- Decreased initiation of IADL secondary to endurance and tonal changes
- Decreased functional use of the left UE to complete ADLs and IADLs
- Developing reach and grasp patterns with fluctuating tone with volitional movement
- Decreased strength and endurance for return to work and functional independence
- Dependent for community mobility on public transportation

Occupational Therapy Goal List

- Marie will be independent for ADLs and IADLs, demonstrating active arm reach and hand grasp/release patterns for object manipulation.
- Marie will display active grasp and release patterns of the UE to manipulate large objects as a component of meal preparation.
- Marie will independently complete a laundry load using her left UE to assist in loading laundry/dryer machines and folding laundry.
- Marie will return to work on a part-time basis, increasing to full-time employment as endurance improves.

Intervention

To facilitate and strengthen an active reach-and-release pattern overriding flexor synergies, NMES electrical stimulation was used to strengthen volitional movement patterns of mass extension/reach of the left UE. Participation in food preparation and laundry was incorporated into the stimulated movement patterns and was triggered using an external trigger to the stimulator. Active participation in movements and activities, combined with electrically stimulated movement, was used to strengthen and facilitate outcomes.^{42,57}

Owing to increased flexor tone in the left biceps and wrist/finger flexors, targeted muscles for NMES to facilitate a mass reach-and-release pattern will involve a dual-channel

stimulation, targeting the muscles of the left anterior deltoid and triceps/posterior deltoid (channel 1) and wrist/finger extensors (channel 2).

NMES Parameters

- **Rate:** 35 pps
- **Waveform:** Asymmetrical
- **On:Off Cycle:**
 - 1:3
 - 1:3 to 1:1 for endurance
 - 1:5 for power
- **Ramp:** 2 seconds

Reeducation

- Proceed with 10 to 20 minutes of muscle stimulation as tolerated.
- May need to adjust for accommodation.
- Watch for signs of fatigue.
- To improve strength and endurance, treatment time should start at 30 minutes per session and increase to 60 minutes daily, 4 to 6 days per week. Research is variable in terms of length of treatment and frequency, but some studies indicate that longer treatment times, even at a sensory level without muscle contraction, and if treatment occurs more often (3–6 days/week), will improve function and hemiplegic UE use.^{58–60}

Best Evidence for Physical Agent Modalities Used in Occupational Therapy

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Neuromuscular Electrical Stimulation (NMES) ⁶¹	The study used a specially designed NMES system to target shoulder flexion, elbow extension, and wrist-and-finger extension to improve motor control and functional use of the UE in chronic stroke patients.	15 participants with chronic (>1 year following CVA) upper limb hemiparesis	Upper limb training for 60 minutes/day, 6 days/week, for 2 weeks, using both a shoulder-and-elbow stimulation device and a wrist-and-finger stimulation device	Randomized controlled trial Level I	Multi-muscle stimulation approach and method appears to be a feasible approach and adjunctive method for chronic stroke patients. Participants demonstrated improved motor control and functional upper limb use.	Significant improvements in the UE component of the Fugl-Meyer (F-M) assessment and Action Research Arm Test (ARAT) scores ($p < 0.01$) were found. There were also significant reductions in Modified Ashworth Scale scores for the elbow and wrist flexors ($p < 0.01$).

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
NMES ⁶²	Systematic review of FES following CVA to determine effect of electrical stimulation (FES) in improving activity and to investigate whether FES is more effective than training alone	18 articles included in review; randomized and controlled trials Population: poststroke	Varied with each study	Systematic review and meta-analysis of 18 research articles Level I	FES moderately improved activity (specifically UE activity) when compared with no intervention or training alone.	FES had a moderate effect on activity (standardized mean difference [SMD], 0.40; 95% confidence interval [CI], .09 - .72) compared with no or placebo intervention. FES had moderate effect on activity (SMD, 0.56; 95% CI, .29 - .92) compared with training alone. When subgroup analyses were performed, FES had large effect on upper limb activity (SMD, 0.69; 95% CI, .33 - 1.05) and small effect on walking speed (mean difference, 0.08 m/s; 95% CI, .02 - .15) compared with control groups.
NMES ⁶³	Use of NMES to the hand muscles combined with repetitive task practice to determine effect on skilled hand performance in patients following CVA. All participants received repetitive task practice, but control group received sham electrical stimulation.	40 patients poststroke between the ages of 45 and 65 (first CVA)	NMES for 30 minutes, 3x/week for 8 weeks	Randomized controlled trial (pre/post-treatment measurements) Level I	Repetitive task practice combined with electrical stimulation improved skilled hand performance in terms of hand motor function, skills, and ROM in stroke patients. Patients in experimental group showed significant improvement in fine motor control and hand function compared with those in control group.	Motor assessment scale score was 4.25 ± 0.63 for experimental group and 3.35 ± 0.74 for control group ($t = -3.50$ and $p = 0.0001$). Time to complete Jebsen Taylor Test was 180.90 ± 7.04 for experimental group and 192.80 ± 6.87 for control group ($t = 4.50$ and $p = 0.0001$).

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Functional Electrical Stimulation (FES) ⁶⁴	FES and use of advanced iterative learning control (ILC) technology to improve functional control and UE use	Five CVA patients, aged >18 years and at least 6 months post-CVA	60 minutes/session for 18 treatment sessions	Randomized controlled trial Level I	Combining low-cost technology with advanced FES controllers ILC, strengthens upper limb movement and function and may decrease UE impairments poststroke.	A one-tailed, paired <i>t</i> test, with a significance level of $p < 0.05$, was used to compare pre- and postintervention F-M and ARAT outcome measures.

Chapter 25

Wheelchair and Seating Selection

Michelle L. Lange

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Recognize when wheelchair seating is indicated for a client.
2. Recognize when current wheelchair seating is not appropriate and requires modification or replacement.
3. Describe general components of a wheelchair seating assessment.
4. Describe general seating system categories.
5. Recognize when client mobility is inefficient and intervention is indicated.
6. Describe general components of a wheelchair mobility assessment.
7. Describe major mobility device categories.
8. Describe impact of manual wheelchair configuration on self-propulsion.
9. List several proportional and nonproportional power wheelchair driving methods.
10. Describe strategies to develop further competence in the area of wheelchair seating and mobility.

CHAPTER OUTLINE

Wheelchair Seating and Mobility in Daily Occupation
Motor, Visual, Cognitive, and Sensory Impairments that Underlie the Need for Seating and Mobility Devices
Wheelchair Seating and Mobility Screening and Assessment
Conceptual Foundation Underlying Interventions for Seating and Mobility Impairment
Specific Interventions for Skill Dysfunction
Case Study

TERMINOLOGY

Manual wheelchair (MWC): a mobility base consisting of a frame, rear wheels, and front casters designed for self-propulsion or dependent mobility.

Power assist add-ons: additions to a manual wheel chair that are placed under and behind the wheelchair and can be activated to assist in propulsion as needed for longer distances.

Power assist wheels: alternative to standard wheels on a manual wheelchair to increase the force of the client's propulsion stroke for increased distance and speed.

Power-operated vehicle (POV): (aka scooters) mobility bases that have three or four wheels, a driving tiller, and a consumer-style seat.

Power wheelchair (PWC): a mobility base consisting of a frame, drive wheels, and casters designed for independent mobility through a driving method such as a joystick.

Pressure injury: a breakdown of the skin and sometimes underlying tissues owing to unrelieved pressure in conjunction with other contributing factors.

Primary support surfaces: the seat, back, footplates, and arm pads of the wheelchair and seating system.

Secondary supports: anterior (e.g., pelvic positioning belt or anterior trunk support), posterior (e.g., calf strap), or superior (e.g., foot straps) supports.

Secondary support surfaces: anterior (e.g., anterior lower leg support aka knee block), lateral (e.g., lateral trunk support), posterior (e.g., posterior head support), and medial (i.e., medial knee support) support surfaces designed to keep the client aligned with the primary support surfaces.

Shear: forces created when body tissues and seating surfaces move laterally in relation to each other.

Wheelchair Seating and Mobility in Daily Occupation

Wheelchair seating and mobility is an area of assistive technology (AT) that is broad and deep. This chapter is intended as an introduction to this area of practice. The entry-level occupational therapist should be able to screen a client to determine whether a formal seating and mobility evaluation is required. Referral can then be made to a qualified wheelchair seating and mobility team.

Think about how your body is positioned right now. Perhaps you are sitting at a desk, leaning forward over this book, highlighter in hand. We each position our bodies for specific tasks to optimize our functioning. If a person is seeking a position of rest while watching a football game, he or she may sink back into the couch cushions to minimize the effort required to sustain his or her position. Assuming the best position for a specific task provides stability to optimize function during occupation. For clients who have motor, visual, cognitive, and/or sensory impairments, assuming and sustaining the most appropriate position may only be possible through wheelchair seating.¹ The seating system may allow the client to participate in activities of daily living (ADLs), work tasks, school tasks, or use ATs such as a wheelchair or a speech-generating device (SGD).

We are mobile people. We are often on the move, whether to accomplish a specific task of daily occupation or just for the sake of movement itself. Our clients require movement, as well. If a person is nonambulatory or inefficient in his or her mobility, a variety of mobility devices are available. When augmented mobility devices, such as walkers, are inadequate to meet someone's needs, wheelchairs can provide dependent or independent mobility. Lack of efficient mobility is a significant barrier to participation and independence in occupation.

Motor, Visual, Cognitive and Sensory Impairments That Underlie the Need for Seating and Mobility Devices

Who can benefit from wheelchair seating and mobility interventions? Anyone who requires a mobility base also requires a seating system. In general, a mobility base is indicated if a client needs dependent or independent mobility that cannot be achieved through ambulation or use of augmented mobility devices. Seating systems not only provide a surface to sit on, but also can provide postural support and pressure relief.

Specific impairments may indicate a need for wheelchair seating.¹ Motor impairments may limit the client's ability to assume and sustain an upright sitting posture. Maintaining this posture relies on the body's ability to balance muscle groups (flexors and extensors). If the client has low or high muscle tone, the ability to balance these muscle groups is diminished. If a client has muscle weakness, he or she may be unable to assume or maintain a sitting posture as adequate muscle strength and endurance is not present. If paralysis is present, the brain is unable to communicate with the nerves controlling muscle groups. Visual impairments can also impact posture. We rely on vision to dictate an upright and midline posture. For example, people with impaired or lack of vision often display asymmetrical head positions. If a client has significant cognitive impairment, he or she may not shift his or her weight in response to discomfort, increasing risk for pressure injuries. This is common in people with advanced dementia. Finally, clients who lack sensation (often due to spinal cord injury) will not feel discomfort and so are less likely to shift their weight, again increasing risk for pressure injuries.

Specific impairments may also indicate a need for a wheelchair for mobility.¹ Motor impairments limit a person’s ability to ambulate and may also limit ability to use mobility devices. Motor impairments impacting mobility include decreased motor skills, decreased coordination, abnormal muscle tone, muscle weakness, and paralysis. Impaired vision can certainly impact our ability to move throughout the environment, though many people with impaired or no vision are successfully mobile. Using a mobility device, particularly a power wheelchair (PWC), requires certain cognitive skills, though many toddlers are successful at this task. Finally, moving through space is a multisensory task, and clients with sensory issues may require time to accommodate to this activity.

These impairments may be seen in clients with a variety of diagnoses, across the age span and in multiple environments. Diagnosis, age, and environment may dictate more specific interventions.

Wheelchair Seating and Mobility Screening and Assessment

Wheelchair seating and mobility interventions may be recommended for a client who does not have any equipment, perhaps due to young age or an acquired injury. Current equipment may no longer be meeting a client’s needs, and reassessment is required. Screening can help us determine whether a client is positioned adequately in his or her current seating system before a recommendation for a formal assessment (see Box 25-1).

Box 25-1

How Do I Know if the Client Is Positioned Adequately in His or Her Mobility Base?

Positioning Checklist

This checklist is designed to screen the student to determine whether a formal seating evaluation is required. Please refer the student, as indicated, to a qualified wheelchair seating team in your area.

___	1.	Pelvis: is the pelvis in a neutral position within the seating system? This includes neutral pelvic tilt, obliquity, and rotation.
___	2.	Pelvis: if the pelvis is not in a neutral position, can you correct the pelvis, and is this corrected position maintained over time in the current seating system?
___	3.	Trunk: is the trunk upright and midline?
___	4.	Head: is the head upright and midline, balanced over the trunk, without neck hyperextension?
___	5.	Lower extremities: are the lower extremities aligned with the pelvis? Without adduction, abduction, or rotation?
___	6.	Back height: with the pelvis in a neutral orientation, is the back at the correct height? For students who require full support or who use anterior trunk supports, this is at or just above the shoulders.
___	7.	Seat depth: with the pelvis in a neutral orientation, is there approximately 1 inch between the end of the cushion and the back of the knee? If there is more than 1 inch, the seat depth is too short. If the back of the knee is contacting the front of the seat or not allowing the pelvis to be placed in a neutral tilt, the seat depth is too long.
___	8.	Lower leg length: with the pelvis in a neutral orientation, is the distance between the top of the seat and the footplate correct? If the distal thighs are unweighted, the distance may be too short. If the feet are not making full contact with the footplates, the distance may be too long. If you marked “No” for any of these items, further assessment is indicated.

Wheelchair Seating Screening

When screening a client in his or her current seating system, the following items are noted:

- Is the pelvis in a neutral position in the seating system, without tilt, obliquity, or rotation?
- If the pelvis is not in a neutral position, can you correct the pelvis, and is this corrected position maintained over time in the current seating system?
- Is the trunk upright and midline?
- Is the head upright and midline, balanced over the trunk, without neck hyperextension?
- Are the lower extremities aligned with the pelvis, without adduction, abduction, or rotation?
- Back height: With the pelvis in a neutral orientation, is the back at the correct height? For clients who require full support or who use anterior trunk supports, this height should be at or just above the shoulders.
- Seat depth: With the pelvis in a neutral orientation, is there approximately 1 inch between the end of the cushion and the back of the knee? If there is more than 1 inch, the seat depth may be too short. If the back of the knee/calf is contacting the front of the seat or not allowing the pelvis to be placed in a neutral tilt, the seat depth is too long.
- Lower leg length: With the pelvis in a neutral orientation, is the distance between the top of the seat and the footplate correct? If the distal thighs are unweighted, the distance may be too short. If the feet are not making full contact with the footplates, the distance may be too long.

If the answer to any of these items is “no,” then further seating assessment is indicated.

The Wheelchair Seating and Mobility Assessment Team

The wheelchair seating and mobility assessment team includes the client, caregivers, clinicians (occupational and/or physical therapists), and the equipment supplier. Wheelchair seating falls under the area of Complex Rehabilitation Technology (CRT). Occupational therapists need to understand the importance of appropriate positioning and recognize when a seating system is not meeting a client’s needs. Occupational therapists who perform these assessments typically have additional training and experience and may be certified in this area by the Rehabilitation Engineering and Assistive Technology Society of North America (RESNA) as an assistive technology professional (ATP) and/or seating and mobility specialist (SMS). The equipment supplier working with CRT should also have specialized training, experience, and certification including the ATP and sometimes the CRTS (Certified Complex Rehabilitation Technology Supplier, available through the National Registry of Rehabilitation Technology Suppliers/RRRTS). See Most Commonly Used Standardized Assessments for Mobility table at the end of this chapter.

Wheelchair Seating Assessment

Wheelchair seating assessment includes gathering information/intake, assessment of current posture and equipment, the mat examination, simulation, equipment trials, fabrication and fitting, and follow-up. The intake is more than just gathering information and demographics. It provides critical information to develop client parameters that are then matched to appropriate equipment. The intake provides context and direction and should include client goals, home and vehicle accessibility, medical issues, independence in ADLs, and current equipment. Assessment of the client’s posture in the current equipment includes noting the position of the pelvis, trunk, neck and extremities.

The mat examination is a key part of wheelchair seating assessment. The purpose of the mat examination is to determine available range of motion for a seated posture, where support surfaces are required and what seated angles will be used.² What we can support with our hands, the seating system can also support (see Figs. 25-1 and 25-2).

Figure 25-1 Client sitting on examiner's lap, uncorrected.

Figure 25-2 Client sitting on examiner's lap with hands-on support.

During the mat examination, describe reflexes and muscle tone and the influence of these on body movements and posture. Note any range of motion limitations. When noting postural challenges, look for the causes and not just the effect. The client is examined sitting on the edge of the mat table as well as in supine. On the edge of the mat table, note the position of the head, shoulders, upper extremities, trunk, pelvis, hips, and lower extremities (see Fig. 25-1). Determine what angles and support are required to achieve a neutral position (see Fig. 25-2). Supine allows examination without the influence of gravity. The evaluator places the pelvis in a neutral position and then begins to flex the hip. When the pelvis begins to rock posteriorly, this indicates the end of available hip flexion, which, in turn, determines the seat-to-back angle of the seating system. This is rechecked with the knees at 90° of extension or more to ensure the client can be placed at this amount of hip flexion with the feet on the footplates (see Fig. 25-3).

Figure 25-3 The mat examination in supine.

The mat examination determines the approximate available range, where support is required and at what angles. Simulation allows us to “test drive” our recommendations to fine-tune and assess effectiveness. This requires a seating simulator or equipment that can be trialed. Pressure mapping may occur at this stage of the assessment to determine whether pressure is well distributed. Pressure mapping can also be used with the client’s current seat.

Wheelchair Mobility Screening

Wheelchair mobility is all about efficiency. Efficiency is a combination of time and effort. If the current method of mobility is taking too long or too much effort, then another method of mobility may be more appropriate. For example, if a high school student is using a **manual wheelchair (MWC)** to self-propel between classes and is often late to class and too fatigued to learn, this is not efficient. That same student may be able to use a PWC for these longer distances, arriving to class on time and ready to participate.

Safety is also a concern. If a client can ambulate, but is inefficient, he or she may be at risk of falling, in addition to taking too long and using too much energy. Energy expenditure is a significant medical concern. Energy conservation is required for clients with cardiopulmonary insufficiency. Fatigue can lead to an exacerbation of symptoms (e.g., clients with multiple sclerosis), lead to an increase in muscle tone (e.g., clients with cerebral palsy), or limit how long a person can use his or her mobility base. Some clients may not achieve independent mobility in any mobility base and will still require a base for dependent use, allowing a caregiver to push. To summarize, if a client is not currently mobile or is inefficient or unsafe in his or her mobility, further evaluation is required.

Wheelchair Mobility Assessment

Assessment is typically done with a wheelchair supplier. Many MWC and PWC are considered CRT, which is typically recommended by a professional who is a certified as an ATP or SMS. The assessment determines the most appropriate wheeled mobility category, which is addressed in more detail later in this chapter. If power mobility is being assessed, the evaluation determines the client’s readiness for this task. If the client is an appropriate candidate for a PWC, the evaluation also determines the most appropriate seating system, driving method, power seating (e.g., power tilt), and other required features.

Conceptual Foundation Underlying Interventions for Seating and Mobility Impairment

What are the goals of providing wheelchair seating and mobility? First and foremost is function. The seating system should provide optimal and aligned postural support and stability to improve functional skills and compensate for motor, sensory, visual, and cognitive impairment. Function will vary by client. For one client, proper seating may result in increased independence in ADLs. For another client, the seating system may promote vision, breathing, and swallowing by aligning the trunk and head. The wheelchair provides mobility, whether independent or dependent, and that increases function.

Other goals of wheelchair seating and mobility include:

- **Postural alignment:** To the degree possible, to the evaluation team strives for the client to approach an upright and symmetrical alignment. Range of motion losses and orthopedic changes may limit the client's ability to fully achieve neutral alignment, sometimes referred to as a fixed or nonreducible asymmetry. In this case, the team corrects what is flexible or reducible and accommodates what is fixed or nonreducible. It is important not to place a joint or muscle on stretch because this leads to pain, possible damage, and may elicit a stretch reflex, leading to the muscle tightening further.
- **Postural support and stability:** Once the most aligned position is identified, primary and secondary support surfaces, as well as secondary supports, are identified to provide adequate postural support to maintain that position. The more force required to maintain a position, the larger the support may need to be to adequately distribute pressure. For example, it is not appropriate to use a lateral trunk support that is only a few inches wide along the side of the ribcage if significant force is required at this area to maintain trunk alignment. A larger lateral trunk support will provide increased support and pressure distribution.

Adequate postural support typically increases stability for the client. Stability is essential to allow the client to be functional and to disassociate the extremities or head from the trunk.³ Proximal stability increases distal control.

- **Pressure distribution:** The more pressure is distributed over a surface, the less likely the client will develop focused areas of pressure, which can lead to injury. Sitting on a bean bag provides more pressure distribution/contact than sitting on a flat metal bleacher. Various materials have features that better distribute pressure and so are often used in wheelchair seating systems. Distributing pressure can reduce client risk of developing pressure injuries.
- **Pressure relief:** Pressure distribution itself is not adequate to prevent pressure injury development.⁴ It is also essential that the pressure is relieved for periods of time. If you are sitting through a long movie, you relieve pressure by getting up out of your seat. Clients using wheelchair seating and mobility typically perform a weight shift, such as using a tilt system. Some cushions off-load or completely unweight the ischial tuberosities to prevent pressure from developing in this area.
- **Mobility:** The mobility base is designed to provide independent or dependent mobility for the client.

Wheelchair seating and mobility is *not* intended to meet therapy goals, such as stretching, strengthening, and balance. For example, if a client has tight hamstrings, the wheelchair should not intentionally place the hamstring on stretch (e.g., using a footrest hanger with a large angle). This only results in eliciting a stretch response and can actually lead to a loss of range in this muscle. Some therapists have advocated for less postural support in a wheelchair seating system in an effort to increase trunk and head control. It is unrealistic to work on trunk and head control all day, and this reduces the client's ability to be functional in his or her wheelchair. These goals are best addressed in therapy, rather than in the wheelchair itself.

Specific Interventions for Skill Dysfunction

Wheelchair Seating System Categories

Wheelchair seating systems fall into a hierarchy of categories. The decision-making process matches the client's needs and goals, which have been determined in the evaluation, to the simplest category possible. Many funding sources require that documentation address why a less costly seating system was not recommended. This isn't just about cost savings; our documentation must reflect that a hierarchy of options was considered.

Seating systems are comprised of primary support surfaces, secondary support surfaces, and secondary supports. **Primary support surfaces** include the seat, back, footplates, and arm pads of the wheelchair and seating system and are the minimal surfaces required to maintain a seating position.⁵ **Secondary support surfaces** include anterior (e.g., anterior lower leg support aka knee block), lateral (e.g., lateral trunk support), posterior (e.g., posterior head support), and medial (e.g., medial knee support) support surfaces and are designed to keep the client aligned with the primary support surfaces. **Secondary supports** include anterior (e.g., pelvic positioning belt or anterior trunk support), posterior (e.g., calf strap), or superior (e.g., foot straps) supports, which are also referred to as soft goods.

Wheelchair seating systems fall into the following general categories:

- Sling upholstery
- Captain's seat (available only on power mobility bases)
- Linear seating
- Generic contoured seating
- Aggressively contoured seating
- Molded seating

Sling upholstery is commonly found on transport and fleet wheelchairs (these mobility base categories will be discussed further in this chapter). The seating and back surfaces consist of a vinyl sling. The seat depth and back height are not adjustable. Sling upholstery does not provide adequate postural support or pressure distribution for any client, so this option is used on bases where the client is only seated for short periods of time (e.g., from the car to the doctor's office). The "hammocking" of these slings tends to promote a pelvic posterior tilt, trunk kyphosis, and lower extremity adduction and internal rotation (see Fig. 25-4).

Figure 25-4 Sling seat and back. (Courtesy of pngimg.com.)

Captain's seats are similar to the seats found in many motor vehicles. These include generic contours that fit an "average" sized person. Captain's seats are used on many scooters or consumer-level PWCs. These are comprised of foam and vinyl and may include a separate head support. This category of seating is not designed for a client who sits in his or her mobility base for long periods of time, but rather for the client who transfers to other seating (e.g., a standard chair) once arriving at his or her destination. Pressure distribution and postural support are minimal (see Fig. 25-5).

Figure 25-5 Captain's seat. (© Sunrise Medical.)

Linear seating is comprised of flat surfaces, both on the primary support surfaces and the secondary support surfaces. This category of wheelchair seating includes a wide variety of material and upholstery types. The exact dimensions of the seating system are specified to achieve the required seat width and depth, as well as back width and height. Linear seating is often used with the pediatric population because this can easily be grown. Generic contours are sometimes used to encourage the client to remain in position within the seating system. The seating system may be custom build for an individual or be comprised of “off-the-shelf” cushions and/or backs (see Fig. 25-6).

Figure 25-6 Off-the-shelf cushion. (© Sunrise Medical.)

Aggressively contoured seating systems use a variety of strategies to provide more intimate contact with the client's body for increased postural support and pressure distribution. These contours can also impede transfers and movement within the seating system, so it is imperative to determine, through evaluation, if a lesser seating category will still meet the client's needs and goals.

Molded seating systems provide the most contact with the client. This category of seating is often selected for clients who have significant orthopedic asymmetries (e.g., significant scoliosis) and require very intimate contact for postural support and pressure distribution. Once the client is placed in the desired position, his or her "shape" is captured using a variety of techniques that are unique to each manufacturer. For example, the client may be placed on top of thin plastic bags filled with small beads. Air is gradually removed from the bag, and the bag is "shaped" to the client. Once the shape is captured, the seating system is manufactured based on this information. Molded seating systems are the most difficult to modify for growth or other changes (see Fig. 25-7).

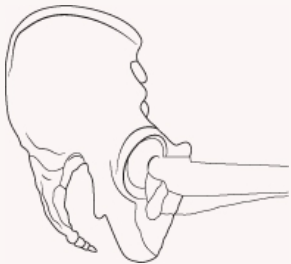

Figure 25-7 Molded seating system.

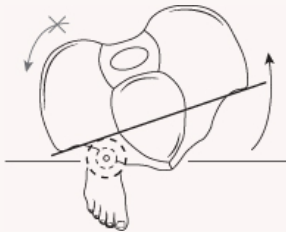

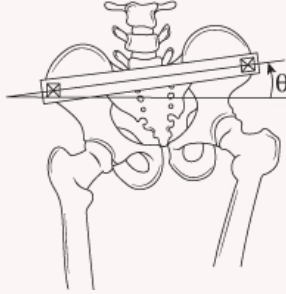

Common Positioning Challenges and Strategies

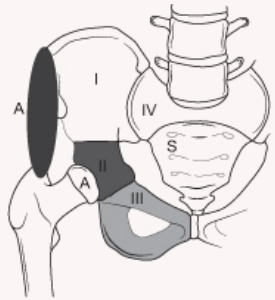

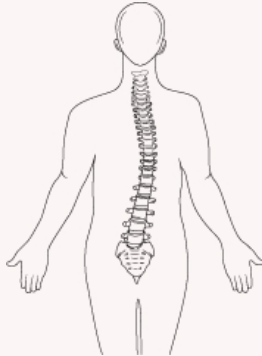

In general, wheelchair seating interventions include mitigating pressure issues, determining angles of support, using specific strategies to address common positioning challenges, and then matching needs to specific product solutions. This can be quite complex and is addressed in-depth in other resources¹ (see Table 25-1).

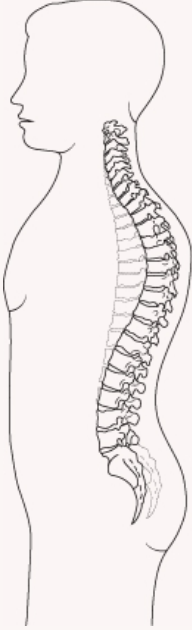

Table 25-1. Positioning Chart

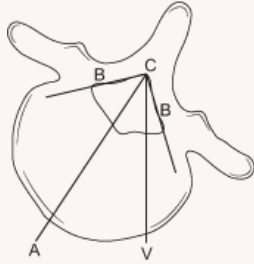

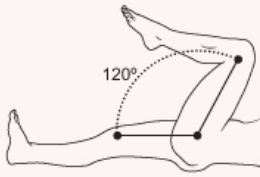

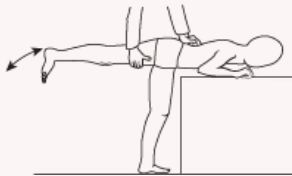

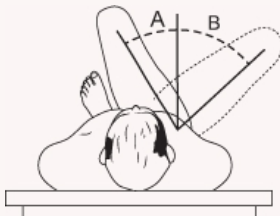

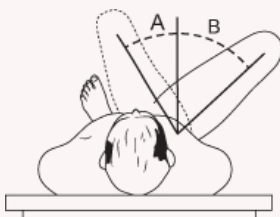

PROBLEM	POSSIBLE CAUSE	SUGGESTIONS FOR INTERVENTION	GOALS
Pelvis Posterior Pelvic Tilt <ul style="list-style-type: none"> Top of the pelvis is tipped backward. 	<ul style="list-style-type: none"> Low abdominal/trunk tone 	<ul style="list-style-type: none"> Provide support to posterior superior surface of the pelvis to block rearward movement Anteriorly sloped seat Drop the footrests to allow hip extension Biangular back, PSIS pad 	<ul style="list-style-type: none"> Neutral alignment of the pelvis Support anatomical curvatures of the spine (i.e., prevent kyphosis) Promote weight bearing on ischial tuberosities, reduce pressure risks Best alignment for biomechanical function

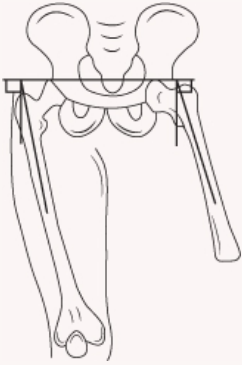

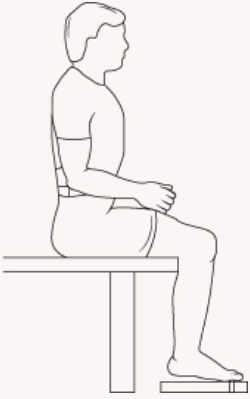

PROBLEM	POSSIBLE CAUSE	SUGGESTIONS FOR INTERVENTION	GOALS
Lower Extremity Amputation	<ul style="list-style-type: none"> • Congenital • Acquired 	Below knee <ul style="list-style-type: none"> • Increase pressure distribution along thigh as much as possible • Use calf pad or panel to support lower leg • Avoid weight bearing on distal end of leg • Above knee • Ensure pelvis is level 	<ul style="list-style-type: none"> • Distribute pressure • Comfort • Not to interfere with transfers
Upper Extremities			
Shoulder Retraction <ul style="list-style-type: none"> • Often in conjunction with elbow flexion 	<ul style="list-style-type: none"> • Increased tone in scapular adductors or retractors • Weakness of muscles in shoulder girdle with decreased ability to protract shoulder • “Fixing” pattern to extend trunk against gravity, stabilize, or as a righting response • Anxiety, startle 	<ul style="list-style-type: none"> • Build up posterior back support with wedges or increased foam behind scapular area • Adjust tilt-in space • Strap forearms (trunk must be anteriorly supported) • Provide stability elsewhere to breakup fixing pattern 	<ul style="list-style-type: none"> • Neutral alignment for function • Reduce risk of injury (arms may get caught in doorways) • Breakup fixing patterns for function • Reduce neck hyperextension often seen in conjunction with scapular retraction • Protect integrity of shoulder girdle
Elbow Extension <ul style="list-style-type: none"> • Often in conjunction with shoulder horizontal abduction 	<ul style="list-style-type: none"> • Muscle imbalance • Habitual pattern to laterally stabilize trunk • Habitual pattern to extend trunk • ATNR • Anxiety, startle • Effort or stress 	<ul style="list-style-type: none"> • Pad attached to back cushion or tray to block upper extremity laterally and/or posteriorly • Strap forearms 	<ul style="list-style-type: none"> • Neutral alignment for function • Reduce risk of injury (arms may get caught in doorways) • Minimize orthopedic risks to elbow joint • Breakup muscle tone patterns for function
Uncontrolled Movement of Upper Extremities	<ul style="list-style-type: none"> • Increased tone due to effort • Athetosis/dystonia • Anxiety 	<ul style="list-style-type: none"> • Block or strapping to decrease movement • Forearm weights • Dynamic strapping to allow some movement but decreasing extraneous movement • Distal stabilizer for independent grasp 	<ul style="list-style-type: none"> • Stabilization • Reduce anxiety • To allow dependent tasks, such as feeding, to proceed
Self-Abusive Behavior	<ul style="list-style-type: none"> • Self-abuse • Self-stimulation 	<ul style="list-style-type: none"> • Same as uncontrolled movement interventions • Provide alternate sensory input, if appropriate 	<ul style="list-style-type: none"> • To reduce risk of injury to user or others • To calm
Shoulder Subluxation or Dislocation <ul style="list-style-type: none"> • Usually in conjunction with upper extremity weakness 	<ul style="list-style-type: none"> • Decreased shoulder or upper extremity strength • Paralysis • Decreased muscle control • Decreased tone • Increased tone • Postures that continually pull humerus 	<ul style="list-style-type: none"> • Upper Extremity Support System (tray) • Widened armrests • Arm trough • Posterior or lateral elbow blocks • Forearm straps • Dual shoulder straps crossing the clavicle and acromion processes • Slings 	<ul style="list-style-type: none"> • Comfort • Enhance functional use of arm • Prevent further loss of integrity of shoulder girdle
Head			

PROBLEM	POSSIBLE CAUSE	SUGGESTIONS FOR INTERVENTION	GOALS
Decreased or No Head Control	<ul style="list-style-type: none"> • Decreased neck strength • Hyperextension of neck in compensation for poor trunk control • Forward tonal pull • Visual impairment, particularly a vertical midline shift 	<ul style="list-style-type: none"> • Posterior head support • Providing only support at the neck may elicit increased neck extension and may not provide adequate surface area support, particularly in tilt • Change pull of gravity against head by reclining or tilting seating system <p>Solutions for little or no head control:</p> <ul style="list-style-type: none"> • Collars • Forehead strap or pad • Snug lateral supports • Chin support/orthosis • Superior head support (head pod) • Refer to behavioral optometrist, if appropriate 	<ul style="list-style-type: none"> • Elongation of neck extensors (if shortened by neck hyperextension) • Capital flexion (e.g., “chin tuck”) • Visual attention to the environment, peers, and so on • Increased function • Improved swallow, feeding, breathing • Prevent subsequent orthopedic changes to neck and shoulder girdle • Prevent overstretching of neck extensors and shortening of neck flexors (if head is usually hanging down)
Lateral Neck Flexion	<ul style="list-style-type: none"> • Decreased neck strength • Muscle imbalance/tone • ATNR • Scoliosis • Visual impairment, particularly a horizontal midline shift 	<ul style="list-style-type: none"> • Address scoliosis • Headrest with lateral support • Posterior support with three-point lateral control; either side of head and along jawline that is deviated laterally • Custom molded headrest • Horizontal tilt, if severe and if pressure OK • Refer to behavioral optometrist, if appropriate 	<ul style="list-style-type: none"> • Prevent subsequent orthopedic changes to neck and shoulder girdle • Right head for vision, feeding, and respiratory status

ADLs, activities of daily living; ASIS, anterior superior iliac spine; ATNR, asymmetrical tonic neck reflex; PSIS, posterior superior iliac spine; ROM, range of motion; TLSO, thoracolumbosacral orthosis.

Pressure

The National Pressure Ulcer Advisory Panel (NPUAP) defines a **pressure injury** (formerly referred to as pressure sores or pressure ulcers) as “localized injury to the skin and/or underlying tissue usually over a bony prominence, as a result of pressure, or pressure in combination with shear and/or friction.”⁶ Pressure injuries, just like the term suggests, are caused by pressure over an area of tissue, which leads to reduced or loss of blood flow and subsequent tissue death. Many factors place the client at a higher risk of pressure injury, including heat, moisture, poor pressure distribution, lack of sensation, incontinence, poor hygiene, poor nutrition, prior pressure injuries, immobility, friction, **shear** (forces created when body tissues and seating surfaces move laterally in relation to each other), inactivity, and decreased mental status. Pressure injuries are staged with stage 1 being the least amount of damage and stage 4 being the most involved.

In general, wheelchair seating can reduce risk of pressure injury in several ways. First, seat shape and materials can be used to distribute pressure over as large an area as possible (see Table 25-2). A highly contoured shape can distribute pressure well, but can also impede independent transfers. Some cushion materials that distribute pressure well are less stable and so do not provide as much postural control. Risk of pressure injury must be weighed against function. Second, pressure relief unweights specific areas of the body for specific lengths of time. Tilt and recline can be used to relieve pressure under the buttocks while shifting weight to the posterior trunk for short periods of time (see Fig. 25-8). The client may also be able to shift his or her weight (e.g., a forward lean) within the

seating system. Third, seating and upholstery materials that reduce both heat and moisture can be used.

Figure 25-8 Tilt-in space wheelchair. (© Sunrise Medical.)

Table 25-2. Cushion Types and Examples

CLASSIFICATION	ADVANTAGES	DISADVANTAGES	EXAMPLE
Foam	Lightweight	Uneven pressure relief	T-Foam by Alimed
	Easily sized, shaped	Poor durability	
	Low cost	Hard to clean	
Gel-filled	Self-contouring	Heavy to move	Jay Cushion by Jay Medical
	Posture control	Temperature sensitive	
	Sitting balance	Leaking, maintenance	
Air-filled	Lightweight	Reduced control/balance	High or Low Profile by Roho
	Even pressure relief	Requires attention to air-pressure tending	
	Little shear	Potentially requires repair of puncture/air leaking	
Honeycomb	Lightweight	Uneven pressure relief	Supracor Stimulite Contoured
	Easy to clean	Difficult to shape	
	Low maintenance	Excessive thickness	
Custom-contoured foam	Surface area coverage	Expense	Contour U Pindot by Invacare
	Reduced shearing	Longevity with change	
	Better postural control	Reduced weight shift	
Alternating pressure systems	Scheduled relief cycle	Cost and availability	Bellows Air Support Equipment by Talley Medical
	Reduces user effort	Uneven pressure relief	
	Self-contouring	Unsteady sitting balance	

Angles of Support

Seating systems are more than support surfaces and strapping. Angles are essential to optimize biomechanics and subsequent function. Stability allows for dissociation and control of movement. An appropriate wheelchair seating system matches the required seated angles identified during the mat examination to accommodate range limitations, optimize trunk and head control, and provide stability.

The primary seated angles that must be determined include the pelvis (trunk-to-upper leg angle), the knee (upper leg-to-lower leg angle), and the ankle (lower leg-to-foot angle). It is also important to determine the overall position in space, including tilt and recline.

The trunk-to-upper leg angle is often referred to as the seat-to-back angle, referring to the angle between the seat rails and back canes of the wheelchair frame. This angle will be different from the client's actual trunk-to-upper leg angle, so it is important to measure both and clearly communicate what is required to the team. A neutral seat-to-back angle is at 90°. Let's try this for a moment. Sit up nice and tall with your trunk-to-upper thigh angle at about 90°. Although this position may make your Grandma proud, it is difficult to maintain because of the muscle strength required. For a client with low muscle tone, particularly in the trunk; muscle weakness; or paralysis, this position often cannot be achieved or maintained. For clients with abnormal muscle tone, co-contraction of the flexors and extensors in the trunk are impaired, also impacting the ability to sit at this angle. The angle is often "opened" past 90° to provide a position of rest and to recruit gravity to assist the client in maintaining upright sitting. If this angle is too open, extensor tone may increase, and the client may not be in a functional position. Often, an angle of just 100° can be adequate—again, this is determined during the mat examination.

Occasionally, a client will be placed in a closed seat-to-back angle (<90°), sometimes referred to as a "task performance position." This position has been demonstrated to improve upper extremity control in some clients and may need to be combined with a posterior tilt to prevent the client from falling forward.

The upper leg-to-lower leg angle is primarily determined by hamstring length and the front castors of the wheelchair. If the hamstrings are tight, this angle must not be open enough to place the muscles on stretch. Pulling on the hamstrings will only lead to the client sliding forward into a posterior pelvic tilt to relieve this stretch. However, if angle is closed, the footplate may interfere with the front castors, getting in the way for turning. Various product design strategies are available to address this issue.

The lower leg-to-foot angle is primarily determined by ankle range. The footplate angle can be adjusted on many wheelchair frames to accommodate limitations in plantar or dorsiflexion, as well as inversion and eversion. If a client must be positioned in plantar flexion owing to range limitations, this can affect ground and castor clearance.

The client's position in space can be changed manually by a caregiver on some MWCs or independently by the client on a PWC. This includes recline and tilt. These technologies are used for a variety of reasons. Recline opens the seat-to-back angle (see Fig. 25-9), whereas tilt moves the entire seating system posteriorly without changing the seated angles (see Fig. 25-8). Anterior and lateral tilts are also available, but posterior tilt is by far the most common.

Figure 25-9 Recline with elevating legrests on a power wheelchair. (© Sunrise Medical.)

Advantages of recline and tilt include:

- Pressure redistribution
- Postural management
- Fatigue management
- Medical management

Recline also allows for easier catheterization in the wheelchair, provides passive range of motion at the hips and knees, may relieve orthostatic hypotension, and may ease transfers. However, opening the seat-to-back angle can lead to shear forces, which can disrupt alignment and increase pressure over the sacral area. Opening this angle can also set off spasms in some clients and will pull the client out of position if range is limited at the hips or knees.

Tilt maintains the seated angles that may inhibit muscle tone and help to maintain the client's posture. Any other AT devices remain in position in relation to the client (such as a mounted SGD). Range limitations are accommodated, and tilt systems can be used with contoured and molded seating systems because there is no shear during movement to disrupt alignment with these intimate shapes.

Common Positioning Challenges

It is beyond the scope of this chapter to address specific wheelchair seating strategies in depth. It is important, however, to understand common positioning challenges and recognize when intervention is required. Please refer to Appendix 2 for further information. These positioning challenges may be flexible or fixed and are often seen in combination with one another.

Common positioning challenges seen at the pelvis include tilt, rotation, and obliquity. A posterior pelvic tilt is a very common challenge and occurs when the pelvic tips posteriorly. Let's try it. Sit on your hands for a moment. You should be able to feel two bony prominences. These are your ischial tuberosities (ITs). Let your pelvis slide forward. The ITs have now moved forward and off your hands. What is your spine doing? A posterior pelvic tilt leads to a flexed trunk or kyphosis. Sit up straight again and then tip the top of your pelvis forward. This is an anterior pelvic tilt. The ITs have now moved posteriorly. What is your spine doing? Anterior pelvic tilt leads to a hyperextended lower spine or lordosis. Sit up straight again and place one knee further forward of the other. One IT is now off of your hand. Your pelvis is now rotated, with one side forward of the other. If you then attempt to face forward, your spine will be rotated, as well. Finally, return to a neutral position and then cross one leg over the other. This creates a mild obliquity, where one side of the pelvis is higher than the other. Both ITs are still over your

hands; however, one side is creating more pressure. Think about what your spine is doing. Pelvic obliquity leads to a lateral trunk lean or scoliosis.

Common positioning challenges seen at the lower extremities include hip adduction and abduction, hip or knee flexion, hip or knee extension, and ankle and foot limitations. Any of these positions deviate from a neutral lower leg position and need to be addressed through the wheelchair seating system.

Common positioning challenges seen at the head include decreased head control, lack of any head control, and lateral flexion and rotation. Although a wide variety of head supports are available (see Figs. 25-10 and 25-11), a thorough mat examination and seating assessment is critical to identify strategies to optimize head control and position before choosing a specific head support.

Figure 25-10 Poor head position.

Figure 25-11 Corrected head position with appropriate head support.

Seating assessment:

- Identifies pressure injury risks and makes related recommendations to mitigate this risk
- Determines the appropriate angle of support surfaces and components
- Identifies specific seating challenges
- Develops intervention strategies and matches this to appropriate products. These interventions can be applied to multiple seating system categories.

Specific Populations

Wheelchair seating recommendations will vary based on specific client populations. Common populations requiring wheelchair seating include pediatrics, bariatrics, and geriatrics as well as degenerative conditions. Geriatric clients may have limited funding because of their living situation (e.g., long-term care facility) and by Medicare funding regulations. These clients often have comorbidities that impact their seating needs, such as diabetes, osteoporosis, kyphosis, and dementia. Skin and underlying tissues also become more fragile as we age, increasing pressure injury risk. All too frequently, geriatric clients do not receive optimal equipment because of seating equipment being misconstrued as a restraint.⁷ Services are often limited in this population, and competent wheelchair seating evaluation is critical.

Bariatric clients have larger body dimensions and require wheelchairs and seating systems that accommodate those dimensions as well as have higher weight limits. Seating goals are different with this population. Rather than focus on posture, the seating system primarily accommodates body size and shape, as well as protects the client from pressure injuries. Skin integrity is typically compromised. Comfort is also important because pain is common in these clients. The client's weight can fluctuate, so the seating system needs to accommodate these changes.

When working with a client who has a degenerative condition, the seating system must accommodate changing needs. Often, more postural support is required over time, and pressure risk may increase as movement decreases. The client's body shape may change because of weight loss, muscle atrophy, and/or orthopedic changes. Depending on the

specific diagnosis, these changes can occur rapidly. It is important to anticipate needs, so the recommended equipment can meet those needs for as long as possible.

Wheelchair seating can be fairly straightforward for clients who are not at risk for pressure injuries and who do not require much postural support or stability for alignment and function. However, many clients have more complex needs. It is critical to screen clients who use or need wheelchair seating to ensure that their needs are being adequately met. Screening can direct the occupational therapist to make a referral to a wheeled seating and mobility team for comprehensive evaluation.

Wheeled Mobility Categories

Wheeled mobility products are categorized in a hierarchy from simple to complex and are matched to client need and ability through a mobility assessment. The assessment determines the simplest device that will meet a client's needs and goals, and documentation generally must include why a lesser category of mobility device would not meet those needs. Much of this determination centers on efficiency, which is a combination of effort and time to move between specific locations. As discussed in the section on Mobility Screening, even if a client can move a mobility device, use must be efficient, or a higher mobility category may be indicated.

Augmented Mobility Devices

Augmented mobility devices include walking aids (canes and crutches), walkers, and gait trainers. These are not considered wheeled mobility devices; however, many people use both. This is an important category to keep in mind because this is a simpler category than dependent mobility bases and so must be addressed in documentation.

Dependent Mobility Bases

Dependent mobility bases are not designed for self-propulsion and include adaptive strollers, transport chairs, and the following MWCs: tilt-in space, reclining, and standard. Adaptive strollers are most often used with very young children who require small dimensions and specific features including the ability to face the caregiver (for careful monitoring), tilt, recline, and ease of transport (folding and lightweight) (see Fig. 25-12). Caregivers are often more willing to accept an adaptive stroller than a pediatric MWC for very young children. Strollers are also used as a backup to an MWC at times, owing to ease of use and transport.

Figure 25-12 Adaptive stroller. (© Sunrise Medical.)

Transport chairs are designed just for that—transport. The client may take short trips in this dependent mobility base, for example, from the car to the doctor’s office waiting room. The client would typically ride in a standard passenger seat in the vehicle and then transfer to a waiting room chair. Transport chairs are inexpensive but include minimal seating and offer no frame adjustments. The small wheels provide no opportunity for self-propulsion and are difficult to push over varied terrain. Standard wheelchairs (see Fig. 25-4) are similar to transport chairs and are designed for temporary use. These are commonly used in hospitals to transport a client from one location to another. These are inexpensive and fold for transport but are too heavy for self-propulsion and have very limited seating and frame adjustment options.

Tilt-in space MWCs (see Fig. 25-8) are not generally designed for self-propulsion. The few models that are designed for self-propulsion are quite heavy. Clinical indicators for use of tilt were addressed earlier in this chapter. Most tilt wheelchairs can support a wide variety of seating systems, grow, fold, and include a wide variety of frame adjustments to meet a specific client’s needs. Reclining MWCs are also not designed for self-propulsion and are not intended for long-term use. Instead, reclining wheelchairs are typically used postsurgery to provide a more open seat-to-back angle. Seating options and frame adjustments are limited. The reclining mechanism creates a high degree of shear.

Manual Mobility Bases

MWCs fall into many categories, which are primarily dictated by Medicare. The categories are in a hierarchy, from simplest to most complex. Documentation generally must indicate why a “lesser” category of MWC will not meet a client’s needs.

- **Standard wheelchair (K0001):** Dependent wheelchair (see earlier), weight over 35 lb, limited sizes, adjustments, modifications, and seating (see Fig. 25-4)
- **Standard hemi wheelchair (K0002):** Standard wheelchair with lower seat to floor height to allow for foot propulsion. *Hemi* refers to decreased control on one side of the body, such as clients who have had a stroke. This client may propel with one arm and

one foot. This is not an ideal wheelchair for any form of self-propulsion owing to weight and lack of adjustment.

- **Lightweight wheelchair (K0003):** Weighs less than 36 lb, 28 lb average. More sizes available, but little or no frame adjustments. Limited options and accessories. Appropriate for a client who cannot propel a standard wheelchair but can propel a lightweight wheelchair. Not designed for long-term use or extensive self-propelling.
- **Lightweight wheelchair (K0004):** Weighs less than 34 lb, average 26 lb. More sizes, options and accessories, minimal frame adjustments, and minimal adjustable axle plate. Appropriate for a client who cannot propel a lesser category of wheelchair owing to weight and setup and requires frame adjustments to optimize self-propulsion (see Fig. 25-13).

Figure 25-13 Lightweight wheelchair K0004. (© Sunrise Medical.)

- **Custom lightweight and ultra lightweight wheelchair (K0005):** Weighs less than 30 lb, as low as 17 to 18 lb. Greatest degree of options: size, frame adjustments, suspension, and casters. Designed to maximize self-propulsion efficiency and reduce repetitive stress injury (RSI) risk. Appropriate for a client who is self-propelling using both arms for a significant time period. Rigid and folding frame options. Folding frames are easier to transport and often have more growth. Rigid frames are lighter, more durable,⁸ and more energy efficient (see Fig. 25-14).

Figure 25-14 Ultra lightweight wheelchair. (© Sunrise Medical.)

- **Pediatric wheelchair:** Accommodates smaller dimensions, growth varies frame to frame, low seat to floor height.
- **Bariatric wheelchair:** Wider frames, higher weight limits. Heavier frames are harder to push, and the width of the wheelchair places the wheels too far from the client for self-propulsion. The frame may not fit through doorways if very wide.
- **Specialty wheelchairs:** These are generally a second wheelchair and often paid for out-of-pocket. Includes sports, all terrain, and beach wheelchairs.

Manual Wheelchairs—Power Assist

Power assist wheels replace the standard wheels on an MWC to increase the force of the client's propulsion stroke for increased distance and speed. Conversely, the power assist wheels can also help the client slow down the wheelchair when descending an incline. These are indicated for clients who do not have enough strength and endurance for longer distances or varied terrain, but do not require a PWC. Power assist wheels do add to the weight of the wheelchair and need to be charged. **Power assist add-ons** are placed under and behind the wheelchair and can be activated as needed for longer distances. The client pushes the wheels, and the power assist will continue movement of the wheelchair without additional wheel contact. The client can adjust his or her course by short pushes on either wheel as movement continues forward. Power assist can bridge the distance between MWC and PWC and minimize risk of RSI.

Power Mobility Bases

Power-operated vehicles (POVs), also known as scooters, are available in three- and four-wheel bases (see Fig. 25-15). Many clients prefer scooters because these do not look like a wheelchair. The three-wheel versions are more maneuverable, but also less stable and may tip during turns. The four-wheel versions are more stable, but have a larger turning radius. Seating options are limited. The client drives using a tiller, similar to controlling a bicycle. The seat sometimes swivels to the side to ease transfers. Scooters generally have less power, speed, and range than PWCs.

Figure 25-15 Scooter. (Courtesy of Pixabay.com.)

Power wheelchairs (PWCs) are available in consumer-level and complex rehab-level bases. Consumer-level PWCs include a standard captain's style seat, joystick access, and limited power seating. Complex rehab-level PWCs include a full range of seating, driving methods, and power seating options (see Fig. 25-16). Complex rehab-level PWCs also include advanced features, such as infrared (IR) transmission to control devices in the environment; mouse emulation to control computers, tablets, smartphones, and SGDs; and the ability to interface certain AT devices so that the PWC driving method can also be used to access these devices.

Figure 25-16 Complex rehab power wheelchair. (© Sunrise Medical.)

Manual Wheelchair Self-propulsion Considerations

If a client is able to self-propel an MWC, there are a number of factors to consider in order to maximize the client's efficiency and reduce RSI risk. Generally, the lighter the wheelchair, the more efficient it is to propel. This includes the weight of components and

seating. Placement of the rear wheel is also important. If the rear wheel is placed behind the client, the wheelchair is more stable, but the propulsion stroke is less efficient. If the rear wheel is placed too far forward, the wheelchair will be tippy rearward. Configuration must achieve a balance of stability and maneuverability that fits an individual's needs. For example, if the client performs "wheelies" to manage certain obstacles, the point of balance of the wheelchair must allow for this function. Another consideration for rear wheel placement is optimizing self-propulsion and reducing RSI risk. With an arm hanging down at the client's side, the axle should be in line with the shoulder and the tip of the middle finger.

Research has demonstrated that people using MWCs tend to use one of four propulsion patterns. This includes a semicircular, single-loop over, double-loop over, and arcing pattern. The propulsion patterns that are most efficient and less likely to lead to RSI are the semicircular or double loop.⁹ It is important to train the client in the use of this pattern during self-propulsion. Camber changes the angle of the wheels in relation to the ground. Increasing camber increases stability and maneuverability in turning. This also increases the overall width of the wheelchair base.

The front caster also impacts propulsion. Smaller casters allow tight turns and result in less interference with the footplates. However, larger casters better manage varied terrains. The client should be positioned so that most of his or her weight is over the rear wheel. If client is positioned too far forward, the front casters are "loaded," which impedes turning and increases caster wear.

The most efficient means of self-propulsion is using both hands. If the client is unable to do so, a PWC may be indicated. If the client only needs to move short distances, time is not an issue, and surfaces are level and flat, other propulsion methods may be used including one hand, one hand and one foot, or both feet. One-handed propulsion requires a special wheelchair modification. These dual rims allow full directional control with one hand. When both rims are moved forward at the same time, the wheelchair moves forward. If only one rim is moved, the wheelchair will turn in one direction. The client must have large enough hands to grip both rims and have good grip strength. A combination of one hand and one foot may be used for short distances and is often used by clients who have had a stroke. The seat to floor height must be low enough for the feet to rest on the floor, and propulsion tends to be slow and takes a lot of energy. This movement pattern may pull the pelvis forward. Propelling with both feet also requires a low wheelchair and generally pulls the pelvis forward into posterior pelvic tilt.

MWC skills are often trained in therapy and include transfers, wheelies, getting back into the wheelchair from a fall, and even maintenance. The main goal of an MWC is independent mobility, if attainable. Mobility needs to be as efficient as possible and limit RSIs. If a client is not efficient in one category of MWC, consider the next category. If the client is not efficient in any category of MWC, consider power assist, a POV, or a PWC. A seating and mobility evaluation team will have access to the equipment required to make these determinations.

Power Wheelchair Considerations

Drive Wheel Configuration

Complex rehab PWCs are available in front wheel drive (FWD), mid or center wheel drive (MWD), and rear wheel drive (RWD) configurations. Each configuration has advantages and disadvantages, which must be matched to the client's specific needs, including driving method and environment. RWD was more commonly used in the past and is known to be quite stable on a variety of terrains. RWD has the largest turning radius, and the front casters may interfere with the footplates during turns. FWD allows the client to move up close to tables and has no caster interference because these are behind the client; however, these bases tend to "fishtail" at faster speeds. MWD has the

smallest turning radius and is the most intuitive to drive (see Fig. 25-16). These MWD bases do not perform well on aggressive outdoor terrain.

Power Seating

Power seating has many clinical benefits for clients using a PWC.

- **Power tilt:** The advantages of tilt were explored earlier in this chapter under section on Angles of Support.
- **Power recline:** The advantages of recline were also explored earlier in this chapter under section on Angles of Support (see Fig. 25-9).
- **Power tilt/recline** are sometimes used in combination on a PWC. Using these technologies in combination helps to maintain the client's posture, particularly upon return to upright, while providing greater pressure relief through recline.
- **Power adjustable seat height** (see Fig. 25-17) increases seat to floor height that extends functional reach, allows the client to choose an optimal height for a specific transfer, provides access to a variety of work surface heights, expands visual field, and increases social interaction and participation.

Figure 25-17 Power adjustable seat height. (© Sunrise Medical.)

- **Power elevating legrests (ELRs)** (see Fig. 25-9) are often used in combination with a power recline system. ELRs provide passive range of motion at the knees and may improve circulation and reduce edema if used in combination with a power tilt to raise the legs above the level of the heart. ELRs can pull the pelvis forward if the client does not have adequate hamstring length.
- **Power stand** extends the hips and knees partially or fully and provides all the benefits of stationary standing. In addition, standing from a wheelchair extends functional reach, expands the client's visual field, increases social interaction and participation, and increases compliance with a standing program. The client must have adequate range of motion and have medical clearance to participate in a standing program.

Driving Methods

Most clients using a PWC drive with a joystick. However, a joystick may be too difficult for a client to use due to muscle weakness, paralysis, abnormal muscle tone, or lack of motor control. A wide variety of alternative driving methods are available to provide independent driving for these clients.

Joysticks are a proportional driving method. The driver has proportional directional control and speed control. The joystick handle can be moved in a 360° circle, resulting in 360° of wheelchair movement. The farther the joystick handle is deflected from center, the faster the wheelchair will move. If a client cannot use a standard joystick, a variety of other proportional driving methods are available, including mini proportional joysticks

that require significantly less force and travel to drive the PWC. This driving method works well for clients with muscle weakness.

🔴 Digital driving methods are nonproportional and utilize switches. Each switch represents a discreet direction: forward, left, right, and reverse. Speed is not controlled through the driving switch, but rather through other strategies. Any switch type can be used in any location the client can activate the switch for driving. A common digital driving method is the head array (see Fig. 25-18 and Videos 25-1 and 25-2). This head support contains proximity switches in the rear and side pads. Proximity switches are activated when the client's head approaches the pad. No force is required, as these are electrical switches. The materials and upholstery of the pad do not activate this switch type. If the client moves his or her head toward the rear pad, the PWC moves forward. If the client moves his or her head toward the left pad, the wheelchair turns to the left. Finally, if the client moves his or her head toward the right pad, the wheelchair turns to the right.

Figure 25-18 Head array driving method. (Permission to use from Stealth Products, iDrive Head Array.)

A wheeled seating and mobility assessment team can evaluate a client to determine the best driving method owing to level of experience as well as availability of driving methods to trial during the evaluation.

Programming

Programming optimizes drive performance and efficiency. This also enables control of other features such as speed, reverse, and power seating through the driving method. Programming is often performed by the equipment supplier, but can also be done by the clinician. An external programmer or computer is required. It is possible to program a PWC to be downright dangerous, so the programmer must be well qualified. The clinician, even if not actively programming, can observe the client's driving and direct needed changes that the supplier can then implement.

Other Features

Complex rehabilitation PWCs are just that ... complex! Each PWC manufacturer uses a unique electronics system with specific parameters. Besides driving and changing position in space through power seating, the client can take advantage of other features including:

- **Infrared (IR) transmission:** Many devices in the home environment receive IR signals, such as audiovisual equipment. The PWC can store or learn IR signals and then transmit these to the device. Another area of AT that provides this level of control is electronic aids to daily living (EADLs). IR transmission from the PWC poses a few

challenges, however. The client must be in the wheelchair—if the client is in bed, he or she will not have this control without using an EADL. Many devices that traditionally have received IR signals now receive a combination of IR and radiofrequency (RF) signals (e.g., audiovisual equipment). The PWC is not able to learn and transmit RF signals. As IR is being replaced with other technologies, many clients are using the wireless network in their home to control devices in the environment using Apps or voice-based smart home assistants (e.g., Alexa).

- **Mouse emulation:** PWCs can “pair” through Bluetooth with devices such as a computer, tablet, smartphone, or SGD. Specific capabilities vary by PWC electronics system. The device must support mouse access. For example, Apple tablets and smartphones do not currently support mouse access.
- **Interfacing:** Many clients who use a PWC, particularly those requiring alternative driving methods, also require power seating and may use other AT devices, such as an SGD. Using a separate access method to control each device or feature is not typically realistic, because of lack of motor control. Interfacing allows the PWC driving method to be used as the access method for interfaced devices as well. Interfacing has many advantages and disadvantages and requires careful assessment.

Pediatric Power Mobility

Power mobility isn’t just for adults. Research has clearly demonstrated that even very young children can use power mobility.¹⁰ Furthermore, research has shown a clear link between the onset of independent mobility and overall motor, cognitive, visual, and psychosocial development. If a child cannot efficiently use any other mobility device, power mobility should be considered.

Mobility Training

The average teenager must spend 40 to 50 hours practicing how to drive over a period of a year before even taking a driver’s test for a license. This teen typically has average motor, vision, and cognitive skills and has observed drivers his or her entire life. Many PWC candidates have impaired motor, vision, and/or cognitive skills; have never seen anyone drive a PWC before; and receive little training. Mobility training can be used to develop readiness to use a PWC as well as to optimize driving skills.

Power mobility can be complicated. Assessment is a team effort, including the CRT supplier. PWCs can provide independent mobility to clients who would otherwise be dependent or inefficient in their mobility. A variety of driving methods can provide access even to clients with complex needs.

CASE STUDY

Patient Information

Taylor is a teenage boy with the diagnosis of cerebral palsy. He was first evaluated by an occupational therapist specializing in wheelchair seating and mobility at age 8 in conjunction with his private occupational therapist, the complex rehab equipment supplier, and his speech language pathologist. At that time, Taylor attended elementary school and lived at home with his mother in an apartment.

Occupational Therapy Goal List

The goals of this assessment were to evaluate his current positioning, determine a means of independent mobility, and determine a means for Taylor to access an SGD.

Assessment Process and Results

Taylor was positioned in a linear seating system in a tilt-in space MWC (see Fig. 25-19). Taylor was seen twice for seating assessment. A number of changes were

recommended at the first appointment. At the second appointment, the team evaluated the effectiveness of these changes and made further recommendations.

Figure 25-19 Taylor in manual tilt-in space wheelchair and linear seating system and anterior vest.

Wheelchair Seating

Taylor was seated in a linear seating system comprised of an antithrust seat, biangular back, lateral thoracic pads, shoulder straps, pelvic positioning belt, shoe holders, and a standard head support. The seat-to-back angle was approximately 90°. When Taylor was seen at the first appointment at his home, he was wearing an anterior vest for trunk support and this was replaced with shoulder straps to minimize risk of asphyxiation on the vest (as this tends to move up toward the throat when tightened) and to provide better support of the upper trunk (by providing more targeted support). Taylor tended to extend into a posterior pelvic tilt, and the antithrust well was thought to be too long. An antithrust seat employs a “curb” that is positioned immediately in front of the ITs to limit forward migration. Because the “well” posterior to this curb was too long, Taylor could slide forward. This was modified to the correct length; however, Taylor continued to move into a posterior pelvic tilt when reassessed at the second appointment. The angle of the pelvic positioning belt was also changed at the first appointment from a 45° to a 60° angle, which better controls the position of the pelvis, but did not prevent Taylor’s posterior pelvic tilt. The back was too short and needed to be replaced owing to growth. The medial knee support was no longer needed after recent hip surgery (adductor release) and was so removed. A different head support that provided better support was also recommended.

