigators who have demonstrated impaired immunoglobulin opsonic function in HIV-infected subjects, including activity against pneumococcus.[103,104] Thus HIV-infected subjects appear to have dysfunctional pneumococcal antibody in the alveolar space. The reasons for this observation are not known, but could include structural abnormalities in HIV IgG or the lack of a diverse antigenic response (i.e., antibody produced against only a few pneumococcal antigens in HIV-infection compared to a more diverse response in non-HIV-infected subjects).[105] These findings highlight the fact that better correlates are needed for assessing the host response to natural infection or vaccination besides simple measurement of antibody concentrations.[106]

■ PULMONARY DISEASE ASSOCIATED WITH AUTOANTIBODIES

There are many well-described lung diseases associated with the presence of autoantibodies. Classically these have been described in patients with vasculitic processes such as Goodpasteur's syndrome or granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis), and various connective tissue diseases. A discussion of these disorders is beyond the scope of this chapter. However, a great deal of interest is now turning toward the potential role of autoantibodies in some of the more commonly encountered lung diseases.

Chronic obstructive lung disease (COPD) is increasingly being thought of as an autoimmune disease.[107] Patients with COPD

have increased lung titers of autoantibodies against elastin,[108] cytokeratin[109] and against epithelial and endothelial antigens.[110,111] Furthermore, lymphoid follicles consisting of B cells and follicular dendritic cells with adjacent T cells are present in the parenchyma and in bronchial walls of patients with emphysema suggesting that at least some these antibodies may be locally produced.[112] This is further supported by detailed studies demonstrating that the B cells in these aggregates have a limited (oligoclonal) repertoire.[113] That these autoantibodies may be pathogenic is suggested by the presence of immune complex and C3 deposition in the lungs of patients with emphysema.[110] In animal models smoking is able to induce autoantibodies against extracellular matrix proteins in mice,[114] and adoptive transfer of anti-endothelial antibodies can cause emphysema in rats.[115] This discussion would suggest that immunosuppressive medications may be effective in COPD. Indeed, systemic and inhaled corticosteroids result in decreased lymphoid aggregates in the lungs of humans with COPD.[116] Whether reduction in lung B cell immunity is helpful or harmful will depend on whether the B cells are secreting destructive autoantibodies or protective antibodies against microbes that have colonized the airway of these patients.

Another lung disease in which autoantibodies may contribute to pathogenesis is *pulmonary fibrosis*. The current paradigm for the pathogenesis of pulmonary fibrosis starts with lung epithelial and/or microvascular injury leading to an exaggerated inflammatory and fibrotic response. While extensive literature exists on the inflammatory and fibrotic response, much less is known about the inciting event. In pulmonary fibrosis associated with connective tissue disease numerous autoantibodies have been described, including anti-SSA, anti-RNP, and anti-Jo-1.[117–119] Whether similar potential pathogenic roles can be ascribed to autoantibodies in idiopathic pulmonary fibrosis (IPF) is not known. Early on an increase in lung IgG was described in patients with IPF.[120] Up to 30% of patients with IPF have positive antinuclear antibody or rheumatoid factor without other overt signs of autoimmune disease.[121] Anti-phospholipid and anti-endothelial cell antibodies are found in a significant number of patients with IPF.[122] In another study anti-collagen antibodies were found in 81% of patients with IPF.[123] Anti-cytokeratin antibodies are also frequently found in the serum of patients with IPF.[124] Finally, antibodies to heat shock protein 70 identified a group of patients with IPF with a poor prognosis.[125] Thus there is evidence to support a contribution of unchecked humoral immunity in the pathogenesis of fibrotic lung diseases.

Dysregulated humoral immunity also plays a role in lu*ng transplant rejection.* Rejection is associated with upregulation of IgG2 production resulting in an IgG2/IgG1 ratio of greater than 1 in BAL fluid. Since the ratio was normal in serum this strongly argues for local production of IgG2 in the lungs of patients undergoing rejection.[126] In support of this, B cells are a prominent finding in areas of the lung demonstrating obliterative bronchiolitis, the pathologic hallmark of lung rejection,[127] and these cells preferentially produce IgG2.[128] Subsequent work in animal models[129] and humans[130,131] has shown that the major antigens driving this response are collagen V and k-α tubulin. In fact, the presence of circulating anti-collagen V antibody predicts primary graft dysfunction after transplant.[129] That these antibodies may have a pathogenic role in lung transplant rejection is further supported by observations that rituximab or intravenous immunoglobulin therapy reduces the concentration of the autoantibody and reduces the severity of bronchiolitis obliterans syndrome.[130] The current paradigm for lung transplant rejection holds that ischemic injury during the transplant process "uncovers" normally hidden collagen V epitopes that elicit an autoimmune response.[132] This is strongly supported by recent work showing increased collagen V expression in obliterative bronchiolitis lesions and the presence of collagen V antibodies in the lungs of patients who had lung transplant rejection.[133]

PULMONARY ANTIBODY RESPONSES TO VACCINATION

The pulmonary antibody response to vaccination against common pathogens is an important consideration in disease prevention and is discussed below.