After these initial changes, Taylor continued to demonstrate strong extension and move into a posterior pelvic tilt. He had been unable to tolerate his AFOs and so was not wearing shoes or contacting the footrests consistently. As his feet were not kept in contact with the footplates using ankle straps or shoe holders, he could extend his legs, increasing overall extension and making a neutral pelvis very challenging to maintain. He was on oral Baclofen to reduce muscle tone, and his resting tone was not as much of a challenge as his dynamic tone. Options to control the position of pelvis included a four-point pelvic positioning belt, subASIS bar, and anterior knee blocks. The team did not believe that adding an additional angle of pull on the pelvic positioning belt would control his pelvis (a four-point belt has two straps on either side of the pelvic to provide two angles of pull). He was so short (only 23 lb) that the team was concerned that a subASIS bar (a rigid padded anterior pelvic support) or knee blocks (pads placed anterior to the lower leg, just under the knees) would be too large or could cause harm. Taylor was also at high risk for developing spinal asymmetries due to high muscle tone.

The team recommended a molded seating system to control the position of the pelvis and reduce overall extension through intimate contact with a larger surface area of the body. This system would also reduce the risk or delay the onset of spinal asymmetries because of the intimate contact and support of the trunk. The seat could also be moved between the MWC and a future PWC.

Wheelchair Mobility

When Taylor was seen for his first appointment, he was screened for power mobility. Switches were placed on mounts behind and to either side of his head on his MWC. When Taylor activated a switch, the chair was pushed by this therapist in the corresponding direction. Taylor quickly demonstrated cause-and-effect, directional concepts, stop-and-go concepts and adequate vision to navigate a parking lot outside his home.

At the second appointment, Taylor's linear seating system was placed into a PWC base with a head array. This access method consists of a tripod head support with proximity switches embedded in each pad for directional control. At this point of the evaluation, Taylor was very frustrated and upset, but was able to drive the evaluation PWC outside the equipment supplier's office. Based on his performance, the team was confident that Taylor would be able to use a PWC with some basic mobility training.

The team decided to wait for Taylor to receive his molded seating system before recommending a PWC. The molded seating system was placed in an evaluation PWC (see Fig. 25-20), and Taylor once again drove outside the equipment supplier's office, but with better control positioned in this new seat (see Video 25-3). A PWC was recommended with a head array, power tilt, and center mount footplate with shoe holders and padded straps. A reset switch would be needed to allow Taylor, as he developed competence, to access reverse, the power tilt, speeds, and use the right directional switch to send switch signals to the SGD through interfacing. Taylor was able to access an SGD using a switch by the right side of his head, and interfacing allowed him to use a switch in this location for both right turns (PWC) and communication (SGD).

Figure 25-20 Taylor in his new seat and an evaluation power wheelchair.

The home was not accessible to a PWC, and the family did not have an accessible vehicle (they were able to transport the MWC). The PWC could be used at his school, providing Taylor independent mobility in an accessible environment. The PWC could also be transported on the accessible school bus so that Taylor could bring the chair home at times to drive outside. The family was pursuing an adaptive van.

Most Commonly Used Standardized Assessments for Mobility

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Functional Mobility Assessment (FMA)	To measure effectiveness of wheeled mobility and seating interventions	45–60 minutes	Content validity established	Test–retest reliability scores above acceptable level ¹¹	Measures change in function effectively ¹²	Completed at evaluation and specific follow-up dates
Canadian Occupational Performance Measure	To capture a client's self-perception of performance over time	20–60 minutes	Content validity established ¹³	Test–retest reliability scores above acceptable ¹³	Successful in detecting changes over time	Broad focus on occupational performance in all areas, but not wheelchair focused
Power-Mobility Indoor Driving Assessment (PIDA)	To assess the indoor mobility of persons who use power chairs or scooters and who live in institutions	60–120 minutes	Content validity established ¹⁴	Test–retest and inter-rater reliability confirmed ¹⁴	Evaluates change over time	Measures mobility status, not the level of function in other self-care activities
Power-Mobility Community Driving Assessment (PCDA)	To assess the community mobility of persons who use power chairs or scooters	60–120 minutes	Content and concurrent validity results ¹⁵	Moderate-to-good reliability ¹⁵	Evaluates change over time	Useful tool to identify where clients are able to drive safely in community settings and identify specific learning needs
Wheelchair Skills Test	Documents a set of representative wheelchair skills	30 minutes	Valid ¹⁶	Reliable ¹⁶	Can measure change in function over time	Easy and inexpensive to measure. Accompanying training program
Functioning Every day with a Wheelchair (FEW)	To measure function while in wheelchair	45–60 minutes	Good test–retest validity Content validity ¹⁷	Excellent inter-rater reliability ¹⁷	Can measure change in function over time	Self-report tools are not always accurate, though two performance-based companion tools were developed, which validated the FEW.

Chapter 26

Assistive Technology

Debra K. Lindstrom and Cara Masselink

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Explain how the model(s) of occupational therapy practice and assistive technology can be used to address occupational goals.
2. Describe the roles of other professionals on an interprofessional technology team.
3. Describe and give examples of direct and indirect access methods.
4. Explain the purpose of positioning and mounting platforms or accessories such as switches using technology for remediation.
5. Explain the purpose of positioning and mounting platforms or accessories such as switches using technology for compensation.
6. Identify the platform, hardware, software, transmission method (if applicable), and target in a clinical situation.
7. Explain questions to include in an occupational profile for device access and how that is similar/different for electronic aids to daily living (EADLs) access.
8. Identify simple through complex compensatory technology for navigation, selection, and text entry.
9. Describe barriers to successful use of commercially available smarthome technology.

CHAPTER OUTLINE

Technology as an Enabling Part of Occupational Performance
Technology Used for Remediation: Occupational-as-a-Means
Assistive Technology for Occupational Performance
Case Study

TERMINOLOGY

Access method: the process the person uses to activate a target. It can be either direct (any target can be spontaneously selected) or indirect (multiple steps needed to select and activate target).

Control method: the type of action a target requires to produce an effective response. It can be discrete (e.g., power off) or continuous (e.g., volume up).

Electronic aids to daily living (EADLs): commercial- or disability-specific products that enable a person with physical, cognitive, or psychosocial deficits to control electronics in his or her physical environment, including appliances, home theater systems, lights, doors, and more.

Latched switch activation: a switch action that requires one-switch press to turn on the target and one to turn off the target.

Macro: the programming of two or more infrared (IR) codes on one icon to activate multiple targets with one activation.

Momentary switch activation: a switch action that turns on a target for the length of time that the switch is pressed, and is most common in a 1:1 format.

Navigation: the process of browsing and isolating targets on device display.

Selection: the process of activating a target on a device display.

Switch: hardware that closes an electrical circuit when activated. It may be activated through touch, proximity, or other means.

Switch scanning: an indirect access method that groups customized selections on the device display using a scan box; the scan box is moved and a target is activated using programmed switches.

Timed switch activation: a switch action that turns a target on for a specified (often adjustable) amount of time, then turns it off automatically.

Word acceleration techniques: software-based strategies that increase typing speed and may assist with spelling, includes word completion and word prediction.

Technology as an Enabling Part of Occupational Performance

Occupational therapists use technology in two main ways. First, technology can enable the remediation of body function and performance skill deficits. Second, technology enables occupational performance, by helping the person compensate for deficits. In occupational therapy, assistive technology (AT) is often used. The formal definition of AT that is accepted by the American Occupational Therapy Association is taken from The Assistive Technology Act of 2004: “The term ‘assistive technology device’ means any item, piece of equipment, or product system, whether acquired commercially off the shelf, modified, or customized that is used to increase, maintain, or improve functional capabilities of individuals with disabilities.”¹

Technology is used to compensate for limitations in performance skills and body functions using AT or universally available technology to allow a person to complete an occupational task of his or her choice. The same technology can be used to remediate a performance skill or body function (occupation as a means) using a task requiring actions with technology positioned to strengthen or improve performance skills and body functions.

Theoretical Foundations for the Use of Technology in Occupational Therapy

In one way or another, technology (assistive or universal) has been used by occupational therapists for either occupation as an end (compensation) or occupation as a means (remediation). Technology can be included in most of the major models used in occupational therapy that incorporate the environment. The ecological models of practice that specifically address the environment lend themselves well to be guides for assessment and intervention that includes technology.² The Person-Environment-Occupation-Performance (PEOP) model³ is specifically identified AT (as well as universal technology) as being part of the environmental component of the model and follows the World Health Organization’s *International Classification of Functioning, Disability and Health* (ICF). This model specifically designates any technology needed as being part of the environmental factor of the framework.⁴

The theoretical frameworks for using technology for either remediation or compensation are the same frameworks used for other types of remediation interventions. Technology can be used to remediate

- Range of motion, strength, and endurance in the biomechanical framework
- Cognitive skills in the cognitive rehabilitation framework

Postural control, balance, gait, and coordination in the motor learning framework technology are used as compensation in the rehabilitation framework. Although technology applications can be guided through general occupational therapy practice models such as the PEOP, several models have been developed to specifically address guiding AT recommendations. Cook and Hussy⁵ introduced the Human Activity Assistive Technology (HAAT) model, Anson⁶ developed the Human Interface Assessment (HIA), and Scherer⁷ developed the Matching Persons with Technology (MPT) model. Anson’s HIA illustrates technology as the missing piece or interface between a people whose performance skills (human) are not sufficient to perform the demands of the desired occupational task. In these AT models, the technology provides the link that bridges the gap between what the person can do and what the person needs to do to complete the occupational task. Thinking about the technology as the bridge for the person can be helpful to understanding how the occupational therapist needs to conduct an assessment to determine what the person can do and then compare what the person is able to do with the demands of the task the person wants to complete.

Assessment and Clinical Considerations for Using Technology

Because an occupational therapist completes an assessment for the match between a person and technology, there is a significant amount of information that needs to be considered. The occupational therapist will use information gathered from the occupational profile (including contextual information) as well as physical, visual, cognitive, and perceptual assessments of the person’s related abilities in order to determine the best technology and positioning needed (see Fig. 26-1). For remediation, intervention often occurs primarily in the clinical setting with the goal to

improve physical, cognitive, and/or perceptual abilities. When addressing equipment that will enable occupation as an end goal, trials with equipment should occur over a period of time and be generalized to the context where the person will use them. Following the Occupational Therapy Practice Framework,⁸ the role of the occupational therapist is to consider not only the physical demands of using a device but also the psychological, social, emotional, and mental demands of using the device within the specific contexts in which the person will use the device(s). Ideally, equipment trials should occur within the environments where the person plans to use them (i.e., home and community). It is always recommended that the occupational therapist create a situation where the person can try using several devices prior to deciding which actual device will be recommended.

Figure 26-1 In the assistive technology hierarchy, technology services are based on the domain of occupational therapy.

Occupational therapists must consider potential equipment abandonment and the person's decision to stop using the device, when recommending equipment. Critically, assessing equipment abandonment requires taking a "devil's-advocate" approach and listing the reasons why the person may not use the device once he or she receives it. This list may include things such as:

- Usability: The device takes too long or is too difficult to set up or clean. It requires assist of another person to turn on or off. It is too heavy or too big to transport.
- Aesthetics: The person does not like the size, weight, color, or style of the device.
- Durability: The device is not sturdy enough for daily use. The warranty is too short and the device malfunctioned, or the tech support is poor.
- Prognosis: The person only needed a device for a short time. The recommended device did not consider improving or declining abilities.

Trialing equipment provides an opportunity for the person to get an idea of whether or not there are some predisposing factors that might contribute to him or her not wanting to use the device in the future, and to discuss these factors prior to ordering the device. If unable to trial equipment, check into the company's return policy. Whether the device is funded with public money, private money, or personal funds, it is not a good use of anyone's money to recommend the purchase of a device that will soon be discarded or no longer needed.

Interprofessional Team

Matching appropriate technology with the person requires a team approach for optimal outcomes. The person arrives at an AT evaluation with preexisting community and health care teams. The home and community team includes the person and his or her family as well as other providers such as caregivers, teachers, and support coordinators. The health care team may consist of concurrent

active therapy services that may include, but is not limited to, physical and speech therapy, physicians, and social workers. Introducing technology often requires additional professionals. The Rehabilitation and Engineering Society of North America names engineers and technologists, suppliers and manufacturers, and vocational rehabilitation personnel as crucial to the interprofessional team.⁹ In addition, orthotists and prosthetists may add value when configuring custom equipment for people with significant physical disabilities. It is the responsibility of the occupational therapist to ensure that needed team members are included whenever possible in the process to cover the scope of the person's needs. Each included profession should focus on their scope of practice and collaborate on the spheres of shared influence.

Foundational Concepts for Access and Positioning

Whether a person calls his or her friend by touching the phone icon on his or her cell phone's display and pressing "Jim," or saying, "Hey Siri, call Jim," he or she is accessing his or her phone in order to meet the goal of talking to his or her friend. The position of the phone may hinder or enable access; the position may enable control of the phone by touch or, if the phone is far away, may hinder access by voice recognition. The method a person uses to control an object and the position of the object make a significant difference to the usability of the device. An **access method** is the way the person activates a target. A target may be a variety of objects, such as an individual icon on a phone, a key (or keys) on a keyboard, and icons on a computer monitor, toys, lights, or even a door. The target should be motivating for the person and appropriate for their age and cognitive, physical, and psychosocial needs. In addition, it may be an important part of meeting an occupational goal.

People tend to access targets in the most efficient way, whether that's using touch with one finger on a remote control, or 10 fingers when touch typing on a keyboard. To match people with body function or performance skill deficits, occupational therapists need to consider the person's physical, cognitive, and psychosocial abilities as well as the device requirements. This may include considering the layout of targets on the device, the different ways that the device can be controlled (accessed), and positioning of the device.

The layout of the targets on the device must be considered throughout trials of access and positioning, including:

- The targets displayed on the desktop and placed in folders
- The frequency of use, with more frequently used targets placed within easy access
- The spacing of targets
- The color of the background and of the targets
- The labels on the targets, with text and/or symbols

Visual perception and coordination are important considerations with layout because deficits may impair the person's ability to discriminate between icons and may impact the optimal spacing of the targets. The layout should match the person's abilities and goals. Changing the organization of the targets may improve the person's ability to accurately direct select to complete a task efficiently. However, if the goal is remediation of physical abilities, placing the targets at the periphery of the person's range of motion will facilitate reaching and coordination.

Access

The occupational therapy evaluation, especially the performance analysis of physical abilities, will provide the basis for the selection of appropriate access methods to try. When trialing access methods, the occupational therapist must concurrently consider the person's specific occupational goals. An appropriate access method must allow the person to do what he or she want to do, within an appropriate time period. For example, a person may make a phone call or text by voice, but when he or she needs to review an appointment in his or her calendar, he or she may need to use a stylus to open his or her calendar, scroll, and select (see Fig. 26-2). The occupational therapists must ensure that the person is able to place both phone calls and texts, as well as use his or her calendar, if this contributes to his or her occupational competence. The occupational therapist must use clinical reasoning and careful clinical observation when selecting an access method.

Figure 26-2 Example of a Figure 8 holder for a stylus made from splinting material.

There are two main types of access: direct and indirect methods. A person is using direct access to use a device when he or she is able to spontaneously select any available target. Indirect access requires connecting steps between the person and the desired target to select or activate. In other literature, the terms direct and indirect selection are used; however, because access relates the person's connection with the occupational goal, it is used in this chapter. Indirect access is less strenuous but usually slower than direct, but often the only or most appropriate for people with more complex physical disabilities.

Direct Access

The benefits of direct access include efficiency and intuitiveness. For example, the most efficient typists usually use eight fingers and two thumbs to type, using direct access on a keyboard. Direct access requires lower cognitive demands than indirect access, but the person must possess the range of motion, endurance, dexterity, strength, and eye-hand coordination that allows for the accurate selection of various targets. Digits (fingers, toes), voice, or eye gaze may be utilized to directly activate a selected target. Direct access may require additional tools, such as a stylus or a keyguard (a raised grid that lies on top of the device's display), to improve accuracy. Using a combination of tools and body functions may be more complex, but may allow for greater occupational competence.

Voice recognition, or speech recognition, may be used for direct access. Key components that must be considered for the person to use voice recognition are:

- Does the person have a consistent, clear voice? If he or she is fraught with respiratory illnesses frequently his or her voice quality changes considerably throughout a day or week, voice recognition may not be the best access method.
- Is the person capable of learning new commands, or do he or she have a good support system that is able to devote significant time to training?
- Is the person able to problem solve? If the desired action does not occur, is the person able to identify why (after learning the software)?

More complex access is through eye gaze because it requires unique positioning of the device, minimal movement by the person, and often congruent eye movement. Also, the eye gaze device needs to be recalibrated every time the person moves away from the device and returns (as may

occur during a pressure relief, if the device is not mounted correctly on the wheelchair frame). The increased complexity of this device requires more caregiver support and technological knowledge to use on a daily basis, but can be very effective for people with minimal physical movement. Voice and eye gaze can be efficient, but the person must demonstrate appropriate cognitive and physical abilities. Also, a backup method for times when the person is fatigued or has a cold may be needed to enable occupational performance and to avoid equipment abandonment.

Options within software (which directs device function and includes computer programs, apps, and operating systems) or device settings may enable a direct access method to be used with greater accuracy. Activating a “hold” setting will decrease the sensitivity of a touchscreen and require the user to linger on a selected target, within a specified area, for a period of time before it activates. Setting a “repeat” will ignore repeated touches within the same area. An “activate on release” setting will allow the person to drag his or her hand across the monitor, activating the last target touched prior to releasing contact with the monitor. Touch modifications are not universal and may be called by different names. Touch accommodations are built into some devices and operating systems, but are in add-on software in others. If touch modifications are required, they should be trialed within the specific operating system and software that the person will be using when completing the occupational goal.

Switch Use

A **switch** may be used in direct or indirect access and for a wide variety of tasks. The switch simply acts as an electricity conductor or interrupter. When at rest, or not activated, a space exists in the connection so that the target is turned off; when activated, the electrical circuit is completed and the target turns on. The switch is considered hardware because it is a physical object (see Fig. 26-3).

Figure 26-3 Switches with various characteristics. Examples of switches top to bottom, left to right (wireless) Blue2 (AbleNet Inc.); (wired) Micro Light (AbleNet Inc.), Bite Switch (Conceptus), Pal Pad (Adaptation).

Each switch has different physical and sensory characteristics that must be matched with the user’s physical and cognitive needs. Physical characteristics of a switch include the color, size (width, length, and depth), and the force and amount of movement required for activation and deactivation. Sensory characteristics include the auditory, tactile, or visual feedback it provides the user with activation. People with poor strength may need a switch that requires a low force for activation, such as the Micro Light (AbleNet) or Pal Pad (Abilitations) switches. When movement is very limited, the Candy Corn proximity switch (AbleNet) activates with close movement without direct contact.

Switches may be wired or wireless. Wireless switches do not necessarily connect through a wireless connection; they often connect via a Bluetooth connection. Most wireless switches consist of two pieces of hardware:

- The switch

- An adaptor that plugs into the target to receive the wireless signal from the switch when activated, and communicate it to the target

However, some wireless switches are “all-in-one” and capable of connecting via Bluetooth to devices (such as the Blue2 Switch from AbleNet). Wired switches are often more consistent, have fewer pieces to lose, and are lower maintenance; but the wires must be carefully managed to ensure the wires do not get tangled. Wireless switches require charging or batteries and often need to be paired (sometimes before each use) with the device to work.

The simplest type of switch use requires no software and can be thought of in a 1:1 format, which is when one switch activates one target. A 1:1 switch format may be used with battery operated toys that are modified with switch ports for switch control, or with simple electronic aids to daily living (EADLs) devices (see section on EADL). Although very basic, a 1:1 switch setup introduces the foundational concept of “cause” and “effect.” The user learns that when he or she activates a switch (cause), something desirable happens (effect). When trialing the switch, the occupational therapist should practice (and keep data) for trial and error with various targets to determine the best switch the person is capable of using to motivate activation of the device. A 1:1 switch format represents direct access. Once the person demonstrates competency with the concept of cause and effect, the switch access can be expanded into a 1:many format. 1:many formats are considered indirect access, as the person uses one or two switches to access many targets, and may not spontaneously access any target at any time.

Indirect Access

The most common indirect access method commonly found on commercial- and disability-specific devices is switch scanning. **Switch scanning** uses software and hardware to provide a person with very limited physical movement access to multiple selections by only activating one target via a software or hardware interface (see Fig. 26-4). Software interfaces that allow switch scanning include some phones, tablets, most computer operating systems and some augmentative communication software. The software interface should display icons that, when activated, execute an action such as to speak a phrase, turn on or off the television, change a channel, open the internet, or open an app. Icons in the software can be programmed with different actions that can be configured for the person’s unique needs.

Figure 26-4 Row-column 1-switch scanning on an iPad platform.

To increase independence and participation, switch scanning can increase access to targets in a 1:many format. In a 1:many format, one-switch activation starts a scan pattern (highlighting boxes) that moves across available targets in specific, programmable, sequence. Common scan patterns include linear, row-column, column-row, and group or block scanning. A linear scan pattern moves across targets one target at a time. This is the slowest scan pattern, but appropriate for people with cognitive or visual deficits. Linear scan patterns allow for auditory scanning (when the software

speaks a description of each target that the scan box highlights). Row-column scan patterns require the following three-switch presses:

- First switch press: To move the scan box down each row of icons.
- Second switch press: Select the desired row that the desired icon is in; this starts the scan box moving across each column in the selected row.
- Third switch press: Select the desired icon when the scan box highlights it, thereby selecting the icon.

Column-row and group or block scanning are variations of the row-column pattern. When considering an appropriate scan pattern, the type of scan initiation needs to be considered. Two main types of scan initiation exist:

- Automatic: The scan box starts moving with one-switch activation and scans the targets automatically.
- Manual: The user must activate the switch to advance the scan box.

An automatic scan initiation (method used to advance the highlighting box when scanning) is less physically exerting, but requires the person to respond to a set timing. A manual scan initiation requires two unique switch actions, usually programmed on two different switches. The manual scan initiation does not require the person to respond to set timing, but requires more switch activations to navigate to desired targets. It also requires greater cognition to differentiate between the unique actions of two switches.

Switch scanning can be complicated and overwhelming at times, but for people with complex needs, it may provide opportunities for occupational participation that would be otherwise out of reach. The Scanning Wizard website (www.scanningwizard.com) allows for trials of various settings and gathers objective data with printed reports of trials. In addition, each trial provides recommendations that may contribute to more efficient switch setup. Using the Scanning Wizard on a computer requires a Universal Serial Bus (USB) switch adaptor, such as the Swifty (Origin Instruments), to connect wired or wireless switches to the computer. Scanning Wizard documents may be used as a tool to introduce people to switch scanning, to educate users on the benefits of different switches or switch setups, and to contribute to improved clinical decision-making.

Positioning and Mounts

When occupational therapists consider positioning of a device, the person's available active range of motion, strength, endurance, dexterity, coordinated movement, and most consistent voluntary isolated movement (fingers when possible) need to be considered. Additionally, the person's environment(s) and contexts, the number of caregivers, and whether or not the caregivers are consistent, make a difference. To find the ideal placement for a device or switch for the person, different angles, depths, and heights should be trialed. The person's specific accuracy and endurance (length of continuous use) with access should be measured during these trials, to be documented to justify the final equipment selection.

When evaluating for access, the position of the person and the device (which may be an augmentative communication device, tablet, keyboard, or switch) may make a significant difference in accuracy and endurance during active use. The person's vision and physical abilities need to be considered from the onset. Small changes may make a big difference for access. Ensuring that the person's trunk is securely supported may provide a solid base of support that facilitates upper extremity movement. Providing a solid surface as reference for a forearm or elbow may improve accuracy of direct access. The size of the display and the distance between the display and the person should also be considered. When using a smartphone, the person may anchor their thenar eminence on the side of the device and access all quadrants with their thumb or part of a digit. This "hold" allows people with tone or tenodesis to effectively use a touchscreen when the device is stabilized. However, for 7 inches tablets and larger, the user must hover their isolated digit over the display. If the display is on an angle perpendicular to the table (approximately 60°), the user may improve their coordination with targeting and activating icons by stabilizing their elbow on the tabletop while reaching toward the device with an isolated digit. Trials with various positions and access methods are necessary to decide which configuration will meet the person's needs best.

The end goal of positioning is to secure the device in a position that is consistent, stable, and safe, whether the person is in a bed or wheelchair. Mounts may roll (*Tobii Dynavox ConnectIT*

Floorstand, or *Daedalus* Technologies' Daessy Rolling mount) or prop the device into an upright position for tabletop use. There are two main categories of mounts that exist:

- **Flexible:** Adjustable, and allows for movement of the device into various positions without tools. This is best for lightweight devices and those that need to be used in a portrait (vertical) and landscape (horizontal) position. These are often not funded through health insurance. Examples are tabX Tablet Holder from *Modular Hose* and Hover from *AbleNet*.
- **Fixed:** Remain in a static position, requiring tool adjustment to change position. Often heavy duty and able to support heavy devices. May be funded through health insurance when recommended for a speech-generating device. An example is the Rigid and Positioner Mounts, available from *Daessy*.

Flexible mounts (adjustable cradle, arm, and clamp that allow for movement of the device into various positions without tools) are often one piece, whereas a fixed mount (a cradle or mounting plate, arm(s), and clamp that remain in a static position, unless adjusted using tools to change position) is ordered specifically for one main configuration and has multiple parts. A mounting cradle attaches to the person's seating device or bed, allowing for removal of the device and mount for transfers. The stem of the mount fits into the mounting cradle and may have more than one joint and stem to improve specific positioning. A mounting plate specific for the device allows for secure positioning of the device onto the mount. With fixed mounts, careful consideration of the person's use of the device and mount should be considered. It is important to remember that the person will be involved with multiple occupational tasks that need to be taken into account when considering a fixed mount.

Technology Used for Remediation: Occupational-as-a-Means

An occupational therapist uses technology for remediation within an intervention session, or across intervention sessions, to remediate the specific performance skills and person factors that are limiting them in completing their occupational goals. Prior to using technology for remediation, the occupational therapist must gather the same kind of assessment information as he or she would prior to any other treatment. Occupational profile information regarding the person's occupational goals and performance analysis data regarding performance skills and body functions allow the therapist to creatively challenge the physical, cognitive, or perceptual limitations. When done appropriately, the *just-right-challenge* engages the person in exerting maximum effort in order to achieve success at the game, while really addressing restoration of their deficits. The feeling of "flow"¹⁰ motivates the person. Technology for remediation may include computer software, tablet-based apps, lightboards, and virtual reality (VR), as well as accessories that include intentionally positioned switches. The occupational therapist needs to use their clinical reasoning and creativity to continually adapt and grade the activities throughout the treatment session (see Fig. 26-5).¹¹

Figure 26-5 Rakoski's therapeutic use of technology model. (From Rakoski DR, Ferguson RC. The virtual context of occupation: integrating everyday technology into everyday practice. *OT Practice*. 2013;18:CE.1–CE.8.)

General Guidelines for Therapeutic Use of Technology

Occupational therapists should consider the following when using technology in a clinical session (see Fig. 26-6):

Figure 26-6 Person with an end goal to activate garage door opener on visor in car strengthens their upper extremity by activating raised switch in computer game, an example of therapeutic use of technology.

- Remediation activity should always be connected to body function or performance deficit(s) that hinder occupational competence.
- The software program (games, activities, and apps) should relate to the person's intrinsic motivation, encouraging the person to engage in the software to achieve a feeling of “flow”¹⁰ and providing a *just-right-challenge* that balances vigilance, anxiety, and boredom.
- The occupational therapist should engage in the activity for the duration to gauge difficulty and engagement, adjusting the software or hardware maintain the “just right” challenge. The intention is not to “set someone up” to work independently.
- The occupational therapist should determine, prior to use, what objective data from the person's interaction with the technology will be gathered for documentation. The data gathered and documented should relate to the person's deficits, not engagement in technology (e.g., accuracy with movement, distance reached and repetitions, length of engagement with sustained attention, number of items recalled using short-term memory).
- When addressing cognitive, visual, or perceptual deficits, initial setup for physical access to the controls should not be challenged; the person's focus needs to be on the therapeutic part of the treatment, not the access or activation.
- When the person's deficits are physical in nature, the occupational therapist should consider:
 - Writing goals should focus on the strength, range, coordination, or endurance needed to complete the person's targeted occupational goal. The intervention techniques used would include technology for remediation; the focus of occupational therapy intervention is not the technology itself.
 - Computer program/game/app choice should reflect the person's interests (obtained in the occupational profile) in order to enable the person's intrinsic motivation. Activity choice should facilitate use of the person's hindering physical deficits when accessing the controls on the computer/device.
 - Controlling the program/game/app should be a challenging action that requires repetition of a specific physical ability that needs to be restored.¹¹

Virtual Reality

VR can be defined in two main categories: virtual environment (VE) and commercial gaming (CG).¹² VE systems are often more specialized and created with the intention of using for remediation and are considered immersive VR. CG systems may be adapted for use in occupational therapy interventions and may also be called exergaming.¹³ CG are considered nonimmersive VR. Occupational therapists are also able to address remediation of performance components using VR to influence subcortical reactions to remediate balance and postural stability following the motor control theory. Any VR system used in occupational therapy should have the capability of being personalized and customized so that the occupational therapist can grade the task to create the *just-right-challenge* as the person is engaged with the technology.¹⁴ See the Evidence table at the end of this chapter for descriptions of systematic reviews reporting on the evidence of VR interventions used for remediation.

Assistive Technology for Occupational Performance

When people experience physical, psychosocial, or cognitive limitations due to a significant congenital or acquired injury or disease, they may need adaptations or devices to allow them to fully participate in the occupations of their choice. This section focuses on adaptations that can be made

to electronics, including appliances, home theater systems, lights and doors, phones, tablets, and computers. Adapted seating and augmentative communication devices are discussed in other chapters.

Device Access

Device access is the use of a device, including phones, tablets, and computers, to enable occupational performance. Device access includes hardware, software, and a platform. Hardware is the actual, physical equipment. A keyboard, monitor, hard drive, mouse, tablet, and phone are all examples of hardware. Software directs device function and includes computer programs, apps, and operating systems. A device (hardware) and operating system (software) make up a platform. Examples of commonly used platforms include smartphone and tablet operating systems include iOS (Apple), Android (Samsung), and computer operating systems such as Chrome OS (Google Chromebook), Windows (Microsoft), and Mac OS (Apple).

Another consideration in device access is the type and number of ports that the device contains. Examples of device ports include USB, high-definition multimedia interface (HDMI), and Ethernet. Some devices have proprietary ports, for example, Apple's Thunderbolt. In order for the Thunderbolt port to work with external displays, an adapter dongle is needed. These small details are important to consider and should be noted during device trials, to ensure that the recommended equipment will work for the person as intended.

Evaluating for Device Access

Many occupations are enabled by device use, such as online banking, connecting with friends and families on social media, researching a diagnosis, and shopping for clothes or necessities; however, people vary in the way they complete these tasks. For example, online banking may be accessed through an app on a smartphone or tablet, or a website using an Internet web browser. Paying bills, a similar, connected, task may be completed through automatic withdrawal from a bank account, using bill pay services through the bank, or using standard mail. None of these options are wrong, but they all take different paths to meet the same goal.

When occupational therapists work with persons, the person's occupational goal(s) direct the device setup and targets that must be accessed. When matching a person with hardware and software, the occupational therapist should first consider the person's medical condition, including whether it is acute or chronic, temporary or permanent, or static or progressive. Interview the person or his or her caregiver about:

- **Environments:** Home, work, and other community environments
- **Previous device setup:** Determine what has worked and what has not.
- **Current device setup (if one exists):** Document the hardware, software, and platform(s) available.
- **Internet:** Wireless or wired, whether data are capped or unlimited, and if it is a public or private connection. Internet carrier and type is important to know because many software packages are direct downloads from the Internet or require Internet access to work.

The person's physical, cognitive, and psychosocial abilities should be assessed just as they are in a typical occupational therapy evaluation (see Fig. 26-1). Hand dominance, range of motion, muscle strength, fine motor and gross motor coordination, sensation, visual acuity, and visual perception should all be documented. The person's balance both seated and standing (if applicable) should be measured, as well as his or her ability to transport items safely. The person's cognitive abilities, including (but not limited to) orientation, attention, and memory, ability to follow directions, safety, sequencing, organization, and time management, should be assessed. This information will be used in the documentation to support the person's need for and ability to use recommended equipment. The assessment process for these abilities is available in other chapters of this textbook.

Evaluating for Navigation and Selection

After the occupational profile and performance analysis, occupational performance should be assessed in device trials on the person's preferred platform. Device trials need to consider two main concepts:

- **Navigation:** The way a person moves around their computer display. This is often completed through use of mouse control or touchscreen access.

- **Selection:** The primary mouse actions (left single clicks, left double clicks, right clicks, and click and drag mouse actions) and primary touchscreen actions (quick tap, double tap, and tap and hold to activate software or files) that are necessary to open and close programs, files, and select items after navigation.

The person's ability to use his or her current mouse setup or device setup (for touchscreen devices) should be observed and documented. If the person does not use a mouse, start with a standard USB wired, touchpad mouse, or touchscreen device setup at a 60° angle on a table. The goal of navigation is to match the person with the least restrictive (or most standard) equipment that enables occupational performance. This will allow the person to generalize the setup to other devices, if needed.

During the trial, the person should be asked to identify icons in all quadrants of the device screen. Vision and light reading skills can also be observed during this task. If assessing mouse use, the person should be asked to perform:

- **Primary mouse actions:** Left single clicks, left double clicks, right clicks, and click and drag mouse actions
- **Primary touchscreen actions:** Quick tap (single click), double tap (double click, not all touchscreens use this action), and tap and hold to activate software or files
- **Gestures (programmed touch or mouse sequences that execute specific actions):** Available on some mice and touchscreens. May include swipe, pinch, or Apple's 3-D Touch

Efficiency (length of time for navigation), accuracy (number of inaccurate activations), and usability (if the mouse, touchscreen, or gestures support or hinder performance) should be documented.

There are two main movements that a mouse will control. A proportional control enables mouse movement in all directions from one piece of hardware. For example, a standard USB mouse moves the pointer around the monitor in response to physical movement of the mouse. Switched control mouse pointer movement can be identified by one defined activation that produces one defined result. An activation can be made through a sip or a puff, separate switches, or various keys on the keyboard. For example, Mouse Keys (built into the major operating systems) enables four to eight keys (typically select keys on a number pad, keyboard, or the arrow keys) to control the mouse pointer in specific directions; up, down, left, and right. Mouse clicks when using Mouse Keys depend on the platform used. Proportional control is more common and intuitive than switched, but switched may provide more flexibility for physical conditions such as tone or when teaching cause and effect.

Few formal assessments for navigation and selection exist. For computers, the Compass Software for Access Assessment, available from *Koester Performance Research*, assesses different mouse skills including aiming, dragging, and selecting items from a menu. Quantitative results from the software can be gathered at evaluation (baseline) and with each trial. This information contributes to improved decision-making about final equipment and greater justification in the documentation supporting the recommended equipment.

Hardware and Software Associated with Navigation

Hardware, the physical equipment associated with navigation, includes various types of mice, styli, and touchscreens. Each piece of navigation hardware trialed should be evaluated for advantages and disadvantages in relationship to the person's physical, cognitive, and psychosocial strengths and weaknesses. Hardware will be explored starting with simple and moving to complex.

Touchscreens, wired USB mice, and touchpad mice on laptops are simple hardware that offer proportional control for navigation. Wired USB mice and touchpad mice are often included in the price of the laptop, as touchscreens are on tablets. However, people with physical disabilities may not be able to use this equipment successfully. Wired USB mice and touchpad mice require the user to connect the hardware movement to mouse pointer movement. The user must effectively initiate and terminate digit flexion and distinguish between single and double mouse clicks. To execute a click and drag action, the user must exert downward force while moving the hardware horizontally and vertically. Impaired upper extremity strength, fine motor coordination (including the ability to stabilize forearm, wrist, and digit movements), and decreased sensation are a few of the physical deficits that may impede mouse use.

Although touchscreens are more intuitive, they require a greater combination of gross motor skills, fine motor skills, and dexterity than a mouse. A stylus is hardware that may be trialed when the person is unable to isolate a digit; commercial options and patterns for self-fabrication exist (see Figure 8 holder in Fig. 26-2). Touchscreens for commercial devices are often capacitive touchscreens, meaning that they require flow of an electrical current to recognize an activation. This can be tested; if the device responds to the gentle touch of a pencil eraser, it is not a capacitive touchscreen, and virtually anything can be used as a stylus (although sharp objects are not recommended). Many disability-specific devices are not capacitive touchscreens. Conducting an Internet search for “disability, stylus” will bring up options, including those with large grips, telescoping models, and for different body parts including mouth- and head-controlled styli.

Wired USB mice and touchpad mice are considered “simple,” low complexity hardware, but more complex options exist. Medium complexity mice include commercial options such as trackballs or trackpads. Medium complexity mice require less gross motor movement than a wired mouse. Also, the wired or wireless nature of the mouse allows for increased distance between the person and the device display. This may allow the user to stabilize their forearm on the tabletop, which may improve accuracy. In all navigation trials, the same mouse actions should be assessed, and data on the person’s performance should be documented.

Hardware-only navigation methods are often described as “plug-and-play” equipment, meaning that they work when plugged into the appropriate port. Software may provide additional adjustment to facilitate competence. Simple software such as the device’s mouse or display options may enhance performance. Available mouse and display options are unique to each platform. Mouse pointer options often include pointer speed, size, and color. The size of the icon and text can be changed, and display modifications can increase the contrast of content. *Koester Performance Research* produces the Pointing Wizard, a downloadable software onto a Windows computer. This wizard assesses the person’s navigation and selection in relationship to the computer’s *Ease-of-Access* settings, recommending changes for greater efficiency and accuracy after performing simple tasks. Use of the Pointing Wizard may improve outcomes for people using a mouse with a Window’s platform.

Many medium complexity mice may pair with add-on software as well for increased functionality. For example, the TrackballWorks software, Kensington, enables the programming of trackball mouse clicks for the typical single click, double click, click and drag, and right click. Or, for increased function, the buttons may be programmed to page up and page down; scroll up and scroll down; cut, copy, or paste; and more. Pairing a Kensington trackball with TrackballWorks software may increase the efficiency of navigation for a person with disabilities.

Hardware and software options are available for smartphones, tablets, and computers that improve the accessibility of navigation using switched control. As previously stated, the operating system function Mouse Keys provides switched control. Similarly, a disability-specific product, the Hitch 2.0, *AbleNet*, enables five switches, each that execute a defined mouse pointer movement such as up, down, left, or right. For device access, switches offer access through a 1:many format, where one or two switches may enable access to an entire device display through accompanying software. The software may be built-in to the device (e.g., the iOS accessibility option “Switch Control”) or may be an add-on (e.g., E Z Keys from *Words+*). For iOS devices, the Hitch+, *AbleNet*, serves as an interface between an iOS platform and switch(es). Customizing the scanning options for the person is necessary to enable performance; these options are described comprehensively in the previous sections.

Switch Use and Indirect Access

Disability-specific navigation options offering proportional control range from joysticks to eye gaze. Ranging from simple to complex, there are joysticks, trackballs, head-controlled mice, mouth-controlled mice, and eye gaze (see Fig. 26-7) as follows:

Figure 26-7 Examples of common navigation and selection methods, from left to right and top to bottom—Roller Joystick from Traxys, Swifty USB switch adapter, Orin Instruments and Jelly Bean switch, AbleNet Inc., TrackerPro head-controlled mouse from AbleNet Inc., SlimBlade trackball, Kensington, Mouse Mover/Hitch Computer Switch Interface from Able26Net Inc., Jelly Bean and Specs Switches from AbleNet Inc., and Jouse 3 from Compusult Limited.

- **Disability-specific joysticks and trackballs:** Often exist as plug-and-play hardware or may be programmed through the person's power wheelchair joystick using a Bluetooth transmission method. Examples are the n-Abler Pro Joystick and the Optima Joystick, both from *Infogrip*.
- **Head-controlled mouse:** Uses infrared (IR) sensors in a camera-like device to track reflective dots placed on the person's head, nose, or hat brim. Examples are TrackerPro *AbleNet* and Headmouse Extreme *Origin Instruments*, both plug-and-play options.
 - Mouse pointer speed is influenced by the placement of the camera-like device, with closer positioning translating to faster pointer movement.
- **Mouth-controlled mice:** Mounted joystick moved by a person's mouth or chin. Examples are the Jouse 3, *Compusult Limited*, QuadJoy 3 from *Ergoguys*, and the Quadstick FPS from *Quadstick*.
- **Eye gaze:** Camera-like device mounted in front of computer monitor that tracks eye movement. Requires calibration prior to use. Examples are PCEye Mini from *TobiiDynavox* and the mGaze Eye Tracker from *School Health*.

Remember that the abovementioned disability-specific products discuss controlling mouse pointer movement. The person will need access to mouse clicks using hardware or software as well!

Hardware and Software Associated with Selection

In order for navigation to be meaningful to the user, the user must also have a method to select an item. **Selection** is often completed using the primary mouse actions and primary touchscreen actions discussed during device navigation trials, which are actions that are necessary to open and close programs, files, and select items after navigation. Efficient device access will enable the person to navigate to an intended icon, and select accurately after one attempt. Double clicks, differentiating between right and left clicks and performing click and drag actions, can all be difficult for a person with physical and cognitive deficits. However, performing all of these actions are often necessary for complete device access. Traditional USB or wireless mouse clicks can be modified using a range of complexity of hardware and software:

- **Switch selection for proportional mouse pointer movement:** Enables mouse clicks through an external switch to separate mouse pointer movement from mouse clicks. The mouse pointer movement is proportional through the mouse (whether hand, mouth, or eye controlled), but an external switch is plugged into an adaptor for mouse clicks. Examples of adaptors are the Swifty (*Orin Instruments*) for the computer or Tapio (*Orin Instruments*) for iOS devices. Some disability-specific devices may have built-in switch ports. A person will also need a switch and mouse for mouse pointer movement.
- **Dwell software:** A nonphysical method for selection. Dwell software is available in some operating systems, free, or may be built-in the software of a head-controlled, mouth-controlled,

or eye gaze navigation system. The software often “sits” on top of the device display, offering options in icon format for left click, double click, click and drag, or right click. Dwell software requires sequencing multiple steps for effective use:

- First, the mouse pointer or gaze must stabilize on the selected icon for a specified amount of time. The amount of time that stabilization is required is customizable.
 - The software will select the icon after the dwell time and apply the action to the next area (the size of which is also customizable) that the mouse pointer or gaze “dwells” on.
 - The timing and area must be customized to the user for effective use. Too slow or too fast, and the person will likely grow frustrated. If the selection area is too large, the action may select more than one item; however, too small and the person may not be able to stabilize the pointer or their gaze.
- **Eye blink:** Available in many eye gaze systems. Length of blink is customizable.

Selection methods should be intentionally explored because selecting icons can cause frustration if difficulties and inaccurate activations persist.

Considerations with Navigation and Selection

Hardware and software for navigation often need various trials, over a period of time, to determine the optimal setup. For people with inconsistent presentation, such as tone, difficulty maintaining optimal positioning, or cognition that changes over the period of a day or week, the recommended equipment must provide access at their best and worst times of function. People with degenerative diagnoses may need equipment that will continue to provide access as their condition progresses. With trials, change one thing at a time. Often, a “mix-and-match” approach is optimal for hardware and software. Some people may require one method for navigation and another for selection.

Text Entry

Navigating and selecting icons to move between and within software programs are necessary, but to really utilize the full capabilities of a device, the person needs a method to enter text. Text entry (entering text on a device, generally in the form of phrases and sentences) consists of entering text on a device, generally in the form of phrases and sentences. Consider navigating social media. Scrolling through newsfeeds and seeing friends and family’s faces may be fun, but without the ability to comment and socially participate by entering text, the inherent meaning in this occupation (keeping in touch with friends and family) is lost. There are many skills that are needed for successful spontaneous text entry, including composing the text (figuring out what needs to be said), grammar, and spelling (how to say it). After the text is entered, proofreading skills are necessary to ensure that the intended message is conveyed. For responsive text entry, when returning pleasantries through email, for example, reading fluency is an important secondary skill.

Evaluating for Text Entry

When assessing text entry, it is important to ask questions regarding the various components that contribute to successful text entry during the occupational profile:

- Does the person read, and how proficiently?
- How is his or her spelling ability?
- When the person uses a device now, does he or she type out his or her own content? Or, does he or she speak it to the device or another person?
- Is the content appropriate (in context, spelling, and grammar)? Does he or she identify and fix mistakes?
- Most importantly, what occupations does he or she perform that require successful text entry?
The answer to this question is important to keep in mind during the evaluation and throughout the hardware and software trials.

If the person only wants to do text entry for recreation such as researching his or her diagnosis online and keeping in touch with his or her son who lives three states away, text entry demands may be minimal. In addition, an informal message with minimal-to-moderate spelling or grammar mistakes will be understood. However, if the person uses text entry for more formal purposes, such as work as an attorney, he or she may be expected to compose pages of text in professional language with good organization and accurate spelling and grammar. Similarly, a financial advisor will likely need to enter many numbers into spreadsheets and proprietary software or websites. Each of these examples requires different skills. If the intricacies of text entry were not considered during the

device trial, the occupational therapy intervention may not actually enable the needed occupational performance.

The performance analysis for text entry remains similar to navigation and selection. Each person's available body functions, including range of motion, muscle strength, coordination, sensation, vision, and cognition, need to be assessed. The person's strengths and weaknesses can be paired with the access methods discussed in previous text because text entry methods are available that accommodate each access method. The occupational therapist should perform specific observation of current text entry, preferably using the person's preferred platform, including:

- **Positioning:** An effective seated position, with supported trunk if needed, will facilitate effective bilateral upper extremity movement. Owing to the many items (keys) that the person needs to access with text entry, positioning is a greater factor to successful direct access (any available target can be spontaneously selected) than with navigation and selection.
- **Text composition:** Spontaneous and responsive text entry, including the person's proofreading or ability to identify and fix mistakes.
- **Typing method:** Typing using a hunt-and-peck method refers to using one or two digits, on one or both hands, to activate keys. A touch typist places his or her hands on the home row, using all 10 digits to activate keys.

Consider the body functions that are needed for each type of typist. Hunt-and-peck typists require visual attention to the keyboard because they do not have consistent hand placement and often do not have the keyboard memorized. Touch typists are generally able to type without visual attention to the keyboard. Requiring visual attention to the keyboard to enter text decreases text entry speed and corrections. Some research is available regarding text entry rates (TER) for different types of access interfaces that have been used by people with physical disabilities to help the occupational therapist in the selection process.¹⁵

There are more formal assessments for text entry than for navigation and selection. Typing speed, measured in words per minute (wpm), is important to document. The Compass Software for Access Assessment from *Koester Performance Research* assesses various word and sentence text entry. Furthermore, the software will assess performance with alternative hardware and software. This allows the clinician to gather information at baseline (with the person's own setup or a standard setup used for evaluation) and then with the various recommended equipment during trials. Wpm or data from the Compass Software gathered at evaluation (baseline) and with each configuration of hardware and software during trials (after appropriate trial period) will provide important information that can be used when making final equipment recommendations.

As with navigation, the goal of text entry is to match the person with the least restrictive (or most standard) equipment that enables occupational performance. This increases the generalizability of their setup to other devices, allowing for successful text entry in various contexts and settings.

Hardware for Text Entry

The physical and sensory characteristics that apply to switches also apply to hardware for text entry. Physical characteristics of hardware for text entry include the color (and contrast), size (width, length, and depth of each key and the keyboard), and the force and movement required for activation and deactivation of a key (see Fig. 26-8). Sensory characteristics of hardware for text entry include the auditory, tactile, and/or visual aspects of the keys and keyboard, both when stationary and when in use. Assessing these characteristics of the hardware apart from the person, then observing how the different characteristics interact with the person's body function strengths and deficits during use of the hardware, will contribute to greater clinical reasoning skills as well as support the occupational therapist when justifying the selected hardware in documentation.

Figure 26-8 Common equipment for text entry including (left to right, top to bottom) compact keyboard (multiple manufacturers), on-screen keyboard (built-in to OS), Keyboard with Keyguard from Infogrip, Inc., and BigKeys keyboard, Greystone Digital.

Devices come standard with their own text entry method. The devices that most often come with hardware keyboards are Chromebooks, laptop, and desktop computers. Software keyboards that “pop up” on displays, called on-screen keyboards, exist also. Smartphones and tablets come with on-screen software keyboards, although an external physical keyboard may be a very useful accessory for some people. Both commercial- and disability-specific keyboards exist. Keyboards may be large, standard, or compact in size; may or may not have a number pad; and may connect to the device through a wired or wireless connection (with wireless often connecting to the device through Bluetooth).

Basic Trials for Text Entry

Trials for text entry should start with positioning. As with navigation and selection, the distance between the keyboard and the person may make a significant difference. Laptop keyboards may be too close to the person and encourage a kyphotic position; if this occurs, there are two options:

1. Trial an external keyboard (wired or wireless) to increase the distance between the display and the keyboard. The display then can be raised into a more appropriate position.
2. Trial a second monitor. The second display may be extended (so the person has two displays) or duplicated (the content on the primary display is copied onto the secondary display). The laptop keyboard can continue to be used for text entry, whereas the monitor can be placed at a height that encourages an upright trunk position.

When making a recommendation, consider the person’s environments and what will increase efficiency and independence. Does the person transport his or her laptop often? If so, a keyboard will likely be easier to carry and set up than a second monitor.

Devices contain accessibility settings that may change how the keyboard (physical or on-screen) accepts touch. Using built-in accessibility settings is less complex than changing hardware or adding on software and is generalizable between devices with the same platform. The accessibility options on a device are located in the device’s settings, often under an “Accessibility” or “Ease-of-Access” label. Accessibility settings for text entry that apply to physical or on-screen keyboards often include:

- **Slow Keys:** Controls the amount of time a person must press down a key before the key is activated; allows people with ataxic movements to move around various keys before they settle on the intended key.
- **Bounce Keys:** Ignores multiple (same) key presses for a set period of time after that key is pressed; is helpful for people with tremors, when the person has difficulty gauging the force of a movement or difficulty terminating fine motor movement.

- **Repeat Keys:** Ignores any key presses for a specified amount of time after the first key is pressed; may help a person who has poor coordination and difficulty controlling extraneous movements.
- **Sticky Keys:** Enables keyboard access to two-key actions for one-handed typists. Holds down the Shift, Control, Command, Alt, or Windows key with one key press and then applies that action to the next key pressed. For example, if a one-handed typist wished to type a capital “S,” he would press the “Shift,” release the “Shift,” and press “S,” which would result in typing a capital “S.”

Commonly, people will turn on the “Caps Lock” Key, press the “S,” and press “Caps Lock” again; using Sticky Keys reduces one key press. Keyboard shortcuts (such as “Control-C” for copying highlighted content) are efficient with Sticky Keys. These built-in operating systems should be trialed prior to trialing other hardware keyboards.

Another option to trial before purchasing equipment is the on-screen keyboard. On-screen keyboards are prevalent on touchscreen devices, but Chromebooks and Windows and Mac computers also have on-screen keyboards built-in to the operating system. Features of the keyboards vary between manufacturers. Some of the keyboards use **word acceleration techniques** such as word prediction and word completion. When the keyboard presents choices to complete a started word, the keyboard is using word completion. Words presented that predict the next word the person will type, before the person starts typing, is called word prediction. Many on-screen keyboards learn the person’s typing style and form the word prediction list around common words and phrases typed. When the person clicks on a presented word, the word will be inserted on the display where the cursor lies. This may increase text entry speed for the person in that fewer letters are typed, and a decreased chance of spelling error exists. However, the person must visually scan the word list while typing and be able to select the appropriate word. On-screen keyboards also maintain the person’s vision on the display. If the person must have visual attention to the keyboard when typing and has physical deficits, an on-screen keyboard is good text entry software to try. Trialing built-in software options that guide keyboard access is less complex than physical hardware or add-on keyboard software and should be explored prior to progressing to more complex equipment.

Voice recognition (also called speech recognition or voice-to-text) software enables access to text entry when people are performing other tasks, or when people need to make a quick note. Some device voice recognition software programs are more like systems. They may also manage reminders, set alarms, and make phone calls. Most all devices have a type of voice recognition software built-in to the operating system; however, they vary widely. Components of voice recognition include dictation and transcription (process of translating the person’s speech into text, completed by the software program used; may or may not need internet access, depending on the voice recognition program). The person dictates, or speaks, into a microphone. The software transcribes the entry, attempting to translate the person’s speech into text accurately. Built-in voice recognition software is perceived as simple. However, a complete activity analysis should be conducted on the person, including the physical and cognitive strengths and deficit areas, goals, and the voice recognition software. Each platform’s voice recognition software requires knowledge of unique commands to work at the highest potential, and therapists should research the capabilities of the software on the platform prior to recommending the equipment. Additional steps, such as pressing a button to activate and terminate dictation, may impede the ability of the person to use the software effectively. Additionally, built-in voice recognition software may not work without access to the Internet. If the person has a data-capped Internet service, inconsistent access to Internet, or a public hook-up, built-in voice recognition may not be the best access method for consistent text entry.

Built-in software will work most effectively within the operating system software and should be specifically tested in add-on software and on web pages. The manufacturers of add-on software and web designers may, or may not, have built-in compatibility with accessibility options.

More Complex Trials for Text Entry

A wide variety of commercial keyboards exist, and the inventory changes daily. If specific physical or sensory characteristics of a commercial keyboard appear as though it may improve function, through the in-depth analysis of the person and the hardware, the new keyboard should be trialed. The addition of typing splints (such as the Wanchik Slip-on Typing Aid from Patterson Medical) may be trialed on keyboards for text entry also, although the need to put the splint on and store it should also be considered.

Although changing the keyboard hardware may improve direct access, hardware may be difficult to generalize from one computer system to another. Hardware also requires transportation and setup

for effective use. Common disability-specific keyboards include:

- **Large key keyboards:** Keyboard with large keys, may accommodate for vision deficits or ataxic movements because of tone. However, the large size limits the stabilization of the palm or forearm, which often improves accuracy of movement. An example is BigKeys LX from BigKeys.
- **Keyboard with Keyguard:** Keyguards are made from solid material that lies on top of a keyboard, with a hole for each key, which allows the person to stabilize his or her hand on top of the keyguard and facilitates digit isolation to press the desired key. Keyguards exist for standard and large keyboards, and on-screen tablet keyboards. Keyguards for on-screen keyboards should be recommended cautiously because the orientation of the display (and sometimes the software or app) changes the keyboard location and size.

An example is the Keyboard with Keyguard/USB, available from *Infogrip*.

If built-in options and hardware do not work, add-on software may improve text entry.

Add-on software may be local (installed on the person's own computer only) or networked (accessible through any computer on a network, most often in a vocational environment). Add-on software may also need permission from an information technology (IT) department to install and may or may not work with proprietary software (such as that for accounting, or data entry). Add-on software is available to assist with text entry and pretext entry skills, such as reading, spelling, and text composition. Common add-on software that specifically addresses text entry includes simple on-screen keyboards to more complex options such as voice recognition software. In the past 5 years, add-on onscreen keyboards that support text entry using various access methods have faded out as built-in on-screen keyboards have improved. Currently, most add-on on-screen keyboards are a combination of text entry, navigation, and selection software. *E Z Keys (Words+)* is an example of a software system that provides control of text entry, navigation, and selection for access methods including single and two-switch scanning and eye gaze. The *PCEye Mini TobiiDynavox* software package includes an on-screen keyboard as well.

The *Jouse 3 (Compusult Solutions for AT)* takes another approach. Although the *Jouse 3* may be used with an on-screen keyboard, the hardware has built-in Morse code. Morse code, an indirect access method, matches each letter of the alphabet with a combination of dots and dashes. The code for each letter itself takes time to learn, but enables text entry of the full alphabet using one or two switches (in this case, the *Jouse 3* acts as the switch). Other hardware and software is available to use Morse code as a text entry method as well. Although it is rarely used, it can be quite efficient for people with significant physical limitations.

Add-on voice recognition software also exists, most notably the commercial products within the *Dragon* series (*Nuance Communications, Inc.*). Voice recognition software does two things: enables text entry by voice and assists with spelling. *Dragon* will not spell a word wrong, but may transcribe the wrong word. This has produced some amusing (although often not professional) entries that either will need outside proofreading assist before publication, or a tolerant audience. Add-on voice recognition has evolved into a powerful product. Whereas the early editions, like *Dragon Dictate*, required stilted and supremely clear speech on a Windows-only platform, the newer products span various platforms and thrive on natural speech patterns. The *Dragon* products on laptops and computers do not require Internet access to work. However, the person's voice profile is local to one machine. This means that any custom words, commands, or training that the person has done will remain on the computer that he or she trained them on.

If voice recognition is not appropriate, other add-on software programs exist that assist with spelling, grammar, and proofreading. *WordQ (ST4 Learning)* provides options for spelling with a word list that provides word prediction and word completion options. These options may be read aloud and may also be read in context of their definition to aid comprehension and word choice. The software also facilitates proofreading using options that speak aloud each letter, word, or sentence as typed. Finally, the software may act as a text-to-speech software and will read aloud highlighted words anywhere on the computer. *WordQ* is easy to use because it floats above other software programs and is customizable. *Grammarly* (available from company by the same name) is another software program that assists with syntax in writing. It can be configured for use online or off-line. As with any software though, it is necessary to customize these programs to the person's needs to reduce risk of equipment abandonment.

There are other robust programs that aid with reading digital content, called text-to-speech programs. Text-to-speech programs range greatly from simple (such as Google Chrome extension SpeakIt! and text-to-speech shortcuts built into MacOS and Adobe Reader), to moderate (Read & Write Gold, *TextHelp*), to complex (WYNN Wizard from *Access Ingenuity* and *Kurzweil Education*). These software programs should not be confused with screen readers (such as JAWS from *Freedom Scientific*), which read aloud the content on a computer screen to aid navigation for people with visual impairments. Text-to-speech readers may be used to provide a multisensory reading environment to aid reading fluency, comprehension, and attention to task, or to accommodate for physical deficits and the inability to manage a physical book. When choosing text-to-speech software, it is important to first look at the file format of the content. File formats dictate the way that digital information is stored and displayed, with common formats being .doc (Microsoft Office Word document), .pdf (Portable Document Format, which preserves the document's format), and .jpg (images). Check to ensure that the text-to-speech software can read aloud the content in that file format. Components to consider in text-to-speech software include the quality and customizability of the voices, the ability to highlight and extract text, text masking properties, and bookmarking (the ability to return to specific place in the text). The person's needs should be considered as well. Consider if the person is using the software for leisurely reading or for vocational purposes.

Electronic Aids to Daily Living

Electronic aids to daily living (EADLs) enable a person with physical, cognitive, or psychosocial deficits to control electronics in his or her physical environment, including appliances, home theater systems, lights, doors, and more. EADLs encompass a wide category of commercial- and disability-specific products, with the commercial products advancing in capability and accessibility over the past few years. EADLs are exciting and captivating, and they appear deceptively simply. However, advancing technology has contributed to this being an increasingly complex category that now extends to smarthome technology, smart televisions, DVD players and smart DVD players, home theater systems, and smarthome theater systems, as well as smart speakers, smart hubs, and more. The addition of wireless features into today's technology requires that occupational therapists must examine each person's own technology carefully and conduct in-depth research before cautiously recommending additional technology for accessibility. Although no-tech options exist that support the performance of occupations in the person's own environment, this section is focused on the occupations that involve technology. Several research studies have focused on people's perceptions and subjective meanings of how EADL have affected people's lives with limited mobility.^{16,17}

Evaluating for EADL Equipment

The basic technology and routines of the person are essential to evaluate when conducting the occupational profile.

1. Identify the person's main occupation-based goals and priorities.
2. Document routines for the occupation-based goals. Include the frequency of engagement, the process used, and the specific equipment. For example, if a person mentions watching television. Ask if the person likes to watch shows or movies and ask if he or she uses a television, Netflix, Amazon Prime, or another method. If the person uses a television, ask about cable or satellite services and ask if he or she uses a digital video recorder (DVR). Ask about smart speakers such as Amazon Alexa, and smarthubs such as the Samsung SmartThings Smart home Hub. When exploring the person's equipment, take note of the brand and product name, whether or not it has smart features, why and when the person uses it (e.g., at night to watch evening shows, during the day watching Netflix), and how the person accesses it (e.g., pushes buttons on an IR remote control).

Performance analysis for EADLs begins with an assessment of the person's available body functions, including range of motion, muscle strength, coordination, sensation, vision, and cognition. The person's physical, cognitive, and psychosocial strengths and weaknesses should be considered alongside the previously discussed access methods, with potential access methods noted. During observation of occupational performance, the occupational therapist should observe the person using his or her current equipment.

A few important concepts are necessary to understand when describing EADLs (see Fig. 26-9). First, appliances and electronics may use discrete or continuous **control methods**:

Figure 26-9 Simple and Complex EADL including the access method and transmission method to the device; transmission method from device to target for both. EADL, electronic aids to daily living.

- **Discrete control method:** Executes two actions, for example, power on and off an appliance or open and close blinds; or selects one target, such as a channel for the television or a prestored radio station
- **Continuous control method:** Allows for increasing flexibility in the outcome. This is necessary for adjusting volume on a television or radio or when raising and lowering the head of a bed.

Transmission methods are also important. Transmission methods are the ways that an EADL device communicates with a target (in this example, the television). There are four main transmission methods:

- **Direct connection:** A wired connection exists between the EADL device and the target. Direct connections may increase the consistency of the equipment working, but they require that the person to remain in a limited area while the device is in use (e.g., landline phone, a bed control, some external speakers).¹⁸
- **House wiring:** Enables signals to be carried from one room to another within the wiring built into houses. Modules that plug into the wall receive information from a remote control and activate or deactivate simple appliances such as radios, fans, or lamps. An example is an X10 device, seen in many older devices.
- **Infrared (IR):** Uses invisible light to transmit unique codes to the target. IR requires an open “line of sight” between the remote control and the target in order for the target to receive the light, which limits IR to a single room. IR allows for discrete or continuous control through unique IR commands that exist for each brand, product, and action. Most televisions controlled by a remote control use an IR transmission.
- **Radio frequency (RF):** Uses RF waves to communicate with the target object (e.g., most garage doors). The receiver for the garage door is inside of the garage, out of the “line of sight.”

However, when activated, the RF waves pass through the closed garage door to activate the opener, which opens the door. RF has expanded with advancing technology and now contains subcategories as follows:

- **Bluetooth** uses low-power radio waves to connect items within close proximity, often a maximum of 30 feet, or shorter depending on building infrastructure and interference. EADL devices may use Bluetooth, but Bluetooth can be a less reliable transmission method than wireless. However, devices such as smart door locks and light bulbs may use Bluetooth.
- **Wi-Fi** uses the existing wireless Internet network to connect objects. Apps on smartphones that control a smart television, cable, or satellite box often use Wi-Fi.
- **Wireless** is similar to Wi-Fi but uses its own (not the existing) wireless network. Examples are Z-Wave, ZigBee, and Thread.

Both IR and RF are the most common transmission methods. It is important to research prior to recommending an accessory or device that uses IR whether or not the device has the necessary codes built-in that will allow it to transmit the necessary actions to the target. If not, the device needs to be capable of “learning” the codes. This can be complicated and referencing the instruction manual or calling the manufacturer are sometimes needed. Wi-Fi and wireless transmission methods are quickly rising in popularity. They work with a variety of equipment and provide great opportunities for improved independence and participation. However, be cautious of the quality of network when recommending equipment. Private Internet with no data cap is ideal, but not often the case (especially in rural areas). The speed of the Internet service makes a difference to products working efficiently and whether or not the service can sustain numerous products working simultaneously. Public Wi-Fi networks are not considered stable or secure, and devices on these networks may be kicked off often, requiring reconnection to work. In an area with data caps or public Internet access, clinicians should consider products that do not use wireless transmission methods (non-Smart devices).

Assessing for EADLs requires consideration of the person’s environment as well. Responsible occupational therapists should observe the physical layout, family/caregiver support, and other assistive devices when evaluating for EADL access and consider safety when providing equipment recommendations.

Platforms for EADLs

Remember that a platform is an operating system. Examples of platforms commonly used for EADL devices include tablet operating systems such as iOS (Apple) and Android, and computer operating systems such as Windows (Microsoft) and Macintosh (Apple). Very simple EADL devices that control only one or two items, such as the Powerlink 4 (*AbleNet Inc.*) and LinkSwitch (*Adaptivation*), do not have platforms. They act as the interface between the wired device and the switch interface. Simple EADLs may use operating systems though, such as the Phillips Hue products and Belkin WeMo products. The Phillips Hue iOS or Android app, when installed on the appropriate model phone, can act as an interface between the human and the target.

EADL platforms are often commercial, but the EADL software and accompanying accessories may be produced commercially for the entire population or specifically for people with disabilities. If the product was produced commercially, pay attention to the brand names. For example, Samsung products tend to work best with Google platforms and may not be available or compatible with Apple accessories. For example, it is a long process for an Amazon Prime movie app to become available on Microsoft Xbox. Typically, people have brand preferences that don’t significantly impact recommended equipment, but brand compatibility should be considered during the selection process.

Disability-specific products tend to be more stable because they are generally not as affected by updates. This allows the person to use the device consistently to control his or her environment (once it is set up and the person is trained), with less interruptions or changes from software updates. If interruptions do occur, the product manufacturers often understand the context of disability better than a commercial manufacturer and may provide better customer support. Disability-specific products often emphasize accessibility and accommodate a variety of access methods; and the display interfaces are often simpler or can be adjusted for the user. However, this flexibility and customizability comes at a price. The research and development that contributes to a disability-specific device is significant, and when combined with the potential smaller population, increases the price tag of the device and accessories. Technology compatible with disability-specific devices may also fall behind the commercial products because the manufacturers often respond to

the commercial market. Therefore, if a person has a new smart television and the latest home theater system, there may be difficulty controlling it through a disability-specific EADL device. Researches, through instruction manuals and manufacturer support, are available resources to help guide product choice.

Customizing EADL Devices

People with disabilities often need devices customized to improve efficiency with accessing electronics. Learning IR codes, and the ability of the EADL device to put one or more IR codes together to form a **macro**, may be an important feature. Making macros can improve the efficiency of the person navigating to specific television channels, by enabling the device to emit IR codes for two- or three-digit channel numbers with one selection. The EADL device display is also important to consider. Icons supporting text and/or symbols may be important so that the device doesn't appear too young or too old for the user. Icon placement should be intuitive. For example, an icon for "TV Power" in the upper left-hand corner, and arrow buttons in a compass format, makes sense to many people. The most frequently used icons should be placed in an area that the person is able to access easily. If the person uses direct access with his or her right pointer finger, the icons may be best placed in the right lower quadrant. If he or she using switch scanning, perhaps the upper left quadrant, where the scanning box initiates the scan pattern. Intuitive icon placement results in greater efficiency and endurance with EADL device use.

Single-purpose EADLs

EADL devices that control one object, such as a bed, door, fan, lights, blinds, or remote door lock, are considered single-purpose EADLs. Many single-purpose EADLs control the power of the target. A simple test can be used to determine whether the target (e.g., plug-in fan or light, or even radio) can be used for power control. Plug the target into a powered electrical outlet and turn it on into the desired configuration (e.g., specific radio station). Keeping the target on, unplug the target, and then plug it back in. If the target, once plugged back in, returns automatically to the desired configuration, it will work with a simple EADL device. However, if it remains off (as some digital devices do), it will not.

Commercial products for EADLs are often wireless in nature and require a hardware component and software for control. For example, the Wemo Insight Smart Plug (*Belkin*) can be used to control a plug-in fan or desk lamp. The fan or desk lamp plugs into the Smart Plug, which plugs into the wall. The person must have a smartphone or tablet, download the WeMo app, and pair the Smart Plug, which enables control of the light or fan through the phone display. The phone could be controlled with a variety of access methods, making the phone the person's EADL device. However, as it is not a native Apple or Android app, the access method should be trialed directly with the app to make sure it will work. Other commercial products exist that may work with various access methods to provide occupational competence. For example, bed control may be accomplished through with a smart bed (see the Sleep Number products). Door management requires consideration of the door itself and the lock, both onsite and remote. Door openers are often disability specific (such as *Open Sesame*) and are managed through wired transmission (using a wall plate) or RF (using a door opener). However, the locking mechanism needs to unlock or lock for safety and security. A smart lock (such as the August Smart Lock Pro from *August Home Secure Access*) may be useful, which enables lock control through an app. Additionally, onsite or remote surveillance may be accomplished through the Ring or other similar commercially available products. Mixing and matching single-purpose products may be necessary for occupational performance.

Disability-specific options for single-purpose EADLs are often wired or RF, such as in the door management example in the previous paragraph. The Powerlink 4 (*AbleNet*) or LinkSwitch (*Adaptivation*) are two examples of devices that work with wired targets, such as plug-in lamps and appliances, to offer momentary, timed, or latched control, through switch access (see Fig. 26-10). Momentary and timed switch activations only require one-switch activation for an action to occur, but vary in the length of time that they activate the target. A **momentary switch activation** activates the target for the length of time that the switch is pressed and is most common in a 1:1 format. A **timed switch activation** will maintain the connection for a specified (often adjustable) amount of time, then turn off automatically. The **latched switch activation** requires two-switch presses, one to start the target activation and another to stop the action.

Figure 26-10 Powerlink 4 and Jelly Bean switch (AbleNet Inc.) setup with commercial fan.

This section provided examples of only a few single-purpose EADLs. This area changes quickly with advancing technology, so specific examples provided are few. When matching people with single-purpose EADLs, research is required. See the content in Considerations with Recommending Equipment for more information on choosing quality products.

Multi-purpose EADLs

Multi-purpose EADL devices enable access to more than one target and often communicate in more than one transmission method. Commercial products that work as multi-purpose EADLs are often home automation in nature. For example, SmartHome accessories can manage plug-in appliances such as lights and fans, thermostat, and peripherals such as home theater systems and surveillance, all of which can be managed by their software or an app, after initial setup. Addition of other technology, such as the Amazon Echo Dot, enables voice control of these products. Similarly, the Wemo (*Belkin*) products and *August Smart Lock Pro* can be managed through the HomeKit (Apple) app. In this situation, the HomeKit app on an iOS device serves as the person's EADL. Commercial EADLs are created with the goal of home automation for the user, so compatibility with access methods must be verified.

Disability-specific multi-purpose EADLs range from moderately complex to significantly complex. Midlevel disability-specific devices have fewer customizable features (they may not support changes to the display, such as names or placement of the icons), control less products, but still enable access through multiple features and are less costly (\$299 through around \$5,000) than significantly complex disability-specific EADLs. Examples of moderately complex EADLs include the EyeR (*TobiiDynavox*), Relax, Primo!, and HouseMate for iOS (each from *AbleNet*), and PocketMate (Saje Technology). All of the devices come on their own proprietary platform, except the EyeR (Fig. 26-11) and HouseMate. The EyeR comes with software and hardware (USB IR emitter) that turn a tablet or computer into an IR EADL, and the HouseMate turns an iOS device into an IR remote control.

Figure 26-11 EyeR (TobiiDynavox) USB dongle with infrared emitter pair with the Virtual Remote computer software to create a computer-based electronic aids to daily living (EADL).

Significantly complex disability-specific EADLs may be stand-alone or built into an Augmentative Communication device. EADLs may cost from \$7,000 through \$15,000, depending on the device and access method used (eye gaze augmentative communication systems are expensive). These powerful stand-alone EADLs are often built on a computer platform. For example, the REACH (available through *AbleNet*, *Break Boundaries*) as well as the *autonoME* (*Accessibility Services, Inc.*) utilize Windows tablets. Various accessories can be purchased to enable independence with environmental control, including light switches (that work using an X-10 transmission method), door openers, and blinds. These accessories should be customized to meet the person's goals. Complex disability-specific EADL device displays should be configured for each individual person.

Augmentative Communication devices may have built-in EADL capabilities as well. Devices including the I-12+ and I-15+ (*TobiiDynavox*) (see Fig. 26-11), *Accent* devices (*Prentke Romich*), and *Eyegaze Edge* (*LC Technologies, Inc.*) have EADL features built-in to the software program, but may require accessories or upgrades to utilize the IR capabilities.

Each complex EADL should be configured for the person in two main ways. First, the aesthetics of icon and page, including the symbols and text on each icon and background of the software set, can be changed to reflect the person's wants and needs. For example, if the person has figure ground issues, a plain background can be set, using contrasting colors to the icons. If the person often watches NBC, an icon can be added or changed to state "NBC" and even a picture of the NBC symbol. Intentional software configuration is important. For example, creating or programming at least two TV pages is helpful. The first for TV controls (such as power, guide, menu, info, arrow, and ok/select buttons), and the second with icons programmed with macros that give the person quick access to often watched TV channels. Thinking further, it is often helpful to have volume up/down and/or mute on both pages, giving quick access to the volume in case someone comes into the room to talk to the person, or the phone rings. These purposeful design principles lead to the second modification that each icon must be programmed with meaningful actions. Each icon holds a set of hidden actions. These actions may be navigation actions, such as "go back to previous page" or "go back to home page" or may be IR commands such as "Power on" or "Volume up." Programming the numbers into the IR database in the device allows for multiple numbers to be programmed on one icon, to be sent out as a macro. These IR commands may be built-in the device or trained if the device accepts IR learning (which most significantly complex EADL devices will). Considering how the person controls the environment, his or her familiarity with technology, and routines when watching movies and shows should guide the way that the device is set up.

Funding for EADL

Health care insurance is not usually an option for AT devices that are not considered a medical necessity. In some situations, EADL may be funded by a health care insurance if the system is built into the AAC system at the time it is requested. In certain circumstances, Worker Compensation insurance, Vocational Rehabilitation programs, the Veterans Administration, or no-fault insurance may be able to fund some AT devices if the equipment is specifically needed for employment.

When an occupational therapist is requesting an employer, family, organization, or foundation to consider funding AT, some or all of the following information may be helpful (depending on to whom you are making the request):

- **Client information:** Name, birthdate, physician name, date of evaluation, and diagnosis
- **Purpose of evaluation:** Client's goals
- **Background information:** Including prior medical history, therapy experience, experience with AT, description of the person's routines and environments, current technology pertinent to purpose of evaluation (e.g., computer, electronics in home environment)
- **Performance analysis:** The person's physical, cognitive, and perceptual abilities
- **AT trials:** Description of the person's various equipment trials (most funding sources require a minimum of three)
- **Recommendations:** Numerical list of specific recommended equipment, including a short statement describing the purpose of the equipment.

CASE STUDY

Patient Information

James is a 57-year-old, right-handed male. He presents with a diagnosis of brainstem stroke, locked-in syndrome, with an onset 8 weeks ago. Prior medical history included hypertension; prior surgical history included G-tube placement and tracheostomy. Prior to the stroke, James worked as an architect and owned his own company. He was very active and enjoyed playing golf and cards with his friends.

Directly after the cerebrovascular accident (CVA), James was admitted to intensive care unit (ICU). After medical stabilization, James was transferred to inpatient rehabilitation and then was discharged to home 5 weeks later. Inpatient rehabilitation focused on training of his wife and daughter for care and attempting to facilitate volitional movement.

During the evaluation, James demonstrated the ability to answer yes/no questions with eye blink. Owing to significant physical and psychosocial limitations that were expected to persist over time, AT, specifically a communication device, was trialed with both eye gaze and switch scanning access methods. James demonstrated switch scanning with row-column intact with Micro Light switch with left thumb when his hand was in a fist position, ulnar side lying on the bed; but he required moderate assistance to maintain thumb position against gravity. James trialed eye gaze for increased independence and efficiency with communication; however, the inpatient therapist documented inaccurate selections 8/10 trials and difficulty calibrating the James' eyes to the eye gaze unit. At discharge, James' only active movement was right thumb adduction in a gravity eliminated plane. He went home with a loaner Micro Light switch and beeper device, a switch-enabled device that sounded upon activation.

Assessment Process and Results

James was transferred home where he lived with his wife and grown daughter who are his primary caregivers. Home health occupational therapy assessment included an occupational profile, which focused on James' interests, recovery, adaptive equipment, and profile of existing technology within the home. Precautions included allergy to penicillin and to monitor pulse oxygen (maintain above 92%).

Upon arrival, James is in a front room of the home, laying in a hospital bed with the head of bed raised at about 30°. The occupational therapist notes a tilt-in-space manual wheelchair in the hallway. There is a bathroom off to the left of the room, and an LG television setup across from James. There is a Comcast cable box below the television. James' daughter verifies that they have Comcast cable and wireless Internet throughout the home. James mainly watches cable television shows and does not record shows on the DVR. Currently, James and his daughter and wife are communicating using the Micro Light switch and the beeper device, but they report that they are having trouble setting the switch up for independent use; they often resort to yes/no questions using one blink for "no" and two for "yes." However, James' cannot reach his wife and daughter with urgent needs if they leave the room, and this makes them uneasy. James' wife and daughter are great advocates for him to engage in any activities, and they note that he enjoys watching sports, especially golf and poker on television.

The performance analysis assessed cognition and physical motor skills. James was able to answer yes/no questions accurately about demographic and historical information. He followed commands for the visual motor screen, where the occupational therapist noted his left eye tracking slower than his right eye in the horizontal plane. Active range of motion of bilateral upper extremities demonstrated right thumb adduction 0° to 20° with forearm pronated and resting on the bed; no other active movement was noted other than eye blinks. Passive range of motion of bilateral upper extremities was intact in all joints and planes, and sensation was intact for light touch except on his left upper extremity below elbow in the ulnar nerve innervation. James was dependent for transfers using a Hoyer lift and dependent for all basic activities of daily living. James' receives all nutrition through G-tube. James actively engaged visually with the therapist for 15 minutes of the session before falling asleep. The family verified that this was typical for James' activity tolerance at this time.

Occupational Therapy Problem List

- James is unable to spontaneously call caregivers for help because of an inability to speak.
- James is unable to participate with basic ADLs because of dependent functional mobility and lack of active upper extremity control.
- James is unable to control the television and cable by standard remote control because of only active movement in right thumb 0° to 20°.
- James attends to task for 15 minutes prior to sleeping because of difficulty regulating level of arousal.

Occupational Therapy Goal List

- James will activate Micro Light switch modified independence × 5 to call caregiver in other room in one treatment session in 2 weeks.
- James will create and speak one five-word phrase modified independence with a maximum of one inaccurate activation per word on speech-generating device utilizing appropriate access method in 5 minutes in 4 weeks.
- James will control television, demonstrating power on, review the guide, and change the channel × 2 modified independence in 4 weeks.
- James will attend to therapy task for 30 minutes without falling asleep in 4 weeks.

Intervention

James was treated in occupational therapy 1 to 2 times a week. James was seen first with the occupational therapist to explore access methods. The occupational therapist found that resting James' hand on a towel in a fist position, palm down, allowed James to abduct and adduct his thumb independently in a gravity eliminated position. James was then able to activate the Micro Light independently, when placing the Micro Light switch in between his pointer finger and thumb. Once James demonstrated competence with this task in the session, his family was trained in the setup and use of the switch outside occupational therapy for caregiver call. They reported that this setup worked well and provided them with a level of peace, knowing that James could activate the switch to beep if he needed them.

Once James was proficient with the single switch, the occupational therapist and speech therapist met to trial speech-generating devices. The Tobii I12 (TobiiDynavox) and Eyegaze Edge (LC Technologies) were trialed with James. Eyegaze continued to be difficult to configure with James' incongruent eye movement, but James' was able to follow directions for switch scanning on the Tobii I12. First, the occupational therapist trialed the Scanning Wizard with James' to introduce him to row-column scanning and to identify optimal switch settings to initially program into the Tobii I12. Second, the occupational therapist duplicated the switch settings, lowering the time slightly to accommodate for James' learning the software, and trialed the Tobii I12 with single switch scanning, with the Micro Light placed at James' right thumb. James demonstrated typing three words at three to four letters each, with five inaccurate selections on his first trial. Over the next 2 weeks, James improved to typing 10-word novel phrases using word prediction and completion with one to two inaccurate selections overall in 3 to 4 minutes. The Tobii I12 was identified, in collaboration with James, his wife and daughter, and the speech therapist, to be the optimal device for his communication needs. The Daessy Rolling Mount was recommended as well, to enable secure and consistent positioning of the Tobii I12 when James was in bed or up in his wheelchair.

The television and cable IR commands were programmed into the EADL pages. Custom pages were made to improve access. First, the power, volume up and down, mute, guide, up, down, right, left, ok, and exit were programmed. Second, 10 of James' most frequently watched stations were programmed. James demonstrated accessing the commands appropriately to watch television with only two inaccurate selections upon initial trial, progressing to zero inaccurate selections.

Given James' proficiency with the Micro Light switch and James' daughter and wife's advocacy for his participation, the occupational therapist inquired about James' recommended wheelchair. A tilt-in-space wheelchair was in process for James'; however, if the family and James agreed, the occupational therapist felt that James might be able to operate a power wheelchair with single switch scanning. James and the family agreed to trial a power wheelchair.

Over time, James progressed significantly. James trialed power wheelchairs and was able to drive through single switch scanning. The wheelchair was recommended with single switch scanning, but also a joystick, to accommodate for progression. When received, James demonstrated an ability to drive the wheelchair using the joystick with a t-handle.

James' increased hand movement related to other functional tasks as well. James' returned to AT to trial computer access 1 year later. James' trialed wheelchair access using his joystick to control the mouse pointer, but preferred to use the computer from bed level. James trialed the laptop touchpad, touchscreen (as his right upper extremity gross and fine motor had improved) with right powered arm support, and a trackball mouse. When lying in bed, James' preferred method for navigation and selection was the trackball mouse using preprogrammed mouse and page up and down clicks with right his hand suspended over the mouse (his wrist propped on a towel).

Best Evidence for Assistive Technology Used in Occupational Therapy

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Systematic review and meta-analysis of randomized controlled trial (RCT) and quasi-randomized clinical trials of interactive gaming and/or interactive engagement with hardware or software ¹³	Data pooled from 11 studies; 7 outcomes of interest	466 participants with diagnosis (dx) of multiple sclerosis (MS) (65.8% female)	Most 1:1 with physical therapy (PT); two studies were home-based; one telerehabilitation. Frequency: 1–5×/week. intensity: 20–60 minutes duration: 3–12 weeks; 10–48 sessions.	Systematic review and meta-analysis; Level I evidence; quality assessment with PEDro scale; Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines	VR training is at least as effective as convention training and more effective than no intervention for balance and gait for people with MS.	Postural control improvement when compared to no intervention: standardized mean difference (SMD) = -0.64; 95% confidence interval (CI) = -1.05 to 0.07; $p = 0.002$. No significant overall effect compared with conventional training: SMD = -0.04; 95% CI = -0.70, 0.62; $p = 0.90$.
Systematic review of RCT using VR for people with stroke dx ¹⁹	All 54 trials/studies had intervention protocol and follow-up, focus on upper limbs and or lower limbs and/or balance.	1,811 participants; 14 trials body structure, 20 body functions, 17 activity, 8 participation; personal and one environmental factor	Upper extremity (UE) (arm, hand) ranged from 3 to 7 times/week for 4–6 weeks, mean dose of 17.6 hours. For self-care, an average intervention time of 13 hours. Household tasks ranged from 10 to 15 hours.	Systematic review of RCT with PRISMA; Level I evidence	Positive results were seen for VR for UE (arm, hand) with immersive, semi-immersive, and nonimmersive VR in people with subacute and chronic stroke. For self-care, 5 of the 12 trials found positive effects, whereas 7 found no difference between control and experimental groups.	Statistical results not reported in article.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Meta-analysis of 33 RCT studies comparing VR rehabilitation for upper limb function poststroke with conventional therapy (CT) ¹²	VR (user-computer interface) (real-time simulation with patient interaction) and CT addressing upper limb motor, cognitive or ADL; CT = PT or occupational therapy (OT)	971 total participants, 492 VR (mean [M] = 14.9, standard deviation [SD] = 10.9/study); 479 participants received CT; average age 60; time poststroke varied 1.9–427.8 weeks	Mean doses in minutes; intensity: overall: 685 daily; 42 minutes weekly; 153.9 frequency/week 3 sessions (range = 1–5). Median duration: 18 sessions (range 4–36 sessions)	Systematic review and meta-analysis using the PRISMA	Benefits of VR over CT for immediate- and longer-term gains in motor function and cognitive and motor activities poststroke	Average effect sizes for VR interventions small to medium but significant benefit for VR compared to CT. Upper limb: small to-medium overall effects were seen for body structures/function and activity outcomes, where participation outcomes were insignificant.
Comparison of purposeful movements in the UE between video games and traditional therapy for people with stroke ²⁰	Individuals with chronic stroke wore wrist accelerometers to measure purposeful and nonpurposeful repetitions of weaker and stronger UE while playing video games with a partner or in traditional therapy (perform movement and functional tasks).	RCT: 29 participants with chronic stroke, mean age 59 years, 1–7 years poststroke. 15 in traditional therapy TTG, 14 played video games in group VGG	1–2 sessions with OT; 30 minutes videotaped sessions	RCT Level II evidence	Video games elicit more UE purposeful repetitions and higher acceleration of movement than traditional therapy.	Compared number of purposeful movement and activity counts between two groups; VGG: 27 and 37,970; TTG: 48 and 14,872; $z = -3.0, p = 0.001$; $z = -1.9, p = 0.0$ Video games elicit more UE purposeful repetitions and higher acceleration of movement than TTG in people with stroke.
Survey questionnaire on perception of Environmental Control Units (ECUs) ¹⁶	Veterans Affairs (VA) hospital; surveys distributed to current patients or recently discharge patients	150 VA patients with spinal cord injury/disorder (SCI/D); 70 inpatients; 80 discharged patients completed questionnaires for perceptions of ECU	One-time questionnaire for either inpatients or recently discharged patients	Survey research; Level VII evidence	ECUs well accepted	Descriptive statistics inpatient/discharged watching TV/motion picture (81%), using a computer mouse (81%), using a computer keyboard (81%), using a computer mouse (81%), using a computer keyboard (81%)
Explored subjective meaning of ECU for people with high cervical SCI ¹⁷	In-depth interviews regarding meaning of using an ECU	Five participants with high cervical SCI, ranged in age from 22 to 55 years old; all at least 3 years following rehab discharge were provided ECU devices and training.	Participants provided with ECS starter pack. ECS was fitted, customized, and left for trial of unspecified period of time. 41–56-minute in-depth interviews at conclusion of trial	Qualitative: Interpretive Phenomenological Analysis (IPA) to explore personal meaning of ECU according recommended IPA guidelines. Level VI evidence	Using an ECU helps a person reclaim a little of what he or she can do and helps him or her to feel enabled—supports value of widespread access to ECU.	Yardley's guidelines for ensuring quality and rigor followed for sensitivity to context, commitment and rigor, transparency coherence, and impact and importance.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Systematic review of AT access interfaces used for text entry rates (TER) for common interfaces ¹⁵	39 studies met criteria—7 interfaces included and TER reported in either WPM or could be converted to WMP.	295 individuals with physical impairments (majority SCI quadriplegia or cerebral palsy) control sites for interface included: hands, head, mouthstick, chin, tongue, neck, and eye.	All studies meeting criteria collected TER via WPM for a user on a type of interface	Systematic review of descriptive studies Level V evidence	Average TER for different interfaces can be used as a comparison with individual TER to help with decision-making process for best interface for person.	Averages for TE for each type of interface were based on at least four studies and subjects.
Exploration of rates, barriers, and facilitators of electronic assistive technology (EAT) users ²¹	Semi-structured interviews and published measures of support need, EAT satisfaction, and psychosocial impact	22 identified EAT users with acquired brain injury (ABI); 72.7% male, mean age 43.7. All were living in shared supported homes in Australia.	EAT users identified and recruited. Research data included semi-structured interviews, Care and Needs Scale (CANS), Psychosocial Impact of Assistive Devices Scale (PIADS), and Quebec User Evaluation of Satisfaction with Assistive Technology (QUEST).	Mixed-method design Level VI evidence	EAT can positively influence everyday function and participation for people with ABI if given a skilled prescription and ongoing support for use.	Descriptive stats used for QUEST and PIADS. Qualitative analysis for barriers to effective use of E

Section 4 Restoration of Independent and Community Living Roles

Chapter 27

Restoring Activities of Daily Living

Rochelle J. Mendonca Susan Santalucia Taliah Cook and Colleen Maher

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the components of activities of daily living (ADLs) and their relationship to the Occupational Therapy Practice Framework (OTFP-3).
2. Describe the procedures for client-centered ADL evaluations including occupational profiles and assessments to document client priorities and functional independence.
3. Describe how functional physical, visual-perceptual, and cognitive limitations can impact ADL performance.
4. Modify task performance techniques for clients with functional limitations to support ADL engagement.
5. Describe principles of altering the task environment to enable maximal participation in ADLs.
6. Evaluate the need for and recommend adaptive equipment to enable safe and independent ADL performance for clients with functional limitations.
7. Train clients with functional limitations in modified task performance techniques and adaptive equipment use to progress toward occupation-based goals and functional independence.

CHAPTER OUTLINE

Activities of Daily Living
Evaluation of Activities of Daily Living
Activities of Daily Living Intervention Techniques
Case Study

TERMINOLOGY

Activities of daily living (ADLs): activities oriented toward taking care of one's body and include bathing and showering, toileting and toilet hygiene, dressing, swallowing and eating, functional mobility, personal device care, personal hygiene and grooming, and sexual activity. They are also referred to as personal activities of daily living (PADLs) or basic activities of daily living (BADLs).¹

Adaptive equipment: devices, tools, or products that are used to assist individuals with disabilities to engage in occupations within their natural contexts and environments; also referred to as assistive technology, assistive devices, or adaptive devices.

Client-centered approach: an approach to service delivery that includes respect for and collaboration with clients (individuals, groups, agencies, governments, or corporations). Therapists involve clients in decision-making, advocate for and with clients to meet needs, and recognize clients' experience and knowledge.²

Durable medical equipment (DME): supplies that provide therapeutic benefit to clients experiencing difficulty or functional deficits resulting from medical conditions or illnesses. DME must be prescribed by physicians or health care providers authorized by state law. DME must be reusable and primarily used in the home.

Occupational profile: a component of the occupational therapy evaluation that provides information about clients' occupational histories and experiences, daily living patterns, interests, values, needs, reasons for seeking services, and concerns related to occupational performance and disruption.¹

Occupations: activities that individuals, groups, or populations engage in that are meaningful and include activities of daily living, instrumental activities of daily living, rest and sleep, education, work, play, leisure, and social participation.¹

Activities of Daily Living

Occupations are defined as activities that provide a sense of identity and meaning to individuals, groups, and populations.^{1,3} The American Occupational Therapy Association's official practice document, the *Occupational Therapy Practice Framework*, Third Edition (OTPF-3), identifies eight areas of occupation, including **activities of daily living (ADLs)**, instrumental activities of daily living (IADLs), rest and sleep, education, work, play, leisure, and social participation.¹ Individuals who are satisfied with their life roles have the resources and capabilities needed to accomplish everyday tasks, whether they perform tasks themselves or seek assistance. Difficulties in occupational engagement lead to loss of functional independence and reduced quality of life.^{4,5} Occupational therapists are skilled in evaluating, remediating, and restoring occupational performance limitations due to injury, disease, or disability.

ADLs are defined as activities needed to care for one's body¹; they are also referred to as personal activities of daily living (PADLs) and basic activities of daily living (BADLs). ADLs include nine different categories: (1) bathing and showering, (2) toileting and toilet hygiene, (3) dressing, (4) swallowing and eating, (5) feeding, (6) functional mobility, (7) personal device care, (8) personal hygiene and grooming, and (9) sexual activity.¹ This chapter describes strategies and intervention techniques used by occupational therapists to restore ADL performance for individuals with impairments. Intervention strategies for eight ADLs are addressed: (1) bed mobility (part of functional mobility), (2) bathing and showering, (3) toileting and toilet hygiene, (4) personal hygiene and grooming, (5) dressing, (6) feeding, (7) personal device care, and (8) sexual activity.

Challenges or difficulties in ADL performance can occur secondary to disability, illness, or injury¹ and lead to activity limitations and participation restrictions.⁶ This chapter addresses the above noted ADLs for clients with weakness, low endurance and fatigue, limited or restricted range of motion (ROM), incoordination and poor dexterity, decreased sensation, lost use of one upper extremity (UE) or one body side, lower extremity (LE) amputation, low or limited vision, bariatric considerations, and memory deficits.

Evaluation of Activities of Daily Living

The occupational therapy (OT) process begins with an evaluation that informs intervention and defines therapy outcomes. The goal of evaluation and intervention is to promote occupational function through remediation of client skills and adaptation of tasks and environments. Occupational therapists use a **client-centered approach** involving collaboration with clients and caregivers to prioritize therapy outcomes.⁷

Chart Review

Evaluation begins with a thorough chart review. It is important to determine the exact prescription for OT evaluation and intervention. The chart will inform therapists about any restrictions or contraindications including other comorbidities, current ambulation or weight-bearing status, and current equipment use. The chart will also provide preliminary information about clients' prior ADL status, home environment, and support system. Therapists should review notes from other professionals, including, but not limited to, physical therapists, speech therapists, social workers, dieticians, and nurses. Prior to beginning a detailed evaluation, it is often useful to complete a quick screening, including a brief interview and observation of some ADLs to determine whether further evaluation and intervention are warranted.

Occupational Profile

If, after screening, it is determined that an evaluation is needed, therapists complete **occupational profiles** to gain information about client factors, performance skills and patterns, contexts, and occupations.¹ Occupational profiles help therapists to understand client abilities, capacities, interests, values, roles, habits, routines, environments, and needs related to occupational engagement. It is important to ask the following questions:

- What is the client's current lifestyle?
- What was the client's ADL status prior to injury, disease, or illness?
- What are the client's current occupational challenges?
- What comprises the client's typical day-to-day routines?
- What occupations are meaningful to the client?
- In what environments does the client currently navigate to complete occupations?

Assessment of Activity of Daily Living Performance

A critical component of evaluation is ADL observation and analysis. Therapists can evaluate ADL performance by asking clients to provide a self-report of their performance or use performance-based ADL assessments. It is often important to assess client factors and skills such as ROM, strength, sensation, balance, and cognition prior to beginning ADL assessments. Ideally, ADL performance should be assessed in the environments in which they are typically done, or the environment should closely simulate clients' natural environments. ADL tasks to be assessed should range from simple to complex and should be based on the information obtained from the referral, chart review, and occupational profile. Therapists may use standardized ADL assessments such as the Functional Independence Measure (FIM); the Klein-Bell Activities of Daily Living Scale; the Katz Index of Independence in Activities of Daily Living; Performance Assessment of Self-Care Skills (PASS); Disabilities of the Arm, Shoulder, and Head (DASH) Assessment; and the Barthel ADL Index; or nonstandardized measures such as ADL checklists.⁸⁻¹³ These standardized assessments can be used for re-evaluation to measure outcomes and to determine whether clients met their goals.

Levels of Independence

When evaluating ADL performance, occupational therapists use terminology to describe the level or amount of assistance required to perform ADLs. The following are general categories and definitions to categorize levels of independence.

- **Independent:** Clients can perform the activity independently; without modification of technique, assistive devices, or aids; and within a reasonable time frame.
- **Modified independence:** Clients either require an assistive device to complete the activity, the activity takes more than a reasonable time, or safety considerations exist.
- **Supervision (standby assistance):** Clients require a therapist to stand by for safety in case of balance loss. Therapists may provide verbal cues for safety.
- **Contact guard:** Therapists place one or two hands on the client's body to maintain balance, dynamic stability, or safety; however, they do not assist in task performance.
- **Minimal assistance:** Therapists provide 25% of assistance (physical or verbal), and clients are able to perform 75% or more of the activity.
- **Moderate assistance:** Therapists provide 50% of assistance (physical or verbal), and clients are able to perform 50% to 74% of the activity.
- **Maximal assistance:** Therapists provide 75% of assistance (physical or verbal), and clients are able to perform 25% to 49% of the activity.
- **Dependent:** Therapist provides more than 75% of assistance (physical or verbal), and clients are able to perform less than 25% of the activity.

When assessing ADLs using levels of independence, it is important to note whether clients require assistance from more than one person, and the amount of assistance provided by each person. Also note clients' ability to direct their care despite physical

dependence. If clients are satisfied with their ability to direct their care, they may be considered independent.¹

Other Factors to Consider in Activities of Daily Living Evaluations

It is important to consider the contextual and environmental factors that might impact client performance. Physical environmental factors such as clutter, barriers to access, rugs, steps, or stairways should be eliminated or adapted for safe ADL performance. Cultural and social factors also impact ADL performance and should be incorporated in evaluation and intervention when possible and desired by clients. Therapists should determine whether clients desire family and caregivers to be present and should comply with Health Insurance Portability and Accountability Act of 1996 (HIPAA) regulations.

Therapists working in acute or intensive care settings must consider the client's medical complexity. When evaluating and intervening with clients in these settings, therapists should understand and monitor lab values, vital signs, and code status repeatedly, as well as documented precautions for clients. Therapists should be familiar with equipment typically encountered in this setting, including electrocardiogram (EKG) monitors, ventilators, lines, catheters, tubes, dialysis equipment, pacemakers, mechanical circulatory devices, and respiratory care equipment. Isolation precautions, if applicable, should be reviewed and followed. This information is usually available in client charts and posted on hospital room doors.

Settings for Activities of Daily Living Evaluation and Intervention

ADLs are the focus of evaluation and intervention in most settings in which occupational therapists work including intensive care, acute care, acute rehabilitation, subacute rehabilitation, skilled nursing facilities, outpatient facilities, home care, and hand therapy. ADLs are typically assessed through observation of task performance in all of the abovementioned settings. In the practice area of hand therapy, ADLs may sometimes be assessed through self-report or interview.

Activities of Daily Living Intervention Techniques

Evaluation information—including interviews, occupational profiles, and assessment instruments—are integrated to develop intervention plans, goals, and outcomes. Long- and short-term goals should focus on remediating client skills, modifying performance techniques, altering the environment, or using **adaptive equipment**, to maximize independent ADL performance. Prior to beginning ADL intervention sessions, it is important to plan therapy sessions, set up the environment, and ensure that chosen activities provide the “just right challenge.”¹⁴ The complexity of ADL intervention should be increased gradually over time.

OT interventions can include preparatory methods and tasks such as physical agent modalities, ROM exercises, or strengthening approaches. Preparatory methods can be followed by purposeful activities, such as donning button-down shirts or cooking family meals.¹ Restoration and modification approaches are most often used in ADL interventions.¹ The restoration approach focuses on remediating client skills, which may have been lost due to injury or disease, to promote occupational resumption.¹ Sometimes, clients do not regain full capabilities and require modification to participate in ADLs. In these situations, the modification approach is used involving either (1) modification of the task performance technique (e.g., leaning against a sink when clients fatigue easily while brushing teeth) or (2) using adaptive equipment and altering the environment (e.g., using toothbrushes with built-up handles for clients with decreased grasp strength). Often, adaptation involves the use of **durable medical equipment (DME)**, which provides therapeutic benefits to clients with functional deficits resulting from medical conditions or illnesses. With the advent of 3-D printing, creating adaptations that enable ADLs has become easier. The following section addresses ADL modifications as they apply to the 10 conditions.

Weakness

Weakness in the limbs, trunk, or overall body can result in difficulty in dynamic and static balance, posture, transfers, functional mobility, reaching, and grasping. The techniques used and the amount of assistance provided to clients will differ based on upper and lower body weakness, trunk weakness, or overall body weakness. Some modifications and adaptive equipment used to enhance ADLs for clients with weakness are outlined in the subsequent sections.

Bed Mobility

Bed mobility is the ability to bridge in bed, roll from supine to side-lying, scoot up and down in bed, move from supine to sitting and sitting to supine, and sit at the edge of the bed. Teaching bed mobility skills to clients with weakness promotes ADL participation.

Modification of Technique

-  **Bridging in bed:** For clients with weakness, bridging in bed can assist with strengthening the back, abdominals, quadriceps, and gluteal muscles. Bridging enables clients to move their hips to allow independence or assistance with ADLs in bed such as lower body dressing, toileting, and perineal hygiene (Video 27-1).
 - Clients should lay flat on their back, bend the knees, and bring the feet flat on the bed.
 - Lift the buttocks, upper legs, and lower back on the bed using the back and hip extensors. Move the hips toward the desired position.
 - Therapists can help stabilize the knees and feet if clients have difficulty holding the lower extremities (LEs) in position.
 - Clients can place their hands flat on the bed for stabilization if required.
-  **Rolling in bed:** Rolling in bed is a critical component of bed mobility. It allows clients to change position by shifting weight in bed, assists with lower body dressing, and prepares the body to sit up in bed (Video 27-2).
 - Clients should bend both knees by sliding their heels toward their buttocks.
 - Abduct one UE to 90° or less and horizontally adduct the other UE.
 - Lower the knees on the side of the abducted UE and turn the hips and shoulder to roll onto the side.
 - If clients have weakness on one side, have them reach across their body with their unaffected side to grip the bedrail or halo. Lower the knees on the affected side and turn the hips and shoulder to roll onto the affected side.
 - If clients have weakness secondary to spinal disease or injury, and have precautions to avoid twisting the spine, have them hold onto a bedrail and drop the knees while turning their shoulders and hips at the same time like a log (log rolling).
 - If clients require assistance to roll in bed, therapists can assist clients with shoulder protraction, grabbing the bedrail, flexing the knees, and guiding the roll.
-  **Scooting in bed:** Scooting allows clients to be mobile in bed and build strength in the trunk and LE muscles (Videos 27-3 and 27-4).
 - To scoot to the head of the bed, clients should flex the hips and knees with feet flat on the bed. Bring the heels close to the buttocks. Shoulders should be slightly abducted and elbows should be flexed so that hands are flat on the bed next to the waist. Clients should raise their pelvis using bridging techniques and push on the LEs, while depressing and adducting their shoulders simultaneously to move up in bed.
 - To move down in bed, clients should flex their hips and knees with feet flat on the bed. Shoulders should be adducted, and elbows flexed with hands flat on the bed next to the buttocks. Clients should pull on their LEs to push their buttocks closer to their heels while simultaneously pushing up with the shoulders and abducting the shoulders to move down in bed.
 - For clients who need more assistance because of weakness, therapists can assist by stabilizing the knees and feet.

- Alternatively, to scoot to the head of the bed, lower the head of the bed to make it flat, place a sheet under the client, and use a two-person assist to pull the sheet toward the head.
- ***Side-lying to sitting at the edge of the bed:*** Sitting at the edge of the bed allows clients to prepare to stand, transfer to a mobility device, and complete ADLs such as grooming, feeding, and hygiene in a seated position. To move from a side-lying position to sitting in bed, ask the client to:
 - Bring their legs over the side of the bed.
 - Use forearms and hands to push up to a sitting position with legs over the side of the bed.
 - To scoot to the edge of the bed, clients should place both hands flat on the bed and weight shift to one side of the body, while moving the opposite buttock forward. Then move the weight to the other side of the body, while moving the opposite buttock forward. Repeat until clients are comfortably seated at the edge of the bed.
 - If clients have weakness on one side of the body, they should roll onto the affected side, reach across the chest with the unaffected UE and use the unaffected hand to push up to a sitting position.
 - For clients who have whole-body weakness, or one-sided weakness but still require help to move to a seated position, therapists should bring the clients' legs to the edge of the bed and stabilize their knees between their legs. Then assist clients to an upright position by guiding the scapula and the hips.
 - For seated clients with one-sided, lower body, or whole-body weakness who require help to move the buttocks toward the bed edge, therapists can stabilize the clients' legs between their knees, and place both hands under the clients' buttocks or behind their knees to gradually move their body forward.
- ***Sitting at the edge of the bed to supine:***
 - Clients should sit close to the head of the bed. They should scoot back further in the bed by placing both hands flat on the bed and weight shifting on one side while pulling their opposite pelvis backward until they are seated with their thighs fully supported in bed.
 - Lift LEs with knees slightly bent onto the bed, while simultaneously leaning down on one forearm or holding the handrail with the hand closest to the head of the bed.
 - Clients should then roll onto their back using their UEs and LEs to guide the roll.
 - For clients with one-sided weakness, therapists should place both hands under the clients' buttocks to scoot them back in the bed, while stabilizing their LEs between their knees. To move to side-lying, have clients lay down on their affected side in the bed by holding onto the handrail with the unaffected UE and placing the forearm of the affected UE on the bed for support. Hook their unaffected LE below the affected LE to simultaneously lift both legs onto the bed.
 - For clients with LE or whole-body weakness, therapists can place both hands under the clients' buttocks to move them back into the bed. When moving to a side-lying position, therapists can guide clients by placing one hand under the scapula of the side closer to the head of the bed to lower clients in bed; the other hand guides the LEs onto the bed.

Use of Adaptive Equipment or Altering the Task Environment

- Use bed rope ladders or overhead trapeze bars for clients with LE/trunk weakness.
- Electric or adjustable beds with powered head and knee controls assist with moving from supine to sitting and sitting to supine in bed.
- Bedrails or halos provide support for changing bed position (Fig. 27-1A to D).

Figure 27-1 Bedrails or halos provide support for changing bed position. A. Single full-length hospital bedrail. B. Two part full-length hospital bedrail. C. Portable hand bedrail. D. Halo.

- Leg lifters assist with lifting clients' legs into or out of bed, one leg at a time (Fig. 27-2).

Figure 27-2 Leg lifters assist with lifting clients' legs into or out of bed.

- Transfer sheets or draw sheets help with rolling and moving to the edge of the bed; two people should always assist with transfers for safety.
- Hoyer lifts move clients out of bed into seated positions. Two people should always assist with Hoyer lift transfers to ensure safety.

Bathing and Showering

Clients with weakness may have difficulty transferring into the bathtub or shower, standing or sitting in the shower, and grasping and holding onto items such as soap.

Modification of Technique

- Start with sponge bathing in bed (clients may need to begin with the upper body and progress to the whole body as tolerated). Clients should roll on their side to wash their back or allow caregivers to assist. Progress to bedside sponge bathing, then bathing at the bathroom sink, followed by a walk-in shower with a shower chair, and finally showering in a tub with a bath bench.
- Crossing one leg over the other while seated to wash alternate lower limbs is easier than bending down to wash limbs.
- If clients have a back brace, ensure that there is a second set that can be worn in the shower.

Use of Adaptive Equipment or Altering the Task Environment

- Use 3-in-1 commodes that can be used as a shower chair, shower chair only (Fig. 27-3A and B), transfer tub bench with or without arm rests depending on trunk control and if

arms are needed for transfers (Fig. 27-4), wheeled shower chair for clients who have difficulty ambulating to the shower (Fig. 27-5) or bath lifts.

Figure 27-3 A. Shower chair. B. Shower chair with arm rests.

Figure 27-4 Transfer tub bench.

Figure 27-5 Wheeled shower chair.

- Walk-in bathtubs eliminate the need to transfer over the bathtub.
- Grab bars or portable safety rails assist with standing showers or transfers (Fig. 27-6).

Figure 27-6 Grab bars.

- Nonslip mats provide stability in the shower.
- Soap on a rope or wash mitts with soap inserted in pocket reduce the need for grip strength.
- Use pump or automatic soap dispensers for clients who are unable to lift and squeeze.
- Long-handled sponges, brushes, and toe brushes allow clients to reach all body parts with minimal effort (Fig. 27-7).

Figure 27-7 Long-handled sponges.

- Use long, large, or lever shower handles for easier grip or touchless faucet adapters.
- Handheld adjustable shower hose or shower slide bars reduce the amount of movement needed in the shower.
- Use shower wraps to dry body for clients who have difficulty manipulating and using towels.
- Temperature-control shower valves eliminate sudden water temperatures changes. Avoid hot water as this may cause a temporary increase in weakness. Water temperature can also be lowered at the water heater.

Toileting and Toilet Hygiene

Toileting requires a person to be able to don and doff clothing, sit on and rise from the toilet, reach and grasp toilet tissue, and clean perianal areas. Clients with weakness may have difficulty grasping and holding onto clothes and cleaning supplies, as well as transferring onto and off of toilets.

Modification of Technique

- Establish routines or use alarms for regular bowel and bladder voiding.
- Use bed pans or adult diapers for clients who have difficulty getting to the toilet in time or completing toileting activities.
- Clients who have weakness due to spinal cord injury may have loss of bowel and bladder control. Specific bowel and bladder management techniques are described in Chapter 39.

Use of Adaptive Equipment or Altering the Task Environment

- Use raised toilet seats (Fig. 27-8) and grab bars or arm rests for easier transfer on and off toilets.

Figure 27-8 Raised toilet seat.

- Use 3-in-1 bedside commodes with pails to avoid the need to ambulate to the bathroom (Fig. 27-9).

Figure 27-9 3-in-1 commode with pail.

- Use toilet seat lifts to mechanically move clients from sitting on a toilet seat to standing or moving to a mobility device.
- Use floor-to-ceiling grab bars to increase safety while transferring.
- Use drop-arm commodes for clients who need to reach behind for toilet hygiene.
- Bidet-toilet combos or bidet-toilet seats eliminate the need for toilet paper.
- Comfort-wipe extended-handle toilet paper holder or tongs reduce the amount of effort required to reach perianal areas for toilet hygiene.

Personal Hygiene and Grooming

Clients with weakness, especially of the UE, will have difficulty grasping and holding onto grooming supplies, such as combs, brushes, makeup, and shampoo.

Modification of Technique

- Sit at the sink or vanity with arms supported on the surface.
- Organize and place required supplies in close proximity to avoid excessive reaching.

Use of Adaptive Equipment or Altering the Task Environment

- Use built-up handles on toothbrushes for individuals with reduced grasp (Fig. 27-10).

Figure 27-10 Built-up handles on toothbrushes and hair brushes.

- Electric toothbrushes reduce the effort required to brush teeth.
- Toothpaste dispensers require less strength to dispense toothpaste on a toothbrush.
- Use waterpiks or dental floss holders for easier teeth flossing.
- Suctioned denture brushes and cleaners (in which dentures soak overnight) allow one-handed cleaning.
- Use pump or automatic dispensers for shampoos and lotions.
- Use dry shampoo and conditioners.
- Use flip-top bottles for easier opening and closing.
- Use built-up handles on combs and brushes (Fig. 27-10).
- Use wall-mounted hair dryers to dry hair.
- Use built-up tubing on manual or electric razors.
- Use hair removal cream to eliminate the need for razors.
- Use jar openers for twist-off caps on lotions or makeup supplies.
- Use universal cuffs to hold combs, brushes, toothbrushes, razors, and lipstick.
- Applying friction material to tool surfaces can reduce the need for grasp strength.
- For deodorants, replace fingertip dispensers with long trigger nozzles to allow clients to spray themselves using all fingers, palm, or fist. Modified nozzles can be used for hair care products as well.
- For nail care, mount the nail clipper and/or nail file to a friction resistant or emery board to allow one-handed use (Fig. 27-11). Nails can be clipped using the palm or fist of the opposite hand. Clients can also use one-handed nail clippers, long-handled and pistol-grip LE toenail clippers, and suction nail brushes.

Figure 27-11 Mounted nail clipper.

Dressing

Clients with weakness or paralysis may have difficulty obtaining clothing, moving extremities into clothing, and manipulating buttons or zippers because of decreased grip and pinch, and decreased sitting balance.

Modification of Technique

The following modification techniques were developed for clients with spinal cord injury, but can be adapted for people with weakness secondary to other diagnoses.¹⁵⁻¹⁸

- Organize closets so that commonly used clothes are placed within easy reach.
- Lower closet pole height to allow easier clothing access.
- Remove closet doors if opening and closing requires too much effort.
- Easy-glide dresser drawers that only require a light push to slide open require less UE strength.

Upper Body Dressing—Shirts and Blouses

■ Donning shirts and blouses: Technique 1

1.  The client should be seated either in a bed or wheelchair (Video 27-5).
2. Position the shirt with the label facing down and the collar toward the knees.
3. Put arms under the shirt and into sleeves and push them up over the elbows.
4. Gather the back of the shirt and hook the thumbs under the gathered back using wrist extension.
5. Place the shirt over the head.
6. Shrug to get the shirt across the shoulder and hook the wrists into each sleeve to straighten them across the UEs.
7. Lean forward and reach back with one hand to pull the shirt down. Alternatively, reach across the body to pull down the shirt back of the opposite side.
8. Line the shirt fronts up and begin buttoning from the bottom up. A buttonhook or Velcro fasteners can be used.

■ Donning shirts and blouses: Technique 2

1.  The client should be seated either in a bed or wheelchair (Video 27-6).
2. Position the shirt with the label facing up and the collar toward the abdomen.
3. Put the arms into the sleeves, and push them up over the elbows.

4. Place the hands under the back of the shirt, tuck the chin, and flip shirt over the top of the head.
5. Once the shirt is flipped, straighten the arms and allow the shirt to fall around body.
6. Align the shirt fronts and begin buttoning from the bottom up. A buttonhook or Velcro fasteners can be used.

■ ***Doffing shirts and blouses***

1.  Push one side and then the other side of the shirt off the shoulders by bending the elbows and using the fingers, fist, or chin to push the sleeve-off shoulder (Video 27-7).
2. Alternately, elevate and depress (shrug) the shoulders to allow gravity to assist in lowering the shirt down the arms.
3. Hook one thumb into the opposite sleeve to pull the shirt over the elbow and remove the arm from the shirt. Then, similarly remove other shirt arm.

■ ***Donning and doffing pullover shirts***

1. An overhead shirt is put on in the same manner as Technique 1.
2. To doff the pullover shirt, hook one thumb in the back of the neckline, gather the shirt back and pull it over the head. The sleeves are then pulled off each arm. Note: This is an alternate method for a button-down shirt (after shirt is unbuttoned).

Lower Body Dressing—Slacks and Pants

■ **Donning slacks and pants: Technique 1**

1.  Client sits in bed with legs extended and the head of the hospital bed elevated, if available (Video 27-8).
2. Position pants with the front up and pant legs over the bottom of the bed.
3. Lift one leg by hooking the opposite wrist or forearm under the knee and put the foot into the pant leg. Hook the thumb of the other hand into a belt loop or pocket to hold the pant leg open. This cross-body position of donning pants provides stability for those with poor balance. Return the knee to extension.
4. Insert the other foot in a similar manner.
5. Use the hands or palms to pat and slide the pants up over the calves, and get the cuffs over the feet.
6. Hook the wrists under the waistband or in the pockets to pull pants up over the knees.
7. Continue to pull on the waistband while moving to a supine position to pull the pants up to the thighs. Hooking the wrist or thumb in the crotch also helps to pull the pants up.
8. If UE strength is good, return to a sitting position and weight shift while leaning on one hand or elbow to pull the pant leg up the opposite buttock. Repeat the process for the other side.
9. If clients are unable to weight shift in a seated position, have them move from a supine to a side-lying position. Hook the thumb of the top arm in the back belt loop and pull the pants over the buttocks. Then roll onto the other side and repeat the process.
10. In a supine position, fasten the pants using a zipper pull loop, Velcro tab, or buttonhook.

■ ***Donning slacks and pants: Technique 2***

1.  This method is useful for clients who have limited forward reach (Video 27-9).
2. Position the pants parallel to the client's legs.

3. Lift one leg by hooking the opposite wrist or forearm under the knee or calf and cross over the other leg.
4. Slide the pant leg all the way over the foot and up to the knee.
5. Uncross the leg and similarly slide the other leg in the pant leg.
6. To pull pants up and over buttocks, use steps 5 to 10 from Technique 1.

■ ***Doffing pants and slacks***

1. Pants are removed by reversing the steps of either technique described earlier and pushing the pants off.

■ ***Donning and doffing bras:*** Either front or back closure bras can be used. The hook and eye fasteners can be replaced with Velcro for easier fastening.

1. If using a back closure bra, position the bra with the cups in the back and hook the fasteners in the front at waist level. Use the fingers, palm, or wrist to rotate the bra so the hooks move to the back and the cups to the front. Place both arms through the shoulder straps. Hook the opposite thumb under a strap and pull it over the shoulder. Repeat for the other shoulder.
2. For front-opening bras, position the bra with the cups in front and hook the bra. Place both arms through the shoulder straps. Hook the opposite thumb under a strap and pull it over the shoulder. Repeat for the other shoulder.
3. To doff the bra, reverse the steps for donning.

■ ***Donning and doffing socks***

1. To don socks, clients can be seated in a bed or wheelchair. Cross one leg over the other. Grasp the sock to put it over the foot and use patting movements with the palm to pull it on.
2. If clients cannot cross their legs, the foot can be placed on a stool or chair.
3. To doff socks, clients can be seated in a wheelchair or bed with legs crossed.
4. Hook the thumb over the sock edge and move the sock off the foot. Clients can also be seated with legs extended in bed and hips flexed to hook thumb over the sock edge and remove socks.

■ ***Donning and doffing shoes***

1. To don shoes, have the client seated with one leg crossed over the other. Balance the shoe sole in the palm and pull the shoe onto the foot. Use the palm to pull the shoe over the heel. Alternatively, place the foot on the floor or the foot pedal of the wheelchair, and push the foot down in the shoe by pushing on the knee.
2. A dressing stick can be used to get the shoe over the toes, and a long-handled shoehorn can be used to get the heel into the shoe (Fig. 27-12).

Figure 27-12 Long-handled shoehorn.

3. To doff shoes, clients can be seated with the legs crossed. Push on the heel of the shoe with the palm, and let the shoe fall off or use palm to push the shoe off the foot. A shoehorn can be used to push on the heel of the shoe and remove it from the foot.
4. Wearing slip-on shoes that are half to one size larger are easier to don and doff.

Additional Considerations for Dressing

- Knit shirts and looser shirts are easier to get on. Avoid shirts with tight necks.
- Pull-on pants are easier to put on. For women, skirts are easier to put on than pants.
- Step-in bras or sports bras are easier to don and doff.

Use of Adaptive Equipment or Altering the Task Environment

- Long-handled dressing sticks with an S-hook on one end can be used to pull pants on or tug clothing into place (Fig. 27-13).

Figure 27-13 Dressing stick.

- Use bras with Velcro front clasps or step-in bras.
- Use loops of fabric attached to the zipper pull of pants, shirts, or jackets to pull the zipper up or down with one finger.
- Use buttonhooks (with built-up handles or placed in universal cuffs) to manipulate buttons (Fig. 27-14).

Figure 27-14 Button hook.

- Replace buttons with Velcro to avoid the need to button.

- Use elastic instead of buttons for shirt cuffs.
- Use reachers to pick up clothing or shoes, or to retrieve clothing from closets.
- Use long-handled shoehorns to reach feet while seated.
- Use shoes with Velcro or shoelaces with lace locks that do not require tying.
- Use sock or stocking aids to reach feet and pull socks up (Fig. 27-15).

Figure 27-15 Sock or stocking aid.

- Use fabric loops around sock cuffs to pull socks up by hooking fingers in the loop.

Feeding

Feeding concerns for clients with weakness are caused by difficulty grasping utensils, cutting food, and bringing food from plate to the mouth.

Modification of Technique

- Position the client close to the table and use the table surface to support the arms while eating.
- Use precut meats and vegetables for eating or have caregivers cut food.

Use of Adaptive Equipment or Altering the Task Environment

- Use lightweight utensils such as heavy-duty plastic eating utensils.
- Built-up utensils allow clients with limited grasp to hold onto utensils (Fig. 27-16).

Figure 27-16 Built-up eating utensils.

- Sporks, which combine spoons and forks, eliminate the need to change utensils while eating.
- Swivel utensils reduce the amount of rotation required to bring food from plate to mouth.
- Rocker knives with or without T-handles allow clients with UE weakness to cut their food with a rocking motion (Fig. 27-17A and B).

Figure 27-17 Rocker knife. **A.** With T-handle. **B.** Without T-handle.

- Glasses or cups with lids prevent spillage.
- Large-handled or two-handled cups reduce the need for a strong grasp.
- Drink-mounting devices for beds or wheelchairs allow clients to drink without holding onto cups.
- Long or flexible straws reduce the need to lift and tilt cups.
- Plate guards and long-lipped plates allow easier scooping of food (Fig. 27-18).

Figure 27-18 Plate guards and long-lipped plates.

- Universal cuffs with eating utensils reduce the need to grasp (Fig. 27-19).

Figure 27-19 Universal cuffs with eating utensils.

- Mobile arm supports promote client horizontal and vertical arm movements to reach plates and mouth. These can be mounted to sinks, wheelchairs, or tables and are portable.
- Food can be stored in containers with easy-to-open lids for one-handed use.

Personal Device Care

Managing and using personal devices such as contact lenses, glucose monitors, and orthotics may arise because of difficulty grasping, pinching, and positioning devices.

Modification of Technique

- Clients should sit at a table with arms supported while using, cleaning, and maintaining personal devices.
- Place commonly used personal devices in close proximity to each other and at easy-to-reach locations.
- LE orthotics should be donned and doffed similarly to donning and doffing socks as described in dressing.
- Use gravity to assist with using and maintaining personal devices.

Use of Adaptive Equipment or Altering the Task Environment

- Optiwand soft contact lens insertion and removal tools hold lenses until placed on the cornea for clients who have limited grasp and pinch. Handles can be built up for weak grasp.
- Large flip-top contact lens cases can be opened and closed with fist movements.

- Use larger eye drop bottles for easier grasp. Or use an autosqueeze eye drop bottle dispenser with a larger grasp area that makes bottle squeezing easier by providing extra leverage.
- The Opticare Arthro eye dropper has extended handles and is easy to squeeze for clients with arm and hand ROM limitations.¹⁹
- Automatic glucose and blood pressure monitors have fewer buttons to use (e.g., automatic on/off and no coding) and have multiple strips filled in the drum to eliminate strip reinsertion with each use.
- Larger hearing aids are easier to grasp and insert into the ear.

Sexual Activity

Sexual activity is often an area of concern for individuals with disabilities. Depending on the extent of their weakness, clients may need help identifying positions that best support engagement in sexual expression. In addition to identifying different positions, it is important to discuss the scope of intimacy (including increasing opportunities to touch, hug, and kiss), to shift the focus from function to pleasure, and to consider the impact of impairment on body image and fears about resuming sex. Several publications describe sexual expression and activity for individuals with weakness.^{20,21}

Modification of Technique

- For clients with weakness of the LEs, trunk, and/or UEs, it is often easier to engage in intercourse while in a wheelchair or while seated and supported by a backrest with the partner positioned on top of them.
- For clients with paralysis, it is better to be positioned below the partner in a missionary position, with a rolled towel or small pillow to support the lumbar spine.
- When clients have hemiparesis, positioning both partners in a side-lying position with the client lying on the affected side allows free movement of the unaffected side.
- Alternatively, clients with hemiparesis can position themselves in a missionary position with their partner on top and supporting some of their weight on the surface on which they are lying.
- Rear entry positions may be used with both partners kneeling and both sets of forearms on the bed or supporting surface; this reduces both partners' energy expenditure.
- For clients with spinal cord injury, it is necessary to complete preparatory activities prior to engaging in sexual activity, such as emptying the bladder and managing catheters.

Use of Adaptive Equipment or Altering the Task Environment

- Use pillows and wedges to assist with positioning during sexual activity.
- Use bedrails or overhead trapezes to reposition self in bed.

Low Endurance and Fatigue

Endurance is the ability to sustain physical activity over time. General endurance is a reflection of cardiopulmonary function and overall fitness. Fatigue is not simply low endurance, but a subjective experience of feeling tired or exhausted.²² Fatigue is multidimensional and includes cognitive, behavioral, and emotional components,²³ as well as physical factors. A person with low endurance and fatigue may experience difficulty initiating or completing ADLs. Therapists should understand the importance of assessing and monitoring endurance and fatigue during ADL performance such as heart rate (HR)/vitals, metabolic equivalent for task (MET) levels, number or repetitions over a period of time, and scales of perceived exertion. A compendium of physical activities based on MET levels is available in Chapter 40; however, this should always be used in combination with monitoring vital signs.²⁴ Therapists should also be aware of precautions and contraindications when performing ADLs for persons with low endurance and fatigue such as holding one's breath during ADLs; isometric contractions for clients with active cardiac histories; significant changes in blood pressure, O₂ rate, and HR (>20 beats over

resting HR); shortness of breath (dyspnea); and angina. When determining ADL interventions for clients with low endurance and fatigue, therapists should carefully consider the client, the activity, and the environment in which the ADL will be performed.²⁵ Modification techniques and use of adaptive equipment to enhance ADLs for clients with low endurance and fatigue should include energy conservation techniques, as outlined in the subsequent sections.

Bed Mobility

Modification of Technique

- Preplan: Prepare the surface to which the patient will transfer and/or the ambulatory device needed.
- Perform bed mobility tasks in steps and take breaks.
- Supine to sit: Log roll independently or, depending on low endurance level, use assistance of one or two persons (see Weakness).
- Bed mobility techniques for weakness apply to clients with low endurance and fatigue.

Use of Adaptive Equipment or Altering the Task Environment

- Adjustable beds assist in bringing patients upright or lowering to supine.
- Use portable bedrails at home.
- Use Hoyer lifts.

Bathing and Showering

Modification of Technique

- Pace activities and incorporate rest breaks.
- If sponge bathing bedside, set all items on tray table or nearby within easy reach.
- It is preferable to take showers instead of baths. Baths require too much energy to get in and out of the tub basin.
- When showering, preplan: Prepare all items needed for showering (place soap, shampoo, clothing, and towels within reach).
- Delegate aspects of the task to be completed by caregivers.
- Use lukewarm water because hot water may increase fatigue level.
- Cross legs to bathe feet while seated on a tub bench (it takes less energy) or use long-handled equipment.

Use of Adaptive Equipment or Altering the Task Environment

- Use tub benches for clients who do not have the endurance to step in and out of the tub.
- Use shower chairs for clients who have the endurance to step in and out of the tub, but who fatigue easily.
- Use long-handled equipment (long-handled bath and toe sponges).
- Use shower hoses or adjustable mounted shower hoses.
- Use shower caddies with all needed items within reach.
- Use soap on a rope placed nearby and bath mitts with soap inserted in pockets to eliminate having to hold soap and washcloths.
- Use walk-in showers or tubs.

Toileting and Toilet Hygiene

Modification of Technique

- Don't strain during a bowel movement.
- Set a routine for bowel management.

Use of Adaptive Equipment or Altering the Task Environment

- Use raised toilet seats.
- Use stools (squatting potty) that raise the feet in a squatting position to promote effortless bowel movements.
- Use toilet-bidet combos for toilet hygiene.