SYSTEMIC VERSUS MUCOSAL VACCINATION

Vaccination against pulmonary pathogens is a common and effective practice against many diseases. However, the mechanisms behind their effectiveness are not always clear. In theory, both IgA and IgG have a role in protection after vaccination. The presence of pathogen-specific IgA should decrease colonization of the respiratory tract by limiting attachment to respiratory epithelium. Since airway colonization is usually the first step in the development of bacterial pneumonia, decreased colonization should lead to a decreased incidence of pneumonia. When pathogens manage to reach the alveolar space, IgG should take on a greater role as an opsonin in the phagocytosis of organisms. Thus the most effective immunity against bacterial infections should involve both an IgG and IgA response. That being said, the vaccine delivery mechanism impacts the type of immune response generated. In general, systemic administration of a protein antigen results in the generation of circulating IgG, some of which will diffuse into the epithelial lining fluid. In contrast, mucosal antigenic challenge results in a more vigorous IgA response locally at the site of challenge.

Despite the recognition that local antibody may be important in pulmonary host defense, there is little information on humoral responses in the respiratory tract after systemic immunization, the standard approach to vaccine strategies. Much of what we know about mucosal immunity comes from animal models. In a mouse model of mucosal immunity against *Mycoplasma pulmonis*, it has been demonstrated that the site of antigen deposition greatly influences the antibody response and subsequent protective immunity.[134] Intranasal challenge resulted in an increase in IgA antibody forming cells in the nasal submucosa and an increase in mycoplasma-specific IgA in nasal washes. Low numbers of IgA antibody forming cells and IgA concentrations were seen in the lung after isolated nasal challenge, but were increased significantly if animals received both nasal and pulmonary immunization. Both nasal and nasal-pulmonary vaccine exposures resulted in equivalent antigen-specific IgA and IgG in the systemic circulation. Both forms of immunization also significantly reduced the ability of mycoplasma to colonize the nasal passages after experimental exposure to a mycoplasma inoculum. However, animals receiving nasal-pulmonary immunization had significantly fewer organisms in the lungs compared to animals that only received nasal immunization. Since serum mycoplasma-specific IgA and IgG were similar after both types of immunization, this suggests that circulating antibody is less effective in protection against pulmonary pathogens compared to locally produced antibody.

In another animal immunization model against a different pulmonary pathogen, *Moraxella catarrhalis,* the site of specific antibody production and protection after intranasal and subcutaneous challenge was examined.[135] Intranasal administration of *M. catarrhalis* surface proteins resulted in antigen-specific IgA and IgG in both nasal washes and BAL. IgA concentrations far exceeded IgG concentrations in both sites. IgA was significantly higher in BAL and nasal washes than in serum, whereas IgG was higher in serum than both mucosal sites. Immunization was associated with a marked increase in bacterial clearance after intranasal challenge with live *M. catarrhalis* organisms. As might be predicted, subcutaneous administration of the same vaccine resulted in production of far greater antigen-specific IgG compared to IgA, especially in the lung, where moraxella-specific IgG in BAL was nearly 20 times greater than that found in nasal washes. Subcutaneous vaccination induced a marked

systemic IgG response, but virtually no antigen-specific IgA in serum, BAL, or nasal washes. Interestingly, despite the brisk systemic and pulmonary IgG response after subcutaneous immunization, intranasal immunization promoted significantly greater bacterial clearance after intranasal challenge with the organisms. These data further support the general premise that while systemic vaccination results in system antigen-specific IgG that may passively diffuse into the epithelial lining fluid in the lung, significant protection will only be afforded if local IgA immune responses are also induced.