Personal Hygiene and Grooming

Modification of Technique

- Sit to perform grooming activities, including brushing teeth, shaving, hair care, and makeup.
- Rest upper arms/elbows on vanity/counter.
- Preplan needed items and position them in easy reach.
- Take rest breaks.

Use of Adaptive Equipment or Altering the Task Environment

- Use electric razors.
- Use electric toothbrushes.
- Use standing or wall-mounted hair dryers.

Dressing

Modification of Technique

- Pace dressing activities, and other ADLs completed before and after dressing, so that clients do not perform multiple ADLs in a row without breaks.
- Incorporate rest breaks.
- Sit to perform dressing.
- Preplan and gather needed items: Organize clothes within easy reach in dressers and closets.
- Crossing the legs to don socks and shoes requires less energy than bending down.
- Wear light, loose clothing (microfiber stretches).
- Dressing techniques for weakness apply to clients with low endurance and fatigue.

Use of Adaptive Equipment or Altering the Task Environment

- Use dressing sticks, reachers, and sock aids.
- Use slip-on shoes or shoes with elastic laces or Velcro.
- Use Velcro closure and zipper pulls.

Feeding

Modification of Technique

- Delegate caregivers to precut food and place meals on table.
- Take rest breaks between courses.
- Consider multiple small meals throughout the day.
- Rest upper arms/elbows on table when feeding.
- Keep all condiments within reach: Consider a Lazy Susan.

Use of Adaptive Equipment or Altering the Task Environment

- Use long-handled and lightweight utensils.
- Mobile arm supports and deltoid aids assist with bringing the hand to the mouth.
- Consider feeding robots (iEat) or electric feeding devices (Mealtime Partner).²⁶
- Use chairs that support the trunk and neck.
- Mount cups with straws to wheelchairs.

Personal Device Care

Modification of Technique

- Rest upper arms on vanity table for support.

Use of Adaptive Equipment or Altering the Task Environment

- See section on Weakness and Limited or Restricted Range of Motion.

Sexual Activity

The American Heart Association provides information on cardiovascular changes that occur during sexual intercourse, guidelines for resuming sex after myocardial infarction or heart surgery, other facts that influence sexual interest and capacity, and actions to take if symptoms arise during sex.²⁷ Sexual activity should be preplanned to provide rest time before and after. Sexual intercourse for the client with low endurance and fatigue is less stressful when positioned on the bottom and laying supine. Positions that require the least movement should be chosen. Sexual activities should be planned for day and week times when energy levels are highest. For additional information, see section on Sexual Activity in Weakness.

Limited or Restricted Range of Motion

Limited or restricted ROM of the limbs, trunk, or overall body could result in difficulty reaching body parts to perform self-care, reaching for objects at different heights, transferring or sitting on surfaces with different heights, functional mobility, and grasping items to complete ADLs. Occupational therapists should understand the functional ranges needed to perform common ADLs.^{28,29} When determining ADL interventions for persons with limited or restricted ROM, therapists should carefully consider the client, the degree of ROM limitation/restriction, the activity, and the environment in which the ADL is performed.²⁵ Modification techniques to enhance ADLs for clients with limited or restricted movement are outlined in the subsequent sections.

Bed Mobility

Modification of Technique

- Use log rolling for clients with restrictions on spine ROM.
- When clients have hip ROM restrictions such as total hip arthroplasty (THA) and hip fracture:
 -  To exit bed: Transfer from stronger side (client should learn to transfer from both sides), prop upper body on forearms, and slowly move LEs to bed edge (avoid hip adduction), followed by the trunk (avoiding hip flexion > 90°) (Video 27-10).
 -  To enter bed: Using rolling walker, back up to the middle or upper one-third of bed, reach back for bed with both hands, and slowly lower buttocks to the bed while extending the affected LE (do not flex hips >90°). Slide back to the middle of the bed and slowly bring legs onto the bed (keeping them abducted) while turning to face the bed end. Scoot buttocks toward the head of bed so that legs are supported comfortably on the bed. Lower upper body onto forearms and then lay down flat onto bed (Video 27-11).
- Shoulder ROM restrictions (one side/UE):
 - To exit bed: Roll toward stronger side and then move legs so that they hang over the bed edge and, at the same time, use the stronger arm to prop trunk upright at the bed edge.
 - To enter bed: Sit on bed edge (middle to upper one-third of bed) with stronger side toward head of bed. Move to a side-lying position by lowering the upper body onto the forearm of the unaffected UE while at the same time bringing legs onto bed.

Slowly move from side-lying to supine. Make certain there is a pillow for the affected extremity to roll onto.

- Shoulder ROM restrictions (both sides/bilateral upper extremities [BUEs]) such as radial artery (RA) and status-post (s/p) coronary artery bypass grafting (CABG).
 - To exit bed: Log roll to side (for sternal precautions, hug a pillow), then move legs so that they hang over the bed edge. At the same time, move the trunk up to the bed edge. Do not pull on bedrail or push off bed.
 - To enter bed: Sit on bed edge (middle to upper one-third of bed). Move to a side-lying position by lowering the upper body to the bed (for sternal precautions, hug a pillow), while at the same time bring legs onto bed. Slowly move from side-lying to supine.

Use of Adaptive Equipment or Altering the Task Environment

- Use leg lifters for clients with limited active or passive LE ROM.
- Electric or adjustable beds can assist with sitting up in bed and sit-to-supine movements.
- Home care therapists can place risers or blocks beneath the bed legs to raise bed height.
- Ladder ropes can assist moving from supine to sitting (requires good UE strength).
- Clients can sleep in adjustable recliner chairs.

Bathing and Showering

Modification of Technique

- Clients can sponge bathe bedside using adjustable tray tables with items at waist level.
- Showering is preferred over tub baths for ROM restrictions of the spine.
- With restricted shoulder ROM of one extremity, a grab bar for the unaffected extremity or a tub bench should be used for safety. When showering, place the affected shoulder in a passive pendulum position to wash the axilla with the unaffected extremity.
- With restricted ROM in both UEs, a tub bench should be used for safety.

Use of Adaptive Equipment or Altering the Task Environment

- Use soap on a rope or bath mitts for limited finger ROM.
- Use adjustable bath benches for clients with LE ROM limitations or restrictions.
- Use adjustable handheld shower hoses.
- Use lever faucet handles.
- Towel racks should be placed so that reaching remains below shoulder level.
- Faucet controls should be at waist level for clients with ROM restrictions of the spine and/or shoulder.
- Use long-handled sponges to bathe feet for clients with hip limitations or restrictions.
- Use long-handled toe brushes to wash toes.
- Use built-up handles on bathing devices for limited finger ROM.
- Bath caddies and shower racks decrease the need to reach.
- Use shower wraps to dry body after bathing.

Toileting and Toilet Hygiene

Use of Adaptive Equipment or Altering the Task Environment

- Use automatic toilet paper dispensers within easy reach.
- Use comfort-wipe extended-handle toilet paper holders or wiping tongs.
- Raise toilet height or use raised toilet seats for limited or restricted hip ROM.
- Use bidet-toilet combos or bidet-toilet seats for clients with limited UE ROM.
- Place toilet paper holders in easy reach or use long-handled toilet paper holders.
- Toilet seat incline lifts assist with sit-to-stand transfers.
- Sanitary napkins with adhesive strips are easier to use than tampons.

Personal Hygiene and Grooming

Modification of Technique

- Limited shoulder ROM: While seated, support proximal UEs on tabletop/vanity (add book/block to increase elevation) and perform grooming/makeup.
- Restricted shoulder ROM: Use a one-handed technique or perform with upper arm adducted to side and use only the distal extremity (elbow and hand).

Use of Adaptive Equipment or Altering the Task Environment

- Use hair dryer stands.
- Use hair removal creams in place of shaving.
- Using the palm, use pump bottles for shampoo, lotions, and makeup.
- Use long- and curved-handled tools for shaving, hair brushing and combing, and applying lotion.
- For limited finger ROM, use built-up handles for toothbrushes, combs, and brushes. For makeup, select large diameter makeup brushes, lip glosses, and eye pencils. Small-diameter makeup items can be built up with duct tape or pencil grips that can be easily cleaned.³⁰
- Use aerosol bottles for deodorants, hair sprays, powders, and perfumes.
- For limited reach, use long-handled clippers for toenails and one-handed mounted clippers for finger nails.
- Use water flossers and electric toothbrushes.

Dressing

Modification of Technique

- Organize closets so that items are within reach (may require lowering closet pole and adding shelves at waist level). Use reachers to gather clothing. Consider open concept by removing closet doors for easy access. Easy-glide dresser drawers that only require a light push to slide open help to address limited finger and UE ROM. Organize dressers so that commonly worn clothing is placed in drawers at waist level or within easy reach.
- LE ROM limitations:
 - Donning: While seated, use a reacher to grasp the waist of pants or skirt and lower toward the floor to dress the affected LE first, then the unaffected leg. Raise garment above the knees toward the hips. Stand (with ambulatory device) and pull garment above hips. Sit to button or zip garment.
 - Doffing: Unzip or unbutton while seated or standing. While standing, push pants below hips toward knees. Sit and use dressing stick to push the affected leg out of pants, followed by the unaffected leg.
 - Socks: Don with sock aid, doff with dressing stick.
 - Shoes: Use long-handled shoehorns, elastic laces, and slip-on shoes. For posterolateral approaches to total hip arthroplasty (THA), position shoehorn on the medial aspect of the foot, which reduces the chance that clients will move the foot into internal rotation while donning shoes. For anterolateral approaches to THA, position shoehorn on the lateral aspect of the foot to reduce the possibility that clients will move the foot into external rotation while donning shoes.
- UE ROM restrictions on one side (status post rotator cuff repair, shoulder fracture):
- Button-down shirt: For one-handed technique, see section on Loss of Use of One UE or One Side of Body. Also clients can don by placing the affected extremity in a semi-passive pendulum position and bringing the sleeve up the arm to the shoulder. Walk the collar around the neck and place the unaffected arm through the sleeve. To button, start at the bottom button to align the button holes. If clients have limited finger ROM, consider a buttonhook.

- ROM limitations of both UEs: Button-down shirts are easier to don and doff (consider a shirt one size larger or made of stretchable microfiber materials). Use a dressing stick or reacher to bring garment around back. Gradually turn bras around so the cups are in front and slip the hands through the straps.
- Use front-opening bras, step-in bras, or sports bras. Replace hook and eye fasteners with Velcro. For UE ROM limitations, hook a back-opening bra in the front at the waist.

Use of Adaptive Equipment or Altering the Task Environment

- Use long-handled equipment (reachers, dressing sticks, sock aids, and long-handled shoehorns) for LE ROM limitations.
- Use elastic laces or slip-on shoes for restricted or limited ROM and clients who can't bend to touch feet.
- Use front-hook bras or step-in bras for limited shoulder internal rotation.
- Use buttonhooks or Velcro closures for limited finger ROM.
- Use loops on pants waist to pull up pants.

Feeding

Modification of Technique

- Eat with one hand if ROM limitation is specific to one side.

Use of Adaptive Equipment or Altering the Task Environment

- Use built-up utensils for clients with limited finger ROM.³¹
- Use long-handled or curved-handled utensils for clients with limited reach.
- Use rocker knives for clients to cut food with one hand.
- Use universal cuffs for clients with moderate-to-severe grasping limitations.
- Use cups with cut-outs for the nose for clients with limited cervical ROM.
- Use cups with long straws for clients with limited elbow flexion.
- Use T-handle cups for clients with limited finger ROM.
- Use long plastic straws for clients with neck, elbow, and shoulder limitations.
- Use adjustable height tray tables.
- Use electric feeding devices.

Personal Device Care

Modification of Technique

- Clients should sit at a sink or vanity with all required items placed within easy reach.
- For clients with limited shoulder ROM, eye drops can be administered lying supine, keeping the affected extremity near side and using elbow flexion while holding bottle horizontally to administer drops.¹⁹

Use of Adaptive Equipment or Altering the Task Environment

- Deep-well, easy flip-top and easy-grip, large ridge contact cases help clients with limited finger ROM.
- Rechargeable In-The-Ear hearing aids are larger and easier to insert for clients with limited finger ROM. Remotes with push-button volume controls are better than dial controls.
- The Opticare Arthro eye dropper has extended handles and is easy to squeeze for clients with arm and hand ROM limitations.¹⁹

Sexual Activity

Modification of Technique

- There are many ways to be intimate with a partner if a client experiences ROM limitations or restrictions, such as kissing, hugging, caressing, and sexual device use. Prior to sexual activity, a warm shower and pain medication can be effective for clients with ROM and pain issues such as arthritis.³² Surgeons must approve the following for clients postsurgery:
 - Face-to-face missionary positions are safe for clients with ROM restrictions from hip and knee replacements. The client with the hip or knee replacement should position a pillow between the knees and lie beneath the partner. The partner on top should limit the amount of weight on the operated hip or knee and facilitate most of the movement.
 - Side-lying positions (client in front and partner entering from behind) can be used for clients with hip ROM limitations. Face-to-face side-lying can also be used with the partner facilitating most of the movement when clients have back problems.
 - Positions described in weakness can apply to clients with ROM restrictions; however, clients must adhere to precautions.

Use of Adaptive Equipment or Altering the Task Environment

- Use abduction pillows.
- Use electric blankets for clients with painful stiff joints.

Incoordination and Poor Dexterity

Incoordination is the loss of precise smooth movements and can result from central nervous system disorders. Incoordination may present as ataxia, dysmetria, dyssynergia, dysdiadochokinesis, tremors, and involuntary movements.³³ Incoordination leads to poor dexterity, which is loss of fine and nimble manipulation, and motor coordination skills.^{34,35} Clients who have incoordination disorders or poor dexterity have difficulty stabilizing body parts and safely coordinating movements and objects to complete ADLs. Stabilizing the body as much as possible by sitting during ADL activities, bearing weight on the UEs, holding the UEs close to the body, or using splints to stabilize selected joints can improve clients' extremity control.³⁶

Bed Mobility

Modification of Technique

- Clients can delegate assistance for bed mobility, especially for safety.

Use of Adaptive Equipment or Altering the Task Environment

- Use bedrails or halos for safety.
- Use Hoyer lifts.
- Adjustable beds can elevate clients to a seated or supine position. Adjustable turning beds can be used if incoordination interferes with turning/rolling in bed.
- Bed hand blocks are helpful when beds are too soft for clients to push off from.

Bathing and Showering

Modification of Technique

Note: Safety precautions must be closely adhered to.

- Clients should shower in a seated position for safety.

Use of Adaptive Equipment or Altering the Task Environment

- Use grab bars for safety.
- Use adjustable mounted shower hoses.

- Use tub benches or shower chairs (both with arms for safety).
- Use bath mitts with soap in a pocket or soap on a rope to prevent soap slippage.
- Use suctioned shower caddies with pump soap or suctioned bottles.
- Use temperature-control shower valves to control water temperature.
- Use nonskid mats in and outside the shower/tub.
- Preset water temperature.

Toileting and Toilet Hygiene

Modification of Technique

Note: Safety precautions must be closely adhered to.

- Weighted wrist cuffs may assist with stabilizing the UEs during toileting.

Use of Adaptive Equipment or Altering the Task Environment

- Use toilet seats with arms for safety.
- Bidet-toilet combos or bidet-toilet seats reduce difficulty with wiping.
- Use comfort-wipe extended-handle toilet paper holders or wiping tongs.
- Use toilet seat incline lifts to assist with sit-to-stand transfers.
- Sanitary napkins with adhesive strips are easier to use than tampons.

Personal Hygiene and Grooming

Modification of Technique

- Weighted cuffs on wrists may help with accuracy of grooming activities (Fig. 27-20).

Figure 27-20 Weighted wrist cuffs for grooming activities.

- Clients can delegate assistance with makeup application (eyeliner, mascara).
- Tattooed eyeliner and eyebrows eliminate coordination demands.
- Clients should rest elbows on vanities for proximal stability or hold upper arms close to chest when performing grooming activities.
- Standing in a corner enables clients with incoordination to stabilize their trunk and head on the wall of the clients' side, and their forearms on the wall in front for activities involving the face (e.g., brushing teeth, shaving, applying makeup).³⁶
- Using a strap attached to grooming tools that are stabilized around the wrist prevents them from falling.

Use of Adaptive Equipment or Altering the Task Environment

- Electric razors are safer to use and provide more stability.
- Electric toothbrushes are heavier and can be held steady during head movement.
- Use standing hair dryers.
- Large-handled makeup brushes, hair brushes, and toothbrushes facilitate grasp.
- Large lipstick tubes are easier to use than small ones with stabilization of the arms.
- Stick deodorants are preferable to spray deodorants to avoid accidentally spraying the eyes.
- Cutting nails can be unsafe for clients with incoordination. Instead, file nails using an emery board mounted to a flat surface and move nails over the emery board.

Dressing

Modification of Technique

- Button-down shirts are easier to don and doff (consider shirts one size larger or shirts with stretchable microfiber material).
- Velcro closures, zipper pulls, and large buttons are easier to open and close than snaps and hooks.
- Elastic waist pants are easier to don and doff.
- Wrinkle-resistant and stain-shedding materials enable clients to appear well groomed throughout the day.
- Sports bras, step-in bras, and elastic straps on bras make donning and doffing bras easier.

Use of Adaptive Equipment or Altering the Task Environment

- Buttonhooks with enlarged or weighted handles can be used instead of fingers for buttoning.
- Zipper pulls allow ease of pulling zippers up and down.
- Slip-on shoes, shoes with elastic laces, and shoehorns assist with easier shoe donning and doffing, especially for clients with LE ataxia.
- Use sock aids to don and doff socks.

Feeding

Modification of Technique

- Clients should rest elbows on tables for proximal stability.
- Use precut food or have caregivers cut food.
- Use weighted wrist cuffs and/or weighted utensils to improve food-to-mouth time and minimize tremors.^{37,38} Recent studies show that weighted utensils and cuffs may not be as effective in decreasing tremors as previously thought^{39,40}; however, they are still common practice for clients with tremors.
- Avoid sharp utensils for safety.
- Consider food types being eaten—for example, liquids easily spill and ravioli easily slide off forks.
- Provide hand-over-hand assistance as needed.

Use of Adaptive Equipment or Altering the Task Environment

- Dycem or nonskid surfaces stabilize plates and cups (Fig. 27-21).

Figure 27-21 Dycem or nonskid surfaces stabilize plates and cups.

- Plate guards and scoop dishes prevent food from falling off plates.
- Use large-handled eating utensils to facilitate grasp, weighted or swivel utensils for stability, and plastic-coated utensils to protect clients' teeth.
- Use universal cuffs for severe incoordination.
- Use cups and water bottles with lids, sipping spouts, or straws to prevent spills.
- Adaptive utensils accommodate tremors and prevent spillage.
- Cups with long straws that are mounted to wheelchairs and beds prevent spillage and reduce the need to grasp (Fig. 27-22).

Figure 27-22 Cups with long straws that are mounted to wheelchairs prevent spills and reduce grasp needs.

Personal Device Care

Modification of Technique

- When applying or removing contacts and hearing aids, stabilize the UEs. Approach eyes from the sides so that the hand can rest on the cheek when applying contacts.
- Wrist weights may minimize tremors.

Use of Adaptive Equipment or Altering the Task Environment

- Use eye drop guides.
- Use eyeglasses on a chain to prevent dropping.

Sexual Activity

Muscle tremors and incoordination can interfere with clients' ability to engage in sexual activity. Physical pain that might accompany uncoordinated and involuntary movements can make sexual activity painful or uncomfortable. The following modifications allow clients with incoordination and poor dexterity to engage in sex:

- Wrist and ankle weights reduce tremor intensity.
- Both partners can stand against a wall or high table. Clients rest the forearms against the table or wall to stabilize the UEs and use their body weight while standing to stabilize the LEs.
- Both partners can kneel with arms resting on a low stool, sofa, or bed, which stabilizes the UEs. Body weight while kneeling stabilizes the LEs.
- Clients can use pillows for comfort and support.

Decreased Sensation

Absent or impaired sensation affect ADL and IADL performance because of the lack of sensory information provided to the motor system. Modification of technique and adaptive equipment to prevent injury is particularly important when interacting with hot or sharp items. Clients with impaired or absent pain, temperature, touch, and position sense should use compensatory strategies for safety when performing ADLs. The following techniques allow clients with impaired or absent sensation to be independent in ADLs:

- Develop habits of attending to the affected part to protect against burns, cuts, pressure sores, and bruising during ADLs.
- Visually inspect the skin for injury and redness regularly during ADLs. Long-handled mirrors can be used to view areas outside the visual field.
- Protect impaired body parts from sharp items or cold/heat. Avoid placing insensate hands in locations outside the visual field.
- Use vision to compensate for decreased sensation and limb position awareness/mobility when using the hands for ADLs.
- Feeding: For loss of sensation in the hands, use built-up handles for feeding to distribute pressure over a greater surface area. Be cautious when holding hot foods right out of the oven or microwave.
- Reduce the amount of force used to grip objects to prevent breaking them and injuring the hand.
- Bathing: Always start and end with cold water when running a bath. Install an anti-scald valve or temperature-control shower valve in the shower to control water temperature and volume. Adjust the water heater thermostat to below 120°F (49°C).⁴¹ Use body parts with intact sensation or bath thermometers to test water temperature.

- Dressing: Select clothes that are snug enough to prevent bunching, but loose enough to avoid binding or excessive pressure. Inspect clothes visually or with an area of intact sensation to avoid wrinkles. Dress warmly in cold weather to prevent frostbite. Fine manipulation needed for fasteners may be affected by decreased hand sensation. Clients can learn to compensate visually or may benefit from larger fasteners or adaptive devices described for people with impaired coordination, such as buttonhooks or Velcro closures.
- Grooming: Use electric razors for safe shaving. Avoid using electric hair curlers, irons, and straighteners.

Loss of Use of One Upper Extremity or One Side of Body

Individuals who have lost use of one UE or one body side (hemiplegia) are taught one-handed techniques to facilitate ADL independence. Clients with cognitive–perceptual disorders, however, may have difficulty learning and retaining information. Many clients who sustained stroke may also have apraxia, a motor perception disorder that affects motor planning and the ability to learn new or perform previously learned motor skills.⁴² Clients who do not have cognitive–perceptual disorders will find it easier to complete one-handed ADLs.

Bed Mobility

For clients with lost use of one UE or one body side, it is essential to teach bed mobility techniques that are safe and that protect the affected shoulder. It is possible for such clients to roll in bed, move from a supine to seated position, and move back to supine independently with some modifications in technique. If required, adaptive equipment can be used to increase safety and provide support.

Modification of Technique

See section on Weakness.

Use of Adaptive Equipment or Altering the Task Environment

- Bedrails or halos provide support to allow clients to change positions in bed.
- Electric or adjustable beds with powered head and knee controls assist with sitting in bed.
- Leg lifters assist with lifting the affected LE.

Bathing and Showering

Individuals with lost use of one UE or one body side may have difficulty obtaining and opening supplies for bathing, washing all body parts, and maintaining stability and balance while bathing.

Modification of Technique

- Progress from sponge bathing in bed with assistance from family or caregiver, to sponge bathing at the sink, and then bathing in a walk-in or tub shower.
- It is always recommended to shower instead of bathe because getting up and down from the tub floor is difficult.
- Sitting on a tub bench or shower chair provides more stability than standing in the shower.
- Ensure that all supplies are gathered and placed within easy reach before showering.
- Avoid hot water when bathing because it can temporarily increase weakness, if present.

Use of Adaptive Equipment or Altering the Task Environment

- 3-in-1 commodes allow clients to transfer in and out of the tub without the need to stand. They also allow clients to reach all body parts and bathe in a seated position.
- Grab bars provide support by allowing clients to change positions safely.

- Adjustable handheld shower hoses allow clients to bathe in a seated position and reach all body parts.
- Nonslip mats reduce falls.
- Long-handled sponges, brushes, and toe cleaners allow clients to bathe difficult-to-reach areas.

Toileting and Toilet Hygiene

Donning and doffing clothing to complete toileting activities, sitting on the toilet and maintaining balance, and completing toilet hygiene activities may be difficult for clients who have lost use of one UE or one body side.

Modification of Technique

- Use toilet paper dispensers that are located on the unaffected side.
- Use the unaffected hand to obtain the desired amount of toilet paper.
- Use the unaffected UE to complete toilet hygiene activities.
- Adult diapers or bed pans may also be used to prevent toileting accidents.

Use of Adaptive Equipment or Altering the Task Environment

- One-handed toilet paper dispensers allow clients to retrieve toilet paper with one hand.
- Raised toilet seats allow clients to get on and off the toilet safely.
- 3-in-1 or bedside commodes with or without drop arms allow clients quicker and easier toilet access.
- Grab bars provide stability for clients to change position.
- Comfort-wipe extended-toilet paper holders or tongs allow for perianal hygiene.
- Bidet-toilet combos eliminate the need for toilet paper.

Personal Hygiene and Grooming

Individuals who have lost use of one UE or one side of the body will have difficulty manipulating bottles, grasping, and holding onto grooming supplies.

Modification of Technique

- Clients should complete grooming activities in a seated position.
- Apply toothpaste to brush while it rests on the sink.
- Put toothpaste in the mouth instead of on the toothbrush.
- Arrange needed items within easy reach.
- Stabilize containers with the ulnar digits. Use the radial digits of the same hand to unscrew containers.

Use of Adaptive Equipment or Altering the Task Environment

- Electric razors are easier to use with one hand compared to manual razors.
- Shampoo pumps and automatic dispensers allow clients to wash hair without having to open containers.
- Flip-top bottles for shampoo, lotions, creams, and toothpaste are easier to use with one hand compared to screw-top containers.
- Lightweight and wall-mounted hair dryers allow the unaffected extremity to brush or comb hair while hair is being dried.
- Long-handled combs or brushes can reach all parts of the head.
- Curling brushes allow clients to dry, curl, and brush hair with one device instead of multiple devices.
- Use suction nail brushes or one-handed nail clippers attached to the sink or counter; use long-handled and pistol-grip LE toenail clippers.
- Use suction emery boards to file nails.
- Use dental floss holders or water flossers.

- Use one-handed pump toothpaste dispensers.
- Use electric toothbrushes.
- Use suctioned denture brushes and cleaners (soaking dentures overnight).
- Spray-on instead of roll-on deodorants require less effort and do not require applicators to contact the body.

Dressing

For clients who have lost use of one UE or one body side, dressing activities can be done while seated or standing. If clients present with muscle weakness and decreased balance, safety awareness, or endurance, dressing should be completed while seated. Clients can be seated in standard chairs with arm rests or in wheelchairs with their feet on the floor. Clothes should be placed within the client's reach. Clients with lost use of one UE or body side require compensatory techniques and adaptive equipment to dress themselves independently.⁴³⁻⁴⁵ Clients should always don clothing on the affected extremity first and remove clothing from the unaffected extremity last.

Modification of Technique

Following are modification techniques for upper body dressing and lower body dressing.

Upper Body Dressing

- **Donning and doffing shirts and blouses: Technique 1 (Over-the-Shoulder Method)**
-  Place the shirt on the lap, label facing up, collar toward the abdomen, with the sleeve of the affected arm hanging between the knees (Video 27-12).
- Use the unaffected hand to put the affected hand into the sleeve and lean forward to let gravity extend the elbow. Using the unaffected hand, slide the sleeve onto the affected arm while holding onto the shirt.
- Grasp the collar at the point closest to the unaffected side.
- Hold tightly to the collar, lean slightly forward, and bring the collar and shirt around the affected side and behind the neck to the unaffected side.
- Put the unaffected hand into the other armhole and raise the arm out and up to push through the sleeve.
- To straighten the shirt, lean forward slightly, and use the unaffected arm to work the shirt down over the shoulders. Reach back and pull the tail down; straighten the sleeve under the affected axilla with the unaffected UE.
- To button the shirt or blouse, align the shirt fronts and match each button with the correct buttonhole. Use one-handed buttoning or a buttonhook, beginning from the bottom up.
-  To doff, unbutton the shirt and use the unaffected hand to throw the shirt off the unaffected shoulder. Work the shirt sleeve off the unaffected arm, pressing the shirt cuff against the leg to pull the arm out. Lean forward slightly and use the unaffected hand to pull the shirt across the back and off the affected arm (Video 27-13).
- **Donning and doffing shirts and blouses: Technique 2 (overhead method):** This method is less confusing for patients with selected perceptual impairments or limited unaffected UE reach.
 1. Place the shirt on the lap, label facing up, and collar next to the abdomen; drape the shirttail over the knees.
 2. Pick up the affected hand and put it into the sleeve.
 3. Pull the sleeve up over the elbow to avoid the hand falling out when continuing to don the shirt.
 4. Put the unaffected hand into the armhole. Raise the arm and push it through the sleeve as far as possible.
 5. Gather the back of the shirt from tail to collar.
 6. Hold the gathered shirt up, lean forward, tuck chin, and put the shirt over the head.

7. To straighten the shirt, lean forward and work the shirt down over the shoulders. Often, shirts get caught on the affected shoulder and must be pushed back over the shoulder.
8. Reach back and pull the shirt down.
9. To button the shirt or blouse, align the shirt fronts and match each button with the current buttonhole. Start buttoning one handed or with a buttonhook from the bottom up.
10. To doff, unbutton the shirt, lean forward, and use the unaffected hand to gather the shirt up over the back of the neck. Tuck chin, pull shirt over the head, then take the shirt off the unaffected arm first.

■ *Donning and doffing pullover garments*

1. Place the pullover garment on the lap, bottom toward chest, and label facing down.
2. Using the unaffected hand, roll up the bottom edge of the shirt back, all the way up to the sleeve on the affected side.
3. Spread the armhole opening as large as possible. Using the unaffected hand, place the affected arm into the armhole and pull the sleeve up onto the arm past the elbow. Alternatively, the sleeve may be positioned between the legs as described in Technique 1 for shirts and blouses.
4. Insert the unaffected arm into the other sleeve.
5. Gather the shirt back from the bottom edge to the neck, lean forward, tuck the chin, and pass the shirt over the head.
6. Adjust the shirt on the unaffected side up and onto the shoulder, and remove twists.
7. To doff a pullover garment, start at the top back, gather the shirt up, lean forward, tuck chin, and pull the shirt forward over the head. Remove the unaffected arm and then the affected arm.

■ *Donning and doffing bras*

1. For back closure bras, position the bra with the cups in the back and pull the straps in front. The bra on the affected side can be held in position by tucking it between the trunk and the affected arm. Hook the fasteners in the front at waist level. Use the unaffected side to rotate the bra so the hook moves to the back and the cups in front. Place the strap over the affected shoulder with the unaffected side. Hook the unaffected thumb under the strap on the unaffected side and pull it over the shoulder.
2. For front-opening bras, position the bra with the cups in the front. The bra on the affected side can be held in position by tucking it between the trunk and the affected arm. Hook the fasteners in the front at waist level. Place the strap over the affected shoulder with the unaffected side. Hook the unaffected thumb under the strap on the unaffected side and pull it over the shoulder.
3. Step-in bras and sports bras can be easier to use and should be donned and doffed using Technique 2, overhead method described for shirts and blouses.
4. A heavier woman may need an adapted front-closing bra if she cannot approximate the two edges of the bra to fasten it. The bra is adapted with a D-ring on the side of the bra opening on the affected side and a pile Velcro strap on the opposite side. After the bra is around the waist, the strap is threaded through the D-ring and pulled to bring the two bra ends together. Hook Velcro must be stitched onto the bra so the strap can be fastened.

Lower Body Dressing

The following techniques described for donning and doffing pants that can be used for underwear.

■ *Donning and doffing pants in a seated position*

1. The client should be seated on a firm surface with feet on the floor and unaffected limb beyond the midline of the body for balance.
2. Grasp the ankle or calf of the affected leg with the unaffected UE and cross the affected leg over the unaffected leg. Alternatively, cup under the affected knee with clasped hands to lift and cross the leg.
3. Pull the pant over the affected leg up to but not above the knee.
4. Uncross the legs.
5. Put the unaffected leg into the other pant leg.
6. Remain sitting. Pull the pants up above the knees as far as possible.
7. To prevent the pants from dropping when standing, put the affected hand into the pant pocket or the thumb into a belt loop. Alternatively, use a pant clip to attach the pants to the shirt so they do not slide down. Pants with elastic waistbands are also less likely to slide when standing up.
8. Stand up. Pull the pants over the hips; button and zip pants while standing. If clients need support while standing, have them lean against a wall or table. Alternatively, clients with poor balance may remain seated and pull the pants up over the hips by shifting from side to side; they should button and zip pants while seated.
9. To doff pants, unfasten the pants while sitting. Stand and let the pants drop past the knees or push the pants down if wearing elastic waist garments. Sit and remove pants from the unaffected leg. Cross the affected leg over the unaffected leg. Remove the pants from the affected leg. Uncross the legs.
10. For clients with poor balance, pants should be doffed in a seated position. Unfasten the pants. Work the pants down on the hips as far as possible by shifting weight from side to side in the chair. Use the unaffected arm to work the pants down past the hip. Remove the pants from the unaffected leg. Cross the affected leg over the unaffected leg. Remove the pants from the affected leg and uncross the legs.

- ***Donning and doffing pants in bed:*** See section on Weakness.
- ***Donning and doffing socks or stockings***

1. The affected leg is crossed over the unaffected leg using the technique described for donning pants in a seated position.
2. The sock is opened by inserting the thumb and index finger of the unaffected hand into the top of the sock and spreading the fingers.
3. Put the sock on the foot by slipping the toes into the opening made under the spread hand. The sock is then pulled over the heel and over the whole leg. Wrinkles are smoothed.
4. Repeat the process for the unaffected leg.
5. To doff socks, the legs are positioned in the same position required for donning, and the socks are pushed off the foot using the unaffected hand.
6. Sock aids are not useful for people who have lost use of one UE because it is difficult to get the sock onto the aid with only one UE.

- ***Donning and doffing shoes***

1. Loafers are put on the affected foot with shoes on the floor. Lift the affected leg by clasping the unaffected hand under the knee. Then place the foot into the shoe. Shoehorns are used to ease the foot into shoes.
2. For tie shoes, cross the affected leg over the unaffected leg. Put the shoe on by grasping the shoe heel with the unaffected hand and work it back and forth over the heel until it goes on completely. Adapted shoe closures such as elastic laces or Velcro ties can be used. Alternatively, one-handed shoe-tying techniques can be used, but require good cognitive, perceptual, and motor planning skills.
3. To doff shoes, either cross the affected leg over the unaffected leg and pull the shoe up with the unaffected hand, or place the unaffected foot behind the shoe heel on the

affected side and push the affected leg forward while pushing on the shoe heel to pull it off.

■ ***Donning and doffing ankle-foot orthoses***

1. Place the ankle-foot orthosis in the shoe.
2. The shoe laces or ties should be loose enough to allow maximum room for inserting the foot into the orthosis and shoe.
3. Use the techniques described for donning shoes to get the foot into the orthosis and shoe.
4. Apply pressure on the knee with the foot flat on the floor to insert the heel into the shoe.
5. The orthosis acts as a shoehorn as the foot slides into the shoe.
6. To doff orthosis, use the techniques described for removing shoes, while pushing down on the orthosis with the unaffected hand to assist with getting the shoes and orthosis off.

Use of Adaptive Equipment or Altering the Task Environment

- Long-handled dressing sticks assist clients in donning and doffing LE clothing.
- Use bras with Velcro front clasps.
- Use buttonhooks to manipulate buttons with one hand or Velcro strips in place of buttons.
- Clip-on neck ties or pretied conventional ties are easier to use than tying a tie.
- Use shoes with elastic laces or Velcro strap shoes.
- Use long-handled shoehorns to reach shoes while seated.
- Use reachers to retrieve clothing from closets.
- Use stocking aids to reach feet and pull up socks.
- Use fabric loops around sock cuffs to pull up socks by hooking fingers in the loop.

Feeding

The following modification techniques were developed for clients with spinal cord injury. Clients with lost use of one UE or one body side may experience difficulty with tasks such as simultaneously holding a fork and cutting foods with a knife.

Modification of Technique

- Place the affected UE on the table and use the table surface to support the arm while eating.
- Use precut meats and vegetables or have caregivers cut them.

Use of Adaptive Equipment or Altering the Task Environment

- Use of a spork, which combines a spoon and fork, reduces the need to change utensils while eating.
- Rocker knives with or without T-handles allow clients with UE weakness to cut food with one hand using a rocking motion (reduces strength requirements).
- Plate guards and long-lipped plates allow easier scooping of food.
- Dycem or nonskid mats prevent plate movement while eating.
- Food can be stored in containers with easy-open lids for one-handed use.

Personal Device Care

The following modification techniques were developed for clients with spinal cord injury. Clients who have lost use of one UE or one body side may have difficulty using and managing personal devices with one hand.

Modification of Technique

- Sit at a table with the affected arm supported while using, cleaning, and maintaining personal devices.
- Place needed personal devices in close proximity to each other and in easy-to-reach locations.

Use of Adaptive Equipment or Altering the Task Environment

- Large flip-top contact lens cases can be opened and closed with one hand.
- Autosqueeze eye drop bottle dispensers can be operated with one hand.
- Automatic glucose and blood pressure monitors can be used with one hand, have fewer buttons to use (e.g., automatic on/off and no coding), and have multiple strips filled in the drum that eliminate strip reinsertion at each use.

Sexual Activity

The following modification techniques were developed for clients with spinal cord injury. Several resources discuss sexuality after stroke.^{21,45,46} It is important to consider clients' sexuality and body image, fears about resuming sex, bowel and bladder control, birth control, pregnancy, decreased endurance, erectile dysfunction, alternative positions, and sexual activity other than intercourse. For a description of compensatory strategies and adaptive devices for clients having sustained a stroke, see the section on Sexual Activity under Weakness.

Lower Extremity Amputation

The following modification techniques were developed for clients with spinal cord injury. LE amputation is the removal of all or part of the LE on one or both sides.⁴⁷ Clients with LE amputations can benefit from many of the adaptations described for people with limited mobility caused by weakness or limited ROM; however, lower body dressing is unique owing to prosthetic device use. Prior to dressing, clients should change the shoe and/or sock on their prosthesis to match the day's clothing.

- Clients with transtibial (below knee) amputations with pants wide enough to pull up to the knee should dress while seated using the following steps:
 1. Place the pants over the unaffected and amputated leg, pulling pants as far up as possible.
 2. Clients who are stable standing on one leg can stand to pull pants up over the hips and fasten them. They can then sit down to don the residual limb stocking and prosthesis, exposing the area by sliding the pant leg up over the knee.
 3. Clients who are not stable standing on one leg should remain seated and don the prosthesis before standing to pull up their pants. This allows stability of both LEs when standing to pull up pants over the hips.
- Clients with transfemoral (above knee) or transtibial amputations who wish to wear fitted pants that cannot slide over the knees should use the following steps to dress:
 1. Slide the end of the pant leg for the amputated limb over the top of the prosthesis so that the prosthesis is dressed first. The shoe and limited ankle mobility will prevent the pants from sliding over the prosthetic foot.
 2. Don the stocking and prosthesis.
 3. Place the unaffected leg into the pants, stand to pull pants over the hips, and fasten.

Low or Limited Vision

The following modification techniques were developed for clients with spinal cord injury. Low vision is defined as visual acuity of 20/70 or worse in the better eye that is not correctable through surgery, pharmaceuticals, glasses, or contact lenses.⁴⁸ It can be caused by eye diseases, inherited conditions of the eye, aging conditions of the eye, and trauma.

Eye diseases that cause low vision include, but are not limited to, age-related macular degeneration (ARMD), glaucoma, diabetic retinopathy, and retinitis pigmentosa.⁴⁹ Depending on the disease or causative factor, vision loss may include blurred vision, lost sight in certain visual fields, blind spots called scotomas, tunnel vision, low-contrast sensitivity, or lack of glare modulation.⁴⁹ Low vision can impact people of all ages but is primarily associated with older adults, although it is not a normal part of aging.⁵⁰ Low vision places people at risk for falls and other injuries and decreases ADL performance. Impaired psychosocial adaptation, social isolation, and depression frequently occur in older adults with low vision.⁵¹ Many compensatory strategies and techniques can be taught, including the use of residual vision, modifying the environment, and using adaptive equipment to support safe ADL performance.

Meyers⁵² outlined four intervention steps for clients with low vision to assist clinical decision-making. Therapists should move through steps 1 to 4 for each intervention task.

1. Maximize visual functioning. Refer the client to the eye doctor to obtain best-corrected vision. Therapists should work with clients to identify and use remaining best vision to compensate for areas of lost vision.
2. Modify the task or environment to enhance visual performance. Use bigger items and magnification devices, increase contrast, simplify or increase visual cues, sit closer, increase or change lighting, decrease glare, and decrease clutter.
3. Modify tasks or environments to reduce or eliminate visual performance. Use tactile cueing or touch, use smell to identify items, use auditory output devices, store items in the same location and order to enhance memory, and substitute different tools or items that do not require vision to accomplish the task.
4. Eliminate tasks or ask caregivers to complete tasks.

The following modification techniques were developed for clients with spinal cord injury. For clients with substantial vision loss, consider referring individuals to low vision optometrists, certified low vision specialists, rehabilitation teachers, orientation and mobility specialists, or specialized low vision occupational therapists for expert guidance in obtaining the appropriate magnification devices and technology.

General recommendations to support clients with low vision include:

- Increase lighting: Use higher watt bulbs and additional room lighting. Use floor or table lamps with hoods (over lights) and adjustable necks to increase illumination directly onto ADL task areas and away from the eyes to avoid glare.
- Reduce glare: Use blinds, curtains, or tinted windows to control outside glare, cover shiny surfaces, and avoid too much lighting (which can create glare).
- Maximize contrast: Increase contrast on objects and surroundings compared to backgrounds (as shown in table arrangement in Fig. 27-21).
- Organize and label items: Reduce clutter in drawers, shelves, and closets. Organize items by maintaining commonly used items together. Label items with markers on high-contrast backgrounds.
- Use tactile cues (e.g., Velcro, buttons, raised marker pens) to identify and differentiate objects, or indicate orientation.
- Use auditory cues on devices such as blood pressure cuffs, glucometers, and alarms.
- Use sense of smell to identify products.
- Remove hazards such as clutter in walkways. Organize furniture consistently to support safe movement.

Bathing and Showering

The following modification techniques were developed for clients with spinal cord injury. Clients with low vision may have difficulty locating and identifying similarly sized bottles and supplies and being safe in the bathroom. The following techniques enable clients with low vision to be safe and functional while bathing and showering.

- Use high contrast in the bathroom between tubs, floors, showers, and bathing equipment to enhance safety.
- Maintain bathing supplies in the same area and order.
- Use visual cues, such as different colored bottles and caps/lids, or adhere different colored tapes to bottles and supplies.
- Use visual or tactile cues to identify hot/cold water faucets or to identify direction in a unilevered faucet.
- Use color-contrasted soap.
- Feel for water level when filling the tub, use talking bath thermometers, lower hot water temperature to below 120°F (49°C), or use temperature-control shower valves.

Toileting and Toilet Hygiene

The following modification techniques were developed for clients with spinal cord injury. Clients with low vision may have difficulty locating the toilet, transferring safely onto the seat, locating grab bars for sit-to-stand support, and locating toilet paper. Modifications to the toilet include the following:

- Select toilet seats or toilets that contrast with the floor color.
- Place contrasting colored tape or nonskid mats on the floor around the toilet base.
- Maintain toilet paper in the same, easy-to-reach, clutter-free area against a contrasting colored surface.
- Use bidet-toilets or toilet seat-bidet combos to ensure thorough cleaning.

Personal Hygiene and Grooming

The following modification techniques were developed for clients with spinal cord injury. Grooming often includes the use of small tools and the application of materials to small areas, which can be difficult for clients with low vision. Techniques that enable clients with low vision to complete grooming activities independently include the following:

- Use magnifiers, lighted magnifiers, or magnified mirror stands to identify small objects or see the face.
- Use labeled tray dividers to hold items like cosmetics and hygiene supplies.
- Organize supplies in the same order using a technique that is intuitive to the client.
- Group commonly used items together. For example, put hair dryers, curling irons, brushes, and other related supplies in a one-handled basket that fits beneath the sink.
- For safety, use electric razors, electric nose and ear hair trimmers, and hair removal creams.
- Use smell to identify supplies.
- Place toothpaste on a finger and then on the toothbrush. Or, squeeze toothpaste into mouth or a cup, and dip toothbrush in.
- Use fingers to apply cosmetics to face area.
- Use the fingers of one hand as a guide when shaving sideburns or applying eyebrow pencil.
- Use emery boards to file nails.
- Avoid aerosol sprays; clients with low vision cannot see the extent of spray.

Dressing

- Increase closet lighting.
- Label drawers with large print or tactile cues.
- Use large colored ribbons tied to closet poles to divide garments into sections for the identification of color, type, and specific outfits.
- Maintain adaptive dressing devices in the same place.
- Maintain shoes in their original boxes, label boxes in large print or tactile cues for identification, and store in a systematic way. When storing shoes, tie them together in

pairs, or slip one inside the other.

- Pin dirty socks together so that socks stay matched when laundered.
- Place small safety pins or other tactile cues inside clothing so that it is worn in the correct orientation.
- Place tactile labels (e.g., Hi-Marks pen dots, iron-on tape) inside clothes to identify colors and match clothing.
- Talking “color identifiers” or phone apps are available in several models from low vision dealers. When pointed at objects, they verbally identify colors.
- An inexpensive voice labeling system called “Pen Friend” allows easy recording onto self-adhesive labels.
- Ask caregivers to place accessories in bags and hang them with appropriate outfits.
- Ask caregivers to hang matching outfits together.

Feeding

The following modification techniques were developed for clients with spinal cord injury. Clients with low vision may have difficulty setting up, arranging, and identifying the location of cups, plates, and utensils. Understanding the location of food on plates, cutting food, and spearing food with a fork may be challenging. Feeding adaptations for clients with low vision include the following:

- Use dishes, cups, and napkins that contrast with the table or table linens.
- Pour liquids into contrasting colored cups (e.g., coffee in a white mug). When pouring liquids, the correct amount can be determined by inserting a clean finger over the cup rim to feel when the liquid is near the top. Liquid-level indicators placed on cup rims provide auditory signals when cups are nearly full.
- Caregivers can use the clock method to describe food location on plates (e.g., meat at 6:00, vegetables at 3:00). Different food items (e.g., meats, vegetables) can be served in consistent locations on plates.
- To locate utensils, plates, and glasses, use a place mat and set items in a grid form. Ensure high contrast between placemat and items.
- To cut food, find food edges with a fork. Move the fork a bite-sized amount into the meat, and then cut the food, keeping the knife in contact with the fork.
- Place main dishes, side dishes, seasonings, and condiments in a semicircle or straight line just outside the client’s place setting area. Place items in the same order at each meal. Shake seasonings into the palm; then apply to food in pinches. Pour ketchup, mustard, sauces, and liquid seasonings in small side bowls or on the side of plates for dipping or spooning as needed.
- Use tactile cues to identify similarly shaped or colored containers, like salt and pepper shakers.
- Use dinner plates with raised lips to avoid spills while eating.
- When reaching for table items, curl fingers and move them slowly along the table until they reach items.

Personal Device Care

- Use tactile cues, visual cues, and olfaction to identify personal care products and cleaners.
- Substitute medical devices with audio output devices such as glucometers and blood pressure cuffs.
- Use handheld or tabletop magnification aids with or without lights.

Bariatric Considerations

The following modification techniques were developed for clients with spinal cord injury. The World Health Organization defines overweight and obesity as abnormal or excessive fat accumulation that may impair health.⁵³ Body mass index (BMI), calculated as body

weight in kilograms divided by height in meters squared (kg/m^2), is commonly used to identify overweight and obesity in adults.⁵³ In adults, BMIs between 18.5 and 25 are desirable. BMIs between 25 and 30 are classified as overweight, 30+ are obese, and 40+ are morbidly obese. Bariatrics is a health care field that relates to or specializes in the investigation, prevention, and treatment of obesity.^{54,55}

Obesity can aggravate osteoarthritis, damage joint structures, destroy cartilage, and cause spinal and peripheral nerve compression—which can lead to difficulty moving and reaching, decreased activity tolerance and mobility, and difficulty accessing the environment. Excessively large individuals with a medical condition may have more occupational performance deficits than are typically seen because of preexisting limitations in strength relative to body mass, limited reach, and decreased endurance.

It is important to complete a thorough functional assessment to identify all occupational performance challenges and to determine the most appropriate adaptive equipment.⁵⁶ Most standard DME is manufactured to serve individuals weighing approximately 250 to 300 lb. Individuals weighing more must have specialized equipment ordered. Bariatric equipment is made extra wide and with materials to provide stable support for obese and morbidly obese individuals. It is important to identify body type and fat distribution to determine the proper equipment that fits the client and environment. Some modifications that can assist in functional activities in bariatric care are outlined in the subsequent sections.

Bed Mobility

- Use handrails, halos, or overhead trapeze bars for repositioning and moving from supine to sitting in bed.
- Electronic bariatric beds are designed to allow for capacities of up to 1,000 lb. They can also be electronically adjusted to assist bed mobility and positioning.
- Overhead lifts and Hoyer lifts used with slings can mechanically assist with turning and repositioning.

Bathing and Showering

- If clients have difficulty standing, bathe while seated on bariatric shower commode chairs, tub seats, tub transfer benches, or shower chairs with or without backs. If back support is required, choose seats with an open area in the lower back to accommodate posterior body mass when seated.
- Use long-handled sponges to wash LEs, back, and buttocks.
- Use long-handled sponges in different sizes to wash between skin folds and difficult-to-reach areas.
- Heavy-duty grab bars can be installed to provide assistance for sit-to-stand transfers to wash and rinse the body.
- Use of adjustable handheld shower hoses allows clients to bathe safely without the need to stand to access areas between skin folds and difficult-to-reach body parts.
- Clients should rinse well and end with cool water to lower skin temperature.
- Use clean towels to dry off. Extra care is needed on areas where skin contacts skin. Use fans or hair dryers (set on cool) to dry skin.
- If clients cannot get into the tub or shower, sponge bathe with assistance at the sink, while seated in a wheelchair or bed. Caregivers can assist to reach and lift skin folds and to access difficult-to-reach places.

Toileting and Toilet Hygiene

- Use reachers and dressing sticks to pull up garments after toileting.
- Use comfort-wipe extended-handle toilet paper holders or toilet tongs to hold/release tissue and extend reach for hygienic cleaning.
- Toilet seat-bidets or toilet-bidet combos eliminate the need for wiping.
- Use raised toilet seats that can accommodate weight.

- Use heavy-duty bariatric commodes that stand alone or over the toilet as a safety frame. Extra wide seats can be ordered. Drop-arm commodes allow transfers when clients cannot stand.

Personal Hygiene and Grooming

- Use spray products such as dry shampoo, hair spray, and deodorant to compensate for decreased reach.
- Wall-mounted hair dryers allow hair to be dried without holding and raising the hair dryer.
- Use long-handled mirrors for skin inspection (Fig. 27-23).

Figure 27-23 Long-handled mirrors for skin inspection.

- Use long-handled brushes and combs.
- Portable and inflatable wash basins allow hair to be washed in bed by caregivers.

Dressing

The following modification techniques were developed for clients with spinal cord injury. Clients with obesity have many body areas with skin folds where skin consistently contacts skin. Air cannot circulate in these areas, and moisture builds, creating irritation and an environment for bacteria and yeast growth.

- Clients should wear natural fibers (such as cotton or rayon) that breathe and pull moisture away from the body, allowing it to evaporate.
- Washable liners should be placed under bras and abdominal liners between skin folds to absorb perspiration and prevent skin irritation.
- For the upper body, wear pullover or front-opening clothing that is stretchable and nonconstrictive. Dressing sticks can be used to assist upper body dressing.
- Wear pants with elastic waists to eliminate the need to reach for zippers and buttons. Use dressing sticks or reachers to don and doff lower body clothing.
- Wear nonbinding extra-width socks. Cotton and polypropylene are best for absorbing perspiration.
- To don socks, use a deluxe sock aid that is flexible, soft, and made larger.
- Slip-on shoes, elastic laces, and Velcro strap shoes can compensate for difficulty reaching the feet. Long-handled shoehorns assist with donning shoes.
- Reachers can be used to retrieve items from the floor and surrounding areas.

Sexual Activity

The following modification techniques were developed for clients with spinal cord injury. Studies of sexual function in obese patients in clinical settings show a relationship between obesity and lower levels of sexual functioning, especially erectile dysfunction.⁵⁷ Positioning can be challenging with larger body sizes and cause increased joint pain. Experiment with positions that alleviate each partner's joint stress. Use large firm pillows for support and positioning. For sexual intercourse, suggested positions include spooning, rear entry, and modified missionary positions with pillows supporting the hips and back.

Memory Deficits

The following modification techniques were developed for clients with spinal cord injury. Cognition involves the ability to perceive, understand, and make use of information.⁵⁸ An important component of cognition is memory, which includes storing and retrieving information for use. Memory deficits can have significant impact on clients' ability to remember ADL steps and sequences. Strategies that can assist clients with memory deficits in independent ADL performance include:

- Use of graded cueing strategies beginning with verbal, then visual, and finally tactile cues.
- Simplifying activities by breaking them into small steps.
- Reducing the amount of physical, visual, and auditory clutter in the environment.
- Developing lists of needed ADL and the order in which they should be completed.
- Posting large, visual, step-by-step instructions in the areas where ADLs are performed (such as toileting instructions in front of the commode).
- Using alarms to remind clients when ADLs need to be completed (such as toileting routines, and eating and medication schedules).
- Journaling to remember tasks that need to be or have been completed.
- Using labels on containers, bottles, and cupboards as organizational reminders.
- Lists, alarms, journals, and reminders can be configured on smartphones and tablets because of programming ease and information portability.
- Intelligent assistive technologies help clients with memory deficits in ADL performance, such as the Archipel (assists with cooking) and COACH (assists with hand washing).⁵⁹⁻⁶¹

CASE STUDY

Patient Information

Lena is an 82-year-old Asian female who lives with her husband in a one-floor, elevator apartment in Chinatown. She has two grown children who live over 4 hours away by car. Every morning, Lena participates in a Tai Chi class in her apartment building. On her way to class, she lost her balance while descending a curb and fell onto the asphalt. She was helped to stand by several people but was unable to bear weight on her right leg. Lena was taken to the hospital where an x-ray revealed a nondisplaced fracture of the right femoral head. Her medical management at the acute care hospital included surgical open reduction, internal fixation (ORIF) of the right hip (hip pinning). The next morning and throughout the day after surgery, Lena's nurses reported that she was very lethargic and had reduced motor activity, confusion, and incoherent speech. She was diagnosed with postoperative hypoactive delirium. At post-op day 3, Lena was still lethargic and had difficulty with short-term memory, but was less confused and spoke coherently. When asked, Lena could not recall her hip precautions. She was discharged to a skilled nursing facility the next day.

Reason for Occupational Therapy Referral

Lena was referred for subacute rehabilitation services that included OT to increase ADL independence. She was weight bearing as tolerated (WBAT) and was required to follow hip precautions. Her cognitive status was of concern as it impacted her safety and

judgment during ADLs. Prior to falling, Lena was independent in ADLs. She cooked both lunch and dinner daily for herself and husband. Lena was very active in her community and participated in the occupations of gardening, Tai Chi, and Chinese sword dancing without assistance. Her medical history included osteoporosis and depression.

Assessment Process and Results

The subacute OT evaluation began with an occupational profile interview. Lena revealed that she lives with her husband in a step-free, elevator apartment. She was able to identify her meaningful occupations and could describe a typical day in her life. Lena told the therapist that she does not use any equipment and has one bathroom with a tub/shower without grab bars, and a small kitchen. She was oriented to her name, but not to date. Lena knew that she was in a hospital but did not know the hospital name. She could not recall any of her hip precautions.

Assessment showed Lena's UE ROM and muscle strength to be within functional limits (WFL). Sensation of BUEs was intact. Pain was a 7/10 for the right hip. Moderate assistance (FIM 3) was needed to move from supine to sitting at bedside. A bed-to-chair transfer using a rolling walker required maximum assistance (FIM 2). Upper body dressing required minimal assistance (FIM 4). Lower body dressing using long-handled devices required maximum assistance (FIM 2). Upper body bathing (at sink) required modified independence. Lower body bathing (at sink) using long-handled devices required maximum assistance (FIM 2). Lena required verbal cues to maintain hip precautions during the evaluation.

Occupational Therapy Problem List

- Decreased independence in BADLs and IADLs
- Decreased performance in transfers
- Decreased memory (leading to safety concerns during ADLs/IADLs)
- Pain in right hip

Occupational Therapy Goal List (By Discharge in 2 Weeks)

- Modified independence with lower body dressing using long-handled devices
- Modified independence with lower body bathing using long-handled devices and tub bench
- Decreased pain in hip to 3/10 during ADLs
- Independence in bed mobility
- Modified independence in all transfers using a rolling walker/cane
- Communicate and demonstrate an understanding of hip precautions during all ADLs
- Modified independence in small meal preparation

Intervention

The first day of treatment began in Lena's room with bed mobility (supine to sit) while adhering to hip precautions. Lena appeared more upbeat and reported her pain at a 3/10, which she attributed to a good night sleep and taking pain medication 30 minutes before therapy. The therapist reviewed hip precautions with Lena and described supine-to-sit movements before beginning. Lena was then instructed to roll onto her left side, push up with her arms, and bring her legs off the bed to a sitting position. She required minimal assistance to move the right leg off the bed.

The therapist adjusted the bed height to assist with transfers from sit to stand to rolling walker. Once seated on the bed edge, Lena was instructed to push off with both hands, making certain not to flex her hip above 90° by straightening the right affected leg out in front when standing. Once standing, she grasped the walker and took small steps toward a chair. Lena required standby assistance and two verbal cues for correct hand placement as she reached for the walker before standing. She walked 10 feet to the chair with close

supervision. Lena was instructed to feel the chair on the back of her legs before sitting. When lowering herself to the chair, the therapist instructed her to reach back for the chair arm with one hand and hold onto the walker with the other hand. When lowering herself to the chair, she was instructed to slide the involved leg out in front. Lena was able to follow these steps with one verbal cue to remind her to reach back with one hand.

The treatment session concluded with Lena practicing lower body dressing from the chair. When asked, Lena was able to recall two-thirds hip precautions. Lena required minimal assistance to don her socks using a sock aid. To don her elastic pants, Lena was instructed to use a reacher to grasp and lower her pants waist toward the floor to dress the affected LE first, followed by the unaffected leg. Then, using the reacher, she raised her pants above her knees toward her hips. Lena then stood with her walker and pulled her pants above her hips. Lena required minimal assistance to stand to pull up her pants, and verbal cues to use the reacher and maintain hip precautions. She was able to don her slip-on shoes with a long-handled shoehorn.

In subsequent sessions, the therapist worked with Lena to further improve her ADL status to modified independence while adhering to hip precautions. Lena became more oriented and interactive in therapy sessions. The therapist also worked with Lena on Tai Chi from a seated position and asked Lena to teach her several movements. This helped prevent deconditioning of Lena's UEs and began reengagement in one of her identified meaningful occupations. Lena was very excited to show the therapist Tai Chi movements and decided to perform Tai Chi in a chair every morning after breakfast. Because Lena cooks at home, Lena and the therapist practiced using her walker to retrieve kitchen items from the refrigerator, cabinets, and oven. At the end of her stay, Lena prepared a small side dish for a traditional Chinese meal while using her rolling walker with a tray to transport cooking items. By discharge, Lena demonstrated safety during all ADLs, and her mild cognitive confusion and decreased memory resolved. Discharge plans included recommendations for home care OT to address safety during ADLs in the home, and ordering of a tub bench and raised toilet seat.

Evidence Table of Studies for ADL Interventions

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Use of everyday life occupations and a client-centered approach in stroke rehabilitation ⁶²	Varied OT interventions that used a client-centered approach or occupation. Interventions included therapeutic occupations or adaptive or compensatory occupations for stroke rehabilitation.	Twenty-five studies with a total of 2,792 patients, relatives, and staff; 75 OTs or staff members; and 9 systematic reviews/meta-analyses	Use of client-centered approaches and everyday occupations varied across included studies.	Systematic review Level I	Using a client-centered approach and/or everyday occupations in OT intervention resulted in improved outcomes in ADLs and participation.	No statistical analysis

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Comparison of two groups of adults with stroke. Control group received a pre-discharge home visit only and intervention group received additional training in bathing assistive devices (ADs) ⁶³	Both groups received prescription and training for bathing ADs in the hospital. Control group received a pre-discharge home visit, but no treatment post-discharge. Intervention group received additional home-based training in AD use by occupational therapists upon discharge including AD use in home and safety.	Fifty-three older adults with stroke randomly assigned to intervention ($n = 30$) and control ($n = 23$) groups	At least two, but not more than three follow-up home services, were provided to intervention group. Control group received one pre-discharge home visit, but no intervention at home.	Randomized controlled trial Level I	Home visits and training in bathing ADs improved independence level, AD use, and satisfaction with AD use for older adults with stroke.	FIM pretest–posttest total mean difference (MD) and motor MD were higher in intervention than control group ($p < 0.001$). At 3 months, FIM motor scores were higher in intervention than control group ($p = 0.051$). QUEST mean score was higher in intervention (4.63) than control group (3.72).
Efficacy of OT interventions in clients with dementia to recover or strengthen residual functional capacities ⁶⁴	Both groups received OT ADL interventions to recover or improve function including washing, personal hygiene, dressing, sanitary services, and eating.	Thirty-five clients with dementia and moderate-to-severe cognitive impairment (14 = vascular dementia, 20 = Alzheimer dementia)	ADL interventions for 40 days including washing, personal hygiene, dressing, sanitary services, and eating	Two group pretest–posttest design Level II	OT ADL interventions improved functional performance in ADLs for individuals with dementia.	Clients in both groups showed statistically significant improvements in washing, sanitary services use, and dressing ($p < 0.00$) measured on the RBEB. No significant differences between groups. Improvements seen in personal hygiene and nutritional functions, but not statistically significant.

Restoring Family, Parenting, and Social Roles

Sharon A. Gutman and Marianne H. Mortera

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Understand how disability impacts family, parenting, and social roles.
2. Understand how occupational therapists use remediation, adaptation, and compensation in client role restoration and assumption.
3. Understand how occupational therapists help clients restore or newly assume parenting roles after disability onset.
4. Identify adaptive strategies and equipment that support parenting roles.
5. Understand how occupational therapists help clients restore or newly assume caregiving of pets and animals assistants after disability onset.
6. Identify adaptive strategies and equipment that support animal caregiving roles.
7. Understand how occupational therapists help clients restore or newly assume dating and courtship roles after disability onset.
8. Identify adaptive strategies that support dating and courtship roles.

CHAPTER OUTLINE

Role Disruption after Physical Disability
Family Roles
Social Roles
Case Study

TERMINOLOGY

Adaptation: an intervention method in which an activity or environment is modified to promote client performance of desired activities and roles.

Compensation: an intervention method in which strategies and devices are used to substitute for impaired client skills that have minimal or no recovery potential after disability.

Family roles: positions in a family unit that support the maintenance of individual member and family functions, including feeding, bathing, clothing, housing, health care provision, companionship, nurturing, and financial assistance.

Remediation: an intervention method in which impaired client skills that have recovery potential are addressed through therapeutic activities designed to restore lost or diminished function after disability.

Role conflict: discordance in role performance resulting from (1) the opposing demands of several different roles held by one individual, or (2) contrasting role performance expectations perceived by the individual, significant others, and larger community.

Role disruption: a temporary or permanent interruption in the ability to carry out and perform the functions associated with a specific family and/or social role as a result of disability, illness, injury, and aging.

Role distress: the occurrence of anxiety and stress resulting from an inability to carry out the perceived essential functions associated with specific desired family or

social roles as a result of skill deficits; lack of needed knowledge; or disability, illness, and aging.

Social roles: positions within a social system that are characterized by a set of behaviors intended to fulfill role expectations defined by the individual, significant others, and larger community and that support community participation.

Role Disruption after Physical Disability

Illness, disease, and injury commonly result in disabilities that disrupt a client's participation in desired family and **social roles**. For example, sustaining traumatic brain injury (TBI) that causes mild-to-severe cognitive, visual perceptual, emotional regulatory, and physical impairments can significantly impede a client's ability to carry out the activities associated with spousal roles, parenting, and elder caregiving, including¹:

- Overseeing bathing, feeding, and clothing of children
- Managing a family home or an elderly parent's residence
- Participating in joint decision-making regarding family concerns
- Earning an income that supports the family's material needs
- Managing a family's financial decisions and assets
- Overseeing health care and medical decisions of an elderly parent
- Maintaining intimate and healthy interpersonal relationships with all family members
- Providing caregiving, nurturance, and companionship

Depending on the severity, **role disruption** resulting from disability can have devastating effects on the ability to maintain the roles that clients constructed prior to disability. Consequently, it is estimated that 50% to 75% of individuals sustaining severe and permanent disability—such as TBI, spinal cord injury (SCI), and cerebrovascular accident—commonly experience family and social role disruption, including divorce, loss of primary parenting responsibilities, and lost connection with predisability friends and social support systems.²⁻⁴

Our primary roles as occupational therapists are to help clients restore desired roles that have been lost as a result of disability and assume new roles desired postdisability. Evaluation should begin with an assessment of the role changes that clients have experienced or are likely to experience when discharged from the hospital. Once role changes postdisability are understood, an assessment of the client's ability to engage in the specific activities supporting each desired role should be made. A client's activity participation will depend on (a) the requirements of the activity (i.e., activity demands), (b) client skills (i.e., cognitive, sensory-motor, musculoskeletal, visual perceptual, and psychosocial skills), and (c) environmental supports and barriers that impede or facilitate activity participation.

Restoring former roles and assisting in the assumption of new roles postdisability requires:

1. **Remediation** of skill deficits having the potential for improved function (e.g., increasing muscular strength, joint range of motion, cognitive executive functions, visual scanning)
2. Adapting an activity or modifying the environment to enhance client performance (e.g., using built-up handles on eating utensils to increase grasp, and installing grab bars and toilet rails to increase safe bathing)
3. Using compensatory strategies and devices to substitute for impaired client functions that have minimal to no potential for recovery (e.g., using electronic reminder systems and voice activated computer features).

Family Roles

A family system is defined as a small group of individuals who are connected to each other by birth, legal union, and/or self-proclaimed feelings of loyalty and reciprocal affection.^{5,6} Although family systems have traditionally been defined in Western society as small units comprised of people related by birth and legal designations (e.g., parents, children, siblings, grandparents, aunts and uncles, extended relatives), such formal relationships have loosened in recent decades, allowing for the broader inclusion of unmarried partners having children, people of the same sex who have either legally married or are in committed partnerships, blended families comprised of parents and children from separate birth families in which the spouses have divorced and remarried, and individuals who are considered as family members because of reciprocal closeness and affection but who are neither related by birth or legal designations. In recent decades, family pets have been elevated to a unique status equivalent, in many instances, to human members. Family members enter through birth, adoption, marriage, or other legal union (e.g., domestic partnership); maintain their membership over time; and leave by death, divorce, mutual consent, and sometimes abandonment. Regardless of the family type noted earlier, most families deal with the similar issues of caregiving and providing nurturance, managing a communal home, earning money sufficient to provide for the family's material needs, child rearing, elder caregiving, sustaining healthy interpersonal relationships, and supporting each members' participation in the larger community.⁷

The most common **family roles** disrupted by adult disability include spousal roles, parenting, and elder caregiving.⁸⁻¹¹ Restoring the activities associated with spousal and elder caregiving roles—providing emotional support and nurturance, self-care and medical assistance, home management and meal preparation, and working to financially support family material needs—is addressed in Chapters 27 and 29. This chapter addresses restoration of parenting roles and caring for pets and animal assistants who are considered to be family members.

Restoring or Newly Assuming Parenting Roles

Approximately 6 to 9 million adults with moderate-to-severe disability (e.g., TBI, SCI, progressive neurological disorders such as multiple sclerosis) have young children under the age of 10 and must seek help for or modify activities needed for parenting.¹² Parenting activities that are commonly impacted by disability include bathing, feeding, and dressing infants and children; engaging in play and recreational activities; and providing affection and healthy limit setting.¹³⁻¹⁶ When clients need to resume or newly assume parenting roles with disability, therapists must first collect information regarding (1) the infant or child's age and any special needs, (2) the type and amount of support available for childcare assistance (e.g., financial resources for equipment and hired caregivers, and the existence of family members who can participate in infant and child care), and (3) the presence of environmental barriers (e.g., inability to access a standard floor tub in which to bathe children).

Therapists should then determine the specific parenting activities for which the client desires resumption or new assumption and implement an activity analysis to understand each task's unique requirements (see Chapter 3). Clients should be observed while attempting to perform each activity in order to evaluate whether they possess sufficient abilities with regard to cognitive, sensory-motor, musculoskeletal, visual perceptual, and psychosocial skills.

Performance should be observed in natural contexts whenever possible and in simulated environments when not possible. Intervention should address (1) remediation of skill deficits having the potential for recovery, (2) **adaptation** or modification of the activity or environment to facilitate performance, and (3) **compensation** using alternative strategies and devices when recovery of skill deficits is not possible.

Transitional Activities: Holding, Carrying, and Transferring

The transitional activities of holding, carrying, and physically transferring infants and toddlers are components embedded within all other caregiving activities (e.g., bathing, feeding, dressing) and must be addressed to support parenting roles. There are a number of adaptive devices designed to aid in the assistance of transitional activities for parents with physical disabilities.

Safety Straps, Harnesses, and Front Packs

Safety straps, harnesses, and front packs allow infants and toddlers to be safely secured to a parent's lap or trunk for transport (see Fig. 28-1). These devices enable a parent's arms and hands to be freed for other activities or to be freed from use when hand function is impaired. When fine motor ability is limited, safety straps, harnesses, and front packs must either be secured by another individual or adapted to match the parent's hand function. These devices allow parents in wheelchairs to transport infants and toddlers with ease and safety.

Figure 28-1 Mother using a safety harness to transport her infant. (Printed with permission from Dorothee Riedel, Spinalisttips, <http://www.spinalisttips.se>)

Fabric Carriers

Fabric carriers are similar to small cradles in which the infant is positioned (see Fig. 28-2). A secure strap is placed over the shoulders to hold the carrier in place as it is positioned on the parent's lap. Fabric carriers allow hands-free transport of infants, particularly for parents using wheelchairs. Such devices, however, may be contraindicated

for parents with poor trunk control or chronic back pain because infant weight is supported in part by the shoulder strap positioned around the parent's upper back and shoulders.

Figure 28-2 Father transporting an infant in a carrier on lap. (Printed with permission from Dorothee Riedel, Spinalisttips, <http://www.spinalisttips.se>)

Adjustable Wheeled Infant Carriers

Adjustable wheeled infant carriers are similar to small cradles on wheels and can be raised or lowered in height to accommodate parent needs (see Fig. 28-3). The infant is strapped securely in the cradle area and can be transported easily by parents in wheelchairs who possess sufficient upper extremity (UE) strength and mobility. This device is particularly beneficial for parents with limited hand function, UE and trunk weakness, lower extremity (LE) paralysis, and who fatigue easily with activity (e.g., multiple sclerosis).

Figure 28-3 Adjustable-height wheeled infant carrier. (Printed with permission from Dorothee Riedel, Spinalisttips, <http://www.spinalisttips.se>)

Wrist Supports

Parents with limited arm and hand movement secondary to weakness and pain (e.g., rheumatoid arthritis) may benefit from the use of wrist supports to reduce joint stress when lifting and carrying their infants and toddlers. Wrist supports should be customized for parents with regard to their specific hand impairments and activity needs.

All of the abovementioned equipment and adaptive devices can be trialed using weighted dolls in order to provide practice opportunities that enhance client performance, safety, and confidence. Additionally, therapists should provide client education regarding safe body mechanics and proper positioning when lifting, holding, and carrying infants and toddlers. Remediation approaches may address activities designed to increase UE strength, trunk control, and dynamic sitting or standing balance when the potential for improvement exists. For example, to enhance functional endurance and activity tolerance, clients could practice lifting and transporting weighted dolls in varying adaptive infant carriers for progressively longer periods. To enhance functional UE strength, clients could practice reaching for infant supplies spread across a table area using proper body mechanics while seated in a wheelchair or standing. To increase task demands, clients could be fitted with weighted wrist cuffs, or retrievable items could be selected to provide a progression of weights and sizes.

Bathing

Parents using wheelchairs, those who cannot stand for long periods of time secondary to LE weakness and balance deficits, and parents with insufficient trunk control to reach toward the floor will have difficulty bathing infants and toddlers in portable baby bathtubs placed within standard floor tubs or on kitchen/bathroom counters. In these cases, bathing infants and toddlers can be achieved by positioning a portable baby bathtub on a secure table (28"-34" [\sim 71-86 cm] high in accordance with the American with Disabilities Act [ADA] standards), allowing wheelchair access near a sink. If the baby bathtub does not possess rubber grips, a nonskid mat can be positioned beneath the tub to safely secure it to the table surface. The tub can be filled and drained using a portable hose connected to the sink faucet and drained into the sink basin; parents, however, must either possess

sufficient hand function to attach the hose or depend on another individual for set up. For parents with UE sensory loss, baby bath temperature readers can be used to reduce possible scalding and ensure safety. C-shaped plastic handles can be attached to infant care products (e.g., shampoo and soap bottles) to enhance grasp when parents possess limited hand mobility; shampoo and liquid soap can also be transferred to pump-style dispensers to reduce the need for functional grasp. Similarly, wash towels can either be sewn into the shape of a mitt or purchased in this form for parents with limited hand function and coordination.

Remediative strategies would include, when possible, activities designed to increase UE strength, trunk control, dynamic sitting balance, functional endurance, and activity tolerance. For example, clients in wheelchairs could practice reaching for, lifting, and transferring a weighted doll into and out of a portable baby bathtub. Clients could also practice retrieving and transporting infant bath supplies having a progression of weights and sizes, and positioned from the client at varying distances. Activity participation time could also be progressively extended as skill proficiency increases.

Diapering and Dressing

Most commercially available changing tables do not provide sufficient wheelchair access and are commonly too high for parents using wheelchairs. Several companies have designed adjustable-height changing tables that allow wheelchair access, are built with side frames to prevent infant falls, and have wheels for easy transport of infants when needed (see Fig. 28-4). Sturdy tables that allow wheelchair accessibility can be adapted to serve as changing tables by securing a standard changing table mattress atop the surface using a nonskid mat to prevent slippage. For safety, Velcro straps can be attached to the mattress to secure the infant in place and prevent possible falls.

Figure 28-4 Adjustable-height changing table. (Printed with permission from Dorothee Riedel, Spinalisttips, <http://www.spinalisttips.se>)

Infant and toddler clothing can be purchased or adapted with Velcro fasteners to reduce the need for fine motor coordination. Velcro-closure cloth or disposable diapers can be used and further adapted with loop closures that may be more easily manipulated by parents with fine motor limitations. Clothing such as pullover tops, elastic waistbands, and slip-on shoes (instead of buttons, zippers, and snaps) reduce the need for fine motor abilities. Clothing can be additionally modified by widening neck, waist, arm, and leg openings that can be tightened with adjustable Velcro straps.

As noted earlier, when recovery potential is possible, remediative strategies would include activities designed to increase UE strength, fine and gross motor control, dynamic sitting balance, functional endurance, and activity tolerance. Compensatory strategies could involve work simplification and energy conservation techniques in which all items needed for an activity would be gathered and placed in one accessible location. Clothing can be stored in closets with lowered or drop-down clothing racks to increase accessibility for those using wheelchairs, or in drawers with pull-strap handles for parents with limited hand function. Therapists should also help patients redesign activities to increase efficiency and reduce step number.

Feeding

Mothers with physical disabilities who breastfeed their infants can use commercially available nursing pillows designed to position the infant at the breast to support latching. Nursing pillows sit on top of the mother's lap and wrap around her waist, providing a stable and comfortable surface for the infant; some pillows can be positioned directly in a wheelchair if needed. The infant's weight is supported by the pillow, reducing the amount of UE strength needed to hold the infant in the arms. Nursing pillows can be adapted with Velcro straps with loop closures to more securely stabilize the infant and prevent possible falls. These types of pillows are particularly beneficial for mothers with UE weakness, poor trunk control, and diminished fine motor control.

Parents with the above-noted physical impairments who bottle feed infants can use adjustable infant carriers that can be raised to accommodate the parent's seated position and can tilt to elevate the infant's head during feeding (see Fig. 28-3). C-shaped handles can be attached to bottles to reduce the need for fine motor control. For parents with UE sensory loss, baby bottle temperature readers can be used to ensure safety. Older infants and toddlers can be spoon fed using universal cuffs with inserted spoons; spoons should be rubber coated or made of flexible plastic to protect the toddler's gums and teeth if accidentally contacted during feeding. Baby food jars can be opened with a number of adaptive devices requiring minimal hand function, including nonskid rubber jar openers, and electronic automatic push-button jar openers that latch to and open jar lids. Adjustable-height high chairs with swing-away trays can be purchased for parents using wheelchairs and those with reduced UE strength and grasp who have difficulty lifting toddlers into standard high chairs.

As noted earlier, when recovery potential is possible, remediative strategies would include activities designed to increase UE strength, fine and gross motor control, dynamic sitting balance, functional endurance, and activity tolerance. Compensatory strategies could involve work simplification and energy conservation techniques in which all items needed for an activity would be gathered in one accessible location, and activities redesigned to reduce step number to a minimum.

Crib Use

Most standard cribs are inaccessible to parents using wheelchairs who can neither stand to reach over crib rails or negotiate wheelchairs sufficiently close to cribs for safe infant and toddler transfers. Traditional drop-down crib rails further prevent wheelchair accessibility. Several adaptive cribs are commercially available for parents using wheelchairs and offer an array of features designed to provide accessibility and safe infant handling. Many adaptive cribs have electronically adjustable heights that can accommodate the specific height requirements of parents using wheelchairs (see Figs. 28-4 and 28-5). This type of obstruction-free undercarriage crib design allows wheelchair users to position their chairs close to the crib while maintaining stable trunk control against the wheelchair backrest. In this position, parents are not forced to lean forward and risk balance loss, and the UEs are freed for safe infant and toddler handling. Common adaptive crib rail designs include double-door rails that swing (see Fig. 28-6) or horizontally slide open (see Fig. 28-7). Both style rails allow parents to easily and safely access and transfer their infants. If

funding for adaptive cribs is not available, standard cribs can be adapted using leg extenders or wood blocks to raise crib height to allow wheelchair accessibility beneath the crib carriage. Raising the crib height would require the additional security measures of stabilizing the crib legs and anchoring the crib to the wall. Standard crib rails can be adapted by converting traditional drop-down rails to double-door swing or slider rails.

Playing with Toddlers and Small Children

Parents using wheelchairs and those unable to bend or reach to the floor may experience difficulty physically playing with toddlers. If funding is available, electronically adjustable-height playpens can be purchased that allow wheelchair access beneath the playpen carriage. Many adaptive playpens are designed with double swing-open or sliding doors that allow parents using wheelchairs to reach into the playpen while maintaining trunk control against the wheelchair backrest. Adaptive playpens allow infants and small

toddlers sufficient space in which to practice gross motor skills, while offering accessibility for parents using wheelchairs or who cannot bend to the floor. Parents with older toddlers may find that children's tables, approximately 18 inches (46 cm) high, are at a height sufficient for interactive play. Some parents with adequate trunk and UE strength may be able to transfer from wheelchairs to lower height sofas or chairs to further enhance play accessibility.

Parenting with Cognitive Impairment

When cognitive impairment accompanies physical disability, parents will need support to understand and organize the steps of many needed activities. Beneficial compensatory strategies include:

- Posting the steps for all activities in written and/or pictorial form in the location in which they will be performed
- Creating and teaching the parent to use checklists for all essential activities and providing opportunities for practice and return demonstration
- Teaching the parent to use preprogrammed smartphone and tablet cuing systems to facilitate activity performance
- Labeling drawers, cabinets, and closets (in written and/or pictorial form) to enhance organization and memory of supplies stored within
- Gathering and locating the supplies for each activity in easily accessible organizational systems (e.g., self-care dispensers, plastic storage shelves and trays) maintained in the area in which the activity will be performed
- Teaching a family member or caregiver in the above compensatory strategies to monitor their use and correct errors.

Restoring or Newly Assuming Caregiving Roles of Pets and Animal Assistants

As noted previously, pets have become elevated to the status of human family members in recent decades, largely because of the emotion, affection, and companionship that they readily offer to owners when positively treated.^{17,18} The perception of pets as family members may be more pronounced for individuals who, as a result of traumatic disability, may have experienced loss of significant others including spouses, friends, and access to a larger support community.¹⁹ Pets may provide the first experience of acceptance after disability and may counter feelings of stigmatization encountered in the larger human community.²⁰ Pets also commonly provide a bridge across which recently disabled individuals may begin to connect and interact with others.^{19,20} Clients who obtain animal assistants to help with the performance of daily activities after disability commonly develop intimate and intense bonds with their animals based on emotional and physical dependence.²¹ In the previous instances, pets and animal assistants likely assume primary emotional and survival roles in client lives, and their ongoing care must be addressed by occupational therapists. The following section provides an overview of the ways in which therapists can adapt animal care routines—particularly of dogs and cats—for clients with physical and/or cognitive disabilities.

Feeding

Pet owners using wheelchairs should store food supplies at an accessible height, preferably in a low cabinet or on a counter that accommodates a wheelchair. Large food bags should be avoided as clients using wheelchairs and having UE weakness and/or chronic back pain will be unable to lift or reach down into them to access food. For pet owners with limited hand function, food bags can be opened with an adaptive scissors. Bagged food should be transferred to and stored within small, lightweight containers with easy-open plastic lids (such as lids with pull straps and C-shaped handles). Dry food can then be retrieved from containers using a universal cuff with an attached scooper. Canned food can be opened with easy-touch electric can openers requiring minimal hand control

to place the device atop the can. A single light touch then latches the device to the can top and opens it without further hand use. Owners can then scoop moist food using a universal cuff with an attached spoon. For large dogs, food should be placed on a standard raised dog tray that is easily accessible for clients using wheelchairs. For smaller dogs and cats, food can be placed on a raised platform with a stool positioned for the animal's easy access.

Toileting

There are a number of commercially available pooper-scoopers that require minimal hand mobility (but do require UE gross motor function) and retrieve dog waste either electronically or through spring action. Such devices are typically inexpensive, lightweight, eliminate the need for bagging waste, and can be secured to a wheelchair with Velcro if needed. Similarly, electronic cat litter box cleaning systems that automatically clean and store waste for up to several weeks (at which time waste removal requires proficient UE mobility) are available. When electronic cat litter boxes are not an option, traditional litter boxes can be located on raised platforms for pet owners using wheelchairs. Those with limited hand function can use a universal cuff with an attached cat litter scooper to remove waste.

Walking and Playing

Most dogs need to be walked a minimum of 30 minutes, twice per day. Pet owners using wheelchairs can secure the lead to the metal frame to free the hands for wheelchair propulsion. In this case, the dog must be trained to walk at the owner's wheelchair side to avoid tangling the leash in the wheels or inappropriately pulling the chair (see Fig. 28-8). For pet owners with limited fine motor ability, slip-dog leashes can be used that easily slide over the animal's head and tighten to fit around the neck. Dog toys, such as balls and tugs, can be adapted with Velcro C-shaped loops and straps for pet owners with limited hand function. Interactive cat toys can be adapted in similar ways by attaching toy handles to universal cuffs, allowing owners to swing stringed, catnip-stuffed mice or birds. Laser pointers can also be secured to universal cuffs, allowing owners to engage their cats in play and exercise with limited fine motor requirements.

Figure 28-8 Pet owner in wheelchair walking her dog.

Bathing and Grooming

Although cats are self-grooming (and can maintain trimmed nails with regular scratching post use), dogs require regular bathing, fur trimming, and nail clipping—the frequency of which depends on breed. Professional grooming can be obtained inexpensively and can maintain the animal's health with no physical requirements of the owner. This is

particularly true of mobile groomers who provide services in the animal's home. Pet owners who wish to bathe their dogs, but who cannot bend to the floor, can use a basin on a raised platform. The basin can be filled and drained with a hose attached to an indoor sink or outdoor faucet. Dog shampoo bottles can be adapted with C-shaped handles, or liquid shampoo can be transferred to pump-style containers to allow use with limited hand function. Washcloths can be purchased or sewn into the shape of a mitt to reduce hand mobility requirements. For owners with UE sensory loss, bath temperature readers can be used to reduce possible scalding and ensure safety. Dog brushes can be inserted into universal cuffs for owners with limited fine motor ability. Owners with UE weakness but good fine motor skills can use electronic nail clippers and fur shears to accomplish these specific grooming activities.

Providing Animal Care When Pet Owners Have Cognitive Impairment

Pet owners with cognitive impairment can still provide care for their pet or animal assistant using compensatory strategies established and taught by occupational therapists. The following strategies can help owners with cognitive deficits to participate in pet care with minimal setup and ongoing supervision:

- The steps for all pet care activities noted previously can be posted in written and/or pictorial form in the area in which the activity will be performed. Steps should be written as simply as possible and include photos or illustrations where possible.
- A checklist for all daily pet care activities should be created and maintained in one location in which the owner commonly accesses. The therapist should teach the owner checklist use, and opportunities for practice with return demonstration should be provided.
- Drawers, cabinets, and closets in which pet supplies are stored should be labeled (in written and/or pictorial form) to enhance organization and ease of item retrieval.
- Electronic cuing systems on smartphones and tablets can be programmed to remind the owner to carry out daily pet care activities such as walking and feeding.
- Automated food dispensers can be programmed to reduce the need for the owner to remember this essential task; however, the owner must be cued or depend on a family member to fill the dispenser when needed.
- An electronic smartphone calendar can be programmed to alert the owner to schedule regular veterinary and grooming appointments.
- A family member or caregiver should be educated to oversee all of the above to ensure optimal animal care.

Social Roles

Social roles are positions within a social system that are characterized by a set of behaviors intended to meet role expectations that support community participation.^{6,22} Role expectations are shaped by both individuals holding specific roles and the larger community in which expected roles are carried out. Common social roles in Western society include family roles as noted earlier, and worker, student, friend, neighbor, coach or facilitator, group participant (e.g., sports team and religious participant), volunteer, consumer or patron, and patient or client roles. The duration of one's social roles varies as a factor of personal need, desire, and interest; family and larger societal demands; and the availability of resources and support needed to maintain specific roles.^{6,22} The behaviors associated with a specific role can also change over time as people age, children mature into adulthood, partners separate or pass away, and societal norms change.²³

It is common for individuals to hold multiple roles and to experience **role conflict** resulting from the opposing demands of several different roles. Role conflict may also occur when individuals' expectations of role behaviors differ from those held by significant others and the larger community.^{24,25} **Role distress** occurs when individuals desire to assume and carry out the specific behaviors characteristic of a role, but are unable

to as a result of skill deficits, lack of needed knowledge, or disability and illness.²⁶ Most social roles are equated with a particular status and value by the larger society, and individuals who lose a desired role can often experience depression and decreased self-esteem.²⁷ For example, when individuals experience divorce as a result of disability and lose their roles as spouse and primary parent, depression and lost life meaning may ensue.²⁸

One social role that is commonly impacted by disability, particularly for young adults, is that of dating and courtship roles. As noted previously, severe disability—such as TBI and SCI—is commonly accompanied by divorce, loss of predisability dating partners, and lost connection to a larger social group of friends. Many individuals with severe disabilities report that loneliness and lost emotional connection are among their most devastating postdisability experiences.²⁹ Clients with severe disabilities who have lost spouses, dating partners, and connection to their social groups commonly desire to resume and sometimes newly assume dating roles. This section addresses the unique ways in which occupational therapists can help clients to enter or restore desired dating and courtship roles, particularly in outpatient and community care settings, after the impact of disability on such roles has become clearer. The restoration of other social roles, such as worker, student, community member, and leisure participant, is explored in Chapter 29.

Restoring Dating and Courtship Roles

When occupational therapists find, through the construction of an occupational profile, that clients have lost spousal and dating roles as a result of disability, and wish to regain such roles, therapists should engage in the evaluation of activity demands and client skills that are needed to support role resumption. Therapists may also find with young adults, whose disabilities occurred in adolescence, that desired skills for dating roles were never acquired and that dating experiences have been limited or nonexistent. In such cases, therapists may need to newly teach and practice underlying skills with clients. Underlying skills primarily address (a) knowledge of where and how to meet potential partners; (b) how to interact through online communication, and in-person verbal and nonverbal skills; and (c) how to navigate dating events given physical and/or cognitive disability.

Meeting Potential Partners

Clients whose disabilities have resulted in diminished self-esteem, particularly when loss of spouse or predisability dating partners has occurred, may feel apprehensive when attempting to meet potential partners. Through discussion, therapists should attempt to understand how clients feel about dating after disability onset, and meeting and describing their disability to potential dating partners. Depending on disability severity and comfort level, some clients may desire to date others with similar disabilities. A number of online dating sites and meet-up groups are available that provide opportunities for people with disabilities to meet similar others. When clients wish to use these types of meeting venues, therapists should help clients identify specific websites and local meet-up events. Other clients may feel comfortable meeting and dating both people with and without disabilities, and therapists must determine client preferences.

Most opportunities to meet potential partners for both people with and without disabilities occur through online dating sites and chat rooms, and in-person local meet-up groups. To access online sites, clients with UE and/or visual perceptual impairment will need assistance to configure adaptive keyboards, screens, smartphones, tablets, and/or computer systems (such adaptive equipment is discussed in Chapter 29). Clients with cognitive impairment will likely require assistance to identify and bookmark online dating sites, create membership accounts, construct dating profiles, upload one or more photographs, and evaluate and select other members with whom to communicate. Such clients will also likely benefit from the posting of written steps to remember how to access the site, view member profiles, and message members. It will also likely be important to assess clients' judgment, insight, awareness, and inhibition with regard to Internet safety.

Clients with cognitive impairment may require assistance to understand the need to identify signs of and protect against possible abuse and predation. Basic protective information regarding privacy—such as refraining from providing residential, work, and email addresses, and newly meeting dates in public places—should be conveyed. Opportunities through which to practice the identification of possible signs of predation should be provided in simulated role-play between the therapist and client.

Communication Skills: Online and In-person

Online communication requires knowledge of specific etiquette that may or may not be understood by clients, particularly those with cognitive impairment. Therapists should provide client education about the following etiquette skills and allow opportunities for practice in simulated role-play together:

- Initial messages should be brief, neutral, and invite response.
- A period of 24 hours in which to receive a response should be allowed; clients with impulsivity and lack of inhibition should be coached to wait for response without sending further messages.
- Clients should be provided with opportunities to practice messaging appropriately neutral questions about another's interests and dating objectives that broach conversation and maintain it in a reciprocal way. Clients with diminished insight and impulsivity control should be helped to understand and avoid personally invasive or intrusive questions (e.g., about religion, politics, salary, sexually related topics). Clients should also practice constructing messages that avoid disclosing too much and oversharing.
- Rejection is difficult for everyone, particularly for people who have lost confidence as a result of disability. Clients with emotional dysregulation and diminished impulse control will need to practice skills to appropriately deal with rejection and to identify and avoid unsuitable behaviors such as perseverative messaging and verbal attacks.
- Clients will also need to identify inappropriate communications from others and understand the procedures for blocking, unmatching, and reporting improper communication to site managers. Such skills should be practiced in simulations with the therapist.

Clients who attend in-person meet-up events or who decide to meet online dates may need to learn and/or practice the skills required to initiate social contact, sustain reciprocal turn-taking conversations, and interpret verbal and nonverbal cues. Nonverbal skills accompany verbal skills in conversation and are used to convey messages through eye contact, personal space, and body language and orientation. Clients will need to practice skills such as maintaining eye contact and others' personal space during interaction, orienting one's body to face others during conversation, and refraining from touching others. Such nonverbal skills may be difficult for clients with diminished inhibition, and opportunities to practice these behaviors within role-play with the therapist will likely be warranted.

Verbal interpersonal skills include knowledge of socially accepted forms of greetings when meeting potential dates, being able to introduce oneself, and engaging in socially appropriate conversation beyond formal introduction. Clients with diminished impulse control may have difficulty engaging in reciprocal, turn-taking conversation and may instead monopolize interactions; have difficulty refraining from verbalizing inappropriate content; and may perseveratively maintain a conversation without allowing it to end. These skills should be practiced in role-play between the therapist and client until performance reaches a socially acceptable level. Such clients will also need to practice verbal skills for expressing interest in future social contact, as well as skills to appropriately deal with rejection if a person of interest declines the client's social invitation.

Intervention should provide opportunities for clients and therapists to role-play the abovementioned skills in one-to-one interactions in simulated scenarios that closely mirror the natural contexts in which clients will use the identified skills. Opportunities to practice desired behaviors in increasingly more natural, unstructured environments should also be provided when possible. Feedback should be offered by therapists to enhance client performance to socially acceptable and personally desired levels.

Navigating Dating Events with a Disability

Clients who reach a stage in which in-person dating events occur must consider and prepare for environmental and emotional variables that can impact dating events. For example, although clients attending initial dates should obtain their own transportation to and from the event for safety, later stage dating may involve situations in which both partners travel together. In such situations, individuals using wheelchairs must ensure that transportation modes are able to safely accommodate one or more wheelchairs. Similarly, although public places (such as restaurants, movie theaters, and dance clubs) are required to be compliant with the ADA, clients should contact business owners to ensure that doorway entrances, restrooms, aisle spaces, ramps, and tables are wheelchair accessible. For example, although a restaurant owner may perceive the environment to be ADA compliant, there may be a disproportionate number of booths to tables (tables are easier than booths for people using wheelchairs), aisle space between tables may be inadequate for wheelchair use, tables may be too small to accommodate two wheelchair users, and ramps to enter the restaurant may be inaccessible if they do not meet ADA specifications or are located on unlevel surfaces. It would be equally important for individuals with low vision or visual perceptual impairment to ensure that the environment was adequately lit, that floor transitions were level and adequately lighted, and that any printed text (e.g., menus, playbills, bills, receipts) could be read with adaptive aids. Therapists should help clients to understand the environmental factors that could impact dating events and the steps needed to research a specific location's safety and accessibility.

It may be important, as well, to provide opportunities in which clients can practice discussing their disability to gain comfort in preparation for real-life conversations with dating partners. As relationships grow more intimate, questions about sexuality, reproductive abilities, and procreative desires as they are impacted by disability will emerge, and clients will benefit from opportunities to practice these discussions in role-play with therapists in simulated scenarios. As a relationship advances to a level of sexual intimacy, clients may need assistance to understand physical positions and adaptive aids that can allow sexual activity despite factors such as UE and LE weakness or paralysis, fatigue and lack of endurance, joint mobility restrictions, sensory loss, and incoordination and poor dexterity. Interventions for such impairments can be found in Chapters 27 and 39.

CASE STUDY

Patient Information

Ellie is a 28-year-old white female who sustained a T3 SCI 12 years ago in a diving accident and is presently 6 months pregnant. After Ellie and her wife, Maddie, decided to conceive a child through artificial insemination, Ellie agreed to carry and give birth to the baby, who through ultrasound was determined to be a girl. Maddie, a 26-year-old Asian American female, also sustained an SCI at T5 7 years ago. Ellie reported that she understands her increased risk of pressure ulcers, urinary tract infection, and the formation of LE blood clots and has taken appropriate precautions to maintain her health and that of the pregnancy. The pregnancy has thus far been typical, and Ellie is expected to give birth in 3 months. Both women have been focused on Ellie's and the baby's health and have not had time to consider needed adaptive equipment and supplies. Ellie's obstetrician has referred Ellie for an occupational therapy consultation

to help determine needed adaptive equipment and to teach both parents about adaptive infant care strategies.

Assessment Process and Results

Because both Ellie's and Maddie's SCIs are in the high thoracic regions, they each possess innervation of the UE muscles (with full fine motor abilities) and long muscles of the back, allowing for moderate trunk control. Ellie reports that her trunk control has decreased in the past 3 months of her pregnancy. Both women possess UE range of motion and strength within normal limits. Muscle innervation below the mid trunk has been lost, resulting in LE paralysis, and both women use wheelchairs for mobility and are independent in self-care, grooming, meal preparation, and home management with adaptive equipment and environmental modifications. The couple lives in a two-bedroom, elevator apartment building with a standard tub/shower and bathroom space sufficient for wheelchair transfers. No modifications have been made to the kitchen to enhance meal preparation from a wheelchair position, although tilted mirrors have been positioned above the stove to better view foods atop the stove burners. The kitchen sink does not accommodate a wheelchair user to position directly beneath the counter. A standard infant crib, changing table, high chair, baby bathtub, and playpen have been donated by Ellie's mother; however, these items are not accessible for parents using wheelchairs. Both women work, have health insurance, and have been provided 6 months of parental leave once the baby is born. Ellie has been provided an additional 1 month in her last trimester. Both sets of grandparents live nearby and are eager to provide assistance in their grandchild's care.

Occupational Therapy Problem List

Both parents will have difficulty using the standard infant equipment that has been donated.

- Neither mother can access the baby bathtub if placed in the tub or on the kitchen counter.
- The standard crib has a drop-down rail and does not permit a wheelchair to be positioned beneath the crib basin. Neither mother is able to stand and reach over the crib rails.
- The changing table sits atop a set of drawers and is inaccessible from a wheelchair, which cannot be positioned directly beneath the changing area.
- The high chair will be too high for Ellie and Maddie to lift the baby into once she is older.
- Neither mother will be able to transfer her infant into or retrieve the baby from the playpen while seated in a wheelchair.

Occupational Therapy Goal List

- Explore funding options to purchase needed adaptive infant equipment.
- Explore resources needed to adapt standard infant equipment to enhance accessibility for both mothers.
- Provide instruction in and practice opportunities to use adapted equipment for bathing, feeding, diapering and dressing, and crib and playpen use.

Intervention

Both sets of in-laws combined their financial resources and purchased an adjustable-height crib with horizontally sliding rails so that Ellie and Maddie could position their wheelchairs directly beneath the crib carriage, slide the rails open, and access their infant safely without the risk of balance loss or infant falls. Ellie's father, who possesses carpentry skills, built a changing table that is wheelchair accessible and has side frames to prevent infant falls. The changing table mattress was secured to the surface with a

nonskid mat to prevent slippage. An adjustable Velcro strap, to secure the infant in place while changing, was attached to the mattress as an additional safety feature. Ellie and Maddie purchased an adjustable-height high chair with a swing-away tray for easy infant lifting into the seat area. Both women were fitted with infant harnesses and carriers to enhance easy and safe infant transport using a wheelchair. Ellie, who will be breastfeeding her infant daughter until she returns to work, was instructed in the use of a nursing pillow and purchased one that fits within the width of her wheelchair. The therapist also helped the mothers set up the portable baby bathtub on their kitchen table (which is wheelchair accessible) near the sink. A detachable hose was secured to the sink faucet to both fill the baby bathtub and empty the bath water into the sink drain once used. Ellie’s father also built a raised platform on which to stabilize the playpen so that both mothers could obtain access from their chairs. The therapist adapted the playpen netting on one side so that it opens and closes with a zippered fastener. These adaptations allow both mothers to retrieve and place their infant in the playpen without risking balance loss or infant falls. Ellie, Maddie, and the therapist practiced the use of all adaptive equipment with a weighted doll until both mothers demonstrated safe use, comfort, and mastery.

At a 3-month follow-up visit after their infant daughter, Kenzie, was born, both mothers reported that they were able to care for their baby independently with the above-noted adaptations and were eager to begin community exploration with Kenzie in tow.

Evidence Table of Studies Assessing Role Restoration for Adults with Disabilities

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Examination of the perceived benefits of occupational therapy services designed to help mothers with arthritis ¹⁶	Mothers received ongoing occupational therapy services in the United Kingdom to address parenting with arthritis, including adaptive equipment and compensatory strategies.	Four mothers with diagnoses of severe arthritis; all having children under the age of 11 years; age range 26–28 years. Two occupational therapists	One-hour occupational therapy sessions in mothers’ homes, followed by 1-hour interview with mothers, and separate 1-hour interviews with therapists	Qualitative case series using observation of occupational therapy sessions, interviews with mothers and therapists, and analysis of clinical documentation	The following interventions were perceived by mothers to be the most beneficial in promoting parenting roles: lightweight infant carriers and slings, supportive infant feeding cushions, preparing and storing milk for 24-hour periods, adjustable-height changing tables, wrist splints, energy conservation techniques, work simplification, and pain management.	No statistical analysis

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Examination of the adaptive methods used by mothers with physical disabilities ¹⁴	Nine of 22 mothers received occupational therapy services to assist with adaptive strategies for parenting roles.	Twenty-two mothers with physical disabilities with children under the age of 10 years. Mean age = 34.8, standard deviation (SD) = 5.3	Not provided	Qualitative semi-structured, open-ended interviews were carried out with 22 mothers with physical disabilities. Each mother participated in a 2-hour one-time phone interview.	The following adaptations were reported as most beneficial (whether derived from occupational therapy services or independently): infant carriers, and modifying standard cribs and changing tables for wheelchair accessibility. Participants who received occupational therapy services reported that services were most beneficial in helping resolve issues with infant feeding, bathing, and carrying.	No statistical analysis
Occupational therapy intervention designed to help adult men with TBI to regain lost preinjury roles, including dating and courtship roles ²⁶	Three tiered intervention in which Tier 1 addressed identifying desired roles after injury, Tier 2 addressed regaining participation in activities supporting role resumption, and Tier 3 addressed attaining desired rites of passages such as living independently and engaging in a committed relationship.	Four men with TBI ranging in age from 27 to 48 (mean = 37), residing in a community-assisted living facility	Intervention was carried out in 3 weekly individual sessions, 1–2 hours in length, over 4 months.	Case series with qualitative analysis through focused interviews and participant observation	All four participants reported greater participation in and satisfaction with desired roles postinjury, including dating and courtship roles. Desired rites of passages—such as participation in a committed relationship—were not attained, but still desired after intervention end.	No statistical analysis

Chapter 29

Restoring Home, Work, and Recreation Roles

Mary W. Hildebrand

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Understand essential home, work, and recreation roles.
2. Identify assessments for home, work, and recreation.
3. Identify barriers and challenges for clients to engage in home, work, and recreational activities.
4. Apply remediation, compensation, and adaptation principles to occupations in the home, workplace, and recreational setting.
5. Apply work simplification and energy conservation principles to occupations in the home, workplace, and recreational setting.
6. Identify adapted methods and equipment that enable persons to regain competence in occupations in the home, workplace, and recreational setting.
7. Define functional capacity evaluations (FCE) and describe an FCE format.
8. Describe resources for job descriptions and job adaptations.
9. Describe components of and differences between work readiness, work hardening, and work conditioning programs.

CHAPTER OUTLINE

Introduction
Restoring Home Management Roles
Restoring Work Roles
Restoring Recreation Roles
Case Study

TERMINOLOGY

Energy conservation: an essential intervention for clients with low endurance or fatigue that is comprised of simple principles that clients may adopt to save energy to perform occupations that are most important to them.

Functional capacity evaluation: standardized batteries of work-related tests that consider the person's body functions and structures, environmental factors, personal factors, and health status used to make recommendations for participation in work.

Home management: activities that involve obtaining and maintaining personal and household possessions and environment (e.g., home, yard, garden, appliances, vehicles), including maintaining and repairing personal possessions (e.g., clothing, household items) and knowing how to seek help or whom to contact.

Job analysis: part of a functional work assessment that includes a systematic evaluation of the physical, cognitive, social, and psychological requirements of a job.

Leisure: free time or “non-obligatory activity that is intrinsically motivated and engaged in during discretionary time—that is, time not committed to obligatory occupations such as work, self-care, or sleep.”¹

Recreation: activities that people do to relax, have fun, or that provide amusement or enjoyment.

Work conditioning: work treatment program focused on basic physical conditioning such as restoration of flexibility, strength, coordination, and endurance; typically conducted after completion of acute care and before work hardening.

Work hardening: multidisciplinary structured, graded return-to-work treatment program that progressively introduces greater rehabilitation requirements to achieve full capability of the worker to meet job demands; includes psychosocial, communication, physical, and vocational needs and incorporates work simulation as treatment modalities.

Work readiness: work programs to help individuals identify work goals, interests, and skills.

Work simplification: strategies to reduce the amount of energy expended in occupations by clients with low endurance or fatigue; similar to energy conservation.

Introduction

Adults experience higher quality of life and life satisfaction when they participate in self-reported meaningful activities, including **home management**, active community participation, paid employment or volunteerism, and recreational activities. Adults with disabilities or chronic conditions, however, often withdraw from engaging in productive, leisure, and social activities as a result of physical, emotional, and psychological impairments associated with disability or environmental barriers.

Researchers have examined the effect of disability severity and participation in productive activities (e.g., work, volunteer, home management) and recreation (e.g., sports) on self-reported well-being of adults with disabilities. They found that performing productive and recreational activities is integral to maintaining well-being and postulated that these activities offer adults with disabilities the opportunity to fulfill essential productive and social roles.²

Participation in home management, recreation, and community activities contributes to personal identity, well-being, and quality of life and is a vital source for social interaction. People with disabilities, however, are less likely to participate in such activities and, thus, are more socially isolated. Community participation has been found particularly beneficial to people with disabilities and older adults by increasing their sense of empowerment and their number of social interactions. When people with disabilities or older adults participate in civic or religious organizations, not only do they benefit, but their communities do as well.³ Volunteer contributions from older adults, for example, help to maintain a functioning society.⁴

Similar to home management and community participation, work is the occupation from which people receive meaning and spend most of their time. Work is a source of personal identity, income, and social interaction and offers psychological well-being. Conversely, the relationship between work and health can be negative. When a disability disrupts participation in productive activities, the emotional and financial costs are significant for persons unable to work, their families, employers, and society. The majority of people who experience work disability want to return to work.⁵

Recreation is often seen as the adult version of play. Like play, **recreation** or **leisure** has positive effects on physical and emotional health by improving physical fitness, creating opportunities for social interaction, coping with stress, improving cognitive skills, and increasing quality of life. A disabling event, such as a brain injury, typically leads to decreased participation in former leisure activities, particularly those with greater physical or cognitive demands.⁶ Given the benefits of participation in recreation, it is important that occupational therapists address recreation with clients with disabilities and chronic conditions.

Therapists provide interventions to clients that target remediation of client factors, and performance skills and patterns that limit participation in desired occupations. Therapists also recommend compensatory strategies and adaptations to occupations or the environment to support occupational performance. This chapter provides an overview of common assessments and interventions to improve client involvement in the roles of home manager, worker, and recreational participant—which overlap with and support larger community member roles.

Occupational Performance Assessments for Home Management, Work, and Recreation Roles

The first step in the occupational therapy process is performance of a top-down assessment to identify the occupations that the client, a person after a disabling event or with a chronic condition, wishes to perform. Top-down assessment in these categories begins with participation measures that assess a client's desire to perform home management, work, and recreational activities. Examples of these assessments include the Activity Card Sort (ACS),⁷ the Canadian Occupational Performance Measure (COPM),⁸ and the Occupational Performance History Interview-II (OPHI-II).⁹ The ACS, an interview-based assessment, consists of full-color photographs of adults performing 20 instrumental, 35 low-demand leisure, 17 high-demand leisure, and 17 social activities. It is used to compare an adult's premorbid participation in activities with their current participation level and is useful for goal setting, intervention planning, and monitoring changes in participation.⁷ The COPM is a semi-structured interview that asks clients to identify and prioritize occupations with which they are experiencing difficulty in the categories of self-care, leisure, and productivity. Clients are asked

to choose their top five priorities and to rate their performance of and satisfaction with the five activities. The COPM is an outcome measure, is useful for goal setting and intervention planning, and may be administered in all types of rehabilitation settings and with clients with a wide variety of conditions.⁸ The OPHI-II is also interview based. It has a rating scale of occupational function and elicits the client's life history narrative. The OPHI-II provides information with which to develop client occupational profiles, identify their strengths and weaknesses, and create an intervention plan⁹ (see Assessment table at the end of this chapter).

The ACS, COPM, and OPHI-II provide therapists with an opportunity to build rapport and gain a deeper understanding of the client and, thus, guide treatment planning. These measures motivate clients to participate in occupational therapy because client priorities are heard and addressed in treatment. The assessments provide evidence of the benefits of therapy by assessing outcomes. In addition, they guide the therapist's next steps in further assessment of occupational performance.

Selecting the Intervention Approach: Remediation, Compensation, or Adaptation

Intervention to improve performance or increase participation in home management, work, and recreation roles includes remediation and compensation or adaptation. Remediation techniques, such as improving range of motion (ROM), strength, endurance, motor control, or cognition, change the client in order to develop or restore a skill. When using remedial techniques with appropriate clients, it is important for clients to understand that practicing occupations will aid in remediation and improve performance. For example, when strength is impaired, the preparatory method of exercise should be followed by real-life activities impacted by client weakness (e.g., laundry, cooking) to improve client strength needed to perform those occupations. Compensation or adaptation involves finding ways to change the context, environment, tools, or occupation to allow clients to participate in desired occupations with greater independence. It does not focus solely on changing client factors.

Compensation or Adaptation

Basic principles of compensation or adaptation depend on the client's functional limitations and can be applied in home management, work, or recreational occupations.

- **Limited ROM:** Increase the client's reach with extended handles or reorganize workspace to place frequently used items within reach.
- **Weakness and low endurance:** Use lightweight and/or power equipment and allow gravity to assist. Use work simplification and energy conservation techniques.
- **Chronic pain:** Use proper body mechanics, work simplification, and energy conservation techniques.
- **Unilateral loss of motor control and limb function:** Use affected limb to stabilize objects when possible. Use one-handed adaptive techniques or equipment for bilateral activities.
- **Incoordination:** Stabilize at proximal joints to reduce the degrees of freedom of movement necessary for control. Use weighted objects to minimize distal incoordination.
- **Visual impairments:** Use senses of smell, touch, and hearing to substitute for vision. With low vision impairments, improve lighting, reduce glare, or increase contrast.
- **Cognitive limitations:** Employ visual and auditory aids to enhance memory and organization. Work in familiar environments and reduce distractions.

Work Simplification and Energy Conservation

Therapists teach the principles of **work simplification** and **energy conservation** when home management, work, and recreational occupations are too demanding for those with physical impairments. Basic principles of work simplification and energy conservation include:

- **Limit the amount of work:** Ask others to perform heavier tasks when possible. When financially feasible, use prepared items or power tools to decrease time and energy expenditure.
- **Plan ahead:** Schedule and evenly distribute energy-demanding tasks throughout the week.
- **Prioritize:** Schedule important activities and tasks first to complete them before fatiguing.
- **Organize:** De-clutter and reorganize work areas; store frequently used items within reach.
- **Sit to work:** Avoid standing when an activity or task can be performed while sitting.
- **Use efficient methods:** Identify and gather items needed before beginning a task. Instead of carrying items, use a utility cart to move them or slide them along a work surface.
- **Use correct equipment and techniques:** Use good body mechanics in all tasks, assistive equipment to decrease bending and reaching, and power equipment or tools to reduce work.

- **Balance physical tasks with rest breaks:** Perform physically demanding tasks early in the day and take frequent rest breaks (5–10 minutes) throughout the day.

Therapists also teach clients ergonomic guidelines for home management, work, and recreational activities. Ergonomics help to reduce muscle fatigue and injury risk and are important work simplification and energy conservation interventions. Chapter 21 provides a detailed discussion of ergonomic assessment and intervention for workplace settings.

Restoring Home Management Roles

Restoring competence in home management roles following a disabling event can enhance self-efficacy and esteem. This section reviews assessment of and interventions to restore instrumental activities of daily living (IADLs) that involve home management roles for people with disabilities and temporary or chronic health conditions. These occupations include meal preparation and cleanup, shopping, and home and financial management. They are categorized as IADLs because they support daily life within the home but may be more complex than activities of daily living (ADLs) or self-care. Although home management can be addressed at any time in the rehabilitation process, it is typically addressed after clients approach or achieve ADL independence.

Performance-Based Measures of Home Management Occupational Roles

After identifying the client’s priorities in home management occupations, the next step should be evaluation of the client’s performance of those occupations. In practice, this often occurs through informal observation to determine where client performance fails.

A standardized, quantitative measure of the client’s progress in goals—including home management occupations and the efficacy of the therapist’s interventions—is Goal Attainment Scaling (GAS).¹⁰ GAS has been used in rehabilitation settings to construct personalized client goals and measure client outcomes. Examples of successful implementation of GAS have been reported in home health with patients with complex needs,^{11,12} an intensive aphasia program,¹³ and in outpatient rehabilitation clinics with clients with traumatic brain injury (TBI).¹⁴ Using GAS, the therapist creates a five-point graded series or scale for each client goal composed of treatment outcomes from least favorable to most favorable. Box 29-1 shows an example of GAS with a meal preparation goal.

Box 29-1

Goal Attainment Scaling (GAS): Home Management Example

Goal: Client will prepare a simple meal with supervision using adaptive equipment, such as a one-handed jar opener, a rocker knife, and Dycem, and minimal verbal cueing to use energy conservation techniques in two sessions.		
Predicted Attainment	Score	Goals
Most favorable outcome likely	+2	Client prepares a simple meal with adaptive equipment without assistance and independently uses energy conservation techniques.
Greater than expected outcome	+1	Client prepares a simple meal with adaptive equipment without assistance and one verbal cue to use energy conservation techniques.
Expected outcome	0	Client prepares a simple meal with adaptive equipment with supervision and two verbal cues to use energy conservation techniques.
Less than expected outcome	-1	Client is provided instruction on use of adaptive equipment for making a simple meal and on energy conservation techniques.
Least favorable outcome	-2	Client is unable to prepare a simple meal with adaptive equipment and requires maximum physical assistance and three or more verbal cues to use energy conservation techniques.

Other standardized evaluations assess home management occupations (see Assessment table). The Performance Assessment of Self-Care Skills (PASS), version 3.1 is an observational, performance-based assessment of mobility, self-care, and IADL tasks. Home management occupations include housework, home maintenance, and cooking safety.¹⁵

The Assessment of Motor and Process Skills (AMPS) is an observational assessment in which clients choose three to five activities that they wish to perform from a list of 85 ADLs and IADLs. Therapists rate client performance of the chosen activities on 16 motor and 20 process skills.¹⁶

The Executive Function Performance Test (EFPT) assesses functional cognition in four IADL tasks: simple cooking, telephone use, taking medication, and paying bills.¹⁷ The EFPT determines which executive functions are impaired and the type and amount of assistance clients require to complete tasks.

The final step in assessment of occupational performance in home management roles involves selected analysis of clients' performance skills (e.g., motor or process skills), performance patterns (e.g., habits, routines), context or environment (e.g., cultural, natural, built), and client factors (e.g., body functions or structures, activity demands).¹⁸ These assessments are discussed in depth in other chapters of this textbook.

Intervention to Restore Home Management Occupational Roles

Included in IADLs and discussed here are meal preparation and cleanup, and home and financial management. Remediation to restore or prevent limitations in these occupations for clients with an impairment includes home exercise programs and exercise classes to improve balance, strength, ROM, and activity tolerance or endurance. Therapists may also recommend home programs and group activities to remediate cognitive skills that have been affected by disabling events such as brain injury.

Following the basic principles of compensation and adaptation techniques, therapists provide education in adaptive techniques, training in adaptive equipment use, and recommendations and training in home modifications. Therapists will also analyze occupations and provide education in work simplification and energy conservation techniques.

Meal Preparation and Cleanup

Meal preparation and cleanup is defined as "Planning, preparing, and serving well-balanced, nutritious meals and cleaning up food and utensils after meals."¹⁸ Efficient kitchen work areas and storage, adaptive techniques, and assistive devices will enhance client safety and participation in meal preparation and cleanup.

Kitchen Work Areas and Storage

Cost-effective home modifications include placing frequently used kitchenware and cookware within easy reach: from the floor, between 15 and 48 inches (38–122 cm) for wheelchair users and between 30 and 60 inches (76–152 cm) for those who are ambulatory. Reducing clutter and clearing pathways may decrease client accident risk and conserve energy. High-end home modifications to enhance meal preparation might include installing wheelchair accessible counters (28–34 inches [71–86.36 cm] from the floor and with a depth clearance of 24 inches [61 cm] underneath for wheelchair leg rests¹⁹), pullout shelves or turntables in cabinets, and appliances with accessible controls.

Gathering and Transporting Items

To transport multiple or larger items, a wheeled utility cart is useful in the kitchen (Fig. 29-1). For wheelchair users, lap trays and cup holders can attach to armrests. Optional walker accessories include attachable trays, baskets, and walker bags for transporting small items (Fig. 29-2). Long-handled reachers may be useful for retrieving lightweight, unbreakable items from high or low cabinets (Fig. 29-3). Attaching a reusable grocery bag or basket to a walker may help with transporting small, lightweight items and is inexpensive.

Figure 29-1 To transport multiple or larger items, a wheeled utility cart is useful in the kitchen.

Figure 29-2 Optional walker accessories include attachable trays, baskets, and walker bags for transporting small items.

Figure 29-3 Long-handled reachers may be useful for retrieving lightweight, unbreakable items from high or low cabinets.

Food Preparation and Cooking

There are many assistive devices on the market that can make food preparation easier. For one-handed performance after a stroke, upper extremity injury, or an amputation, an adapted cutting board with spikes is useful for holding vegetables or fruit to cut (Fig. 29-4).

Figure 29-4 For one-handed performance after a stroke, upper extremity injury, or an amputation, an adapted cutting board with spikes is useful for holding vegetables or fruit to cut.

For clients with weak, or otherwise impaired grip, there are kitchen utensils that have ergonomic handles, freestanding and mounted jar openers, adapted kitchen scissors for opening packaging or cutting foods, and lightweight pots and pans with easy-to-grip heat-resistant handles or double-handled pots. Attaching a rope, cord, or zip-tie loop to appliance door handles is an inexpensive way to allow clients to pull the door open with a weak grip. Loops can be added to other kitchenware to aid in retrieval from shelves or cabinets (Fig. 29-5).

Figure 29-5 Attaching a rope, cord, or zip-tie loop to appliance door handles is an inexpensive way to allow clients to pull the door open with a weak grip. Loops can be added to other kitchenware to aid in retrieval from shelves or cabinets.

To reduce the amount of work and save time in meal preparation, there are a variety of small electric appliances from which to choose such as can openers, blenders, food processors, and knives. For wheelchair users, a typical range (i.e., stovetop and oven) should have accessible front-operated controls and a wall-mounted mirror angled to see food cooking on the stovetop. If it is not economically feasible to replace the range, small electrical appliances may substitute if placed safely on a stable wheelchair accessible surface (i.e., electric griddles, skilletts, toaster ovens, or microwaves).

Cleanup and Dishwashing

Energy conservation techniques for cleanup include lining baking pans with foil to reduce washing, serving food directly from cooking pots, organizing tasks to flow in a single direction, sitting on a stool to wash dishes, using electric dishwashers, and air-drying dishes.

If washing dishes at wheelchair level, place a wooden rack on the sink bottom to reduce its depth, making it easier to reach dishes, and remove cabinet doors under the sink to provide knee and footrest space. A swing-away, lever-handled faucet is easier to control with limited hand function; installing it on the sink's side rather than the back is easier to reach. Clients with limited grasp can also use terry cloth mitts to wash dishes. For one-handed dishwashing, there are bottle brushes and scrub brushes for cleaning glasses, bottles, and utensils that can be suctioned to the sink's side.

Grocery Shopping

Planning ahead is the key to successful grocery shopping and energy conservation. Organizing the shopping list by grocery store layout will minimize the time and effort needed to search for groceries. Many printable grocery shopping lists are available online and have space for weekly menus and food items by category. Shopping lists can be printed or laminated and items to be bought the next week checked off. The client can then photograph the shopping list with a smart phone. There are also smart phone applications (apps) on which the client can add and organize items by category. While shopping, the apps check off items when acquired. When shopping in-

person, it is best to shop during off-peak hours when there are fewer customers, aisles are not crowded, and store employees are available to help as needed.

A shopping cart may be used by clients who are ambulatory. Adapted shopping carts for wheelchair users and motorized scooters for clients with poor endurance and mobility are also available at most large grocery stores (Fig. 29-6).

Figure 29-6 Adapted shopping carts for wheelchair users and motorized scooters for clients with poor endurance and mobility are also available at most large grocery stores.

Many stores offer online shopping with either home delivery or store pickup. Home delivery, though expensive, is convenient for clients who lack access to transportation or are physically unable to go to the store. When clients can drive or have someone who can drive them to the store, curbside pickup service is convenient and costs less than home delivery. There are also newer options for home food delivery such as food plan services that create menus and deliver ingredients and instructions for each recipe.

Home Management

Home management is defined as “Obtaining and maintaining personal and household possessions and environment (e.g., home, yard, garden, appliances, vehicles), including maintaining and repairing personal possessions (e.g., clothing, household items) and knowing how to seek help or whom to contact.”¹⁸

Laundry and Clothing Care

Sorting soiled laundry is a step that can be eliminated by placing it in separate hampers or bags when undressing. Use of in-home appliances, self-service laundries, or laundry services is dependent on client living situation and financial resources. In-home washers and dryers may be front-loading and top-loading. Top-loading appliances require less bending, whereas front-loading appliances are better for persons who perform laundry while seated. A knob turner may make it easier to turn appliance knobs for clients with weak grip (Fig. 29-7). If taking clothing to a self-service or commercial laundry, a rolling basket to transport laundry and premeasured detergent save energy. Clothes can be folded while sitting or standing at a table, and sheets can be reused immediately to bypass folding. If clothing is not permanent press and ironing is required, it should

be performed with a lightweight iron and board that can be adjusted for sitting or standing. A tabletop ironing board may also be an option.

Figure 29-7 A knob turner may make it easier to turn appliance knobs for clients with weak grip.

Indoor Household Maintenance

Many tasks are involved in maintaining a home. Bedmaking can be simplified by straightening sheets and blankets before getting out of bed or by adjusting one side of the bed before moving to the other side. Loose fitted sheets and lightweight blankets or comforters may be easier to manage for persons with poor strength or endurance. Dusting can be adapted using long-handled, lightweight dusters. For persons with poor grip, a mitt can be used as a dusting cloth. When clients have poor hand strength, they can purchase adapted spray handles for household cleaning products. Floor care is a heavy cleaning task, but there are available products that make it easier, such as lightweight vacuums, long-handled brush and dustpans, self-wringing mops, and mops that spray cleaning fluid. Bathroom care is also a heavy household cleaning task. Spray-on products for the bathtub and sink, and drop-in toilet cleaning tablets reduce heavy scrubbing demands. To safely clean bathtubs, clients can use long-handled brushes and scrubbing sponges. Sliding glass doors may get in the way of bathtub cleaning. Replacing them with shower curtains provides better tub access for both bathing and cleaning.

Outdoor Household Maintenance

Lawn care and gardening are important occupations for many clients. Self-propelled or riding lawn mowers and lightweight or battery-powered lawn tools, such as weed trimmers and edgers, may aid those with poor endurance or strength. Ergonomic shovels and gardening tools, long-handled gardening tools, and gardening stools can also be purchased. Tools can be transported around the garden in apron pockets or a child's wagon. Raised beds for flowers and vegetables can increase a person's access to gardening from a wheelchair. Container gardening is also an option for those with limited mobility.

For all home management occupations, therapists should always address work simplification, energy conservation, proper body mechanics, and safety.

Financial Management

Financial management is defined as “Using fiscal resources, including alternate methods of financial transaction, and planning and using finances with long-term and short-term goals.”¹⁸ Being unable to manage their own finances places people with disabilities at risk for being exploited. Basic financial management typically includes money handling and banking tasks. Traditional ways to pay bills consisted of handwriting checks, keeping track of bank account balances by recording credits and debits in check registers, and mailing checks. Adaptive aids are available to help clients with conditions such as low vision, poor fine motor skills, and cognitive impairment—for example, pocket check writing guides, writing aids to hold pens for poor grip, low vision check registers, preprinted envelopes, and signature ink stamps.

Online and mobile banking are gaining popularity and have the potential to provide greater access to financial management for people with disabilities.²⁰ Financial institutions’ websites should follow the Web Content Accessibility Guidelines (WCAG) and be compatible with input devices and screen readers.²⁰ Mobile phone banking has unique features that persons with disabilities may find useful. For example, assessable banking apps are available that take and upload photos of checks for remote check deposits. Persons with hearing impairment can utilize text messaging or video conferencing with sign language interpreters for communicating with bank employees. Online and mobile banking technologies continue to advance quickly, and therapists must maintain knowledge of such devices.

Home Management with Cognitive Impairment

When cognitive impairment accompanies physical disability, clients will need support to understand and organize the steps of many of the abovementioned activities. Beneficial compensatory strategies include:

- Posting the steps for all activities in written and/or pictorial form in the location in which they will be performed.
- Creating and teaching clients to use checklists for all essential activities and providing opportunities for practice and return demonstration.
- Teaching clients to use preprogrammed smartphone and tablet cuing systems to facilitate activity performance.
- Labeling drawers, cabinets, and closets (in written and/or pictorial form) to enhance organization and memory of supplies stored within.
- Gathering and locating the supplies for each activity in easily accessible organizational systems (e.g., self-care dispensers, plastic storage shelves and trays) maintained in the area in which the activity will be performed.
- Teaching a family member or caregiver in the abovementioned compensatory strategies to monitor their use and correct errors.

Efficacy of Interventions for Home Management

There is little evidence of the efficacy of interventions to improve home management roles specifically as broader assessments of IADL are typically used as outcomes measures in research. A systematic review of occupational therapy interventions to improve IADL performance in community-dwelling older adults found that four types of interventions were effective.²¹ Home management was not the sole focus of this review but was included, and some of the same interventions discussed earlier were implemented. Strong evidence was found for IADL improvement after cognitive interventions with a focus on functional task exercises. There was moderate evidence indicating that self-management interventions or Stanford University’s Chronic Disease Self-Management Program led by an occupational therapist improved activity participation, quality of life, and self-efficacy for older adults with multimorbidities. Strong evidence was found for interventions to prevent deterioration in IADL performance, including education regarding depression, problem-solving, health promotion behaviors, and energy conservation. Other interventions that prevented IADL deterioration were exercise, home modifications, follow-up visits when transitioning from hospital to home, and a Tai Chi program. Home-based rehabilitation had strong evidence that indicated improvement in IADL performance. These studies included both occupational and physical therapy in client-centered home rehabilitation programs, addressing daily activity participation, task modification, assistive devices, falls prevention, chronic disease self-management, and mobility (see Evidence table at the end of this chapter).