The effect of the intranasal and intramuscular polysaccharide pneumococcal vaccine has also been studied in a mouse model.[136] Intranasal vaccination, when accompanied by IL-12 administration (which increases IF-γ production), resulted in increased serum IgG2a anti-pneumococcal antibody, consistent with the known stimulatory effect of IF-γ on IgG2a production.[56] This regimen also resulted in increased pneumococcal-specific IgA in BAL fluid. The serum antibody response was functional in opsonophagocytosis assays. Interestingly, intramuscular vaccination afforded more protection against subsequent intraperitoneal pneumococcal challenge compared to intranasal vaccination. In contrast, intranasal vaccination was more effective in reducing nasopharyngeal colonization after nasal challenge of the organism compared to intramuscular vaccination, despite the higher serum IgG response after the latter. Finally, using IgA knockout mice, these investigators demonstrated that IgA was responsible for reducing pneumococcal colonization after vaccination and intranasal challenge.[136] These results again highlight the general principal that systemic immunization is more effective in providing protection against systemic challenges, while mucosal immunization is more protective against mucosal challenges.

There are significantly fewer studies on the pulmonary response to vaccines in humans. One study compared oral and nasal administration of a cholera toxin B subunit vaccine.[137] Nasal immunization resulted in a fivefold increase in the levels of specific IgA antibodies in BAL fluid. No significant specific IgA responses were seen after oral immunization. Specific IgG antibody concentrations increased eightfold in BAL fluid in the nasally vaccinated subjects, though this was felt to be from transudation from serum rather than local production. Several studies have examined systemic and salivary pneumococcal-specific antibody titers after systemic vaccination in children. Infants given the 7-valent conjugated pneumococcal vaccine at 2, 4, 6, and 15 months had significant plasma IgG responses at 7 months.[138] However, salivary pneumococcal-specific IgG and IgA concentrations were minimal at this time and did not appear till a booster vaccine was given at 15 months. Further studies suggested the salivary IgG was derived from serum while the salivary IgA was locally produced. This same group demonstrated that by age 4 to 5 years, anti-pneumococcal IgA, especially IgA1, was still present in saliva.[139] Interestingly, there was no difference in pneumococcal-specific antibody titers between vaccinated and unvaccinated children at age 4 to 5 years, suggesting that natural environmental exposure also resulted in mucosal immunity. Finally, immunization with the pneumococcal polysaccharide vaccine has been shown to lead to an increase in salivary pneumococcal-specific IgG and IgA in adults as well.[140] In other studies, despite the lack of immunologic correlation, systemic pneumococcal vaccination appears to decrease the incidence of nasopharyngeal carriage of vaccine-specific serotypes.[141]

In total, these studies suggest that in general systemic vaccination induces primarily an IgG response whereas mucosal vaccination induces primarily an IgA response (Fig. 24-6). While it is clear that systemic immunization can result in some local lung IgA production, the strongest mucosal immunity is induced when antigen is introduced directly into the respiratory tract. Intranasal and inhaled vaccines offer advantages in addition to the potential for improved local immunity, including the ability to immunize large populations at less cost.[142] In safety trials of intranasal vaccination against influenza using a virosome formulated inactivated virus the vaccine was associated with high serum concentrations of influenza-specific IgG and the presence of specific IgA in nasal lavage fluid.[143] Similarly, an inhaled measles vaccine has been shown to be immunogenic (as determined by serum measurement of measles-specific IgG) in a large children population.[144]

VACCINATION AGAINST PNEUMOCOCCAL DISEASE

There are currently two active vaccines against pneumococcal disease: the 23-valent pneumococcal polysaccharide vaccine (23-PPV) and the 13-valent pneumococcal conjugate vaccine. Because the conjugated vaccine contains protein linked to various polysaccharides, it is theoretically more immunogenic by virtue of its ability to induce T cell help for antibody secretion. The 23-PPV comprises capsular polysaccharide from 23 of the 90 serotypes of *S. pneumoniae*. Cross-reactivity between serogroups and the epidemiology of disease[145,146] suggest that if adequately immunogenic, this vaccine

should be effective against more than 90% of disease episodes worldwide.[147]

In humans the pneumococcal vaccine is clearly effective in reducing the morbidity and mortality of invasive pneumococcal disease.[148,149] However, studies describing the effect of vaccination on respiratory tract antibody concentrations are lacking. Most studies assessing the immune response to the pneumococcal vaccine focus on serum and salivary antibody titers. Only a few studies have tried to analyse the pulmonary response after vaccination. One study found no difference in the opsonic function of BAL IgG against pneumococcus 1 and 6 months after systemic immunization with the conjugate pneumococcal vaccine.[150] In another study the effect of intramuscular administration of the 23-valent vaccine was compared to inhalation of the same preparation.[151] BAL was performed one month after vaccination. Intramuscular administration resulted in significant increases in serum and BAL pneumococcal-specific IgG titers. Pneumococcal-specific IgA1 titers increased in serum, but not in BAL. This observation supports the concept that mucosal exposure is needed to get a local IgA response. However, no change was seen in any serum or BAL measurement in subjects who inhaled the vaccine. This contrasts with two other studies that found a mild systemic IgG response to inhaled pneumococcal vaccine.[152,153] Lung specific measurements were not assessed in these latter two studies. Thus the conclusion from currently available data suggests effective immunization against pneumococcus still requires systemic (intramuscular) immunization.