A common occupational therapy intervention for improving participation in home management roles is energy conservation. Sometimes called fatigue management, much research, particularly

with people with multiple sclerosis, has been conducted on Managing Fatigue using energy conservation interventions. The presumption is that managing one's fatigue will improve participation in meaningful occupations. The Managing Fatigue program was developed for people with chronic conditions and has been successful in multiple research studies when presented in group and teleconference formats. In a one-to-one, 6-week long format with adults with chronic conditions, the Managing Fatigue course resulted in statistically significant decreases in fatigue and increases in self-efficacy and quality of life.²² Participants reported that they implemented energy conservation strategies in their everyday activities.

Home modifications are another commonly used intervention to improve participation in home management roles. A systematic review found strong evidence to support that home modifications improved function of frail older adults, adults aging with a disability, adults after hip repair, those with low vision, and those with schizophrenia. Moderate evidence was found for using home modifications to support caregivers of people with dementia. Studies of fall risk reduction also found strong evidence supporting home modifications by occupational therapists²³ (see Evidence table).

Restoring Work Roles

Background

The components of work include employment interests and pursuits, employment seeking and acquisition, job performance, retirement preparation and adjustment, and volunteer exploration and participation.¹⁸ Work meets multiple needs. In addition to being an economic necessity to finance essentials, such as food and shelter, and nonessentials such as leisure activities, work may also bestow identity, provide meaning or a sense of purpose, give structure to the day, provide social opportunities, and confer status within one's community.⁵ These benefits of work may not be realized for persons whose health impairments prevent or interrupt their work.

In 2017, unemployment for adults with disabilities between the ages of 16 and 64 years was over twice as high as for adults without disabilities (10% and 4.2%, respectively).²⁴ Occupational therapists must be aware that racial disparities in work participation exist for persons with disabilities. Blacks with disability have a higher unemployment rate (13.8%) than Hispanics (10.2%), whites (8.5%), and Asians (6.6%).²⁴ The unemployment rate is defined as the percentage of persons in the workforce who had no employment at the time they were interviewed, were available to work, and were actively seeking employment. The unemployment figure, however, may understate the problem because 80% of persons with disabilities are not in the workforce compared to 30% without disabilities. A more revealing statistic is that only 29.3% of adults with disabilities in the prime working age range, 16 to 64, were employed compared to 73.5% for those without disabilities.²⁴

Adults aged 65+ may also want to remain in the workforce for financial reasons, to be active, for personal fulfillment, or health care access. However, only 7.3% of adults aged 65+ with disabilities are working compared to 23.4% of adults older than 65 years without disabilities.²⁴ Volunteering has many benefits for people with disabilities and their communities and may lead to employment, but volunteering is also less common in people with disabilities.³

Many people with disabilities want to work. A scoping review found that work remains meaningful and important to the lives of those with disabilities. For people with cancer, HIV/AIDS, brain injury, musculoskeletal disorders, and spinal cord injury, work provided many benefits: a sense of identity, activity and social engagement, structure in their day, decreased boredom, financial independence, fulfillment, and self-worth.⁵

In spite of their desire to work, people with disabilities find many barriers to joining or returning to the workforce. Pain, fatigue, headaches, weakness, medication side effects, bodily changes, cognitive difficulties, illness susceptibility, and numerous medical appointments act as barriers to work participation and result from health conditions or medical treatment.⁵ There are also environmental barriers such as lack of accommodations, inaccessible workplace, loss of social security benefits and income support, mismatches in physical or cognitive job demands, poor relationships with supervisors or coworkers, and stigmatization.⁵

A challenge for occupational therapists in the assessment process is to discover the meaning and importance of work to clients both before and after illness or injury. Focusing intervention on the meaning of their work can be a strong motivator for clients.⁵ Further, therapists must also identify

the complex barriers to work that clients face and provide interventions and recommendations to help them overcome those barriers.

Performance-Based Measures of Worker Roles

Once the client's priorities for work are identified with an assessment such as the ACS, COPM, or OPHI-II, performance-based measures should be administered. The assessments discussed here focus on those that target adults with disabilities or injuries who may or may not return to their former vocation.

Functional Work Assessments

Functional work assessments typically have two steps: (1) a job analysis and (2) a client evaluation.

Job Analysis

A **job analysis** is a systematic evaluation of the physical, cognitive, social, and psychological requirements of a job. It is an important first step in becoming familiar with a job's demands and should be performed early in the work rehabilitation process so that the occupational therapist is aware of the skills required in order to tailor therapy appropriately.²⁵ A job analysis requires going to the job site; observing workers performing tasks; interviewing workers and supervisors; and writing detailed descriptions of tools, equipment, services or materials produced, and environmental characteristics of the worksite. A helpful source of information about occupations is the US Department of Labor/Employment and Training Administration's Occupational Information Network (O*NET).²⁶ O*NET replaced the Dictionary of Occupational Titles (DOT) and is a publicly available, free database that has descriptions of approximately 1,000 occupations. For each occupation in O*NET, there is a report that includes details about technology skills, knowledge, abilities, activities and tasks, context, education, tools, styles, and values that are needed to perform the occupation. It lists core and supplemental tasks for each occupation with core tasks defined as those that are critical and supplemental tasks as less important to the occupation. O*NET may also be utilized for career exploration, determining career interests, writing job descriptions, or identifying skills for advancement.²⁶

Uses of job analysis data or O*NET information may include:

- Involve the employer in the work rehabilitation process.
- Develop or select a functional capacity evaluation (FCE).
- Develop preplacement, post-job offer screenings that enable companies to place new hires in positions that minimize potential future injuries.
- Tailor goals and intervention to job demands.
- Match the injured workers' capabilities to job task requirements.
- Place previously injured workers on light duty or return to work.
- Identify risk factors associated with work-related musculoskeletal disorders.
- Identify essential functions.
- Write job descriptions using Americans with Disabilities Act (ADA) of 1990 terminology.
- Describe and advertise jobs.

Functional Capacity Evaluations

A **functional capacity evaluation (FCE)** is a performance-based measure of a person's ability to participate in work. It compares a person's health status, body functions, and body structures with the demands of a job.²⁷ An FCE may also be known as a functional capacity assessment (FCA), a physical capacity assessment (PCA), a physical capacity evaluation (PCE), a work capacity assessment (WCA), or a work capacity evaluation (WCE). FCEs can be used in industrial settings for preemployment and postoffer screenings, in clinical settings for developing goal and treatment plans, and for determining workers' ability to return to their job duties.

An FCE consists of two parts: (1) a general evaluation of the physical and cognitive abilities of the client and (2) a job-specific evaluation. This is analogous to assessment in traditional occupational therapy settings in which the client's physical and cognitive abilities and occupational performance are assessed, and from which goals and interventions are developed. FCEs include a review of a client's medical record, a work and educational history interview, a basic musculoskeletal evaluation, performance evaluations, and a comparison of the results with the client's job requirements.

The general evaluation of a client's physical abilities consists of measures of flexibility, strength, balance, coordination, cardiovascular condition, and body mechanics. It may include assessment of the person's ability to sit, stand, walk, squat, kneel, carry, bend, climb, reach, stoop, and perform fine motor or repetitive motions. The evaluator should document weight lifting/pushing/pulling limits, activity tolerance, environmental restrictions, side effects of medications, and note any report of pain or observations of pain behaviors. The general evaluation of cognitive abilities may include observations about following instructions, safety, memory, communication skills, or decision-making. Psychosocial behavioral assessments are not consistently included in FCEs, but occupational therapists should administer brief depression and anxiety screenings. These mood disorders commonly coexist with and may exacerbate physical and cognitive problems.

The second part of the FCE is analysis of the client's ability to perform job-specific tasks. Therapists begin by identifying the most difficult and important task components of the job. For example, if a carpenter is required to lift 10-lb tools and a 50-lb toolbox, the more difficult and important task component to be assessed will be lifting a 50-lb toolbox. Work simulations are also performed. They are more complex and have greater face validity than assessing a person's ability to perform a task component because they combine multiple constructs such as strength, balance, and fine motor skills. Using the carpenter as an example, a work simulation may involve standing on a stepladder (balance) while using a 4-lb cordless power drill overhead for 15 minutes (strength and activity tolerance) and then changing the drill bit (grip strength and fine motor coordination).

The results of an FCE can be used to match a client's residual capacities with the demands of a specific job, as evidence to determine disability status, and as a baseline for new employees. However, choosing the appropriate FCE can be difficult. There are many FCEs available; they differ in the physical, cognitive, and psychosocial factors assessed and in the training required to administer and interpret them.

FCEs are primarily conducted in artificial environments with engineered physical work tasks. The Assessment of Work Performance (AWP) was developed by occupational therapists and may be used in real-life work situations or in artificial environments with clients who have different kinds of work-related problems and diagnoses.²⁸ It does not target specific work tasks but assesses work skills in three domains: motor, process, and communication and interaction skills. Each of the 14 AWP test items is rated by the observer on a four-point Likert scale, ranging from incompetent to competent performance (see Assessment table).

Intervention

AOTA lists the goals of work rehabilitation as maximizing work function, facilitating safe and timely return to work through remediation, and assisting workers to retain or resume their worker role and prevent future impairments following injury or illness.²⁹ There are different types of work rehabilitation programs: work readiness, work conditioning, and work hardening. These interventions principally employ techniques to establish or remediate the client's ability to work by changing client variables (e.g., strength, activity tolerance).

Work Remediation

Work Readiness

Work readiness programs allow clients to explore other options if they cannot return to a previous occupation. These programs help individuals to identify work goals, interests, and skills. Clients may be referred to their state Department of Rehabilitation for job training and placement after participating in a work readiness program.

Work Conditioning

Work conditioning generally follows acute care and precedes work hardening. It focuses on remediation of physical or cognitive deficits to improve work function. It may include warm-up exercises, conditioning exercises based on job requirements, and job-related tasks that replicate essential task components (Fig. 29-8). A program may begin with hour-long sessions and progress to 8 hours per day as the client's condition improves.

Figure 29-8 Work conditioning may include warm-up exercises, conditioning exercises based on job requirements, and job-related tasks that replicate essential task components.

Work Hardening

Work hardening is a multidisciplinary structured treatment designed to maximize a client's ability to return to work. The psychosocial, communication, cognitive, and physical components of a job are addressed. Work hardening aims to replicate a specific job or classification of jobs, and differs from work conditioning in that it uses graded real or simulated work activities. The work hardening environment should replicate the workplace as closely as possible in aspects such as space, equipment, interactions with others, hours, breaks, and performance standards. Other disciplines that may be included in work hardening programs are physical therapy, vocational rehabilitation, psychology, social work, social services, drug and alcohol counseling, nutrition, and education.

Work Adaptation or Compensation

The ADA prohibits discrimination on the basis of disability and requires an employer to provide reasonable accommodations to a qualified person with a disability who is an employee or an applicant for employment.³⁰ However, to reiterate, barriers to employment remain with only 29.3% of adults with disabilities in the prime working age group, 16 to 64, employed compared to 73.5% for those without disabilities.²⁴ Identifying and recommending reasonable accommodations is a common compensation or adaptation intervention by occupational therapists who specialize in work-oriented therapy or return to work. Identifying reasonable accommodations requires collaboration between the client, employer, and occupational therapist. The best resource for identifying appropriate accommodations for a worker with a disability is the Job Accommodation Network (JAN) funded by the US Department of Labor, Office of Disability Employment Policy.³¹ JAN provides menus of accommodations in four categories: disability (e.g., stroke), limitation (e.g., pain), work-related function (e.g., manipulate items), and topic (e.g., accessibility).

Some adaptations for the current computer-based work environment are explained in the subsequent sections.

Voice Recognition Software

Voice recognition software (VRS) identifies words and phrases in spoken language and converts them to a readable format. When using a keyboard is physically difficult, an individual can use VRS to take notes, send emails, or perform other computer-related work tasks. VRS has been used for individuals with motor impairment conditions, such as cerebral palsy, Parkinson disease, TBI, and motor neuron diseases.³²

Screen Reader Software

Screen reader software (SRS) programs read text that is displayed on computer, tablet, or smartphone screens with a speech synthesizer, sound icons, or a Braille display. SRS programs can be beneficial for clients with vision impairments who have difficulty reading a computer screen, thus enabling access to digital information and computer-related work tasks. An SRS program can also benefit clients with a learning disability or a cognitive impairment that slows their reading speed, including persons with TBI and stroke.

Browsers That Provide User-Friendly and Customizable Web Interface

Computers have settings that allow users to adjust the screen lighting, contrast, mouse size and speed, and other accessibility features to enhance computer and Internet use. There are also web browsers that further provide user-friendly and customizable web interface, such as Web Trek and MozBraille. Web Trek is a web browser designed for individuals with intellectual impairment. To reduce the complexity of the web browser and eliminate barriers for individuals with cognitive impairments, Web Trek has a built-in SRS, enlarged images, and minimizes clutter on the page.³³ MozBraille is designed specifically for individuals with visual impairments and is customizable. Users can transform Mozilla or Firefox with an SRS, large character view, or a Braille terminal to access the Internet.³⁴

Color-Coded Keyboards

A color-coded computer keyboard or keyboard cover is designed to provide a high-visibility keyboard option by designating specific colors on certain keys (e.g., red vowels, yellow shift key). Persons with vision impairments may find this helpful in locating important keys or in finger placement on the keyboard. Color-coded keyboards may also help persons with cognitive impairments to more easily learn how to use a keyboard.

Efficacy of Interventions for Restoring Work Roles

Blas et al. performed a scoping review of occupational therapy interventions that targeted work-related outcomes.³⁵ They found 46 articles with 163 different occupational therapy interventions. The interventions included altering the work activities, the environment, and body functions and structures. The most frequently used interventions included acquisition of new skills; using health services, products, and technology; handling psychosocial demands; and work preparation. The most often targeted work-related outcomes they identified were remunerative employment, sensation and pain perception, ability to handle psychosocial demands, emotional function, economic self-sufficiency, and muscular and cardiovascular endurance.

Four systematic reviews examined remediation interventions for work-related injuries, including low back³⁶; conditions of the forearm, wrist, and hand³⁷; elbow injuries³⁸; and shoulder injuries.³⁹ However, only one reported results of return-to-work interventions.³⁶ Snodgrass performed a systematic review of interventions for work-related lower back injuries and found that therapeutic exercises, client education in body mechanics, work reconditioning and graduated return to work, ergonomic modifications, cognitive behavioral strategies such as progressive relaxation, and physical agent modalities were supported in the literature.³⁶

A systematic review for effective return-to-work interventions after acquired brain injury (ABI) found strong evidence that adaptation of working tasks, hours, and the environment; vocational counseling; person-centered goals; supported employment; and access to support and education increased the likelihood of return to work.⁴⁰

Restoring Recreation Roles

Background

Balancing work with recreation is essential for mental and physical health and promotes a less stressful and more satisfying life. In the literature, the terms recreation and leisure are often used interchangeably. However, leisure is more properly defined as free time or time that is not spent in obligatory occupations, whereas recreation indicates an activity that is performed for pleasure or

amusement. Law and colleagues⁴¹ used the term leisure rather than recreation and described three categories of leisure activities: quiet leisure or activities such as reading or sewing, active leisure or activities that require physical exertion such as wheelchair rugby, and socialization or activities that involve interaction with other people such as going out to a restaurant.

Adults with physical disabilities tend to engage in quiet leisure and to reduce their participation in physically demanding recreational activities. After a disabling event such as stroke, research has shown that there is a significant decrease in participation in high-demand leisure activity.⁴² Participating in physically demanding recreational activities is important to physical and mental health and wellness for people with disabilities. Occupational therapists can encourage clients by providing physically demanding activities and experiences, recommending adaptive techniques or adaptive equipment, and providing resources for existing activity programs in their community. One such resource is recreational programming offered by therapeutic recreation specialists. Similar to occupational therapy's beginnings after World War I, therapeutic recreation is a field that has gained prominence since World War II when they used recreational activities for treatment of war veterans with disabilities. Therapeutic recreation specialists have played a major role in developing leisure programs in medical settings, such as rehabilitation hospitals. The distinguishing difference between the two professions is that therapeutic recreation specialists always use recreational activity as their primary form of treatment.

Assessment of Recreation Roles

To identify appropriate leisure interests and activities for the client, there are many leisure exploration assessments that occupational therapists may administer. As noted previously, one of the COPM categories asks clients about their leisure interests and the ACS explores pre- and postdisability participation in high- and low-demand leisure and social activities. There are interest checklists available from both the occupational therapy and therapeutic recreation professions. Beard and Ragheb have developed a series of leisure questionnaires that may be used by therapeutic recreation specialists or occupational therapists. The Leisure Interest Measure can determine the level of interest in types of leisure activities and can be used to monitor change.⁴³ The Leisure Satisfaction Measure assesses whether clients perceive their leisure activities as meeting their needs or benefiting them⁴⁴ (see Assessment table). Based on the results of the assessments discussed, occupational therapists can help clients resume premorbid recreational interests or explore new options.

Intervention for Quiet and Active Leisure or Recreational Pursuits

Quiet Leisure

Basic principles of compensation or adaptation also apply to enabling participation in recreation activities. The quiet leisure activities of needlecrafts, reading, table games, playing cards, drawing or painting, puzzles, or writing may be performed with limited ROM by organizing and placing items within reach and building up tool handles in the case of poor grip or pinch. Persons with weakness, low endurance, or incoordination may use proximal stabilization (i.e., sitting with feet on the floor, trunk supported, and elbows or forearms supported on a table to limit the degrees of freedom of movement) as an adaptive technique for performing quiet leisure activities involving fine motor skills. With unilateral loss of motor control and limb function, objects should be stabilized with the weaker side or adaptive equipment used to hold the craft or card. An embroidery hoop holder and/or a playing card holder are examples. For visual impairments, there are many tools on the market for increased lighting and magnification of needlecrafts and handcrafts. There are enlarged print cards and games and items with Braille symbols. With chronic pain, clients should be instructed in proper body mechanics, work simplification, and energy conservation techniques. Visual aids or simplified instructions may facilitate participation in crafts or games for those with cognitive impairment.

Active Leisure

Compensatory techniques and adaptation of the environment, tools, or activity may also be necessary to facilitate participation in active leisure for clients with disabilities. For example, many high-demand sports activities have their counterpart for wheelchair users. Wheelchair users with specialized wheelchairs or equipment may participate in racing, rugby, basketball, tennis, soccer, snow skiing, water skiing, mountain biking, sailing, kayaking, canoeing, golf, and swimming, to name some of the most popular sports (Fig. 29-9). Chair yoga and Tai Chi have gained popularity for people with many types of disabilities who may be unable to assume certain poses. Specialized wheelchairs for rough terrain allow users to go hiking and access the beach. There are often

precautions for clients with certain conditions that must be observed when participating in active leisure. For example, a client with rheumatoid arthritis may be prohibited from strenuous physical activity during an acute phase or may need to practice joint protection strategies when performing a sport. Condition-specific precautions are discussed in later chapters.

Figure 29-9 Wheelchair users with specialized wheelchairs or equipment may participate in a variety of leisure sports.

Resources for Recreational Activities

There are many resources for participation in active leisure and recreational pursuits. The National Center on Health, Physical Activity and Disability (NCHPAD) is a health promotion resource to help people with disabilities and chronic health conditions achieve health benefits from participation in physical and social activities.⁴⁵ The NCHPAD website has links to programs, organizations, equipment, parks, and personal trainers for people with disabilities and health conditions by state, city, or zip code.

The National Sports Center for Disabled,⁴⁶ Disabled Sports USA,⁴⁷ and Adaptive Sports USA⁴⁸ are organizations that provide leadership, opportunities, and expertise in adaptive sports. They offer a wide variety of active sports and recreational activities year-round for people of all ability levels. Sports camps, clinics, and events have also been developed to introduce active leisure to people with disabilities. These may specialize in specific sports, or they may be aimed at people with certain diagnoses. Occupational therapists are often involved in directing, working for, or volunteering for sports camps or clinics. Volunteering for them is an excellent service learning opportunity for occupational therapy students.

Efficacy of Interventions for Restoring Recreation Roles

Smallfield and Molitor performed a systematic review of the evidence for the effectiveness of occupational therapy interventions to address leisure participation in older, community-dwelling adults.⁴⁹ They found strong evidence in support of leisure education programs by occupational therapists targeting increased leisure activity participation by this population. Moderate evidence supported a self-management of chronic disease program that was led by occupational therapists in promoting an increase in leisure performance and satisfaction. A study of assistive device use to facilitate leisure participation found that assistive devices increased the likelihood of older adults attempting leisure activities; however, further research on this intervention is required.

CASE STUDY

Patient Information

Tom is a 68-year-old white male who is a farmer with 200-acres of soybeans. He returned home 1 month ago from a 2-day acute care hospitalization for a left total knee arthroplasty (TKA) as a result of knee osteoarthritis (OA). Tom also has OA in the lower lumbar spine and right thumb.

Prior to the TKA, Tom complained of back pain when driving his tractors and soybean combine, pain in his right thumb when gripping tools, and pain in both knees when ambulating and working in his equipment workshop. Tom received 3 weeks of home health care physical therapy to increase his left knee ROM and ability to ambulate safely for longer distances on uneven terrain.

Reason for Occupational Therapy Referral

The physical therapist has referred Tom to the local AgrAbility program, a state affiliate of the National AgrAbility Project.⁵⁰ The state program contracts with an occupational therapist to perform worksite farm visits to evaluate farmers with disabilities, assess their work tasks and farm and home environments, and make recommendations for worksite and homesite modifications.

Assessment Process and Results

The occupational therapist prepared for Tom's initial evaluation by reviewing the treatment notes provided by the physical therapist and the O*NET core tasks for the occupation of farmer. O*NET listed several core tasks including operating irrigation equipment and tractors and tractor-drawn machinery to plow/plant/harvest crops and repairing and maintaining farm vehicles and equipment. The occupational therapist first administered the COPM and found that Tom's top five priorities were as follows:

Occupation	Importance	Performance	Satisfaction
1. Operate tractor and soybean combine to harvest crops (Work)	10	2	1
2. Maintain farm vehicles and equipment (Work)	10	3	1
3. Resume leading his 4-H group of teens who raise lambs (Community participation)	9	2	1
4. Drive into town and grocery shop with his wife (Home management)	7	2	2
5. Go bass fishing (Recreation)	7	3	1

Because the visit was to Tom's home and farm, the occupational therapist scored the AWP while observing Tom perform two work tasks: (1) climb onto his tractor and drive it in a field and (2) change the oil in the tractor in his workshop. In motor skills, Tom scored 2 of 4 (limited performance) in mobility, strength, and physical energy. In process skills, he scored 3 of 4 (questionable performance) in organization of space and objects and adaptation. In communication and interaction skills, he scored 4 of 4 (competent performance) in all areas. On the AWP, the therapist analyzed Tom's limitations and concluded that he had limited knee ROM, decreased lower extremity strength, and poor physical energy that impaired his ability to climb the four vertical ladder rungs into the tractor. He also reported bilateral knee pain (5 on a 10-point pain scale) when climbing the four rungs. When driving the tractor, Tom complained of knee pain when using foot pedals, thumb pain (3 on a 10-point pain scale) while gripping the steering wheel, and back pain (4 on a 10-point pain scale) after 30 minutes of driving on rough terrain. When changing the oil in the tractor, he complained of back pain while standing on the concrete floor and bending over to pickup tools (5 on a 10-point pain scale) and hand pain when using a socket wrench (3 on a 10-point pain scale).

The therapist assessed the worksite, vehicles, and equipment while Tom was performing the work tasks. She noted that Tom did not utilize adaptive techniques or equipment for access and seating in farm vehicles, tool adaptations, or pain and fatigue management techniques.

The occupational therapist also questioned Tom about his work, volunteer, and leisure schedules. As with most farmers, she found that during planting and harvest seasons, Tom reported working very long hours on heavy equipment with few rest breaks. He also reported that pain was exacerbating his fatigue and that he had no energy for those things he enjoyed such as working with teenagers in 4-H and going bass fishing. His wife was present for the interview and stated that she missed having him along for trips into town for grocery shopping and visiting their

grandchildren. He agreed with her, but he stated that his priority was work and that he was too tired to go.

Occupational Therapy Problem List

- Significant difficulty climbing tractor rungs and into soybean combine due to pain, decreased knee ROM, and decreased lower extremity strength as a result of left TKA and right knee OA.
- Pain from carpometacarpal OA in right thumb reduces Tom's ability to perform tasks that require a tight grasp such as hand tool use to repair farm equipment.
- Lower back pain from OA of the lumbar spine limits his ability to operate heavy farm vehicles, stand on concrete workshop floor, and bend and lift when repairing farm equipment.
- Tom is unable to resume his 4-H volunteer position or go trout fishing due to fatigue.
- Tom is unable to accompany his wife to shop and visit family due to fatigue.

Occupational Therapy Goal List

- Tom will climb onto his tractor and soybean combine with Modified Independence using adaptive equipment in 4 weeks.
- Tom will operate his tractor, soybean combine, and truck while reporting decreased back pain, from a self-rating of 5 to 2 on a 10-point pain scale, while using adaptive equipment and pain management strategies in 2 weeks.
- Tom will repair and drive farm vehicles and equipment with Modified Independence while utilizing adaptive equipment for reducing OA pain in 2 weeks.
- Tom will participate in volunteer and leisure activities for 2 hours per week while using energy conservation strategies by 4 weeks.
- Tom will grocery shop with his wife one time per week while using energy conservation strategies in 2 weeks.
- Tom will be able to perform work, volunteer, and leisure activities with report of decreased pain and fatigue by following a home exercise program three times per week to increase strength and activity tolerance in 1 month.

Intervention

The occupational therapist began the intervention process by researching adaptive equipment options for arthritis and pain in the Job Accommodations Network. She also searched the National AgrAbility Project Toolbox⁵¹ for adaptive equipment specific to farm tasks and equipment.

To aid in climbing onto tractors and the soybean combine, the therapist recommended two possible modifications, add-on tractor steps for the bottom of each vehicle's ladders to shorten the distance and reduce the strength needed for climbing onto the first rung⁵² or installing a power standing platform lift for each vehicle.⁵³ To reduce back and hand pain when driving the farm vehicles, the therapist provided resources for antivibration seat cushions, lumbar support cushions, and padding and antivibration steering wheel covers. Vibration dampening gloves can also reduce pain and protect joints when driving heavy equipment or using power tools.

The occupational therapist recommended antifatigue standing mats for the workshop concrete floor to reduce back and lower extremity pain and fatigue while working. She recommended pain and fatigue management strategies such as reorganizing the workshop to reduce bending and reaching by placing tools at waist level on a rolling cart, using a power socket wrench and other power tools rather than manual tools, and padding handles of other tools to reduce contact with hard surfaces that cause pain in his hand.

The therapist provided education in energy conservation and pain management techniques to reduce his pain and fatigue. These included taking brief rest and stretch breaks throughout his workday. Planning ahead is often difficult for farmers because of unpredictable conditions, but the therapist worked with Tom to make a weekly schedule with lighter work tasks on 1 day per week so that he had energy to go shopping with his wife and on 2 days per month to go fishing. She discussed saving energy when shopping such as planning the grocery list by the layout of the store. The therapist explored ways that Tom could share responsibility for his 4-H club, and he was able to identify another community member he could mentor and with whom he could alternate club activities. The therapist emphasized the importance of exercise as an energy conservation technique and of continuing to follow a home exercise program to improve his

strength and ROM. Finally, the therapist provided information for grants and loans to pay for equipment through the US Department of Agriculture and other farm and rural support organizations.

Assessment Table of Instruments for Home Management, Work, and Recreation Roles

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Occupational Performance Assessments for ADLs						
Activity Card Sort (ACS) ⁷	Interview-based, card sorting task for older adults in four categories: instrumental, low-demand leisure, high-demand leisure, and social activities	20–60 minutes	Concurrent validity was established by comparing versions with other assessments. Content validity was based on consultation with community living older adults.	Test–retest reliability = 0.74 Internal consistency with Cronbach α from 0.71 to 0.93	Not established	Strengths: May be used in many types of settings to determine retention of premorbid activities and for planning of occupation-based intervention Weaknesses: Does not provide information regarding length of time spent engaged in activities, frequency of activity participation, social interactions during activities, nor difficulty experienced performing an activity.
Canadian Occupational Performance Measure (COPM) ⁸	Semi-structured, interview-based rating scale to identify and prioritize self-care, leisure, and productivity occupations	30–40 minutes	COPM scores were responsive to self-perceived changes in performance. Other instruments used COPM as a valid measure of occupational performance.	Test–retest reliability ranged from 0.63 to 0.89 for performance and 0.76 to 0.88 for satisfaction.	A two-point change in score is considered clinically significant.	Strengths: Problem list serves as guide for client-centered intervention. Can be used in many settings with variety of conditions. Weaknesses: Dependent on interview style of administrator. Only used in limited clinical fields and disciplines. Not suitable depending on the practice setting or if clients lack insight.
Occupational Performance History Interview-II (OPHI-II), Version 2.1 ⁹	Semi-structured interview, rating scale, and life history narrative to elicit a detailed history of a client's work, play, and self-care and the impact of impairment	60 minutes	Validated using Rasch analysis	Test–retest reliability not available	Not established	Strengths: Used to develop an occupational profile to guide intervention. Can be used with adult clients who are able to perform an in-depth interview. Weaknesses: Dependent on client's willingness to share information; clients can feel vulnerable if no rapport is built. Often cannot be administered in a single session.
Home Management Assessments						
Assessment of Motor and Process Skills (AMPS) ¹⁶	Observation-based rating, designed to measure quality of performance in basic ADLs and IADLs	30–40 minutes	Established validity across age, culture, ethnic, and diagnostic groups and genders through various studies. Also used widely to examine ADL differences between different diagnostic groups.	Test–retest reliability for motor scale ranged from 0.88 to 0.91 and the process scale ranged from 0.86 to 0.90	Not established	Strengths: Assist in intervention planning and used to compare reevaluation results to assess intervention success. Weaknesses: Measures reflecting normal variation overlap for many age groups. Items needed are dependent on task patient wishes to perform. Time commitment and cost of administrator training

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Occupational Performance Assessments for ADLs						
Performance Assessment of Self-Care Skills (PASS) version 3.1 ¹⁵	Observation based to determine performance for daily living skills in the clinic or home	1.5–3 hours	Content validity was established by an investigation of ADL/IADL categories and tasks in relationship to ADL and functional assessment tools in rehab. Construct validity was based on a comparison of scores with controls and persons with dementia.	Inter-observer reliability scores ranged from 0.80 to 0.99. Test–retest reliability ranged from 0.82 to 0.97.	Not established	Strengths: Establishes baseline functional status; can assist in treatment planning. Aids in discharge planning by identifying type and amount of support required. Weaknesses: Time required to complete assessment is lengthy.
Work Assessments						
DSI Work Solutions Functional Capacity Assessment (DSI FCA) ⁵⁵	Designed as an objective measure of an individual's ability to perform various work-related tasks	Three-hour administration for one-part FCA, 5-hour administration for two-part; FCA over the course of 2 days	Validity was demonstrated by comparing performances health clients and clients with chronic nonspecific back pain.	Intraclass correlation coefficient was ≥ 0.75 . Test–retest reliability is considered acceptable based on analysis of ceiling and criterion tests.	Not established	Strengths: Supported by extensive research on kinesiophysical approach; report focuses on evaluatee's abilities; report is brief. Weaknesses: Extensive time to complete
Work Assessments						
Assessment of Work Performance (AWP) ²⁸	Based on the model of human occupation; assesses a patient's observable work performance skills	Not predetermined; can vary from a few hours to weeks	Adequate face validity and acceptable content validity have been established based on principal component analysis.	High-item separation reliability (0.99) indicates good internal consistency.	Statistically sensitive and discriminated between clients	Strengths: Observation based; theory based; comprehensive assessment; motor, process, and communication/interaction skills; instructions were clear. Weaknesses: Further assessments are necessary to determine client's abilities; use of ordinal scoring psychometrically questionable; administrators stated they had to spend time to become comfortable administering.
Recreation Assessments						
Leisure Satisfaction Measure ⁴⁴	Questionnaire-based rating scale; measuring the amount to which a person feels that his or her general needs are being met through leisure activities	5–25 minutes	Validity was established based on a factor analysis to which conventional item and test analysis techniques fell within an acceptable range.	Reliability coefficient (α) = 0.96	Not established	Strengths: Can be used to explore new areas of leisure to increase satisfaction; includes current or existing leisure program. Weaknesses: Requires quiet room to administer; patient must be Level 7 or above on Rancho Los Amigos Scale.

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Occupational Performance Assessments for ADLs						
Leisure Interest Measure ⁴³	Questionnaire based, designed to determine the level of interest in leisure activities and what activities they are interested in	5–25 minutes	Measures both intensity of breadth of leisure interest; Pearson correlation coefficients evaluated whether domains were interrelated—physical and outdoor domains did not show any statistically significant interrelationships.	Internal consistency (α) = 0.87	Not established	Strengths: Assesses various domains of leisure; can be used to ensure individual has activities available that are interesting to him or her used to point out areas where therapist can provide education to create new leisure activities. Weaknesses: Domains are not all interrelated; does not assess current leisure participation satisfactorily

Evidence Table of Intervention Studies for Restoring Home Management, Work, and Recreation Occupational Roles

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Home Management Roles						
Interventions within the scope of occupational therapy practice aimed at IADL performance ²¹	Interventions since 2012 were investigated for efficacy in improving or slowing the decline in IADL performance of older adults with disabilities: cognitive, self-management, prevention, and home-based multidisciplinary rehabilitation, client centered.	Fourteen peer-reviewed, scientific articles (13 Level I and 1 Level III) examining community-dwelling individuals aged 65 years and older		Systematic review Level I	Four areas of intervention were found to improve or slow the decline in IADL performance: cognitive, self-management, prevention, and home-based multidisciplinary rehabilitation, client centered. Chronic Disease Self-Management Program improved participation and perceived performance.	No statistical analysis
One-to-one fatigue management course delivered by occupational therapy practitioners or students ²²	Five modules were as follows: basics of fatigue, communication and fatigue, body mechanics and environment, analyzing and modifying environment, and living a balanced lifestyle.	Forty-nine adults with chronic disease and moderate or severe fatigue as dictated by an average score of 4/7 or higher on the Fatigue Severity Scale	1–2-hour sessions for 4–6 weeks until all modules were completed.	One-group, pretest–posttest, follow-up design	Participants experienced significant decreases in fatigue and significant increases in self-efficacy and most components of quality of life from pretest to posttest.	Large effect size was mentioned.
Work Roles						

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Interventions within the scope of occupational therapy aimed at increasing work participation ⁵⁴	Evidence-based interventions within occupational therapy's scope of practice that have been studied because the enactment of the ADA were investigated for efficacy in increasing participation in work for individuals with disabilities.	Forty-six peer-reviewed, scientific articles (27 Level I, 6 Level II, 12 Level III, and 1 Level IV) studying work-related interventions for individuals with a variety of disabilities including mental, physical, cognitive, and hearing		Systematic review Level I	Most effective interventions for physical disability were peer mentorship and multidisciplinary health care for work-related satisfaction and self-efficacy; for neurological disability were one-on-one intervention in supported competitive employment and assistive technology; and for intellectual disability, using apps and telehealth services. Overall, technology, coaching, peer mentorship, and work accommodations were most effective.	No statistical analysis
Return-to-work interventions ⁴⁰	Return-to-work interventions delivered in four continents were analyzed to find those most effective for individuals with acquired brain injuries of both a traumatic and nontraumatic nature. Combinations of the following were studied: work-directed intervention, education and coaching, skills training, cognitive rehabilitation, and supported employment.	Twelve studies (5 Level I and 7 Level IV) with return to work as a primary or secondary outcome for employed adults with nonprogressive acquired brain injuries		Systematic review Level I	Strong evidence supports the efficacy of combining work-directed intervention, such as task adaptation, with education or coaching. Complementing those interventions with skills training involving the employee and the employer was also indicated. Overall, the best return-to-work outcomes involved workplace support and employer collaboration.	No statistical analysis
Recreational Roles						

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Interventions within the scope of occupational therapy practice aimed at social participation and leisure engagement ⁴⁹	Interventions within the scope of occupational therapy practice were investigated for efficacy in improving social participation and leisure engagement for community-dwelling older adults.	Fourteen articles (11 Level I, 1 Level II, 1 Level III, and 1 Level IV) studying interventions within the scope of occupational therapy practice aimed at social participation and leisure engagement for individuals with an average age of 65 years or older living in the community, a retirement home, an assisted living facility, or a medical setting being discharged home. Individuals with chronic conditions were included in the studies.		Systematic review Level I	Effective and recommended interventions to promote social participant and leisure engagement for older adults are as follows: leisure education programs and chronic disease self-management programs aimed at leisure participation. Based on individual client factors, community-based group interventions and electronic games aimed at social participation are also supported.	No statistical analysis

Chapter 30

Restoring Transfers and Functional Mobility

Anita Perr

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Select and describe the most appropriate transfers as a result of an assessment and in collaboration with the client depending on the abilities, preferences, environmental conditions, and support available.
2. Describe treatment approaches, potential risks, and documentation of transfers.
3. Describe the occupational therapy assessment for manual and power wheelchair mobility.
4. Describe intervention approaches for manual and power wheelchair mobility.

CHAPTER OUTLINE

Introduction
Transfers
Functional Mobility
Case Study

TERMINOLOGY

Lateral transfer (popover transfer): moving from one surface to another in a mostly seated position, and using the arms to lift from the surface on which they sit to the landing surface; such transfers may be performed in one movement where the person moves from the original surface to the landing surface in one movement or they may be performed in increments where the person moves in multiple, short movements, repositioning his or her body, hands, and arms or to rest.

Manual wheelchair: a wheeled mobility device that is propelled by physical exertion by the user and/or an assistant.

Modified stand pivot transfer: similar to a stand pivot transfer, but the person does not stand fully, instead remaining in a crouched position.

Power wheelchair: a wheeled mobility device that has a motor and battery and is controlled electronically via a joystick or other control.

Sliding board transfer: a seated transfer performed with a transfer aid, such as a sliding board or Beasy Board placed under the person providing a surface upon which he or she may slide.

Stand pivot transfer: the person moving from one surface to another stands fully, or nearly fully, upright, then pivots his or her feet to back up to the landing surface, and then sits on that surface.

Transfer: the process of moving from one surface to another without standing and/or walking and usually refers to movement performed by people with disabilities who are unable to easily stand or move from one surface to another.

Wheelchair: a wheeled mobility device comprised of a sitting surface atop wheels.

Wheellie: a position assumed by manual wheelchair users, whereby the casters (front wheels) are lifted off the ground and maintained by the wheelchair user by holding his or her center of gravity over the rear wheels axle position; partial wheelie is lifting the casters of a manual wheelchair off of the ground momentarily to navigate over small obstacles.

Introduction

People move routinely throughout the day. These movements are critical aspects of functional mobility and allow people to get from point A to point B in order to participate in preferred activities. This chapter focuses primarily on two areas of functional mobility: **transfers** and **wheelchair** use. In each of these two areas, you will learn about the reasons for deficits in these areas and the principles of assessment and interventions to improve function through remediation and adaptation.

Transfers

Deficits in the ability to move from one surface to another occur for various reasons including impairments in body functions such as mental, sensory, cardiovascular, respiratory, neuromuscular, and movement-related functions or impairments in body structures such as the nervous system, cardiovascular and respiratory systems, and structures related to movement. The skin and related structures are also addressed during transfers as pressure, abrasion, and shearing encountered during the transfer can lead to damage to skin and the structures below the skin, resulting in pressure injuries.¹ The level of importance is raised in people at risk for pressure injury development.

Assessment for Transfers

The assessment for transfers comprises many other assessments that are often completed in the course of the occupational therapy (OT) evaluation. Such assessments included those for cognitive function, visual acuity and perception, motor function, and sensory function. Identifying these underlying deficits helps to guide goal writing and treatment planning. For instance, deficits in memory or problem-solving may portend unsafe movements during transfers, such as attempting to move prior to engaging wheelchair wheel locks or placing the feet on the floor rather than wheelchair footrests.

In addition to identifying these underlying impairments, the assessment also includes performance of the transfers themselves. By having the person perform the transfer, the occupational therapist determines how the interactions of the underlying impairments impact the movement in each transfer environment. The therapist can then determine the level of function: whether a seated or standing transfer is most appropriate; the amount and location of hands-on assistance; and the type, frequency, and style of verbal and nonverbal cues or instructions. As with all decisions, this is determined with input from the person transferring. Depending on the person's abilities, he or she may have more or less input.

Environmental attributes also influence the person's abilities during the transfer and should be assessed in each new transfer environment. The most common are transfers to and from the bed, toilet and bathing equipment, a car seat, or other transportation system. When assessing the environment, it is important to note whether there is space for the wheelchair or other equipment to be placed in optimal locations and whether obstacles or barriers can be removed or eased.

After completing the assessment and the activity analysis of the transfer, goals are written in collaboration with the person transferring and others involved in his or her care. Transfer goals should include the type of transfer to be completed, the location where the transfer will take place, the amount and type of assistance needed, any

alternative techniques or equipment to be used, and the timeline for attaining the goal. Sample goals include the following:

- The client will perform stand pivot transfers to and from the wheelchair and bed, including wheelchair setup, with distant supervision and occasional verbal cues for safety and technique within 2 weeks.
- The client will demonstrate good safety techniques during a controlled fall from the wheelchair and when regaining a seated position in the wheelchair within 1 week.
- The client will perform a popover transfer to and from surfaces that are up to 3 inches (7.62 cm) difference in height within two sessions.
- The client will perform wheelchair safety skills and transfer setup with three to four verbal reminders for memory loss and problem-solving difficulties by 1 week.
- The client will direct assistance in **sliding board transfers** including wheelchair setup, sliding board placement and removal, and the actual transfer by 1 week (see Fig. 30-1).

Figure 30-1 Examples of different sliding boards. **A.** Offset transfer board fits around the wheel of the wheelchair when the armrest is removed. (Courtesy of North Coast Medical, Morgan Hill, CA.) **B.** Transfer board with hand holes and notches allows transfers from either side. **C.** Beasy Board has a disc that the person sits on. The disc rides in a groove, making it easier for some people to move from one surface to the other.

Other qualifiers of performance that can be used to document progress are the amount of time required for the transfer, the number of cues required for setup and transfer, and the amount of assistance provided. Documentation regarding the transfer assessment is usually very brief and may be part of the activities of daily living (ADLs) or functional mobility status.

The assessment documentation includes your findings in the areas that are crucial for any given person, including visual acuity and perception, cognition, and motor function.

The documentation should clearly identify how difficulties in these areas lead to difficulty in transfers. Documentation should include the following points:

- Type of transfer
- Locations: Starting surface and ending surface
- Amount and type of assistance required
- Amount and type of cuing/direction required
- Ambulation and/or wheeled mobility devices used

Intervention for Transfers

The intervention for improving transfers comprises two approaches: remediation and adaptation. For example, if the person demonstrates impaired attention, the occupational therapist should focus part of the therapy sessions on activities to improve attention, a remedial approach. Transfer training should take place initially in a quiet environment, free of distractions; an adaptive strategy whereby changing the context in which treatment takes place allows the person to focus intently on the task. If the assessment reveals difficulty following verbal directions and impaired safety judgment, then the intervention focuses on improving these skills. The intervention can include practicing during transfers, but any other activities addressing these cognitive skills are also useful. For instance, an occupational therapist might develop a multiple step scavenger hunt that even includes identification of unsafe situations in pictures, such as a transfer setup with too much distance between the two surfaces, the wheelchair positioned at a poor angle, and the wheel lock disengaged.

If the assessment reveals impaired standing balance, strength, and coordination, activities that target these skills can be developed for the intervention. The same goes for any other difficulties identified. Of course, creativity in intervention planning will help keep the person interested and may allow him or her further improvement without realizing it. It is important to explain how the chosen activities relate to the person's priorities and relate directly to achievement of goals. Interventions themselves should be upgraded or downgraded based on the person's performance. As with other interventions, finding the balance between challenge and success is part of the key to making progress.

Interventions for improving transfers may include addressing the underlying impairments as well as direct transfer training. Each underlying impairment can be addressed alone or in combination. They should be addressed in a variety of activities in addition to practicing the actual transfers. Environmental attributes can also be varied during transfer training such as varying the heights of the transfer surfaces.

Transfer Principles

There are a few basic principles underlying most transfers. For ease of explanation, the following information refers to transfers between a wheelchair and another seating surface. Beyond the principles discussed in this chapter, there are typical transfer methods, but these are often adapted depending on the person's abilities and the environmental constraints.

The first principle is making sure the equipment is set up appropriately. The optimal setup puts the feet in a position where they can just pivot without having to take any steps. In order for the feet to be in this position, the wheelchair should be set up at about a 45° angle from the other transfer surface (Fig. 30-2). People who have more advanced skills may not need to focus as highly on setup. They are more able to compensate for less than optimal setups. For instance, people who are adept at and experienced with transfers may not lock their wheel locks or take their feet off the wheelchair footrests prior to transferring.

Figure 30-2 Setup for transfer. Wheelchair is positioned at approximately 45° to transfer surface. Wheel locks are engaged. Foot rests are out of the way.

Clients with more safety concerns, less experience, or less ability should attend to setup more critically. Such concerns are especially relevant for people who are attached to medical lines. This might be a person in a hospital intensive care unit or a hospital room that is hooked up to a ventilator or oxygen, urinary catheters with collection devices on the person or on a transfer surface, and/or intravenous (IV) lines. Assistance should be provided to insure that all of the lines are in a position where they will not impede the transfer.

The second principle has to do with weight shifts and body mechanics. Transfer movements are eased when the person shifts his or her weight forward bringing his or her center of gravity over his or her feet. Depending on the person's abilities and conditions, he or she should maintain the best positions attainable. Insuring that low back muscles are not overstretched and that the tenodesis hand grip is preserved are the types of body mechanics principles to which the person should adhere.

The third principle is preparing for the transfer. Double-checking the setup, ensuring that the wheelchair's wheel locks are engaged, and positioning oneself (such as feet off the footrests and in position) all prepare the person for a safe and efficient transfer.

The fourth principle is using momentum. Momentum can often be used to compensate for weakness during transfers.

Assistance

If the person transferring needs help, it is important for the assistant(s) to be trained and for the person transferring to know how to instruct others in assistance. The amount of assistance varies from distant supervision to maximal (or dependent) assistance. This training often includes wheelchair parts management and mobility as well, but for transfers, the areas of concentration are the transfer techniques themselves, problem-solving for unique situations, and safety of both the person being transferred and the person providing assistance. The assistant may merely be providing standby assistance or supervision, but he or she still needs to know the best hand holds and techniques when further assistance is needed. Reinforcing slow movements, double-checking the setup, including stability of the two surfaces and training the assistant and the person transferring in coordinated movements, is beneficial. It is also important for the assistant to know the specific needs of the person. Some people need specialized instructions and hand holds that can be practiced during treatment sessions, and it is important to teach client-specific safety concerns, such as protecting the upper limbs on the affected side of a stroke survivor to prevent overstretching or even subluxation. Instead of holding the person's arms, the assistant should hold the person's trunk.

In addition to focusing on body mechanics of the person transferring, it is also necessary to consider the body mechanics of the occupational therapist assessing and training the client as well as the body mechanics of the assistant.

During these training sessions, the person transferring should also be trained in instructing others in how to assist them. This is useful for regular assistance, but is also very helpful when someone not associated with the person must assist. This can take practice because many people do not like to ask for help and many are reticent to correct helpers or give very specific instructions. The specificity is quite helpful, however, because most people are unaware of how to offer assistance.

Variations by Age and Ability/Disability

It is important to consider each person's abilities and conditions during transfers and training. Conditions such as orthostatic hypotension may influence the person's ability to change positions as he or she moves from supine to sitting at the edge of bed to moving from sit to stand. He or she might need rest breaks to acclimate to the changes in position. People with arthritis may need to take extra care to position their bodies and limbs safely and in a position that does not cause joint irritation or pain.

Addressing cognition is also imperative for safety. Assistants, as well as the person transferring, may need to slow down and use simple instructions in order to transfer. Quiet environments are suggested for training sessions so that the person does not get distracted.

Some people have difficulty shifting their weight forward to make the transfer to standing easier. If the difficulty is caused by fear of falling forward, care should be taken to work on that forward movement until the person feels more comfortable. This can be addressed during a variety of intervention activities.

If the person is unable to shift his or her weight forward because of hip flexion range of motion limitations or owing to the presence of heterotopic ossification, the technique may need to be altered. For instance, because the weight shift predisposes the person to be able to unweight his or her buttocks, he or she may need to use a sliding board or use more assistance that might otherwise be needed.

Optimal Techniques

During **stand pivot transfers**, the person pushes up from the seating surface to rise to standing and regains his or her balance. The person then pivots his or her feet such that he or she is standing with his or her back to the surface to which he or she is transferring. At that point, the person reaches back and slowly sits. In a **modified stand**

pivot transfer, the person stays in a somewhat crouched position. He or she may reach for or hold on to the surface to which he or she is transferring.

People who transfer while remaining in a seated position often both push from the transfer surface and pull to the destination surface while leaning forward to shift their weight over their feet. Seated transfers may be performed in a single step or in multiple smaller steps. When a sliding board is used, the person shifts his or her weight to the side opposite the destination surface in order to unweight his or her buttocks to place the board under his or her buttocks and thigh. The board should be placed far enough forward under the thigh so that he or she does not slide forward off of the board during the transfer. After transferring to the destination surface, the person should shift his or her weight away from the original surface in order to unweight his buttocks and remove the sliding board. The sliding board should then be stowed in the location where it will be accessible the next time it is needed.

Seated transfers can lead to pressure ulcer development if the person is unable to unweight is buttocks sufficiently. During the seated transfer, the skin may be abraded as it scrapes along the transfer surfaces. Even more damage can occur if the person drags his or her buttocks over the top of the wheelchair wheel during the transfer. Shearing can also occur between the tissue under the skin of the buttocks and the body prominences if the person drags himself or herself across the sliding board or other surfaces. The greater the friction between the buttocks and the transfer surface, the more likely it is for these kinds of injuries to occur. In order to lessen the likelihood of this occurrence, intervention should include activities to strengthen the upper body and improve balance so that the person is able to lift himself or herself farther off the seating surfaces, unweighting the buttocks and making the transfer easier.

The abrasion and shearing that occurs during these sliding transfers can be even worse if the person's skin is unclothed and wet, such as during transfers to the toilet, commode, tub bench, or bath seat. Some people place a towel on the sliding board to ease the slide. Others place powder or cornstarch on the surface to make it slipperier. Using sliding boards on these slick surfaces of toileting and bathing equipment is also a bit more dangerous because the sliding board may shift during the transfer. Care must be taken to insure proper placement and to insure that the sliding board does not shift during use.

A dependent person may use a mechanical lift that offers dependent assistance, such as a mobile lift or ceiling-mounted lift. These are usually comprised of a single sling or a sling system that is placed under the person being lifted, often while he or she is supine in bed. The slings are then attached to the hoist that is controlled electronically, hydraulically, or mechanically. These lifting aids are also used within facilities and at home to help the assistant avoid musculoskeletal injuries² (see Fig. 30-3).

Figure 30-3 Client using mobile lift with assistance.

Special Considerations by Transfer Location

People transfer to and from a variety of surfaces and in a variety of locations. There are certain considerations that can ease the difficulty of these transfers.

Bed

Transfers from the bed to the wheelchair are often the first to be addressed by occupational therapists working on inpatient hospital units. Considerations for the bed include:

- Making sure the wheel locks are secured so the bed does not shift during the movement
- Raising or lowering the bed height to the same height of the wheelchair's seating surface. This height should allow the person to place his or her feet on the floor for stability. If standing transfers are being performed, it is important that person be able to reach the floor when seated at the edge of the bed. If the bed cannot lower far enough to be even with the wheelchair, the transfer to the lower surface may be easier and the transfer to the higher surface more difficult. In any case, practice is important, and activities that simulation these changes in level are suggested during treatment sessions.

Bathroom

Transfers to and from a toilet or commode may require the person to stand from and sit to a rather low surface. The person's ability to do this should be considered when making suggestions for environmental adaptations. The bathroom is often the smallest space in the person's home, so practicing maneuvering the wheelchair into position, moving the armrests or footrests, and placing any transfer equipment can ease the

transition home. Some toileting equipment, such as rolling shower commode chairs, are available with a drop-arm feature that can make sliding and **lateral transfers** easier.

The placement of the tub bench or bath seat often dictates the setup for the transfer and should be assessed and simulated for practice. These transfers may be complicated by the lack of clothing and water on the body or in the area. Care should be taken during training to address these concerns.

Tub transfers include lifting the legs over the side of the tub or stepping over the side. This is often one of the more difficult aspects of the transfers. One activity that may be helpful is practicing in a doorway. Place a piece of tape low to the floor, across the open door space, and have the person side step over it while holding to the door jam. Each time the person is successful, raise the tape just a bit until it is near the height of the tub side. This is often easier than stepping over the actual tub side because the height can be adjusted to match the person's abilities and because the surfaces on both sides of the tape are level and the same height where many tub surfaces are higher inside the tub than outside. This activity is very easy to grade depending on the person's abilities. It can be set up to simulate transfers in the same direction and those that the person will do at home. Practicing in an actual tub and as part of the bathing process should occur concurrently. It is not uncommon that the person needs additional instruction and assistance for wet transfers. By working simultaneously in the actual tub setting and in the simulated setting of the doorway, the person is able to practice the different steps in the transfer process.

Car

Car transfers can be difficult because the space between the wheelchair and the car is often larger than that encountered during a typical transfer. The two seating surfaces are rarely level, and many car seats have a bucketed shape. If the person has a choice in the car's upholstery, leather or leatherette is easier to slide on than fabric seats. In addition, the car door itself limits the space for maneuvering. Some car doors open wider than others, and some wheelchair users select their cars based, in part, on the space available when the door is open. The wheelchair should be positioned adjacent to the seat where the person will ride. It may be necessary to move or remove the footrests prior to pulling the wheelchair into the small space. Finding secure hand holds to use during the transfer, both on the original surface and the destination surface, helps make this transfer easier. The person should use nonmoving surfaces such as the car seat or dashboard to hold to rather than moving car parts, like the door. The door may swing, causing the person to lose his or her hold or balance, and the fingers may be pinched if the hands slip or the door mistakenly closes.

Many wheelchair users drive. People who are able transfer to the driver's seat and lift their equipment into the car either onto the passenger seat or the back seat. Riding in the vehicle's own seat is safer than being transported or driving from the wheelchair. This option is not always the best, especially if the repeated transfers throughout the day limit the person's energy for other activities. Most **power wheelchairs**, including scooters, are too heavy for this maneuver.

If the person can walk short distances, he or she can place the wheelchair in the trunk or back seat of the car and walk the short distance to the driver's seat. If the person travels with a companion or assistant, he or she can transfer to the driver's or passenger's seat and have the assistant stow the equipment.

There are electronic, hydraulic, and mechanical devices to assist with placement of wheelchair and other mobility aids on the car. These include lifts that place the wheelchair inside the automobile's trunk, on a rack outside the back of the car, or on a stowage device on the roof of the car.

Buses, Trains, and Subways

Transfers to and from seats in public transportation should be assessed, and intervention should be provided as needed. Being transported in the vehicle's own seat is safer than riding in the wheelchair, whenever possible. Transferring to or from a bus or train seat is complicated because tight spaces limit the person's ability to set up his or her wheelchair in its optimal position. Some bus and train seat armrests move out of the way for lateral transfers. For transfers to bus or train seats, the person may need closer supervision or more assistance than is usually required. Bus drivers and train conductors are often able to assist with securing the wheelchair, but not with the transfer itself. These transfers will also be complicated if they are performed while the transportation device is moving.

Whether the wheelchair user rides on the transport system in his or her wheelchair or in the vehicle's seat, it is important that securement be available for both the rider and the device. Tie-down and lock-down systems are used to secure wheelchairs to the vehicle's floor. This securement is necessary so the wheelchair does not become a projectile in the event of an accident.

Airplanes

When accessing an airplane, some **manual wheelchair** users are able to use their own wheelchairs as some have wheels at the end of the antitip bars and when the large wheels of the wheelchair are removed, the mobility device can be rolled on the casters and small antitipper wheels. Manual wheelchair users who are independent in propulsion often need help with navigation when relying on the small wheels only. On entering the plane and rolling in the aisle, the person's wheelchair should be placed in the optimal position for transfers. This is often parallel to the seat and facing forward because of the limited space on board the plane. Many manual wheelchair users can perform this transfer, but some may need help because of the limited space for optimal wheelchair placement.

Other manual wheelchair users and powered wheelchair users must transfer to a transport chair (or aisle chair) supplied by the airline. If the person is using a transport chair, the transfer from the wheelchair will take place in the gate area. The person may need assistance because the transport chair is very small and unstable. The transport chair and the user are then wheeled onto the plane. The transport chair is then placed parallel to the passenger's airplane seat, facing in the same direction as the seat. A stand pivot, lateral, or dependent transfer can then be performed to the airplane seat. Aisle seats on airplanes have locked armrests, but these can often be released by airline personnel, freeing up space for the transfer. Care must be taken that the person is positioned well in the seat, that his or her clothing is smoothed so as not to cause pressure under the buttocks and thighs. Reclining the seat and using positioning aids may also be necessary.

Floor

Not everyone needs or wants to learn to transfer to or from the floor, but it should be discussed with most people, especially those at risk for falling. These transfers are especially useful for people who wish to spend time on the floor, such as for exercise routines or leisure, and for children who play on floor surfaces. It is also helpful for the most active wheelchair users because the environments they frequent and their own wheelchair skills may put them at risk for falling.

For power wheelchair users who want or need access the floor, the transfer is quite similar. Once the person is on the floor, it will be nearly impossible to move the wheelchair so he or she will need to be able to crawl or scoot to the wheelchair for the return transfer. An assistant may be needed to help with the setup and to help with the

transfer. There are pediatric power wheelchairs that have a seat-lowering function to bring children to the floor level for playing, exploration, and participation in school activities.

Ambulation Aids

Ambulation aids, such as canes, crutches, and walkers, are used to help people move from one place to another. They may assist with ambulation or compensate for the inability to stand and walk to meet the needs of a given person and are often useful during transfers. A straight cane offers the least stability of the ambulation aids. During a standing transfer, the person may hold one hand on his or her cane while pushing up from the sitting surface with the other. The same strategy may be used with a four-prong or quad cane.

A standard walker with four legs gives the user bilateral support for balance and stability while walking. When used during standing transfers, the person may hold one handle of the walker while pushing up from the seating surface with the other arm (Fig. 30-4). Once he or she is able, that arm is moved to the walker. Once the person is standing and steady, he or she pivots while moving the walker in an arc, step-by-step, until he or she can back up against the second surface. He or she then reaches back for the destination surface and sits. A similar strategy is used with a rolling walker, except that walker may pivot more smoothly. When an ambulation aid is used, it must be included in the associated documentation.

Figure 30-4 Teaching safe use of a walker: Sitting down: First, tell the patient to stand with the back of his stronger leg against the front of the chair, his weaker leg slightly off the floor, and the walker directly in front. Tell him to grasp the armrests on the chair one arm at a time while supporting most of his weight on the stronger leg. (In the illustrations, the patient has left leg weakness.) Tell the patient to lower himself into the chair and slide backward. After he's seated, he should place the walker beside the chair.

Functional Mobility

If the person is unable to walk, with or without an ambulation aid, or is unable to walk to meet all of his or her needs, a wheelchair should be considered. If the person can walk short distances or for short periods of time or on certain days, depending on how he or she is feeling, a wheelchair should be provided for longer excursions or for whenever it is needed. One important point of the mobility aid is to enable the person to have sufficient energy to participate in desired activities. If the transit from one location to the other uses the person's energy, he or she will be unable to participate as fully as desired. This can be a difficult conversation to have because some people are concerned that moving from walking with an ambulation aid to using a wheelchair is a sign of deterioration or failure. By focusing the conversation on the activities in which the person wishes to participate, he or she may be more willing to consider using a wheeled mobility device.

The primary purpose of a wheelchair is to facilitate movement within and between environments and to allow exploration of those environments. Some wheelchair users independently navigate their wheelchairs through environments, whereas others need assistance for some or all of their maneuvers. Efficiency, body mechanics, planning and judgment, and safety are a few of the principles that underlie effective navigation. These are all intertwined. For instance, efficiency is using the most efficient route of travel over the surfaces that are navigable to reserve energy for participation in the desired activities at the destination. Efficiency also refers to the person's technique for manual propulsion so that he or she uses the most efficient body movements to reserve energy and prevent overuse or injury. For power wheelchair users, efficiency is related to the battery life of their wheelchair. Depending on the usage, a power wheelchair user may select short routes and turn off his or her wheelchair when stopped in order to conserve battery power.

Assessment for Functional Mobility

As with transfers, the assessment for wheelchair navigation comprised of many other assessments that are often completed in the course of the OT evaluation. Such areas include assessment of the nervous system, vision and hearing, and structures related to movement. Besides assessing the structures, the assessment should include actual wheelchair propulsion. Environmental conditions should also be assessed. This includes environments where training will take place, such as a patient's hospital room and therapy area. It should also include environments where the person is expected to participate in his or her chosen activities.

Body mechanics and posture need to be considered during navigation. Of primary importance is maintaining optimal posture for function. If the wheelchair user loses his or her position during navigation, his or her function will likely be limited, and the seating and positioning aids may need to be adjusted to provide sufficient support. Besides maintaining posture for function, it is also important for manual wheelchair users to feel comfortable with moving his or her own body position in relation to their wheelchair, or knowing their center of gravity. This is important for skills such as popping a **wheelie** and rolling up and down ramps. The assessment also determines the method the wheelchair user will use to propel his or her wheelchair. If upper extremity strength, endurance, and coordination are sufficient, the person may be able to use a manual wheelchair to meet his or her needs. If he or she is able to use one hand and one foot, such as following a stroke, this will indicate wheelchair propulsion using those extremities. If the person is unable to propel a manual wheelchair sufficiently, a power wheelchair should be considered. In addition to physical abilities, cognitive function, the person's social support, and the environments the person uses should also be assessed.

Planning and judgment are two cognitive skills that influence a wheelchair users ability to get to and from his or her desired locations. This might include getting from home to work taking public transportation, or it might include navigating around an obstacle, such as in sidewalk construction. In order to demonstrate good judgment, people need to have insight into their abilities and strengths in order to compensate for difficulties. For instance, a person with good insight will likely be better able to know how close he or she can roll to a curbside without tipping into the street. The assessment reveals this information. There are additional considerations for power wheelchair users, such as the ability to perform regular maintenance including charging the battery as needed. Manual and power wheelchair use is complicated, and the assessment for the use of these wheeled mobility devices often takes multiple sessions. At the completion of the assessment, the occupational therapist should be able to determine the best strategies for navigation and a plan to improve performance via goals. The goals are developed in collaboration with the wheelchair user and others in the social support system. Goals might address endurance for propulsion, speed, accuracy, obstacle

climbing abilities, and so on. Goals also must include consideration of safety, planning, and judgment.

Intervention for Functional Mobility

Safety, of course, is the priority. In many wheelchair mobility training programs, the first skill that is taught is falling safely. People with paraplegia, for instance, can hold one arm across their thighs and the bend their heads forward and protect their head with their other arm so that (1) their legs do not bend and their knees hit their face and (2) they do not hit the back of their heads if the wheelchair tips backward, as may happen when popping a wheelie.