VACCINATION AGAINST INFLUENZA

Like the pneumococcal vaccine, vaccination against influenza is highly effective in preventing morbidity and mortality.[154,155] There are two currently available routes for influenza vaccination in humans. The more commonly administered trivalent vaccine consists of neuraminidase and hemagglutinin antigens from three viral strains and is usually given as an intramuscular injection. A second formulation consists of a live attenuated influenza vaccine and is given intranasally. Because it is a live vaccine it is not given to individuals with underdeveloped or impaired immunity. Thus candidates for the nasal vaccine are individuals between the age of 2 and 49 and no existing potentially immunosuppressive condition, including pregnancy.[156]

Because there are systemic and mucosal vaccination options for influenza, more is known about the pulmonary immune response to these vaccines.[157] In one study comparison of inactivated intramuscular and live intranasal influenza vaccines in young children undergoing primary immunization demonstrated that the intranasal preparation induced longer lasting protective antibody concentrations.[158] Nasal secretory IgA developed almost exclusively in nasally vaccinated individuals, whereas nasal IgG was detected in both nasal and intramuscular vaccine recipients. In general, studies show that the trivalent vaccine administered systemically induces a strong IgG response but minimal mucosal influenza-specific IgA. In contrast, the nasal live attenuated vaccine gives a stronger mucosal IgA response. Furthermore, because it results in low level infection, intranasal formulation also induces a specific cellular (cytotoxic T cell) response. Despite these differences, both appear to have similar efficacy in reducing morbidity and mortality from influenza.

Newer vaccine strategies are being developed to enhance population vaccination strategies and improve immunogenicity in individuals with poor antibody responses. In a controlled clinical trial, high dose trivalent influenza vaccination was more immunogenic than standard dose vaccination in subjects over 65, a population known to have a poorer vaccine response.[159] Adjuvants are also being developed to augment the immune response. In humans, using the adjuvant MF59 improves the immune response to the trivalent vaccine.[160] Another innovative approach is to target more conserved influenza antigens, which would obviate the need for yearly vaccination.[161,162] However, many conserved epitopes are poorly immunogenic, indicating that novel delivery methods will be necessary to elicit broad immune responses. In an animal study nucleocapsid and matrix proteins, which are not immunogenic, were able to induce protective antibody responses when administered with nanoparticles coated with papaya mosaic virus as an adjuvant.[163] Very recent animal models are exploring the use of adenovirus vectors to immunize with conserved influenza vaccines.[164] Thus recent advances in vaccine strategies offer hope that newer influenza vaccines will generate broader antigenic coverage, induce both humoral and cellular immunity, and provide longer lasting and better protection against this worldwide pathogen.

CONCLUSION

The humoral immune response is essential for host defense against bacteria. After exposure to potential pathogens, antibody responses in the respiratory tract can occur either quickly through activation of resident memory B cells if there has been prior bacterial exposure, or more slowly through the induction of both systemic and local mucosal immunity if the host is naïve to the organism. The resulting production of antigen-specific IgG and IgA act in concert to help clear the invading pathogen and reduce subsequent colonization of respiratory epithelium. The type and concentration of antibody produced is dependent on the site of exposure. Upper airway exposure results in primarily an IgA response. Organisms that reach the lung after passing through the upper airway induce a more systemic response, including increased production of pathogen-specific IgG. The importance of an effective pulmonary antibody response is highlighted by the significant morbidity associated with diseases characterized by deficient or defective antibody production. Increasing evidence is also pointing toward a key role of autoantibodies in many common lung diseases. Finally, vaccination against respiratory pathogens is dependent on an intact humoral immune system. Systemic vaccination against respiratory pathogens, while effective in generating systemic IgG responses and some mucosal IgA responses, may be less effective than vaccination through mucosal surfaces, which induce a brisk IgA and IgG response both locally and systemically depending on the site of vaccine deposition. Future studies should provide further insight on the pulmonary humoral host response to bacterial challenge and optimal vaccine regimens to minimize the burden of respiratory disease caused by pathogenic bacteria.