The initial stages of mobility training take place inside the rehabilitation facility where the person learns how to maneuver on a smooth surface in an open space. Training continues focusing on more difficult skills and depending on the person's intended use. This might include negotiating surfaces such as sand or gravel and navigating over or around obstacles like curbs, steps, and railroad tracks. Training also includes navigation through tight spaces, such as a busy restaurant or office. The occupational therapist can incorporate wheelchair mobility goals within other ADL intervention. For example, if a power wheelchair user is taken to the grocery store to shop for food in preparation for cooking a meal, there is the opportunity to explore wheelchair mobility in a public environment while also carrying items or pushing a shopping cart.

As the person thinks about and attempts community-level mobility, it is also helpful to provide resources regarding accessibility guidelines. In the United States, changes in access to public places often result from advocacy and self-advocacy. Asking for help and providing information about access are skills that most wheelchair users need at one time or another, and some wheelchair users may embrace more fully. The Americans with Disability Act Accessibility guidelines address indoor and outdoor access for people with varying needs, including those who use wheelchairs or ambulation aids, those with hearing or vision impairments and those with cognitive limitations.³

It is important to address the psychosocial impact of using a wheelchair or other mobility device. Focusing on success and practicing skills in community spaces gives the wheelchair user the opportunity to build his or her esteem and is an important component of participation in community-based activities.

Part of the training in the use of a mobility device like a wheelchair is its care and maintenance. Such operations as cleaning the wheelchair, adjusting the wheel locks, adjusting air in tires, charging batteries, or even replacing spokes in the wheels can be performed by the user or assistant. During intervention, occupational therapists should make sure that the wheelchair user and/or assistant can perform wheelchair parts management and everyday care and maintenance. They should also be instructed about whom to contact for repairs and replacement.

There are some terrific resources for clinicians and for wheelchair users. Clinicians can learn the skills they will be teaching at training courses and using manuals and related materials. Materials from the Wheelchair Skills Program can be downloaded at <https://wheelchairskillsprogram.ca/en/>. Associated with this training program is a skills test that can be used to identify each user's skill level.⁴ The skills listed in this test can also be used to determine interventions for individual clients. There are also very useful manuals for wheelchair users and clinicians that describe independent as well as assisted power and manual wheelchair mobility skills.^{5,6}

Manual Wheelchair Navigation

Propulsion

Manual wheelchair propulsion usually occurs by pushing on the push rims that are attached to the outer surface of the rear wheels. According to Boninger et al.,⁷ there are four common propulsion patterns. The least efficient is in an arc moving back and forth from about 12:00 to 2:00. This pattern is often seen when the wheelchair seating surface is too high in relation to the push rims and/or when the rider has limited sitting balance in his or her wheelchair. The pattern that is most efficient and most likely to prevent repetitive stress is semicircular, “with the hand traveling below the pushrim in recovery” (Fig. 30-5). Using this strategy may improve wheelchair propulsion and decrease the tendency for pain and repetitive stress that is shown to occur in the shoulders of people with paraplegic spinal injuries.⁸

Figure 30-5 Manual wheelchair propulsion patterns. **A.** Results from the optimal propulsion pattern. **B.** Results from the least efficient propulsion pattern. DLOP, double-looping; SC, semicircular.

Using both hands/arms is not the only method of propulsion. Manual wheelchairs can also be propelled using both feet; using one arm/hand and one foot, as is common for people who are hemiplegic such as following a stroke; or with one arm/hand. And of course, manual wheelchairs can also be propelled by an assistant, although some of the most highly adjustable wheelchairs may not have push handles as they often impede self-propulsion. If the person is propelling the wheelchair with one or both feet, it is important to insure that the seat height is low enough so the person can reach the floor while maintaining an optimal seated posture. This may require selecting a specially designed low wheelchair or adapting the seat surface so that it is low.

Propulsion on smooth, level surfaces is accomplished by pushing on both push rims evenly. Wide turns can be made by “dragging the hand” on the push rim on the side to which the person wants to turn. For example, if the person wants to turn right to continue down a hallway, he or she could merely hold his or her hand against the right push rim. That slows the roll of that wheel while the left wheel continues at its speed, causing the wheelchair to veer or turn to the right. If a sharp right turn is needed, the person can continue pushing forward on the left push rim and slowing the roll of the right wheel. A very tight turn is accomplished by pushing forward on one wheel and rearward (pulling back) on the other, allowing the person to turn his or her wheelchair on its own axis (Fig. 30-6).

Figure 30-6 View from above: By pulling back on one wheel while pushing forward on the other, the wheelchair and user can make their tightest turn. (Courtesy of Beneficial Designs.)

Ramps and Slopes

The Americans with Disabilities Accessibility (ADA) guidelines state that any change in level over $\frac{1}{2}$ inch (1.27 cm) should be ramped and that ramps should be 5° or less.⁹ For every 1 inch (2.54 cm) of rise (height), the ramp must have 12 inches (30.48) of length (1:12 slope). For example, a 4-inch (10.16 cm) step will require the ramp length to be 48 inches (121.92) in order for a most people to navigate it using a wheelchair. A ramp in a public place must have a surface with a detectable texture for persons with visual impairments. It must have railings and a curb to keep wheelchair wheels from rolling over the edge. There must be 4 feet (1.22 m) of level landing at the top of the ramp.³ Leaning in the uphill direction, whether ascending or descending the ramp, helps to keep the wheelchair from tipping (Fig. 30-7). Skilled manual wheelchair users may descend ramps in a wheelie to prevent falling forward (Fig. 30-8).

Figure 30-7 Leaning forward when ascending a ramp helps to prevent the wheelchair and user from tipping backward. (Courtesy of Beneficial Designs.)

Figure 30-8 Descending a ramp in a wheelie position. (Courtesy of Beneficial Designs.)

Unlike ramps that people negotiate in the forward or backward direction, side slopes impact forward propulsion as the wheelchair continuously veers in the downhill direction. Thus, the downhill arm works much harder to keep the wheelchair moving straight. In the United States, sidewalks are built with a side slope toward the street so that rain drains to the gutter rather than into businesses and homes. Manual wheelchair users traveling long distances on sidewalks and people with low endurance may need to switch sides of the street so they can rest the downhill arm.

Wheelies

Wheelies are an important skill for manual wheelchair users to master, allowing them to propel more easily over uneven surfaces, and providing a seating system where position changes are possible. Even if the wheelchair user cannot complete a full wheelie, leaning back in the wheelchair lightens the load over the front casters, allowing more maneuverability. A pop-up or partial wheelie is very useful for navigating low obstacles like door sills and uneven sidewalks.

To pop a partial wheelie, the user rolls the wheelchair backward a short distance and then grabs the back of the push rims and pushes forward, while weight shifting rearward⁵ (Fig. 30-9). Once the pop-up is achieved, further training and practice can lead to finding the balance point and sustaining a wheelie.

Figure 30-9 Popping a partial wheelie makes rolling over small bumps easier. (Courtesy of Beneficial Designs.)

Changes in Level

Since the passage of the ADA Standards in 1990, curbs on sidewalks at street intersections are becoming less of a problem as curb ramps proliferate; however, at times, the wheelchair user may encounter a curb. In order to ascend a curb, it is easier if the manual wheelchair user can perform a wheelie while moving forward. If that is not possible, the person approaches the curb or step, facing it, pops up to place the casters on the curb, leans forward to redistribute the weight, and propels the large rear wheels up the curb or step with a hearty push. A person must have good balance, upper extremity strength, and hand function to perform this maneuver. To go down a curb or a step, the person approaches it backward, leans forward in the chair, and slowly rolls the rear wheels over the step or curb. An assistant can help by slowing the movement (Fig. 30-10A). Once the rear wheels are lowered, he or she can spin to the left or right, maintaining his or her casters up and turns then bringing the casters to lower surface. An alternative method for going down a curb is to approach the curb facing it, move into the wheelie position, and roll slowly down the curb using the back wheels. The person must have an excellent sense of the balance point of the wheelchair to perform this technique safely. As with all other actions, if a wheelchair user cannot move up or down a curb or step or roll through grass or over uneven surfaces, another person can provide assistance (Fig. 30-10B).

Figure 30-10 A. Descending a curb in the rearward direction with an assistant. B. Descending a curb in the forward direction with an assistant. (Courtesy of Beneficial Designs.)

Stairs

A skilled manual wheelchair user may be able to descend a couple of steps, especially if they have deep platforms, safely by performing a wheelie bouncing down the steps (Fig. 30-11). Some people perform a wheelchair-to-floor transfer and “bump” up or down the steps while pulling the chair along. Skin protection during this task must be understood and practiced (Fig. 30-12).

Figure 30-11 People with exceptional skills can “bump” down a few steps. Deep steps make this maneuver easier. (Courtesy of Beneficial Designs.)

Figure 30-12 Bumping up steps one at a time. (Courtesy of Beneficial Designs.)

Power Wheelchair Navigation

Power wheelchair navigation has many of the same considerations as manual wheelchair mobility. Power wheelchair training should begin in an open, barrier-free environment so that the user can make mistakes without hitting obstacles. As with other OT interventions, arranging the environment and the equipment so the person can be successful is important. This may mean setting the speed of the power wheelchair at a slow setting or giving single-step directions rather than complex directions. Grading the task/activity can then help build the user’s skills and confidence in his or her skills and may lead to success in more complex navigation.

Training often begins with orientation to the mobility device and the controller. The wheelchair user may practice moving the joystick or other controller without moving the wheelchair. It may even be possible to use similar joysticks or switches to activate other devices such as computer games to learn how the controller works. The wheelchair user should also learn how to turn the power wheelchair on and off and to switch between their own various settings. Moving the wheelchair should ideally begin on smooth

surfaces with wide open spaces and then move to more constricted environments so the user can master steering and speed. Moving to environments with distractions or small obstacles might be the next step. Giving the wheelchair user the opportunity to explore the dimensions of his or her own wheelchair and how it moves in the environment allows the user to know how much space he or she occupies and how responsive the equipment is and how reliable his or her own skills are. This will help with navigation around/over/behind obstacles. All of these skills can be performed with the occupational therapist providing support, or spotting, in case the wheelchair user needs assistance.

As the person's abilities improve, he or she can attempt more difficult navigation. Practicing these skills with a spotter or assistant is a good idea. More challenging navigation includes riding over soft surfaces, crossing gaps like on a train or subway platform, and riding over larger obstacles like small curbs. Whenever possible, obstacles like gaps and small curbs should be approached head-on, with the wheelchair perpendicular to the gap or curbs. This helps to prevent a caster or drive wheel from sliding into the space or tipping on a curb.

It is also important for the wheelchair user to be able to instruct others in the procedures for wheelchair skills, especially those that are more challenging. This is especially necessary when the wheelchair breaks down in some way. Most power wheelchairs stop working at some point or another, such as when the battery drains. Power wheelchairs can be moved from their "power mode" to a "manual mode" so the wheelchairs can be pushed manually. This involves disengaging the motors. Each power wheelchair works differently, so it is important to refer to the owner's manual for instruction on engaging and disengaging motors of specific makes and models of power wheelchair.

As of yet, drivers' tests are not required for power mobility use as they are elsewhere in the world. Some therapists working in rehabilitation or specializing in wheelchair use have developed their own checklists for power wheelchair use that act as a driver's test.

Documentation for wheelchair use should include the following information:

- Wheelchair used.
- Method of propulsion.
- Speed and accuracy of navigation in each environment, such as indoors over smooth surfaces, indoors in congested environments, and outdoors over rough terrain.
- Training of assistants should also be documented as should the wheelchair rider's ability to direct his or her care during navigation.
- Safety in performance of each skill. Safety, or safe navigation, is the most important aspect to document.

Emergency Evacuation

Areas of refuge (or rescue) should be located on every floor of every building (other than street level).¹⁰ Local emergency responders are provided with these locations by the building's owner/manager so that the first responders can rescue anyone who is unable to leave the building. Emergency responders should know to check these areas to help people who are unable to evacuate on their own.

Manual and power wheelchair users, as well as people who use ambulation aids or have difficulty negotiating stairs and long distances, should be trained in safe evacuation locations and techniques so that they may instruct assistants when needed. If there are only a few steps and if there are strong and able helpers, the wheelchair user can be bumped down the steps. This can be very tiring and requires two people to lower the wheelchair. If the assistants are unable to manage those techniques, the wheelchair user

can be carried out. Emergency evacuation chairs or mats can be used, so the wheelchair user does not have to be carried bodily (Fig. 30-13A and B).

Figure 30-13 A. Evacuation chair. B. Evacuation mat.

Documentation of Wheelchair Mobility Skills

As with other OT documentation, the goals include the method of performance, the amount of assistance or other qualifiers such as the amount of time needed for a task or the environment where the task performance occurs, and the timeline. Many mobility skills are incorporated into other goals such as for ADLs, instrumental ADLs, work, and leisure. Kirby's wheelchair training program and test can also provide a framework for documentation.⁴

CASE STUDY

Patient Information

Louisa is a 32-year-old woman, s/p C5-6 spinal cord injury (SCI) × 8 years. She owns and lives in a three-story home. The first floor is accessible via a ramp to her back deck and has been adapted with a bedroom equipped with a hospital bed and environmental control unit. The bathroom has been renovated for wheelchair maneuverability and with a roll-in shower. Louisa works full time. She drives an accessible van adapted with hand controls and low-effort acceleration and braking. She has an assist dog that performs difficult tasks for her, such as retrieving objects from the floor, opening and closing doors, and acting as a buffer with other people, thereby increasing Louisa's socialization. She is seen by her psychiatrist on an annual basis and during, her last visit, complained about shoulder pain and fatigue, especially when propelling her manual wheelchair and at the end of her workday. Louisa reported that when she was at her best, she needed occasional minimal assistance for level, sliding board transfers. She reports being concerned about transfers with the powered wheelchair because the seat height is about 3 inch (7.62 cm) higher than her current, manual wheelchair. She is also concerned that her personal care assistants need to be retrained in transfer assistance using the powered wheelchair.

Reason for Occupational Therapy Referral

Louisa was seen in the outpatient seating clinic for evaluation for powered mobility. The assistive technology professional in the seating clinic arranged for the psychiatrist to prescribe outpatient OT for transfer training in preparation for transferring to and from her new, powered wheelchair.

Assessment Process and Results

The occupational therapist performed an assessment of sitting balance, upper extremity strength, and transfers. The occupational therapist determined that Louisa's upper extremity strength has decreased over the past 2 years, as she has full access to previous medical records. The transfer assessment includes performing level transfers to and from her current manual wheelchair. Louisa performed level, sliding board transfers with moderate assistance following setup with a sliding board. She required maximal assistance to transfer without the sliding board. The assessment also included performance of transfers to and from higher and lower surfaces, using an adjustable height mat table. Louisa required verbal directions and maximal assistance to perform these transfers. A brief, nonstandardized cognitive assessment revealed Louisa to have high function in both specific cognitive skills and executive functioning.

Occupational Therapy Problem List

- Decreased upper extremity strength and endurance
- Decreased independence wheelchair transfers

Occupational Therapy Goal List

- Increase strength and endurance for moderate assistance for sliding board transfers to and from higher and lower surfaces sufficiently by 2 weeks.
- Able to instruct care takers in safe techniques during transfers from wheelchair to higher and lower surfaces, including her bed and shower commode chair by 2 weeks.

Intervention

Louisa received outpatient OT twice weekly for 2 weeks. Louisa's assets included being highly motivated and having intact cognition with good problem-solving and judgment. The occupational therapist provided Louisa with recommendations for a strengthening program that Louisa plans to continue to use. During her time in OT, she contacted a personal trainer with whom she works and who has experience working with people with SCI. The trainer will use the exercises and techniques established by the occupational therapist.

During therapy, the occupational therapist introduced the Beasy Board because this transfer board might make Louisa's transfers easier. Louisa and her occupational therapist agreed that the Beasy Board did not make any of the transfers easier, so they decided to stay with the sliding board that she already owns. They also completed transfer training and practice with the current personal care assistants. Louisa realized that none of her current personal care assistants were with her early-on and none had been trained by a therapist. All of the therapy interventions were acceptable to and endorsed by Louisa with the exception of the move to the Beasy Board. Louisa was discharged after four sessions with instructions to contact the occupational therapist and the physiatrist if she needs additional intervention when she receives the power wheelchair, which is expected in 4 to 6 weeks.

Evidence Table of Intervention Studies for Manual Wheelchair Propulsion

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Wheelchair skills training program ¹¹	Training in indoor and outdoor skills	Thirty-five wheelchair users (15 = treatment group; 20 = control group)	Six sessions, 30 minutes each	Two group controlled study; Level II	Wheelchair skills training program is effective.	Control group scores on wheelchair skills test improved by 8% ($p = 0.01$). Treatment group scores on wheelchair skills test improved by 25% ($p = 0.000$).
Wheelchair skills training ¹²	Individualized wheelchair skills training	Hundred and six community-dwelling, manual wheelchair users, Veterans (53 = treatment group; 53 educational control group) began. Eighty-two completed (40 = treatment group; 42 = control group)	Five 1:1 training sessions over 5-week time period	Two group controlled study; Level II	Wheelchair skills improved in testing group. Retention of skills was evident for up to 3 months.	Significant improvement noted in advanced skills for treatment group ($p < 0.0001$) and for the overall wheelchair skills test ($p < 0.0001$).
Wheelchair skills training to impact wheelchair use self-efficacy, skills capacity and performance, and life space mobility ¹³	Peer-led training using WheelSee to pairs of manual wheelchair users	Twenty-eight community-based manual wheelchair users (16 = treatment group; 12 = control group)		Pilot, two group controlled study; Level II	Wheelchair use self-efficacy and wheelchair skill capacity/performance improved in treatment group more than in control group.	Improvement in wheelchair use self-efficacy significant higher in treatment group over control group (Cohen $d = 1.4$). Wheelchair skills capacity and performance were significantly higher in treatment group over control group (Cohen $d = 1.3$, $d = 1.0$, respectively).

Chapter 31

Restoring Driving and Community Mobility

Sherrilene Classen and Beth Pfeiffer

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Conceptualize a definition of driving as an instrumental activity of daily living.
2. Understand the implications of motor vehicle crash statistics and trends over a decade in the United States.
3. Articulate the roles of the occupational therapist generalist and specialist in driver rehabilitation, specifically related to screening, assessment, and intervention.
4. Integrate and synthesize the knowledge on assessment and intervention via a case study example.
5. Understand the impact of community mobility on participation in essential and meaningful activities.
6. Identify the role of occupational therapist in addressing community mobility issues.
7. Understand assessment and intervention processes to improve the person–environment fit for community mobility.

CHAPTER OUTLINE

Driving as an Instrumental Activity of Daily Living
Overview of Crashes in the United States
Driver Rehabilitation
Interventions to Support Driving
Community Mobility
Case Study: Julio
Assessment of Community Mobility
Interventions to Support Community Mobility
Case Study: Tristen

TERMINOLOGY

- Community mobility:** moving around in the community and using public or private transportation, such as driving, walking, bicycling, or accessing and riding in buses, taxi cabs, or other transportation systems.¹
- Community participation:** active involvement in activities that are intrinsically social and either occur outside the home or are part of a nondomestic role.²
- Comprehensive driving evaluation:** a complete evaluation of an individual's driving knowledge, skills, and abilities by a health care professional that includes (1) medical and driving history; (2) clinical assessment of sensory/perceptual, cognitive, or psychomotor functional abilities; (3) on-road assessment, as appropriate; (4) an outcome summary; and (5) recommendations for an inclusive mobility plan including transportation options.³
- Driver rehabilitation specialist (DRS):** professional who provides clinical driving and driving mobility equipment evaluations and intervention to develop or restore driving skills and abilities¹; may or may not have a health professional background; with a health professional background, a DRS can provide the comprehensive driving evaluation.
- Driver rehabilitation specialist, certified:** a DRS certified by the Association for Driver Rehabilitation Specialists (ADED) to hold a specialty certification in driver rehabilitation.
- Fitness to drive:** a characteristic of a driver, defined by the absence of any functional (sensory/perceptual, cognitive, or psychomotor) deficit or medical condition that significantly impairs an individual's ability to fully control the vehicle while conforming to the rules of the road and obeying traffic laws and/or that significantly increases crash risk.⁴
- Occupational therapist generalists:** professional who provides clinical driving evaluations or applies specific assessment tools in order to assess fitness to drive as an instrumental activity

of daily living and intervention to develop or restore driving abilities.⁵

Paratransit: a supplemental form of transportation required by the American with Disability Act (ADA) provided by public transit agencies for individuals with disabilities who cannot use fixed-route transit services because of a disability.⁶

Personal mobility devices: devices used for community mobility when a person cannot walk or has limited walking ability such as a manual or electric wheelchair.

Driving as an Instrumental Activity of Daily Living

Driving is an instrumental activity of daily living (IADL) that requires intact visual, visual attention, visual perceptual, cognitive, executive, other sensory, and motor functions; all executed in a coordinated manner within a complex, dynamic, and unpredictable environment, while achieving control over the vehicle to steer it cautiously and safely in the flow of traffic and while observing the rules of the road and traffic regulations. This task, therefore, represents an integration of the person, the vehicle, and the environment domains and, as such, is embedded in the scope of occupational therapy practice. Driving is considered a privilege, not a right, and is one of the few IADLs that can lead to death or serious injury. But the benefits of being able to drive are multiple. Mainly, driving is an occupation enabler and a mediator of autonomy, freedom, and independence. For older drivers, studies associate mobility afforded by driving with increased life satisfaction, quality of life (QoL), autonomy, and well-being.⁷⁻⁹ In contrast, driving cessation is associated with poor health trajectories, including increased rates of depression, limited life-space mobility, early nursing home admissions, and premature death.¹⁰⁻¹⁴

Our society is standing on the brink of a transportation revolution with the advent of the autonomous vehicles into our society. Although the highly autonomous vehicles may not be available for societal use for another decade or more,¹⁵ we can anticipate that the task of driving, as well as the role of the driver, will change accordingly. Specifically, in the future, the task of driving will be executed by the autonomous vehicle, and the driver will, therefore, have to surrender personal control, show confidence in technology, and trust in the autonomous system. The role of the driver may change from a driver in a standard vehicle, to an operator in a semi-autonomous vehicle, or a passenger in a highly autonomous vehicle. Moreover, drivers and occupational therapists who may assess such drivers will have to be savvy and understand the lingo related to the evolving vehicle technology. Until such time, however, occupational therapists need to understand that driving has inherent risks and that they can make a difference in detecting at-risk drivers. To contextualize the scope of such risk, we will provide an overview of the crash statistics in the United States.

Overview of Crashes in the United States

According to the National Highway Traffic Safety Association (NHTSA), 35,092 road fatalities occurred in the United States in 2015, which is a 7.2% increase over 2014.¹⁶ This is the largest percentage increase recorded in nearly 50 years with a fatality rate of 10.9 per 100,000 inhabitants. Provisional data from the first 9 months of 2016 indicate an additional 8% increase in traffic fatalities over the same period in 2015. Notwithstanding the loss of life, the number of injury crashes, and those who were seriously injured, also increased substantially. The NHTSA estimated that the cost associated with these road fatalities and injuries accounted for 242 billion dollars in 2010. When societal harm is factored in, then the cost increases to 836 billion dollars, which is about 6% of the gross domestic product in the United States.¹⁶ The most vulnerable road users are the teens and the older drivers, as can be seen from Figure 31-1. Since 2010, teens (18–20 years of age) had the highest fatality rates per 100,000 population, followed by older persons (65 years and older).

Figure 31-1 Road fatality rates by age group. Deaths per 100,000 inhabitants in a given age group, 1990 to 2015.74

Occupational therapists are positioned to help turn these statistics around through early detection and intervention. Specifically, human error accounts for 94% of crash-related fatalities or injuries.¹⁶ Human errors, which may include speeding, yielding, gap acceptance, lane maintenance, visual scanning, signaling, and adjustment to stimuli errors, occur, for example, in drowsy drivers, drunk drivers, older driver, and distracted drivers. Because occupational therapists work with people representative of these groups, practice opportunities exist for general client education, and/or screening, assessment, and intervention.

Driver Rehabilitation

Driver rehabilitation entails a process of intervention intended to ameliorate impairments or deficits related to the driving task or alternative methods of mobility.⁴ The outcome of driver rehabilitation is successful implementation of an intervention or course of action that facilitates safe mobility and transportation. Driver rehabilitation usually starts with screening, assessment, intervention, and discharge.

Screening

Screening is the process preceding an assessment and entails obtaining and reviewing data, personal, social, and medical history, to determine the need for assessment and can be done by the person themselves, a proxy rater, or an evaluator.⁴

Self-Screening

For self-screening, an individual obtains and reviews his or her own data to determine the need for further assessment.¹⁷⁻¹⁹ A limited number of valid and reliable screening tools for identifying at-risk older drivers exists.²⁰ For example, Roadwise Review, a self-screening, lacks predictive validity to detect at-risk drivers.²¹ The DriveSafe and DriveAware self-screening accurately predicts the on-road performance of older drivers,²² but as standardized in a country where driving occurs on the left side of the road. A drawback of self-screening tools is an overestimation of the client's driving abilities.²³

Proxy Screening

For proxy screening, an individual may obtain and review data to determine the need for assessment of another person.^{19,24} The Fitness-to-Drive Screening Measure (FTDS),²⁴⁻³⁰ a free, web-based screening tool with established reliability and concurrent criterion validity, identifies at-risk older drivers using a proxy rater that includes family members, close friends, or caregivers who have been passengers in the past 3 months and who are able to rate the driver's skills. The FTDS measure takes approximately 20 minutes to complete and generates one of three driver-risk classifications, indicating that *critical safety concerns* exist that must be addressed immediately; or *some safety concerns* exist with early signs of needing intervention; or *no safety concerns* are present and the driver can continue driving. Based on the specific driver-risk classification, the FTDS provides risk mitigation resources, including a listing of all **driver rehabilitation specialist (DRS)**, as well as recommendations indicating the next logical step to pursue. For more information on the FTDS, see <http://fitnesstodrive.phhp.ufl.edu/us/>.

Evaluator Screening

Evaluator screening is the process through which a professional, skilled in using a specific screening tool, obtains and reviews data to determine the need for assessment for a specific individual. For example, an occupational therapist may decide to use the Mini-Mental State Examination (MMSE) to screen for general cognitive functioning or the Optec 2500, a visual analyzer machine used for

visual screening, to detect aspects of visual functioning, such as contrast sensitive or peripheral vision.³¹ The driving literature supports the notion that an individual who scores lower than 24 on the MMSE should not be considered for an on-road assessment and that individuals who show impairment in visual fields or contrasts should be referred to an eye doctor prior to conducting a **comprehensive driving evaluation**.³¹ These tasks are well within the scope of the occupational therapy generalist, who may, when using these methods, help with detection of potential client factors that may impair **fitness to drive**.

Driving Assessment

Assessments may include clinical assessments, simulated driving assessments, or on-road assessments.

Clinical Assessment

Occupational therapist generalists or (certified) DRSs use clinical assessments to quantify and better understand client factors pertaining to visual (e.g., visual acuity or contrast sensitivity), cognitive (e.g., executive functions or working memory), motor (e.g., range of motion or upper extremity coordination), and other sensory (e.g., proprioception or stereognosis) functions. All of these functions, to a greater or lesser extent, are important for the task of driving. Although it is beyond the scope of this chapter to provide a comprehensive discussion on evidence-based clinical assessments that may be correlated to, or predictive of, driving performance in medically at-risk populations through the life span, the reader is referred to the text on Driving and Community Mobility that contains an excellent chapter on this topic.³¹

Driving Simulator Assessment

The driving simulator, a clinical tool, with excellent face, content and construct validity, as well as reliability for real-world driving performance, is increasingly used in occupational therapy practices.³² This technology uses a computer-controlled environment that presents selected aspects of the driving experience considered representational of real-world driving.⁴ Clients may “drive” a scenario in which their accelerator, brake, and/or steering responses are being assessed. Usually, the data obtained from the assessment allow for objective measurements of the users’ responses to designated driving tasks.³³ This method is particularly appropriate for clients who want to return to driving, but who may still pose considerable risk on the road, and who are, therefore, not ready for on-road assessments. Caution needs to be executed in making generalizations to real-world driving, as simulated driving is a representation of reality and not reality itself.

On-Road Assessment

The on-road driving assessment, sometimes referred to as the behind-the-wheel assessment, is conducted in real-world circumstances (i.e., driving a real vehicle, on the road, while encountering traffic in a dynamic and complex environment). The on-road assessment may incorporate a fixed-route or a variable-route design. The first is usually standardized, and elements of this course, such as the number of straights, and left and right turns, or the setting (residential area, city and highway driving), are controlled for, while the latter allows for options to assess a client’s specific needs, such as an older driver who only wants to drive in daylight and in the absence of peak traffic hours to a selected setting in the community. This assessment, conducted by a **certified DRS**, is the criterion standard for evaluating a driver’s fitness-to-drive abilities.³⁴⁻³⁶ The assessment can be performed in closed road or open on-road conditions. The first may entail no-traffic such as a closed road circuit, or limited traffic such as experienced in a deserted parking lot. These venues allow the driver to become comfortable with the assessment vehicle and the vehicles controls and to perform basic maneuvers in preparation for on-road driving. Each condition has its own innate characteristics pertaining to setting, traffic density, maneuvers (e.g., left turn, stop, yield, straight driving), or other road users that provide challenges for achieving a reliable and valid approach to determine a client’s fitness to drive. Inability to control for these and other environmental conditions (i.e., time of the day, weather, roadway conditions, or other drivers’ behaviors) may increase error during the evaluation.³⁷ As such, the final outcome of the on-road assessment (e.g., a pass/fail determination) may be prone to subjectivity. Table 31-1 illustrates selected on-road assessments and the percentage agreement between the driving maneuvers/behaviors and the driving environment. In a study by Odenheimer et al.,³⁵ the percentage representation of each on-road assessment against the components (driving maneuvers/behaviors and the driving environment) varies from 58% with minor representation of the environment to a 100% representation of the driving environment.³⁶

Table 31-1. Selected Fixed Based Road Courses Matching Driving Maneuvers and Behaviors with Environmental Components³⁶

	DEMOGRAPHICS	PARKING LOT	RESIDENTIAL AREA	SUB-URBAN AREA		CITY	
Driving maneuvers/behaviors	Course length and/or distance in time	Familiarize with test vehicle; basic maneuvers; angle/perpendicular parking; backing up	Low traffic/speed <35 km/hr (22 mph); R/L turn; adjust to stimuli; straight drive; school zones	Med. traffic with speed <70 km/hr (44 mph); changes, straight drive, traffic signals, pedestrian traffic	Four-lane road with med.-high traffic and speed >70 km/hr (44 mph)	Specific inter. include: yield, right of way, stop sign, four-way stop, two-way stop, traffic light protected/unprotected; traffic circle	Bus; shop; cent pede; groc carts; obst

Naturalistic Driving Assessment

To overcome the deficits associated with the on-road assessment, naturalistic driving studies have emerged.^{40–42} These studies are using a methodology to monitor or evaluate driving behavior via instruments or sensors installed in a driver’s own vehicle. Such instruments provide an objective driver identification (ID), as well as driving data for each trip, and operate in a passive manner, requiring no interaction from the driver. Of course, collaboration with skilled team members is necessary to instrument the vehicle, activate the sensors, extract the data, and interpret the data. The main benefit of this method pertains to the objectivity inherent to the assessment process.

Comprehensive Driving Evaluation

This method entails a thorough assessment of an individual’s personal, medical and driving history, driving knowledge, driving skills, and driving abilities by a DRS who may or may not be certified. The comprehensive driving evaluation generally includes clinical assessments of sensory/perceptual, cognitive, or psychomotor functional abilities; an on-road assessment; an outcome summary; and recommendations for an inclusive **community mobility** plan.^{3,31} The outcome of the comprehensive driving evaluation results in a determination of whether the person is fit to continue to drive, requires rehabilitation prior to continued driving, or needs to consider driving cessation and alternative sources of community mobility. This information is usually related to the driver, who is accompanied by a caregiver, within the context of the multidisciplinary team. Clinicians need to be familiar with their state policies, as some states (e.g., California or Oregon) require mandatory reporting to the Department of Motor Vehicles, whereas others (e.g., Florida or Michigan) require voluntary reporting.

Interventions to Support Driving

Although evidence exists to support visual, cognitive, motor, and other sensory assessments in driver rehabilitation,³¹ less is known about the efficacy and effectiveness of driving interventions across medically at-risk populations.^{43,44} As such, occupational therapists are encouraged to design interventions based on best practices and sound clinical reasoning.³ As is the case for other rehabilitation interventions, occupational therapists who are interested in driver rehabilitation make use of interventions pertaining to remediation, compensation, and adaptation.

- **Remediation of driving skills:** Drivers who show a lack of the necessary driving skills or a deterioration of driving skills may be referred to a DRS for behind-the-wheel training. In this case, the DRS may want to work on tactical skills (i.e., those maneuvers necessary for stopping, going, turning, yielding, overtaking, backing up, parking, or other general vehicle control maneuvers).
- **Compensation:** Imagine an older driver with depth perception challenges who stops too close to the lead vehicle at a traffic light. In this case, the occupational therapist may suggest improving the stopping maneuver, via teaching the client a compensatory method of “tire stopping.” This means that the client needs to stop at a distance from the lead vehicle so that he or she can see the back tires of that vehicle. Such a compensatory method ensures safe vehicle positioning, while also overcoming the depth perception challenge.
- **Adaptation:** Much has been written on vehicle adaptations, and the reader is referred to the text on Driving and Community Mobility for an expansive overview of adaptive equipment used in the vehicle.⁴⁵ Such adaptations enable drivers to continue to manipulate the primary (i.e., steering, accelerator, and brake) and secondary (e.g., wind shield wipers, emergency brake, headlights) controls. Such adaptations are particularly helpful for clients with medical conditions impairing their function necessary to operate the vehicle and its controls. For example, orthopedic conditions, such as upper limb deficiencies and amputations; neurological conditions, such as hemiparesis, hemiplegia, or Parkinson disease; or spinal cord injuries, such as paraplegia, pose severe functional limitations on the client’s abilities to safely operate a motor vehicle. Table 31-2 illustrates examples of diagnostic groups, the potential limitations in function, and the adaptive equipment necessary to overcome the functional deficit. Note that most all vehicle adaptations need to be implemented with great caution, requiring the clinical reasoning skills of a DRS and the technical installation skills of a vehicle modifier who meets the industry safety standards. Because this area of practice requires specialty knowledge, we are only introducing the occupational therapist to the concepts of vehicle adaptation and encourage referral of the client to a DRS for all vehicle modifications.

Table 31-2. Examples of Adaptive Equipment for the Vehicle Based on the Client’s Diagnosis, Limitation in Function, and Function of the Adaptive Equipment to Overcome the Limitation

DIAGNOSIS	LIMITATION IN FUNCTION	ADAPTIVE EQUIPMENT	FUNCTION OF THE ADAPTIVE EQUIPMENT
Left upper limb deficiencies	Inability to use bilateral hands for turning maneuver	Spinner knob	Enables adequate steering wheel maneuvering with right hand
Right lower extremity amputation	Inability to manipulate gas and brake with the right lower extremity	Left foot accelerator and brake pedal	Enables client to manipulate accelerator and brake with the left lower extremity
Hemiparesis or paraplegia	Inability to use right lower extremity for accelerator and gas control	Push left-angled hand control or a push-rock hand control	Accelerator is controlled by pulling backward and brake is controlled by pushing forward on the hand control.
Parkinson	Rigidity in the neck and trunk with difficulty in turning to perform a backing up maneuver	Wide angled mirrors or back-up camera to	Provides a rear view scene without the need to turn the trunk
Quadriplegia	Inability to be securely positioned due to limited trunk control	Torso strap for injuries at or above T-12	Torso strap secures the position of the client during driving and especially during turning maneuvers.

Community Mobility

Community mobility is defined as “moving around in the community and using public or private transportation, such as driving, walking, bicycling, or accessing and riding in buses, taxi cabs, or other transportation systems.”⁷¹ Access and availability of transportation is a critical facilitator for **community participation** and inclusion.⁵⁴⁻⁵⁶ The National Council on Disabilities reported in 2015 that the lack of “accessible transportation represents one of the chief barriers to participating in

economic and community life.”⁵⁷ Research examining community participation defines this construct as “active involvement in activities that are intrinsically social and either occur outside of the home or are part of a nondomestic role.”⁵² Community participation can include integrated employment, health services, social events, education, and religious activities.⁵⁸ Recent research identified that perceived transportation and community mobility were predictors of participation restrictions in individuals with physical disabilities.⁵⁶ Older adults associated a sense of freedom and independence to participate in essential and desired activities with driving and community mobility.⁵⁹ As community participation is related to overall QoL,^{60,61} self-determination,^{60,61} and independence,⁶² it is essential to identify needed supports and minimize barriers such as transportation to community participation. Transportation is integral to getting to many activities that are considered essential in the everyday lives of people, such as work, school, errands, medical appointments, and socialization with friends and family.

Types of transportation options for community mobility include personal, public, commercial, and supplemental transportation. Personal transportation involves moving around in the community using one’s body and vehicle.⁶³ This includes traveling in a private automobile (i.e., being driven or driving), using other motorized or nonmotorized mobility devices (e.g., wheelchairs, scooters, biking), and walking. Driving oneself is often a preferred mode of transportation for many, although it may not be a viable option, because of newly acquired or progressing physical and/or sensory disabilities. Whereas driving is considered a privilege, community mobility using other forms of transportation is often considered a right. **Personal mobility devices** are used for community mobility when a person cannot walk or has limited walking ability. Public transportation options are available to everyone and involve moving more than one person at a time.⁶³ This includes both fixed-route transportation such as buses, trains, subways, and ferries, and **paratransit** services for individuals who have impairments that limit access to the fixed-route services. Supplemental transportation is an option for certain individuals, although availability can vary based on type of disability, age, and location. This type of transportation is often offered through volunteers from nonprofit or community-based services for individuals who are unable to use existing transportation services or need flexible travel options.⁶⁴ Finally, commercial transportation services are provided as for-profit entities most often paid by the individual. These can include taxis, transportation network companies (e.g., Uber/Lyft), shuttle/van services, and commercial carriers of airlines and trains. For shorter distances, commercial transportation options are now more affordable with the inception of transportation network companies and can provide greater flexibility than public transportation options. Although, for some of these options, there are accessibility issues for certain consumers when the transportation companies do not meet American with Disability Act (ADA) standards.

CASE STUDY: JULIO

To best illustrate the interplay of deficits in client factors, the assessment process, as well as the interventions necessary to address driving or community mobility, we introduce the reader to Julio via the following case study.^{46,47}

Patient Information

Julio is a 15-year-old male, in the ninth grade, and living in the community with his parents and four siblings. He has never had a learner’s permit or a driver’s license. His parents are curious to know if he is ready to start driving. Currently, he is walking to school with his siblings, and although independent in way finding, he needs safety cues for scanning traffic before crossing the streets. Julio has a diagnosis of autism spectrum disorder (ASD) and shows characteristics consistent with attention-deficit hyperactivity disorder (ADHD). He has received occupational and speech therapies for the past 6 years and is taking medications to manage the symptoms of his medical conditions. His parents reported no medication side or adverse effects.

Clinical Assessments

Julio completed clinical assessments, summarized in Table 31-3, to assess his visual, cognitive, and motor functions. The results indicated that he had intact visual acuity, peripheral vision, depth perception, color discrimination, and phorias. He had intact central vision processing speed, divided visual attention, and selective visual attention skills. His overall ability to integrate visual information with a specific motor response was mildly impaired. Julio had poor skills for simple sequencing, was mildly impaired with complex sequencing and had limitations in attention shifting and planning, and showed difficulty with gross motor coordination and strength.

Table 31-3. Julio’s Clinical Tests, Description, and Scoring

CLINICAL ASSESSMENTS	DESCRIPTION AND SCORING	JULIO'S RESULTS
*/**Vision: Optec 2500 Visual analyzer (Stereo Optical, Inc.)⁴⁸		
Six tests on vision	Acuity, peripheral vision, phorias, depth perception, and color discrimination	Intact for all tests
*/**Visual Attention and Processing Speed⁴⁹		
UFOV risk index	Categories 1–5; 5 = very high risk for motor vehicle crashes	Intact: very low risk: category 1
Visual Motor Integration⁵⁰		
Beery visual motor integration test ⁵⁰	30 possible points (30 = adequate age-based visual motor functioning)	Impaired at the 32nd percentile: 26/30 correct
Cognitive Assessments		
**Comprehensive trail making test ⁵¹	Five trails tests measuring simple to complex sequencing	Overall impaired at the second percentile level
Symbol digit modalities test ⁵²	Measures motor, visual, speech, and executive functions and attention skills with the highest possible score of 110	Impaired: completed 39/110 symbols; 37/39 symbols were recorded with correct numbers
Motor Assessments		
Bruininks-Oseretsky test of motor proficiency (BOT-2): brief form ⁵³	Eight subtests of fine motor precision, motor integration, manual dexterity, bilateral coordination, balance, running speed and agility, upper limb coordination, and strength, with a total possible score of 88 points	Intact: percentile rank 38th Average score: 76 points
*Driving Simulator Assessment		
**Simulator Operational Skills ^a	Measured return demonstration of understanding and using vehicle controls on a VAS (0–10, where 10 = perfect demonstration)	Impaired: mild coordination deficits total VAS = 7.35/10
Driving Errors³⁴		Number of Driving Errors
Lane maintenance errors: including wide turns or encroachments	The lateral lane position of the vehicle	30
Visual scanning errors	Visual scanning monitored at intersections and during lane changes	6
Lane position errors	The anterior and posterior position of the vehicle in relationship to the stop line	0
Speed error: over or under	Intact speed measured within 5 mph of the posted speed limit, or appropriate speed regulation required by maneuver (e.g., turn)	11 over speeding 0 under speeding
Signaling	Correct use of turn signal: timing, direction of signal, and appropriate use for the maneuver	0
Attention to stimuli	Correct response to changes in traffic light, posted signs, and traffic	2
Gap acceptance: overcautious or unsafe	Appropriate gap acceptance during the five unprotected left turns	2 over cautious 0 narrow
Divided attention (DA) responses	Five tasks of DA measured by the client honking when a diamond on the simulated scenario changed to a triangle	1
Speed of response to DA	Speed (norm < 11 seconds) at which the subject honks after the stimuli is presented	1.60 seconds
Number of collisions	Collisions involve either driving off road or hitting a vehicle or a pedestrian.	0
Number of errors at intersections	All errors across the 11 intersections	Impaired at the 50th percentile. Errors: 52

*No adolescent norms available;

**percentile data based on the total driving errors of 18 neurotypical peers in the parent driving study.⁴⁶

Driving Simulator

Julio became confident and comfortable with the driving simulator via return demonstration of understanding and using the vehicle controls. Then, he drove a basic scenario with minimal traffic in an interactive driving simulator with a 180° field of view that afforded an immersive experience, as displayed in Figure 31-2. The DRS sat in the passenger seat and recorded his driving errors throughout the drive. Julio drifted beyond the limits of his lane multiple times on straight roads and showed mild impairments with motor coordination when turning the steering wheel. Although *lane maintenance* errors are common among novice drivers, the frequency of

Julio's errors and lack of his awareness to correct for such errors suggested significant impairments related to visual motor integration and attention shift, which are critical abilities for the task of driving. Julio did not perform *visual scanning* for traffic at cross streets or during lane changes. He approached all intersections with excessive *speed*, causing him to make wide turns to the right and encroaching into oncoming traffic on the left. He was unable to learn from his errors. Julio drove through two red lights and reported that he did not think it was necessary to stop, reflecting his poor understanding of traffic flow as a cause for collisions, and showing *adjustment to stimuli errors*. He made two *gap acceptance errors* related to being overcautious, potentially owing to being a novice driver. Although he had severe difficulty with recognizing the *divided attention* symbols, his speed of response on the one divided attention task was good.

Figure 31-2 The University of Florida's STISIM M 500W interactive driving simulator with life-size images projected on the screen and simulator controls integrated with a 1997 Dodge Neon.

Occupational Therapy Recommendations

Based on the results of the clinical assessments and Julio's simulated driving performance, the Certified Driver Rehabilitation Specialist (CDRS) had to make a decision regarding Julio's readiness to drive. Relevant questions that the CDRS asked to decide if Julio was a candidate for driver training are:

- Was it appropriate to begin driver training?
- If driver training was appropriate, were there skill deficits that require occupational therapy intervention for remediation of underlying skills prior to driver's education?
- If no occupational therapy was required, would traditional driver's education be recommended?
- If driver training (with or without occupational therapy) was not recommended, is driving a possibility in the future?
- If driving was an appropriate future goal, what predriving skills needed to be further developed before learning how to drive?
- If driving was not a likely goal, what community mobility goals should be recommended?

Summary of the Short-Term Goals and Intervention

Based on Julio's personal and medical history, as well as the findings of the clinical assessments and simulated driving performance, the CDRS recommended that Julio was not ready to start driving. The short-term goal is to refer Julio to an occupational therapist to address a community mobility plan and the use of alternative transportation options.

In the next section, the reader will learn more about community mobility as a facilitator for participation.

The physical environment often serves as a facilitator or barrier for community mobility.^{56,65} The ADA, established in 1990, included guidelines for public and private transportation for individuals with disabilities.⁶ According to the ADA, public transportation systems are required to provide information on services in accessible formats for individuals with disabilities, as well as needed equipment and facilities (i.e., lifts, ramps, securement devices, signage, communication devices)

that are in good operating condition.^{57,66} Additionally, public transportation systems must (1) provide adequate time to board and exit a vehicle, (2) allow service animals, (3) provide designated seating and signs on fixed-route systems, and (4) ensure training for operators to provide safe operation of vehicles and equipment, as well as assistance for individuals with disabilities. Specific architectural requirements exist (e.g., lifts and ramps; stop announcements; illumination of stepwells and doorways; slip-resistant surfaces for door and steps) for fixed-route transportation systems to improve accessibility.⁶⁶ Architectural requirements are also required for transit facilities (e.g., accessible paths of travel, boarding ramps, bus shelters). Transit agencies must provide paratransit services, an origin to destination service, where fixed-route services exist for individuals with disabilities who qualify. Private transportation entities (e.g., airport/hotel shuttles, private buses, taxis) that provide services to the public are required by the ADA to meet accessibility requirements. If the vehicles are not accessible to an individual with a disability, the transportation entity must have an equivalent service that provides an accessible vehicle to travel to the same place at the same time and at the same cost. Taxis are not required to purchase accessible automobiles, although they cannot discriminate against individuals with disabilities by refusing service, use of assistant animals, stowing of mobility devices, or charging higher fares.

The ADA provides specific guidelines to promote environmental access to transportation. Environmental factors are some of the most significant barriers to community mobility for individuals with a variety of physical disabilities.^{56,65} A fit between the unique characteristics of the person and the environment is essential for successful community mobility. Although there are many environmental barriers to community mobility that must be considered during the occupational therapy assessment and intervention process, in 2010, the Beverly Foundation identified five A's that were common barriers for the aging population and those with disabilities.⁶⁷ These included availability, accessibility, affordability, acceptability, and adaptability (see Table 31-4). All of these are important considerations when evaluating the fit between the environment and the person.

Table 31-4. Environmental Factors Impacting Transportation Usability⁶⁷

ENVIRONMENTAL FACTOR	DESCRIPTION
Availability	Existence of transportation when needed
Accessibility	Transportation is reached and used in light of riders' abilities/disabilities.
Affordability	The costs are within the users means or reimbursable.
Acceptability	Meets standards of cleanliness, safety, courteous/helpful operators
Adaptability	Modification can be made for disabilities and special needs.

Assessment of Community Mobility

Although assessment and intervention to promote community mobility is not a new area of practice for occupational therapists working with individuals with physical disabilities, it continues to be an emerging area where roles and needs have expanded significantly in recent years. This is likely due to the increased awareness of transportation as a primary barrier to community participation and engagement.^{54,56} Occupational therapy assessments and interventions for community mobility are diverse and varied based on the types of transportation, service delivery model, and the unique needs of the individual with physical disabilities, although all have common elements (Fig. 31-3).

Figure 31-3 Assessing community mobility.

As in any occupational therapy evaluation, it is essential to obtain an occupational profile of the client to determine community mobility needs specific to the individual.⁶⁸ A person-centered approach in which the client is maximally engaged in the assessment and goal development process is essential. This includes identifying the person's important and meaningful activities and providing detailed information about their typical routines in order to understand the necessary mobility requirements and intervention for participation. Typical modes of transporting oneself or being transported by another person may change after an acquired physical disability or a change in a health-related condition making it necessary to reassess the way in which one travels in the community. This could include a change in the type of transportation mode (e.g., using paratransit instead of the taking the bus to get to a medical appointment) or the way in which the person travels in a previously used transportation mode (e.g., using hand devices to operate a car after sustaining an injury resulting in paraplegia).

Once community mobility needs are identified in the occupational profile, it is important to analyze the client and activity demands of the preferred or chosen types of travel modes. This will help determine individualize interventions based on the demands of the type(s) of travel and common environmental factors associated with specific types of travel. An example is an individual using a manual wheelchair due to a recent acquired physical injury who wants to use public transportation to visit his or her family or go shopping for essential items. After leaving home, he or she will need to be able to mobilize the wheelchair safely through the neighborhood to the bus stop and get on and off the bus. Environmental factors are an essential consideration when assessing the activity demands and can serve as either a facilitator or a barrier. For example, the presence of curb cuts on the pavements and a life with a wheelchair securement system on the bus could determine whether the use of a bus from the home is a safe and feasible option.

The evaluation process needs to consider both person factors (i.e., sensory issues, decreased balance, and motor deficits) and environmental barriers and facilitators to community mobility.^{69,70} This allows the therapist and person to develop community mobility goals that match the strengths and needs of the person to environments that promote successful community mobility. The type of transportation often determines the necessary skills needed by the person. Although this can vary significantly, person factors⁶⁸ such as cognitive (i.e., attention, perception, memory, executive functions), sensory (i.e., vision, hearing, balance), and motor functions (i.e., endurance, control of voluntary movement, gait patterns) are often necessary skills for successful community mobility outcomes. Tools available that assess specific aspects of community mobility includes the Functioning Everyday with a Wheelchair (FEW),⁷¹ a criterion-referenced tool that assesses how wheelchair features help the client complete ADLs in situations such as outdoor mobility and use of personal/public transportation. The Life-Space Assessment documents where and how often clients travel and any assistance needed.⁷² The Community Mobility Assessment evaluates physical and cognitive abilities of individuals with traumatic brain injuries to determined safe community

mobility.⁷³ Finally, the Assessment of Readiness for Mobility Transition⁷⁴ provides a method to assess the emotional and attitudinal perceptions of aging adults who acquire a health condition that requires a transition from driving to other methods of transportation for community mobility. Many of these tools assess both person and environmental factors.

Environmental factors consist of both physical and social aspects of the environment that impact on community mobility.⁵⁸ The five A's (i.e., availability, acceptability, accessibility, adaptability, and affordability, see Table 31-4) identify a set of environmental factors that impact transportation usability in the senior and general disability population. This may provide helpful guidelines to assess common environmental factors that can serve as barriers or facilitators to transportation for individuals with disabilities. Observations of the person in the community environments and using preferred transportation is an important component of the assessment and intervention process. For occupational therapy provided in inpatient settings, including community mobility screenings in the assessment process can help prepare a person for discharge and transition back into the home and community environments. Additionally, occupational therapists can complete evaluations for public and private community-based organizations to identify barriers to safe and accessible transportation in these environments.

Interventions to Support Community Mobility

Occupational therapist's role in community mobility interventions varies, based on the unique needs of his or her clients and the service delivery model.⁷⁵⁻⁷⁷ Interventions can be person-centered, such as developing specific foundation skills necessary for mobility (e.g., balance, motor planning, sensory awareness); providing travel training (e.g., pedestrian skills, training to use public transportation); providing assessment, education, and training to acquire and use mobility equipment and devices; and instruction in wheelchair skills and safe wheelchair transport. Occupational therapists may provide parent and caregiver education on how to transport family members and guardians safely. Occupational therapists can also provide organization-based interventions such as assessments for paratransit eligibility and consultation for ADA compliance with transportation providers and community-based organizations.

Community Mobility Plans (CMPs)⁷⁸ provide a conceptual framework to guide the intervention process (Fig. 31-4). The intended outcome of CMPs is to facilitate more independent transportation for community mobility necessary for participation in life activities deemed important by the individual. Person-centered interventions are integral to supporting self-directed goals of the individual that result in better community mobility and outcomes.^{79,80} Community mobility plans outline a person-centered intervention in which the individual first identifies their community mobility goal(s) (e.g., traveling independently to work, coordinating transportation to a social outing with friends) and their preferred methods of transportation (e.g., bus, driving). A targeted assessment of the five A's, travel skills, and resource availability is completed to guide individualized intervention and supports. Using information from the assessment process, goals and preferred methods of transportation are reassessed and adjusted or modified as needed, based on the resource availability, individual's travel skills, and the ability to reduce barriers associated with the five A's. Individualized travel training and supports to obtain needed resources are provided with the targeted outcome of attaining their self-determined goals.

Figure 31-4 Community mobility plans.

Community mobility plans are founded on the premise that community mobility is attained when both the person and environment factors are considered when developing supports and interventions. This includes enhancing the skills necessary to use the preferred modes of transportation, while also addressing the environmental barriers in order to improve the person and environment fit. It is critical to support the ability and skill development of the individual to use available transportation options, but other environmental barriers must also be addressed as part of the assessment and intervention process.

CASE STUDY: TRISTEN

Patient Information

Tristen is a 19-year-old female who is graduating from high school. She was diagnosed with cerebral palsy at birth and uses an electric wheelchair for functional mobility. She is able to independently mobilize in her house and around the neighborhood using the wheelchair. She has functional use of both his hands for all activities of daily living and most fine motor tasks. Tristen excels academically in school and enjoys reading and watching movies. She has strong verbal communication skills. Tristen is planning on starting courses at the local community college and will be continuing her part-time job at a bookstore located in a nearby mall upon graduation. She identified transportation as a main concern upon her graduation in her most recent Individual Education Planning meeting. She currently uses the school bus to get to classes each morning and is dependent on her parents to drive her to work on the weekend. Her work hours will expand after graduation and include weekdays. Tristen wants to be able to travel independently to work and school when needed, as both of her parents work during the day. She identified that she would like to learn to use the bus because there is a bus stop near her house that drops her off at the mall and a few blocks from the community college. She has taken a public transportation bus with a family member in the past, but has never done this on her own.

Occupational Therapy Recommendations

The school occupational therapist who provides transitional services completed an evaluation to assess Tristen's community mobility. She was able to navigate safely to cross streets and maneuver on pavements that had curb cuts. She was not familiar with how to purchase bus passes and plan a trip using the bus (i.e., find schedules, locate routes specific to her travel destinations). Her local transit system has accessible buses that include a lift and securement system for wheelchairs. The bus operators assist patrons in wheelchairs to use a lift to get on and off the bus and ensure proper securement. There were some streets that did not have proper curb cuts, resulting in a need for Tristen to mobilize further to another street to get to her destination. During bad weather days (e.g., rain or snow), Tristen was not able to maneuver her wheel chair safely to get to bus stops.

Summary of Short-Term Goals, Intervention, and Progress

Based on the evaluation of Tristen's community mobility and her self-identified priorities, additional occupation therapy services were added to her IEP to address the following community mobility goals: (1) Tristen will be able to plan and implement a fixed-route trip to the mall using a public transit bus when provided with supervision and environmental adaptations successfully in four out of five trips. (2) Tristen will obtain conditional paratransit eligibility and schedule trips when needed to get to work or school with minimal assistance 90% of the time.

After exploring available transportation options and resources, Tristen and the occupational therapist identified bus transportation as the preferred method of travel to get to work and school. She also wanted to obtain conditional paratransit eligibility for days when she was not able to use the bus because of environmental barriers related to the weather (e.g., inability to mobilize in wheelchair safety when the pavement was wet or had snow on it). Additionally, she needed paratransit services to travel to other destinations that were not easily accessible with public transportation (e.g., medical appointments). Tristen worked with the occupational therapist and transition team at the school to identify the necessary resources and contacts to obtain eligibility for paratransit. This involved completing intake paperwork, obtaining medical documentation, and participating in an in-person assessment with staff at the transit agency. She participated in travel training with the occupational therapist once a week. The occupational therapist used an established travel training curriculum⁸¹ that focused on use of public transportation and worked on foundational skills necessary to travel in the community (e.g., safe wheelchair navigation/securement, safety awareness). This involved direct instruction in the following six core areas, along with individual travel training: (1) Interacting with Individuals in the Community; (2) Signs and Traffic Symbols; (3) Pedestrian Safety and Awareness of Surroundings; (4) Preparing for Your Trip; (5) Travel Practice; and (6) Expect the Unexpected: Dealing with the "What Ifs."

Tristen made significant progress toward her goal after consistent intervention over a 2- to 3-month period of time. She was able to plan trips (e.g., identify the appropriate buses and the schedules; plan out enough time to get to the bus stop) to both the local community college and her part-time job at the mall using public transportation. She worked with the occupational therapist to identify routes to the bus stops that had curb cuts for accessibility purposes. Tristen was able to physically get on and off the bus but continued to work on recognizing when her stop was nearing so she could pull the cord that indicated when she needed to get off. She was demonstrating awareness of safety 90% of the time but continued to need supervision when there were unexpected changes (e.g., construction on a typical pedestrian route, unfamiliar types of interactions with people in the community). Tristen obtained eligibility for paratransit services. She worked with the therapist on how to schedule trips on paratransit and was able to implement a trip without supervision. By the end of the school year, Tristen was using fixed-route bus transportation to get to work at the mall and was able to independently get to the local community college. She started to explore other routes on the bus and other modes of transportation (e.g., Uber and Lyft) to get to the houses of family members and friends.

Section 5 Frames of Reference for Physical Disability Rehabilitation

Chapter 32

The Biomechanical Frame of Reference

Kimatha Oxford Grice

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the theoretical bases of the Biomechanical Frame of Reference.
2. Apply the Biomechanical Frame of Reference for the evaluation of persons who have limitations in occupational performance because of physical impairments.
3. Apply the principles of the Biomechanical Frame of Reference for planning and implementing treatment for persons with physical impairments.
4. Explain the relationship of the Biomechanical Frame of Reference to the occupational therapy practice framework and occupation-based intervention.
5. Describe occupational therapy methods and modalities that are employed in treating persons from a Biomechanical Frame of Reference.

CHAPTER OUTLINE

Introduction
The Biomechanical Frame of Reference Theoretical Base
Function/Dysfunction Continua
Evaluation: Indicators of Function and Dysfunction
Intervention: Postulates Regarding Change
Evidence Regarding the Biomechanical Frame of Reference
Case Study

TERMINOLOGY

- Edema:** the swelling of soft tissues as a result of excess fluid accumulation.
- Endurance:** the ability of muscles to exert their effort or force for extended periods of time.
- Functional range of motion:** the amount of range of motion that is required, at joints of the arm for instance, to enable an individual to perform requisite functional tasks.
- Impairment:** a state of reduced quality or function in a physical characteristic of the body, such as strength, motion, and endurance; can be partial or complete.
- Kinematics:** the science of describing the positions and motions of the body in space.
- Kinetics:** the study of forces that affect motion and the results they have on a body.
- Physical agent modalities (PAMs):** procedures and interventions that are applied to modify specific client factors that may be limiting occupational performance; using various forms of energy to modulate pain, modify tissue healing, increase tissue extensibility, modify skin and scar tissue, decrease edema and inflammation, or decreased function secondary to musculoskeletal conditions; are used as adjunctive or preparatory methods to engagement in occupation.
- Range of motion (ROM):** the pathway of movement possible at a joint; typically measured in degrees of motion.
- Strength:** the ability of a muscle or group of muscles to create a contractile force against a resistance in a single contraction or effort.
- Therapeutic activities:** tasks, including arts, crafts, sports, self-care, home management, and work related, that are used or adapted to meet a functional objective.

Therapeutic exercise: body movement or muscle contraction used to prevent or correct a physical impairment or improve musculoskeletal function; typically repetitive in nature.

Introduction

As a profession, occupational therapy was established and built on theories that support occupation as both a means and an end to enable humans to lead meaningful and productive lives.¹ These theories have helped define what occupational therapists do, how they do it, and why they do it. A theory is a system of ideas intended to explain something and puts forth a set of principles on which the practice of that activity is based; it justifies a course of action.² Frames of Reference (FORs) are based on theoretical principles that guide the evaluation and treatment of deficits. An FOR is a set of criteria or stated values in relation to which measurements or judgments can be made²; it helps determine how something will be approached, perceived, or understood.³ In occupational therapy, FORs help therapists translate theory into intervention methods and approaches through applying clinical reasoning. A FOR is more specific in scope than a model and guides the clinician in the selection of appropriate ways to address the needs and goals of the client.

In the management of physical dysfunction, the more commonly used FORs include the Biomechanical, Sensorimotor, and Rehabilitation.⁴ The Biomechanical FOR is used with musculoskeletal problems and orthopedic conditions; the Sensorimotor FOR is used for individuals with neurological conditions and involvement of the central nervous system; the Rehabilitation FOR can be used with anyone and is focused on returning individuals to their highest level of independence and function, in spite of any residual **impairments**. It is important to note that a therapist may employ more than one FOR with any one individual. For instance, for someone who has experienced a stroke, the therapist most likely would employ a Sensorimotor FOR, and also the Rehabilitation FOR, in choosing appropriate interventions. This chapter will address the Biomechanical FOR.

The Biomechanical Frame of Reference Theoretical Base

Biomechanics is the study of mechanical laws relating to the movement or structures of living bodies²; it is a discipline that uses principles of physics to study how forces interact within a living body.⁵ More specifically, in the human body, principles of **kinetics** and **kinematics** are applied to understand normal movement. Movement is necessary for occupational performance and engagement in most occupations. Loss of motion can limit participation in occupation and, therefore, occupational performance. It is through knowledge and understanding of biomechanics, as well as the anatomy and physiology of the human body and the cardiopulmonary system, that a clinician can assess limitations in movement and occupational performance and prescribe interventions that will alleviate or compensate for this loss.

This FOR is applied to individuals who demonstrate limitations in moving freely, with adequate strength, or in motion sustained over time.⁶ These limitations may be as a result of problems with the musculoskeletal system, the peripheral nervous system, the cardiopulmonary system, or as a result of injury or surgical procedures that require periods of immobilization for tissue healing.

Function/Dysfunction Continua

All occupational performance requires stability and mobility of the human body in varying amounts. Whether turning over in bed, standing at the sink to brush one's teeth, dressing, eating, or writing, some muscles are providing stabilization and others are allowing movement for performance of that activity. The capacity for motion involves three components: the potential for motion at a joint (joint range of motion [ROM]), muscle strength, and endurance. Limitations in any of these, or a combination, result in biomechanical impairments that can affect performance of one's occupations.⁶ In addition, a clinician must look at the force, leverage, and torque required by the body to perform a

task or an activity. Assessment of all of these components will help determine where the limitation lies, as well as what intervention is needed to overcome it.

Range of Motion

All joints in the human body have a normal **range of motion (ROM)** that is possible. This is determined by the structure of specific joints and the elasticity of the connective tissues, muscles, tendons, skin, and other soft tissues that surround that joint. A clinician must know what is “normal” or expected, to be able to recognize deficits, or what is not normal. Limitations in the available ROM at a joint may be caused by damage from injury or disease, **edema** in the surrounding tissues, pain, tightness or shortening of the muscles, tendons, skin, or surrounding tissues, muscle spasticity, or contracture of connective tissues such as the ligaments and joint capsule as a result of immobilization. Common conditions that can affect joint mobility include arthritis, fractures that create swelling and immobilization to allow for healing, and shortening of soft tissues such as the skin after a burn or laceration. ROM is usually measured in degrees of movement.

Strength

Muscles provide the forces necessary for maintaining a posture or position and moving the body in space, both of which are required for participation in occupations. Muscles create movement and stability through the force they exert on the bones of the body. A force can be a push or a pull that can produce, arrest, or modify movement.⁵ The amount of force can vary depending on the size of the muscle, the number of muscle fibers recruited, and the capacity of that muscle. Muscles work simultaneously to provide stability or control at the same time others are causing motion. A deficit in strength, or weakness, has many causes. Primary weakness is a direct result of a condition or disease such as amyotrophic lateral sclerosis or muscular dystrophy or because of disruption of innervation secondary to injury to a peripheral nerve. It can be a secondary symptom as a result of disuse or immobilization such as after a fracture, or from restrictions of soft tissues such as contracture of the skin after a burn injury. **Strength** is usually measured in pounds of force exerted, or by the amount of force a muscle can withstand.

Endurance

The ability of muscles to sustain their effort over time is **endurance**.⁴ Occupational therapists are concerned with endurance for occupational performance to determine whether a person will be able to carry out a certain activity. In addition to the normal capacity of the muscle and its condition, there are other factors that affect endurance. These include the cardiovascular and pulmonary systems of that individual. Limitations or deficits in endurance can be a result of diseases that directly affect the muscles, the cardiovascular or respiratory systems, or loss of normal conditioning from disuse or extended lack of activity.⁶ Endurance is typically measured in time or duration, by repetitions, or by completion of an activity.

A decrease or deficit in any of the abovementioned components: ROM, strength, or endurance, can interfere with occupational performance and normal functioning. An individual may demonstrate a deficit in only one component, or in a combination, that will create dysfunction for him or her. A person with arthritis in the shoulder joint may not be able to wash or groom his or her hair because of the inability to move the shoulder to a position that would allow this activity. This is a result of decreased ROM. An individual who had a heart attack and was confined to bed for some days may not be able to get out of bed without assistance as a result of a decrease in strength and endurance. Someone who was casted following a fracture of the distal radius would have decreased movement at the wrist as well as weakness in the wrist musculature from being immobilized.

Evaluation: Indicators of Function and Dysfunction

In order to determine the extent of a limitation and its effect on function, these components of movement must be evaluated. In addition, through the evaluation process, the therapist

will be able to determine the cause of the limitation and subsequently what intervention is needed to alleviate the problem. For example, if a client presents with decreased ROM at a joint and it is determined that there is edema present, the therapist may conclude that the edema is creating the limitation in joint movement and that intervention to lessen the edema will lead to an increase in the ROM. These measurements, taken in evaluation of the different components, will be used by the therapist to develop goals that will then be used to measure progress.

Range of Motion

ROM is usually measured with a goniometer in degrees of movement. There are accepted “norms” that allow the clinician to determine the extent of a deficit when compared to this norm. For instance, the norm for shoulder flexion is 0° to 180°.7 If a client presents with 0° to 90° of shoulder flexion, this is only about half of the normal range. As mentioned previously, there are many factors that can cause a limitation in movement at a joint, such as edema or pain. If the therapist determines one of these causes is present, then evaluation of that particular cause would be done as well. Edema can be measured using a volumeter and water displacement or circumferentially with a measuring tape. Pain can be assessed using verbal and visual analog scales as well as questionnaires.

Strength

Strength is evaluated primarily with manual muscle testing in which a muscle or group of muscles is assigned a muscle grade based on the amount of resistance provided by the clinician. Grip strength is tested using a dynamometer that measures the amount of force, in pounds, that one can exert grip force on the instrument. Pinch strength is measured using a pinch gauge, which also measures the amount of force exerted in pounds. Strength can also be measured on equipment such as the BTE work simulator. This is useful for evaluating a client’s capacity for certain tasks such as turning a screwdriver or lifting.

Endurance

Endurance can be evaluated in several ways. One way is by the number of repetitions that a person can perform an exercise or activity before fatiguing, such as counting the number of cones a patient can move from the table to the cabinet before tiring. It can also be measured by the length of time that a task can be carried out before tiring, such as cooking a meal. It can be measured in distance; for instance, how far an individual can propel his wheelchair before fatiguing.

Intervention: Postulates Regarding Change

The ultimate outcome for occupational therapy intervention is to enable an individual to be as independent as possible in the performance of his or her desired occupational roles and occupations. In the treatment of physical dysfunction, intervention may address performance skills as outlined in the Occupational Therapy Practice Framework,⁸ including motor skills, process skills, and social interaction skills. The Biomechanical FOR focuses most on motor skills and the client factors of body functions and body structures. Within body functions, sensory function, pain, functions of joints and bones, and movement are specifically addressed.

In addition, occupational therapy intervention for physical dysfunction takes place along a “treatment continuum.”⁹ This continuum represents the progression of occupational performance and intervention from dependence to independence. There are four stages in the continuum that help define the types of intervention needed at that level of performance. The stages are adjunctive methods, enabling activities, purposeful activities, and performance of occupational roles¹⁰ (Fig. 32-1).

Figure 32-1 Treatment continuum in physical dysfunction.

Adjunctive methods prepare the client for occupational performance but are preliminary and preparatory to purposeful activity. They may include **physical agent modalities (PAMs)**, exercises, positioning, sensory stimulation, and use of devices such as braces and splints/orthoses.

Enabling activities simulate purposeful activities and may involve the use of devices and equipment that facilitate the specific performance skills necessary to carry out an occupation. Examples might include driving simulators, work simulators, tabletop activities, and exercise equipment.

Purposeful activities are part of daily-life routines and are relevant and meaningful to the client. They may include dressing, eating, mobility, arts and crafts, communication, and work. Purposeful activities are used to enhance performance in the occupations of activities of daily living (ADLs), education, rest and sleep, work, play, and social participation, as defined in the Occupational Therapy Practice Framework.

The last stage on the treatment continuum is performance of occupational roles. At this point, the client resumes or assumes his or her occupational roles at home and in the community.

When providing treatment from a Biomechanical FOR, many interventions will fall within the adjunctive and enabling methods and many purposeful activities apply biomechanical principles.³ The final goal is for the client to regain the ability to engage in occupation, and this should be kept in mind when choosing interventions along the continuum.

Another aspect of treatment to consider is that the focus of intervention occurs along a continuum as well.¹¹ At one end of the continuum of focus is remediation and at the other end is occupational performance. When the focus is remediation of impairments, the goal is to restore the previously mentioned client factors of body functions and structures and motor skills. When enhanced occupational performance is the focus, then adaptive or compensatory occupation may be used to enable the client to engage in an occupation in spite of impairments that might be present. For example, a person who has limited shoulder motion might not be able to reach his or her back to bathe it. Remediation of the impairment might include exercises to increase the degrees of motion possible (Biomechanical FOR), whereas an adaptive or compensatory method would be to provide the client with a long-handled bath sponge so he or she can bathe his or her back, regardless of whether or not shoulder movement improves (Rehabilitation FOR).

Many times, the focus of intervention may be prevention—attempting to prevent a problem that would require remediation or compensation. For example, many

postoperative protocols allow early motion and activity versus prolonged immobilization, in an attempt to alleviate stiffness and weakness from immobility.

Range of Motion

Occupational therapists want to ensure that an individual achieves the maximum amount of movement of his or her joints. Sometimes, normal movement may be possible, and other times, **functional ROM** may be the goal. They are also concerned with preventing loss of movement. Three concerns for preserving and changing the capacity for functional motion are prevention of deformity, restoration or improvement in the capacity for motion, and compensation for limited motion (which is usually permanent).⁶

Prevention

Ideally, normal active movement at a joint will keep it mobile and prevent stiffness. If active movement is not possible, then assisting the joint in movement or providing passive movement will keep the structures mobile and gliding and prevent loss of motion. Therefore, active, active assistive, and passive ROM exercises can be employed to prevent loss of joint motion.

Deformities can change the normal kinematics of a joint and, therefore, limit or change normal movement. Preventing these changes will ensure maintenance of normal movement. One way to accomplish this is through applying joint protection principles, especially in cases where joint and soft-tissue structures may be damaged by normal forces exerted in everyday activities, as a result of a disease process such as rheumatoid arthritis.

Orthotics can be used to prevent deformities and contractures at joints such as an anticlaw splint for someone who has loss of ulnar nerve function. The splint will prevent a claw deformity and subsequent loss of motion at the finger joints, as well as improve functional use of the hand by keeping it positioned appropriately. Early motion protocols following many surgical procedures use orthoses that will allow controlled movement to prevent scar formation and tissue shortening that would lead to stiffness and contractures from immobilization during healing.

In some instances, modification to the environment can prevent injury to tissues that can lead to pain and other movement limiting issues. Employing ergonomic principles, which in simplest terms means making the environment fit the person, can be used by clinicians to prevent and correct problems with engagement in occupations.

Edema and pain can limit movement, so preventing their occurrence or reducing them if they are present will help prevent loss of ROM.

Remediation/Correction

When loss of motion is present at evaluation, the clinician will need to determine what has contributed to the limitation in order to employ the appropriate intervention to improve the available ROM. For instance, edema may be present after an injury or surgical procedure. Methods that include elevation, massage, compression, and the use of PAMs such as heat, cold, and electrical stimulation can reduce the edema, therefore allowing greater mobility of the joints. ROM exercises, as possible, will help reduce the edema and maintain joint mobility. In addition, active and passive stretching exercises can be used, when not contraindicated, to elongate tissues in preparation for ROM and functional use. All of these fall under the stage of adjunctive or preparatory methods on the treatment continuum. Encouraging functional use of the hand or extremity with simulated and purposeful tasks will help reduce edema and increase ROM as well.

Orthotics, particularly dynamic orthoses, can provide forces that will create lengthening in the muscles, tendons, and other soft tissues that are shortened and limiting normal gliding and movement.

Compensatory/Adaptive

When limitations exist in movement that cannot be remediated, or existing motion is functional, then the clinician's focus with the patient may be on compensatory methods and independence in occupations in spite of decreased ROM. Many times, this will include the use of adaptive devices and equipment or orthoses (Fig. 32-2). Sometimes, it may require a modification to the environment.

Figure 32-2 Use of a dynamic extension outrigger to compensate for loss of finger extension caused by radial nerve palsy following an injury to the radial nerve.

Strength

Strengthening is defined as any intervention that involves an attempt at repetitive, effortful, muscle contraction for the purpose of increasing the capacity of work that the muscle can perform.¹² Activities and occupations require certain amounts of strength in order to perform them. Many times, a minimal amount will be needed for an individual to perform an activity or task independently. Occupational therapists may need to employ interventions for strengthening to enable their clients to have that ability.

Prevention

Participation in daily activities and occupations can serve to maintain existing levels of strength and prevent weakening of muscles. Many individuals choose to also engage in exercise as an occupation, such as jogging, walking, or working out at a gym. Therapists can prescribe a **therapeutic exercise** program that can achieve the same for individuals who have conditions that can lead to loss of strength and, therefore, function. Examples include those with chronic conditions such as arthritis and cardiopulmonary conditions.

Remediation/Correction

Once an individual has lost strength, due to illness, injury, or immobilization, intervention will be used in an attempt to restore and increase strength. In addition to actual participation in occupations, a therapist might use graded **therapeutic activities** and therapeutic exercises to achieve this goal. In using therapeutic exercises, the amount of force, number of repetitions, speed of the exercise, or length of time it is done can be varied to start with a level the client can perform and progress to a more challenging level as tolerated. Examples include the use of resistive bands, graded putty, free weights, and weighted pulleys. In using therapeutic activities, purposeful tasks can be used in targeted ways to increase strength. An example might be to engage the client in a tabletop activity with weights on his arms to increase resistance to the movement while performing the activity. Another example would be to use electrical stimulation to reinforce a movement while performing a particular task, such as weak wrist and finger extensors for opening and releasing objects.

Other options that are more purposeful and functional than therapeutic exercise include the use of equipment like the BTE work simulator which allows simulation of tool use, tasks such as jar opening, driving, and turning door knobs, with grading of the resistance and amount of time the activity is done (Fig. 32-3).

Figure 32-3 Use of the BTE work simulator to increase functional use and strength of the left hand following a distal radius fracture. This client complained of not being able to open jars, so the large jar lid tool is being used.

For an injured worker, work hardening can provide a program in which the worker carries out his or her specific job tasks in a work environment, gradually reaching his maximum potential, in preparation for safely returning to his or her job.

Compensatory/Adaptive

Like with ROM, many conditions may result in a permanent loss of strength. In these instances, activities and occupations will need to be adapted to enable the individual to continue to perform them as independently as possible. For instance, someone with a neuromuscular disease resulting in generalized weakness may not have enough strength in his or her trunk musculature to assume a sitting position from lying in bed. The use of a bed with a feature that brings the head of the bed upright would enable him or her to come to sit without assistance. An individual with chronic weakness in his or her hands due to rheumatoid arthritis and cannot open jars or cans, could use an adaptive jar opener and electric can opener to achieve these tasks independently.

Endurance

Sustaining the strength of a muscle over time is endurance. Varying lengths of time are required for different tasks and occupations. A person may be able to carry out a light task such as folding clothes for a longer period of time than he or she is able to for a more demanding task such as raking leaves. Interventions to improve endurance must grade the resistance and the time. The use of lighter resistance over increasing time has been advocated for endurance training.¹³

Prevention

As previously stated, engagement in normal occupations can help prevent loss of strength. It would follow that this can also prevent decreases in endurance as well.

Remediation/Correction

An individual who fatigues before being able to complete a particular task or occupation demonstrates a deficit in endurance. The therapist can grade therapeutic exercises and activities in such a way as to gradually increase the amount of time involved in the task. With therapeutic exercise, the number of repetitions can be increased incrementally. In an

activity such as knitting, the individual can increase endurance by knitting for a few minutes longer each day. For example, a runner may build up his endurance by running a little farther each week.

Compensatory/Adaptive

The same conditions that may permanently limit strength may also limit endurance. In these cases, the therapist can use the Rehabilitation FOR to teach compensatory techniques for completing desired activities, such as energy conservation and the use of adaptive devices, that will allow completion of the activities. An individual with chronic obstructive pulmonary disease (COPD) may be limited in the distance he or she can walk before becoming fatigued. The use of a wheelchair may allow him or her to cover more distance with less energy expenditure. If this person is able to walk from his or her car to the door of the store, but not farther, the use of a motorized cart or a wheelchair may allow completion of shopping without any other assistance.

Evidence Regarding the Biomechanical Frame of Reference

Evidence-based practice (EBP) is the conscientious use of current best evidence in making decisions about patient care.¹⁴ The goal of EBP is to eliminate unsound or risky practices in favor of those that have better outcomes. This has become more imperative for occupational therapists in recent years. Owing to higher caseloads and limited therapy visits, therapists have less time with each client; in addition, third-party payers have become less inclusive of the treatment for which they will reimburse. Increasingly, their emphasis is on improved functional outcomes. Therefore, clinicians have to choose wisely the interventions they will use in order to optimize the outcomes for their clients. The profession has to look at the evidence for the models, FORs, and treatment methods and modalities that have always been embraced and decide objectively whether they are effective or not.

Historically, the Biomechanical FOR has been shown to be effective in the prevention and remediation of physical impairments, such as ROM, strength, and endurance. However, improvements in these impairments do not necessarily equate to improved occupational performance or function. Third-party payers are no longer likely to reimburse treatment purely for biomechanical gains. Therefore, research is needed that can demonstrate the correlation between biomechanical interventions and improved functional outcomes.

Occupational therapists who work in orthopedic and hand therapy settings have been identified as having a tendency to follow a reductionist biomechanical approach in their practice, potentially losing the occupational focus in their interventions with these populations.¹⁵ Reasons given for less occupation-based intervention are many and include time limitation, space limitation, and lack of resources.¹⁶ Owing to these observations, there has been an increase in the use of functional outcomes, reporting that many achieved by self-report of the patient. In addition, there has been an increase in the research and studies being done to demonstrate the effectiveness of biomechanical interventions for improving function and increased occupational performance. Examples of these types of studies can be found in the Evidence table at the end of this chapter.

CASE STUDY

Patient Information

Selena is a 20-year-old right hand dominant college student who was living with her mother during summer break and working as a bar tender at a local restaurant/bar. She enjoys working out at the gym, walking her dog, and spending time with friends. While at work, she tripped over a box behind the bar while holding a glass goblet in her left hand. When she fell to the floor, the glass shattered, lacerating her left wrist/forearm on the volar surface. She was taken to the emergency room (ER) where the laceration was

dressed, and she was told to seek the attention of a surgeon. All flexor tendons and the ulnar nerve were cut, and the median nerve was “nicked.” Two weeks after the accident, a local general surgeon (no hand surgeons practiced in this area) repaired the tendons and placed her in a cast for 4 weeks. After cast removal, she was returning to college and was encouraged to get therapy in that city.

Her first treatment session was approximately 9 weeks after her injury and 7 weeks after surgery. Selena presented with flexion contractures of all fingers, thenar and hypothenar atrophy, and lack of sensation in the ring and small fingers. She had received no therapy or intervention once the cast had been removed. Based on initial evaluation findings, the occupational therapist/certified hand therapist questioned whether the ulnar nerve was intact. In communication with the surgeon, it was discovered that the ulnar nerve had not been found or repaired.

Assessment Process and Results

Selena had no pain at rest, but had discomfort with any passive ROM of the fingers and wrist. She had no measureable active ROM of the fingers and thumb, and her fingers were in fixed flexion contractures (Fig. 32-4). Sensation testing with the Semmes Weinstein was 2.83 for thumb and index finger, 3.61 for middle finger, and 6.65 for ring and small fingers. She reported being unable to use her left hand for ADLs or other activities because of the inability to grasp or “feel.” She was unable to work out at the gym, except for one-handed exercises. She expressed extreme worry about her hand and the fact that she could not use it. She also expressed embarrassment and reported that she kept it covered or hidden when out in public since the cast was removed.

Figure 32-4 Case example at initial evaluation.

Occupational Therapy Problem List

- Decreased active and passive movement in left fingers, thumb, and wrist
- Contractures/shortening of soft tissues of left fingers and wrist
- Decreased sensation in the left hand; lack of protective sensation in ring and small fingers
- Hard, rigid scar tissue at injury and surgery sites
- Lack of functional use of left hand to perform ADLs or leisure activities

Occupational Therapy Goal List

Selena will:

- Demonstrate passive ROM within normal limits and active ROM within functional limits to facilitate functional use of the left hand.
- Demonstrate knowledge of safety techniques for prevention of tissue injury because of loss of ulnar nerve function in left hand.
- Achieve softening and increased extensibility of the scar tissue to promote gliding of flexor tendons and wrist mobility.
- Demonstrate a gross functional grasp with left hand for assisting with ADLs and leisure tasks.
- Independently perform home program of scar management, ROM.
- Exercises, use of orthoses, and safety measures for lack of sensation.
- Gain confidence in the use of her left hand and acceptance of its appearance to.
- Facilitate a decrease in emotional stress.

Intervention

At the first visit, in addition to an initial evaluation, Selena was educated about her injury, especially loss of ulnar nerve function and protective sensation, the surgery, and what to expect from therapy sessions. She was instructed in a home exercise program of active and passive ROM for her hand and wrist, gentle stretching techniques, and scar massage to soften and desensitize her scars. A functional position orthosis was fabricated for wear at night and during the day when she was not using her hand, to attempt to begin tissue lengthening of the extrinsic finger flexors and reduce the flexion contractures that had developed (Fig. 32-5). Encouragement was provided to help reduce her anxiety about ever being able to use her hand again.

Figure 32-5 Functional position orthosis for night and rest periods.

Over the next 4 weeks, Selena was treated by the occupational therapist two times per week. Once increased extension of the proximal interphalangeal (PIP) joints was achieved, a dynamic extension splint was fabricated for day use to further increase digital extension. She continued to wear her resting splint at night, with the pan serially extended as appropriate. Therapy sessions included manual therapy techniques to increase elasticity of the scar tissue and other soft tissues to allow greater passive and active ROM; therapeutic activities to facilitate functional use of her left hand, including different simulated tasks on the BTE work simulator such as gripping, pinching, and jar opening; strengthening exercises for grip and pinch; and wrist and forearm movements.

Selena was diligent in her home program and progressed well. Her flexion contractures improved to the point that she had functional opening and closing of her fingers (Fig. 32-6). A resting splint (with a ball pan for finger abduction) was fabricated to continue to stretch the extrinsic finger flexors and provide abduction of the fingers,

which was limited because of the lack of ulnar nerve innervation to the finger intrinsics (Fig. 32-7). Selena gained confidence in the ability to use her left hand and returned to her work outs at the gym, using her left hand as much as possible. Her emotional health improved, and she no longer hid her hand, but jokingly called it her “claw,” demonstrating that she had progressed through the grief process to acceptance. She was referred to a local hand surgeon for assessment of further surgery that might be appropriate. It was determined that she would undergo a sural nerve graft for the ulnar nerve so therapy sessions were continued one time per week for the next 6 weeks to prepare for that procedure.

Figure 32-6 Active extension (A) and flexion (B) of injured hand after several months of therapy (about 3 months postinjury).

Figure 32-7 Resting splint with ball pan to increase finger abduction. (A) Dorsal View and (B) Radial View.

Six months after her original injury, Selena underwent the nerve graft for the ulnar nerve of her left hand. Therapy sessions resumed for two times per week for the next several months to address wound and scar management and continue exercises and activities to increase strength and functional use of her left hand. An anticlaw deformity splint was fabricated to allow greater functional use of her hand until her ulnar nerve function was improved (Fig. 32-8). At discharge, Selena had met all of her goals and had reintegrated the use of her left hand into her daily tasks and life. As she stated, “I don’t have to think about my hand anymore—I just use it normally like I did before.” She was pleased with the appearance and the ability to use her hand.

Figure 32-8 Use of anticlaw orthosis to prevent hyperextension of ring and small fingers caused by lack of ulnar nerve innervation and to allow greater functional use of hand. (A) Ulnar View and (B) Dorsal View.

Discharge assessment results demonstrated increased ROM, increased grip strength, and the return of sensation after the nerve graft. Results of the Semmes Weinstein revealed 4.56 for the ring and small fingers. It was hoped that eventually, she would have at least protective sensation in the ulnar nerve distribution of her left hand.

Next Steps

One year following nerve graft, Selena demonstrated protective sensation in the ulnar nerve distribution of the left hand; could extend the ring and small fingers without clawing and had quit using her ant Claw splint; atrophy of the thenar and hypothenar musculature was only apparent to the expert eye. With time, ulnar nerve function should continue to improve.

Best Evidence for the Biomechanical Frame of Reference Regarding Occupational Therapy Process and Functional Outcomes

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance
Use of superficial and deep heat for decreasing pain, increasing ROM and ADL performance in frozen shoulder (adhesive capsulitis) ¹⁷	Three groups received intervention three times per week for 4 weeks: 1—stretching alone 2—superficial heat plus stretching (HP) 3—deep heat plus stretching (SWD).	Thirty subjects, 10 in each group, randomly assigned.	Both HP and SWD groups received treatment three times per week for 4 weeks (12 visits); all groups received standard set of shoulder stretching exercises.	Single-blinded randomized controlled study Level 1B	All groups made improvement in pain, ROM, and function, but deep heat more than the other two groups.	Between-groups shoulder score index was significant ($p = 0.046$); deep heat shoulder score was improved more than stretching alone ($p = 0.036$), and no significant difference between superficial heat and stretching alone.
Multimodal intervention (exercises, splinting, joint protection, use of assistive devices) for thumb carpometacarpal (CMC) osteoarthritis (OA) to reduce pain and increase activity participation ¹⁸	Subjects received three visits—initial, 3-week follow-up, and 6-week follow-up; intervention included prescribed home exercise program (HEP), thumb spica orthosis, education in joint protection and use of adaptive devices.	Seventy-two adults with diagnosis of CMC OA who were not receiving other therapy, had no history of surgery or other inflammatory diseases	Initial visit to establish baseline, instruct in exercises, joint protection, and fabricate orthosis; second visit to review excess and reassess orthosis; third visit to reevaluate	Pre–post design Level 2B	Significant improvement in all outcome measures: pain, ROM, Canadian occupational performance measure (COPM) scores, disabilities of the arm, shoulder, and hand (DASH) scores	Statistically significant ($p = <0.0001$) positive association between pain scores with changes in activity and participation (DASH score); also strength measures statistically significant ($p = 0.05$) association with changes in activity and participation (DASH score)

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance
Use of functional electrical stimulation (FES) to induce beneficial changes in proprioception, functional recovery of the paretic upper limb, and the patient's quality of life ¹⁹	Daily 1-hour sessions over 10 consecutive workdays; FES to the wrist extensor muscles of affected limb while she performed functional movements of grasp, grip, pinch, and gross movement at a workstation; also, during prescribed ROM exercises, FES was applied alternately to the flexor and extensor muscles by the therapist.	Individual case study of a woman who was 11 months following cerebrovascular accident (CVA)	Patient was assessed before and after 10 consecutive therapy sessions.	Individual case control study Level 3B	Favorable change in magnitude of end-position errors in affected wrist, as well as scores for each task (grasp, grip, pinch, and gross); improved quality of life as demonstrated by changes in the SF—36, v. 2.0 scores.	Proprioception: linear regression analysis revealed a significant decrease in time taken to position the segments assessed ($p = <0.05$); upper limb function: all scores improved, but no statistical significance reported; quality of life: patient reported perceived improvement in bathing, dressing, and lifting or carrying bags.

Chapter 33

The Rehabilitation Frame of Reference

Sunny R. Winstead

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the key features of the Rehabilitation Frame of Reference, including the client situations and settings in which this approach is most commonly used.
2. Differentiate among remedial, compensatory, and adaptive approaches to occupational therapy services.
3. Understand key theoretical components of the Rehabilitation Frame of Reference, and how this approach aligns with other frames of reference.
4. Identify characteristics of function and dysfunction consistent with the Rehabilitation Frame of Reference, and understand how these continua influence the evaluation process.
5. Identify proposed mechanisms of change consistent with the Rehabilitation Frame of Reference, and be able to articulate common intervention strategies consistent with these postulates.
6. Summarize the key evidence that supports and challenges the use of the Rehabilitation Frame of Reference in occupational therapy practice.

CHAPTER OUTLINE

Overview of the Rehabilitation Frame of Reference
Background
Theoretical Base and Related Models
Evaluation (Function/Dysfunction Continua and Indicators)
Intervention (Postulates Regarding Change)
Evidence
Case Study

TERMINOLOGY

Adaptation: the process of modifying items, activities, and environments to promote function.

Assistive technology: items, equipment, and systems designed to promote function; may be commercially available, modified, or customized.

Compensation: the use of techniques that allow an individual to complete a desired activity in a modified way.

Compensatory techniques: intentional ways of performing an activity differently; also called *compensatory strategies*.

Continuum of care: a comprehensive range of health-related services provided over time and across levels of intensity.

Environmental modification: a change to the physical or human environment designed to promote function.

Orthotic: a device designed to stabilize a body part, prevent deformity, protect against injury, or assist with function.

Prosthetic: a device designed to replace the function of a missing body part.

Remediation: the process of improving or correcting a deficit.

Overview of the Rehabilitation Frame of Reference

One clinical question faced by therapists in physical disability practice is whether to focus on **remediation**, **compensation**, **adaptation**, or a combination of these approaches. Remedial approaches, such as the biomechanical frame of reference (see Chapter 32) or the motor learning

frame of reference (see Chapter 34), focus on restoring or improving a client's functional abilities by directly addressing impairments in body functions. Remedial approaches are appropriate when it is feasible and desirable to restore abilities such as strength, range of motion, or coordination. In contrast, compensatory and adaptive approaches such as the Rehabilitation Frame of Reference are appropriate when remediating impairments is not possible or is not the immediate goal. The Rehabilitation Frame of Reference promotes the use of **assistive technology**, compensatory strategies, and environmental modifications to maximize clients' abilities to engage in meaningful occupations and to achieve the fullest quality of life. This approach emphasizes clients' strengths rather than their limitations¹ and helps clients make the most of those strengths. The Rehabilitation Frame of Reference aligns with the "modify" approach to intervention outlined in the third edition of the Occupational Therapy Practice Framework (OTPF-3), which also emphasizes compensation and adaptation.²

Although this chapter focuses on the use of the Rehabilitation Frame of Reference for individuals with physical dysfunction, it should be noted that this approach also has wider application. First, it can also be used for clients with cognitive and psychosocial deficits. People with conditions such as dementia, severe and persistent mental illness, and intellectual disabilities have the potential to achieve greater occupational engagement and quality of life through compensatory and adaptive approaches. Second, this frame of reference can be used in the provision of services to groups and populations. Examples could include providing adaptive equipment at an emergency shelter to meet the needs of homeless individuals with disabilities, or adapting the environment of a senior living facility to promote the safety of residents with low vision.³

Background

The Rehabilitation Frame of Reference can guide occupational therapy (OT) services for individuals across the life span and in a range of situations and settings. It can be used alone or in combination with other frames of reference. The following sections identify characteristics of clients, settings, and situations in which this approach is appropriate.

Characteristics of Clients

Individuals with Conditions That Are Considered Chronic, Permanent, or Progressive

Chronic conditions such as arthritis, diabetes, congestive heart failure (CHF), and chronic obstructive pulmonary disorder (COPD) persist or recur over time and can dramatically impact occupational participation. Conditions associated with long-term or permanent physical impairments include amputation, severe acquired brain injuries, spinal cord injuries, and more. Progressive conditions such as Parkinson disease, multiple sclerosis, and dementia also result in impairments that are not likely to improve and will in fact usually get worse over time. These chronic, permanent, and progressive conditions may not be "fixable," but individuals with these conditions can experience significant improvements in occupational participation through the use of assistive technology, compensatory strategies, and modifications to the environment. Following the 2013 *Jimmo vs. Sebelius* court decision (No. 11-cv-17 [D.VT]), the Centers for Medicaid and Medicare (CMS) clarified that an expectation of improvement is not required for payment of skilled therapy: "...the Medicare program covers skilled nursing care and skilled therapy services under Medicare's skilled nursing facility, home health, and outpatient therapy benefits when a beneficiary needs skilled care in order to maintain function or to prevent or slow decline or deterioration (provided all other coverage criteria are met)."⁴ This means that individuals who need skilled therapy to maximize occupational engagement and quality of life can receive these services even when improvement is not the expected outcome. With its focus on compensating for impairments rather than trying to correct them, the Rehabilitation Frame of Reference can guide services for these individuals.

This client category also includes individuals who have limited (or no) ability to actively engage in therapy services, such as people with advanced medical conditions like late-stage dementia, advanced amyotrophic lateral sclerosis (ALS), or late-stage cancer. When working with these individuals, therapists often use the Rehabilitation Frame of Reference in combination with client-centered, psychosocial, and cognitive frames of reference consistent with quality of life and end-of-life concerns. Interventions could include training caregivers in the use of adaptive

equipment and adaptive techniques for activities of daily living (ADLs), recommending assistive mobility devices such as power wheelchairs and vehicle lifts, and modifying the environment to promote safety and social/occupational engagement.

Individuals Who Have Undergone Remediation-Focused Treatment but Still Have Residual Impairments

According to Trombly, “the rehabilitative approach aims to make people as independent as possible in spite of any residual impairment.”^{5(p13)} For example, an individual who has had a severe stroke may receive OT in an acute rehabilitation setting for a number of weeks, with an emphasis on restoring upper extremity (UE) motor coordination, strength, and endurance. After several months, however, this individual may still not have regained full UE function, and the treatment emphasis (e.g., in a community-based setting, such as home health or an outpatient clinic) may, therefore, shift to include adaptive equipment and compensatory strategies to maximize ADL and instrumental activities of daily living (IADLs) performance.

It is important to note that remediation and compensation/adaptation are not mutually exclusive. They can be used sequentially, but often these approaches are used concurrently, with the emphasis shifting from remediation to compensation and adaptation as time passes and residual impairments become apparent. Compensation is sometimes used as an interim approach to maximize function, improve motivation, and limit frustration while a client engages in remediation-focused services. It also introduces strategies that may be needed in the long run if impairments do not resolve or do not resolve fully. For example, following a traumatic brain injury (TBI), a young man may temporarily switch to Velcro sneakers because he values dressing independently. If his strength, balance, and coordination are restored, he may no longer need this compensatory technique and will return to his preferred footwear. However, if residual deficits remain after intervention, the young man may continue to use this useful modification.

Individuals (or Families and Caregivers) Who Prefer a Compensatory or Adaptive Approach

Occupational therapists work collaboratively with clients to understand their experiences and desired goals, and the client’s identified roles and priorities become the focus of OT intervention.⁶ The Rehabilitation Frame of Reference can guide services in those cases where the client, family, or other support persons choose to work specifically on re-establishing function as quickly and efficiently as possible. Participating in a remediation-focused intervention program can be difficult, frustrating, and time-consuming. It, therefore, requires a significant level of motivation on the part of the client, and client motivation can directly impact therapy outcomes. Clients’ motivation and readiness to learn can be negatively impacted by low self-efficacy, depression, cognitive impairment, communication barriers, values, and goals.⁷ If the client prefers a quicker, more functionally oriented approach, or if she or he lacks the motivation for remediation-based intervention, then a compensatory and/or adaptive approach may be appropriate. For example, a client seen in the home health setting following a heart attack may simply prefer to reorganize his kitchen rather than work on strengthening his upper body and regaining endurance to reach the high cupboards. The therapist must always balance clinical judgment, an understanding of relevant evidence, knowledge of client and conditions factors, and the client’s choice when making decisions about the best treatment approach.

Individuals Who Lack Access to Remediation-Focused Treatment

In some cases, a remedial approach may not be practical because of financial constraints or lack of access to therapy.^{8,9} For example, an individual may have inadequate (or no) health insurance to cover the cost of rehabilitation services, or may live in an area where access to comprehensive services is limited. In these cases, the therapist and the individual may collaboratively decide to focus intervention on a compensatory and/or adaptive approach that will allow the individual to achieve maximum function with as little time and cost as possible.

Settings and Situations

Individuals with physical impairments can receive services across a variety of settings, each geared to specific needs and referred to collectively as a **continuum of care**. Depending on the client’s needs, OT services may be provided in inpatient acute care, inpatient rehabilitation, subacute rehabilitation, skilled nursing facilities, intermediate care facilities, assisted living

units, outpatient clinics, home health care, day treatment, or work site programs.¹⁰ The Rehabilitation Frame of Reference can guide therapy in any of these settings, but it is often most useful later in the continuum of care. The early stages of rehabilitation (acute care and inpatient rehabilitation settings) tend to focus on restoring as many performance skills as possible. The Rehabilitation Frame of Reference may be an adjunctive approach during this stage, but if the client has the potential for improvement, the therapy focus is typically on remediation.

As clients move to later levels of care, it is common for services to shift toward maximizing function and quality of life using compensatory and/or adaptive approaches. In describing the community stage of recovery after TBI, Wheeler stated “clients increasingly use compensatory strategies as they increasingly recognize their long-term residual impairments.”^{11(p269)} One compensatory strategy described in the TBI literature is the use of electronic portable assistive devices (EPADs) such as smartphones, personal digital assistants (PDAs), and paging systems to compensate for impaired memory. Baldwin and Powell¹² reported on an experimental case study in which a man received an EPAD (Google Calendar with text alerts) to compensate for severe memory loss following a TBI. The client was seen in an outpatient setting 6 months after his initial injury, and he recognized that residual memory deficits were negatively impacting his life.¹² The client achieved improved functional outcomes after 12 weeks, even though his underlying deficits remained unchanged.¹² This case highlights the potential for functional improvement in the community phase of rehabilitation, using assistive technology that fits a client’s personal context. Figure 33-1 shows athletes using specialized wheelchairs in competition, another example of assistive technology being used to compensate for residual impairments.

Figure 33-1 Use of assistive technology to promote occupational engagement.

It should be noted that most clients do not move through all settings within the continuum of care. Clients may enter the continuum at any point. Ideally, referral decisions at each stage should be based on careful weighing of the options and a determination of which setting best aligns with the client’s most valued goals.¹³ Some clients with physical impairments may skip acute and inpatient rehabilitation altogether and receive therapy in an outpatient or home setting. For example, a college athlete recovering from arthroscopic surgery to repair a rotator cuff tear will likely receive physical therapy and OT in an outpatient setting. A compensatory approach could be used to promote function while the shoulder is immobilized, but the overall goal of rehabilitation would be to fully restore shoulder function using a biomechanical approach.

Some individuals with very serious conditions and limited ability to engage in direct therapy may return to a long-term care setting and receive services to maintain their current status and prevent complications. Although compensatory training for the client may not be appropriate, the Rehabilitation Frame of Reference can guide adaptive intervention focused on staff and family education and environmental modifications for safety and dignity. Figure 33-2 shows the use of a mechanical lift to safely transfer a nursing home resident who is dependent in mobility. The ability to move safely in and out of bed using adaptive equipment will improve this resident’s quality of life, even if he does not have the potential to acquire independent transfer skills.

Figure 33-2 Use of a mechanical lift to promote safety.

Theoretical Base and Related Models

A frame of reference is a system of theoretical concepts that guides evaluation and intervention within OT domains,⁶ or in Mosey's words, "A frame of reference is a link between theory and practice."^{14(p5)} According to Seidel, the Rehabilitation Frame of Reference draws on the knowledge bases of the medical, physical, and social sciences and embraces the philosophy of rehabilitation.^{15(p238)} Trombly stated that the theoretical basis for this approach includes both systems theory and learning theory.¹⁶

The Rehabilitation Frame of Reference has ties to a number of models, including the medical model; the rehabilitation model; the International Classification of Functioning, Disability, and Health (ICF) model; and the client-centered model. It also incorporates principles consistent with the OTPF-3 and other models that emphasize occupation-based practice, client-centered practice, and the importance of environmental and contextual factors.

The Medical Model and the Rehabilitation Model

The term *medical model* refers broadly to a practice approach that focuses on the management of trauma and disease and in which the clinician is viewed as the authority.¹⁷ This model proposes that disability is the direct result of disease and, therefore, requires treatment by medical professionals.¹⁸ While the medical model is most directly related to a remediation-focused approach to therapy, it is also foundational to the rehabilitation model. The rehabilitation model arose primarily after World War II, when there was an enormous need for physical and vocational rehabilitation services for returning service members.¹⁹ Early rehabilitation programs focused on task analysis, compensatory strategies, and adaptive equipment to support function in daily activities.⁶ Using compensatory strategies to help clients regain function, "occupational therapists took over where medicine left off."^{6(p24)} Interestingly, despite the long history of the rehabilitation model, Dutton noted that rehabilitation was not identified as a specific frame of reference in an entry-level OT textbook until 1986.²⁰

The International Classification of Functioning, Disability, and Health Model

In developing the ICF model, the World Health Organization contended that neither the medical model nor the social model could adequately describe disability and its impact on participation and health.¹⁸ Medical diagnosis alone was seen as insufficient to predict service needs or functional outcomes, and the ICF was proposed to provide a new way of framing disability.¹⁸ Intervention under the ICF model can be either remediation based or adaptation based. The ICF also includes language emphasizing the importance of environmental context, stating that functional outcomes are the result of interactions between health conditions, environmental factors, and personal factors.¹⁸ The Rehabilitation Frame of Reference and the ICF share a number of similarities, most notably (1) the idea that intervention goes beyond remediation to include strategies to promote function even if impairments remain unchanged, and (2) the emphasis on context, which underlies environmental modification principles used in the Rehabilitation Frame of Reference.

The Client-Centered Model

Occupational therapists view the client as actively engaged and motivated to achieve personally meaningful goals.²¹ The client is typically an individual, but may also be a group or organization.² In contrast to the medical model, in which the patient is often regarded as a passive recipient of services, the client-centered model promotes an active collaboration between client and professional in which the professional strives to understand the client holistically within her or his context.^{6,21} The Rehabilitation Frame of Reference is inherently client centered because it teaches clients to compensate for temporary or permanent impairments by modifying valued activities and occupations.

Theoretical Assumptions

Dutton identified the following five assumptions underlying the Rehabilitation Frame of Reference^{20(pp166,167)}:

1. Individuals can regain independence using compensation when underlying deficits cannot be remediated.
2. Regaining independence is closely tied to the individual's motivation, which is influenced by values, roles, preferences, and sense of purpose.
3. Motivation for independence cannot be separated from the environmental context, which includes characteristics of the setting, the individual's previous life, family and social support and resources, and cultural background.
4. Certain psychosocial and cognitive skills are needed for the individual to achieve independence because implementing adaptive techniques requires motivation and understanding.
5. The therapist's clinical reasoning should follow a top-down approach.

Evaluation (Function/Dysfunction Continua and Indicators)

OT evaluation includes the development of an occupational profile and an analysis of occupational performance that may include records review, interview with the client or caregiver, observation of the client during activities, observation of the environment, and the use of standardized and/or nonstandardized assessments.² Any of these evaluation techniques can be used with the Rehabilitation Frame of Reference. In some cases, the setting or the client's prognosis may dictate a compensatory or adaptive perspective from the start, but it is also common for the initial evaluation to be performed without a specific expectation of a frame of reference. As noted previously, frame of reference selection can evolve as a client progresses through the continuum of care, and multiple frames of reference can be used simultaneously.

Dutton identified the following components of a top-down approach to evaluation using the Rehabilitation Frame of Reference: (1) identify environmental demands and resources; (2) evaluate motivation, habits, and roles; (3) determine functional abilities; and (4) identify impairments affecting function.^{20(pp167,168)} By integrating these components, an occupational therapist gains an understanding of what is important to the client, what the client can and cannot do, and how the client's context supports or limits function. This understanding allows the

occupational therapist to identify compensatory and/or adaptive approaches to address the functional areas of greatest concern to the client and/or caregiver.

Function and Dysfunction Continua

According to Mosey, a *function–dysfunction continuum* is “a delineation of the component parts of the specified area addressed in the frame of reference.”^{14(p13)} Although there is no set number of continua required, Mosey noted that continua should be mutually exclusive and should cover all the elements of function to which the frame of reference applies.¹⁴ Individuals with physical impairments may experience dysfunction in any of the occupations identified in the OTPF-3. Therefore, function–dysfunction continua in the Rehabilitation Frame of Reference include:

1. ADLs
2. IADLs
3. Work and education
4. Play and leisure
5. Social participation
6. Rest and sleep

Each of these occupations is discussed in detail in other chapters, along with specific assessment tools and techniques that can be used in the evaluation of each occupation.

Indicators of Function and Dysfunction

During the evaluation process, the occupational therapist can use interview, observation, and assessment to determine a client’s location on the continuum between function and dysfunction for each area of occupation. It is important to note that “function” is not the same for every client. Function is relative to the client’s age, medical condition, health status, cultural and contextual background, environment, and personal values and priorities. That said, the following are general indicators of function in occupations, consistent with the Rehabilitation Frame of Reference. These indicators of function apply to each of the six continua identified earlier.

1. The client is able to engage in activities of choice in a way that she or he finds satisfying and meaningful.
2. The client is able to complete activities with an acceptable level of independence.
3. The client is able to complete activities with an acceptable level of safety.
4. The client is able to complete activities with an acceptable level of timeliness or efficiency.
5. The client is able to complete activities with an acceptable level of performance or accuracy.

Dysfunction is considered to be present when these indicators are absent or limited. Table 33-1 provides examples of dysfunction and function for each of the six continua. Each example of function incorporates an intervention consistent with the Rehabilitation Frame of Reference.

Table 33-1. Examples of Dysfunction and Function within Each of Six Continua

CONTINUUM	DYSFUNCTION	FUNCTION
ADLs	William has Parkinson disease and is no longer able to safely shower as a result of impaired dynamic balance. He requires his spouse’s assistance, which he finds unacceptable.	William showers safely and independently with the use of a transfer shower bench, grab bars, handheld shower, and long-handled sponge.
IADLs	Sam has relapsing-remitting multiple sclerosis (MS). She lives alone, except for her miniature poodle Suzy. Some days, Sam is so fatigued that she is not able to walk Suzy. Sam feels guilty and depressed when she cannot fully care for her pet.	Sam hires a contractor to fence her backyard. This allows Sam to let Suzy outside for safe exercise on days when she feels too tired to take Suzy for a walk.
Work and education	Jing has returned to work as a paralegal following a spinal cord injury, but it takes significant time for her to propel back and forth to the copy room. Jing worries that she is no longer as efficient as she used to be.	Jing receives a reasonable accommodation to have her work area relocated so that she is closer to the copy room and can perform her job more efficiently.
Play and leisure	Owing to age-related loss of visual acuity, Evelyn is no longer able to complete the intricate needlework projects she loves.	Using a lighted stand magnifier, Evelyn returns to this valued leisure activity and creates needlework projects with a level of detail that she finds satisfying.

CONTINUUM	DYSFUNCTION	FUNCTION
Social participation	As his COPD has worsened, Draven has become reluctant to leave his home because of increased difficulty breathing. He misses the weekly card games with friends at his church.	Draven uses a portable oxygen concentrator that allows him to leave the house and enjoy social activities with friends.
Rest and sleep	Mateo has late-stage Alzheimer disease and is experiencing increased restlessness at night and difficulty sleeping.	Mateo's caregivers modify his bedroom to make it more conducive to sleep. By addressing temperature, lighting, and noise in the environment, the caregivers are able to help Mateo sleep more soundly.

ADLs, activities of daily living; COPD, chronic obstructive pulmonary disorder; IADLs, instrumental activities of daily living.

Intervention (Postulates Regarding Change)

OT intervention is informed by the results of initial and ongoing evaluation, the client's goals, the chosen frame of reference, and the clinician's synthesis of the available evidence. OT intervention focuses on the interaction of the client, the environment, and the client's occupations or activities.² While remediation-based frames of reference focus on decreasing deficits in body function, the Rehabilitation Frame of Reference focuses primarily on modifying activities and the environment to allow clients to make the best use of their strengths.

According to Mosey, *postulates regarding change* are statements, consistent with a theoretical base, that explain how change is expected to occur.¹⁴ In other words, how and why does a client move from dysfunction to function? The first postulate regarding change in the Rehabilitation Frame of Reference is that the use of compensatory and adaptive approaches can improve the client's ability to participate in desired occupations with greater independence, safety, efficiency, accuracy, and satisfaction. Occupational therapists using this approach assume that a client's deficits cannot be remediated (at least at the present time) by therapeutic interventions. This does not mean, however, that the client's functional status cannot be improved. Compensatory techniques such as one-handed dressing or energy conservation strategies can and do improve function, even when the underlying deficits are not likely to change. Adaptive approaches such as assistive technology or environmental modifications can substitute for lost abilities, thereby moving the client toward greater function in a given continuum. For example, in the continuum of ADLs, a teenage boy with hemiplegia following TBI may experience dissatisfaction and embarrassment when his mother helps with his toilet hygiene. A bidet toilet seat can increase his functional independence and satisfaction with this task, even though the underlying deficit (loss of motor function) remains unchanged.

The second postulate is that a compensatory or adaptive approach is client centered. Therapists using the Rehabilitation Frame of Reference teach clients to recognize and maximize their own strengths as a way to compensate for impairments that cannot be changed. According to Kramer and Hinojosa,²² the process of *occupational synthesis* is critical to OT practice. These authors define occupational synthesis as the process through which the client internalizes activity modifications that have been implemented in OT.²² Once clients are able to do this, they can expand on principles learned in therapy and apply compensatory and adaptive strategies to new problems that arise over time; clients become their own problem solvers. This process is inherently client centered because it requires both the client and therapist to collaboratively develop strategies that reflect the client's values, goals, and context. Kramer and Hinojosa noted that in some cases, the client is not able to articulate goals and choices, and in these instances, the therapist must seek other sources of information in order to maintain a client-centered approach.²²

The third postulate is that compensatory and adaptive approaches require collaboration that recognizes client context and motivation. This final principle builds on the concept of client-centeredness. In order for the occupational therapist to understand which occupations are most important to the client or caregiver, she or he must have the ability to create a meaningful occupational profile and to augment that profile over time. A comprehensive occupational profile not only identifies client needs and priorities and guides intervention decisions; it also forges a relationship between the client and the therapist that is critical to the success of a compensatory and/or adaptive approach. If the client and occupational therapist cannot communicate honestly and effectively, it will be difficult for the therapist to design interventions that address the activities that the client really cares about in a way that recognizes the client's

unique context. For example, the nicest shower bench will fail to promote independence if it does not fit in the client's bathroom. And a perfectly designed orthosis will fail to improve performance at work if the client is embarrassed to wear it. Clients and therapists must communicate effectively to avoid recommendations that do not align with the client's values and context.

Intervention Techniques

Common intervention techniques consistent with the Rehabilitation Frame of Reference include (1) assistive technology, (2) compensatory techniques, (3) environmental modifications, and (4) orthotics and prosthetics. Each intervention technique has the potential to address the characteristics of dysfunction identified earlier. Please see the relevant chapters in this textbook for more information about the application of each technique to specific conditions.

Assistive Technology

Although different definitions exist, *assistive technology* has been formally defined in the Assistive Technology Act of 1998, as amended in 2004 as “any item, piece of equipment, or product system, whether acquired commercially, modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities.”²³(sect 3,line 4) This is a broad definition, inclusive of both specific rehabilitation technology and mainstream technology. This term encompasses *adaptive equipment* as well as *assistive devices*, and *adaptive technology*. In practice, therapists may use these terms in slightly different ways, but for the purposes of this chapter, the broad term assistive technology is used.

Assistive technology includes everything from low-tech, low-cost items such as reachers and sock aids, to high-tech, high-cost items such as wheelchairs, communication systems, and electronic aids for daily living (EADLs). What these items all have in common is that they help individuals be more independent using a device to compensate for an underlying impairment that is limiting function. The use of assistive technology as a therapeutic intervention requires significant training and education to make sure the client understands how and why to use the device. Figure 33-3 shows several pieces of adaptive equipment designed to increase independence with self-care in a home or institutional environment.

Figure 33-3 Adaptive equipment to increase self-care independence. (A) Raised toilet seat; (B) Shower bench and (C) Commode and bed rail.

Compensatory Techniques

Compensatory techniques, or *compensatory strategies*, are intentional ways of performing an activity differently. Common ways in which activities or occupations can be modified include (1) position of the activity, (2) position or location of the person, (3) materials and tools used to complete the activity, (4) sequence of steps, (5) time requirements, and (6) performance

requirements. For example, an occupational therapist working with an older adult with CHF in a home environment might educate the client about compensatory techniques to reduce fatigue during self-care. The therapist might suggest that the client gather all her clothes in one place rather than walk back and forth, that she sit rather than stand while dressing, or that she reduce the number of steps in her grooming routine. Each of these is a compensatory technique that modifies the client's self-care tasks so they require less energy and can, therefore, be completed with greater independence and efficiency.

Environmental Modifications

Environmental modifications are changes to a client's environment, most commonly the physical environment, but sometimes the social (human or nonhuman) environment as well. See Table 33-2 for examples of each. These interventions can include changes designed to address any of the indicators of dysfunction discussed previously: problems with participation, independence, safety, efficiency, performance, or satisfaction. For example, an occupational therapist might recommend that the bed of a nursing home resident with dementia be repositioned so that the resident can more easily see visitors who enter her room. This modification to the environment has both physical and social components, and it helps to address the dysfunction in participation that may result if the resident is unable to visually engage with visitors, or if she becomes agitated when people approach her bed unexpectedly. It should be noted that environmental modifications are an example of an adaptive intervention that can be implemented even if the client is not able to actively engage in therapy.

Table 33-2. Examples of Modifications to the Physical and Social Environments to Improve Function

PHYSICAL ENVIRONMENT	SOCIAL ENVIRONMENT
Increasing lighting levels to compensate for decreased visual acuity	Limiting visitors for an agitated individual following traumatic brain injury
Reorganizing spaces for greater efficiency and safety	Providing a referral for respite services to decrease strain on a caregiver
Limiting clutter to compensate for decreased attention to task	Providing pet therapy services to decrease depression in a long-term care setting
Installing a wheelchair ramp to allow independent access to the home	Participation in group services or activities to promote social engagement and motivation

Orthotics and Prosthetics

An orthosis is “any of a class of external orthopedic appliances, braces, or splints applied to the body to stabilize, control, limit, or immobilize a body part, prevent deformity, protect against injury, or assist with function.”²⁴ Orthoses can have both remedial and compensatory purposes. For example, a dynamic hand splint could be used to restore range of motion following tendon surgery; this would be a remedial use of an **orthotic**. A wrist cock-up could be used to substitute for function in an individual with a cervical level spinal cord injury; this would be a compensatory use of an orthotic. Figure 33-4 shows a customized orthosis with a universal cuff used to promote independence in eating.

Figure 33-4 Use of an orthosis to promote independence with eating.

A prosthesis is a “replacement of a missing part by an artificial substitute, such as an artificial extremity.”²⁵ Prostheses are one component of the intervention approach for many individuals with amputations. Independence with ADL is a common goal after amputation, and occupational therapists can recommend adaptive equipment, compensatory techniques (such as switching hand dominance or using one-handed techniques), environmental modifications, and **prosthetics** to help clients achieve this goal.²⁶

Evidence

Current research supports the use of compensatory and adaptive approaches for a variety of conditions. There is evidence that assistive technology, compensatory strategies, and environmental modifications can have beneficial impacts on function, although some of the studies conducted have had relatively small samples or less rigorous designs. See the Evidence table at the end of this chapter for an overview of the best evidence. Compensatory and adaptive interventions are also consistent with the current literature that validates the importance of using real activities to engage people more effectively and to promote carryover of skills and techniques taught during therapy. The Rehabilitation Frame of Reference guides therapists toward the use of “occupation as ends,” because the focus is on changing task demands or aspects of the environment, rather than on changing the person.²⁷

Although most of the interventions consistent with the Rehabilitation Frame of Reference are evidence based, the use of orthoses such as splints and slings either to improve function or to remediate deficits such as pain, spasticity, and limited range of motion is more controversial. This is especially true in the treatment of stroke. In AOTA’s Occupational Therapy Practice Guidelines for Adults with Stroke, the authors wrote, “In conclusion, the evidence to support the use of positioning devices, orthoses (splints), and stretching seems to be limited. All of the included studies report nonsignificant findings for improving UE function and activity participation.”^{28(p50)} This conclusion is consistent with several systematic reviews that have analyzed the effectiveness of UE splints and slings and found little or no evidence that these devices improved function for people with strokes.²⁹⁻³¹

Clinically, there are several important cautions to keep in mind when using the Rehabilitation Frame of Reference. First, although compensatory and adaptive approaches can improve function, they should be used with consideration of the client’s condition and prognosis. In neurological rehabilitation, focusing on compensation when there is still the potential for remediation can suppress full recovery and contribution to the development of learned non-use.³² In these cases, it may be best for therapists to use the Rehabilitation Frame of Reference in combinations with remediation-based interventions. It is also important for therapists to be aware of the potential psychosocial impacts of a compensatory or adaptive approach. Some clients may perceive assistive technology as a sign of disability and may fear stigma associated with completing daily occupations in a modified way.³³ Other clients may view the use of assistive technology and compensatory techniques as an admission that little or no further recovery is possible.³³ Occupational therapists should use the principles of collaboration and client-centered practice to address these issues.

CASE STUDY

Client Information

Ray is a 78-year-old man with COPD, diabetes, and a recent history of depression. His wife of many years died 4 years ago, and Ray now lives with his two small dogs in a ranch-style house in a rural area. His oldest daughter lives nearby and comes several times a week to help Ray with housework and errands. Although Ray has a car and a license, he rarely drives. He spends most of his time sitting indoors and watching TV, but he does prepare simple meals, care for his dogs, manage his self-care, and occasionally work on Sudoku puzzles. Ray was hospitalized a week ago for exacerbation of his COPD symptoms. He has now returned home and is receiving home health OT, physical therapy, and nursing services. He uses supplemental oxygen at home.

Assessment Process and Results

Process

On her first visit, the occupational therapist completed Ray's occupational profile through interview and talked with him about his priorities and goals. Ray said his top priority was to stay in his own home and take care of himself and his dogs. He said he liked to get outside and "putter" in his shop, but had not been able to do this lately because of fatigue and difficulty managing his oxygen. Next, the occupational therapist completed a quick screening of UE function (range of motion, strength, and sensation), followed by an assessment of ADLs. This assessment was modified to some extent because of Ray's fatigue. Ray was observed during a transfer from bed to chair, simple grooming at the sink, and partial dressing (donning a jacket and attempting to don socks and shoes). Ray stated he had not been able to get into the bathtub to take a shower since returning home. The therapist was able to complete an observational assessment of functional mobility as Ray moved around the bedroom and bathroom using a rolling walker. She also completed an informal assessment of the home environment, including a survey of adaptive equipment and safety elements. Further conversation helped her gather information about how much assistance Ray was currently requiring with IADL tasks such as shopping, cooking, pet care, and getting to appointments. Owing to Ray's low activity tolerance, the occupational therapist decided to complete screenings of cognition and depression at a later visit.

Results

Ray ambulated with a rolling walker and was able to complete functional transfers. Shortness of breath and evident fatigue were observed during functional mobility, and the client required supplemental oxygen. UE range of motion was within functional limits and strength was generally 3+ to 4. Ray was independent with simple grooming (at sink) and dressing (seated), but was not able to don socks and shoes due to dyspnea when bending down. He was not able to shower and had no shower equipment. He reported that he was able to prepare simple meals with difficulty, take care of his dogs with difficulty, and do a very small amount of housework, but that he relied on his daughter for shopping, errands, appointments, housework, and socialization.

Occupational Therapy Problem List

- Fatigue and shortness of breath, made worse by activity
- Low endurance and limited activity tolerance
- Decreased UE strength
- Limited functional mobility due to fatigue, weakness, and limited endurance. Using a rolling walker at the time of evaluation
- Independent in most basic self-care, but with extra time and difficulty
- Unable to take shower due to fatigue, shortness of breath, and inability to transfer into the tub
- Requires support with IADLs (laundry, shopping, community mobility)
- Difficulty with IADLs he or she does complete, including meal preparation and pet care
- Difficulty bending down, such as to reach dogs and put on socks and shoes
- Difficulty completing skin inspection and diabetic foot care
- Loss of previously valued occupations
- Limited social interactions

Occupational Therapy Goal List

- Client will complete daily grooming and dressing with modified independence using energy conservation techniques, a reacher, and a sock-aid.
- Client will safely complete bathing with modified independence using energy conservation techniques, a transfer tub bench, grab bars, and a long-handled sponge.
- Client will safely complete toileting with modified independence using energy conservation techniques and a bedside commode over the toilet.
- Client will complete tub and toilet transfers with modified independence using adaptive equipment and techniques.

- Client will complete skin inspection and diabetic foot care with modified independence using a long-handled inspection mirror, reacher, and long-handled sponge.
- Client will complete simple meal preparation and cleanup using an assistive mobility device (rollator walker), energy conservation techniques, and environmental modifications to improve safety and efficiency.
- Client will complete daily pet care with modified independence using energy conservation techniques and environmental modifications to improve safety and efficiency.

Intervention

Because of the chronic nature of Ray’s primary conditions, the Rehabilitation Frame of Reference is an appropriate guide for OT intervention. Ray’s goals focus on those tasks that he considers most important for his independence and safety at home. Intervention would begin with basic ADL tasks, incorporating adaptive equipment and education on energy conservation and task simplification. As Ray begins to master these compensatory techniques, OT intervention can progress to addressing more complex occupations, such as showering, toileting, cooking, and caring for his pet. The longer term goal would be to help Ray maximize his participation in valued occupations and to improve his quality of life.

1. **Adaptive equipment:** Reacher, sock-aid, long-handled sponge, long-handled inspection mirror, handheld shower, tub bench, three-in-one bedside commode, and rollator walker
2. **Compensatory strategies:** Energy conservation techniques including pacing, taking breaks, sitting, and breaking tasks down; and task simplification techniques to make valued occupations as easy as possible (e.g., modifications to his pet-care routine could include automatic feeder, a riser for food and water bowls, or the use of a pet-walking service)
3. **Environmental modifications:** Reorganize furniture and/or personal items for improved mobility, safety, and efficiency; place chairs strategically for breaks; reduce clutter and trip hazards (especially important with use of home oxygen); improve lighting in bathroom and hallway; install bathroom grab bars; consider emergency response options

Best Evidence for Rehabilitation Interventions in Occupational Therapy

Intervention and Reference	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Activity modification for dementia ³⁴	Activity modification categories included (1) matching client skills and interests, (2) cuing, and (3) compensatory and environmental strategies.	Ten studies addressing self-care and leisure occupations for older adults with Alzheimer disease (7 Level I and 3 Level III)	Varied by study	Systematic review Level I	Yes. Strong evidence that compensatory strategies including environmental modifications and simple adaptive equipment were effective for outcomes, including independence, quality of life, affect, and caregiver burden.	Not reported

Intervention and Reference	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Home modification for community-dwelling adults ³⁵	A variety of home modification interventions within the OT scope of practice were provided to community-dwelling adults with health conditions. Outcomes included functional performance, caregiving, and falls.	Thirty-six studies (25 Level I, 3 Level II, and 8 Level III)	Varied by study	Systematic review Level I	Yes. Strong evidence that home modification improved function and reduced fall rate and risk for adults with various health conditions. Moderate evidence that home modifications reduced caregiver burden.	Not reported
EPADs for acquired brain injury (ABI) ³⁶	Intervention studies evaluating the effectiveness of various EPADs for adults with ABI. EPADs included mobile phones, smartphones, PDAs, voice memos, pagers, and laptops. Multiple outcomes.	Twenty-three studies (1 Level I study, 18 Levels II/III, and 4 Level IV); total N = 357 (77% male)	Varied by study	Systematic review Level II because of lower levels of evidence of the included studies	Yes. Moderate evidence to support the use of EPADs as a compensatory device to support function for people with ABI. More high-quality studies are needed.	Eight studies reported or allowed calculation of effect size (six "large" and two "medium").
Home modification for fall prevention ³⁷	Various interventions within the OT scope of practice to reduce falls for community-dwelling adults. Interventions were classified as (1) multifactorial, (2) physical activity, and (3) home assessment and modification.	Thirty-three studies (31 Level I and 2 Level II)	Varied by study	Systematic review Level I	Yes. Strong evidence that a multifactorial approach reduced number of falls, reduced fear of falling, and helped preserve independence. Moderate evidence that physical activity or home assessment/modification used alone had these benefits.	Not reported

Intervention and Reference	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Adaptive devices after total hip replacement (THR) ³⁸	Patients in the experimental group received additional OT training and monitoring of adaptive equipment use (in person and by phone) over the 6 weeks following THR. Outcomes included pain, muscle strength, independence in ADL.	N = 40; diagnosis of osteoarthritis and THR, aged > 60	Three home visits and 18 phone calls to monitor adaptive equipment use over the 6-week postoperative period	Randomized controlled trial Level I	Yes. Both intervention and control groups achieved statistically significant improvements in pain, muscle strength, and ADL independence between pretest and posttest. However, the improvements made by the experimental group were significantly greater than those of the control group.	Within-group and between-group differences were statistically significant for all outcomes ($p < 0.001$).

Motor Learning and Task-Oriented Approaches

Dawn M. Nilsen and Glen Gillen

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Define motor learning and understand the differences between changes in performance, learning, and generalization of learning.
2. Describe the similarities and differences between various motor learning theories.
3. Define the various types of feedback and practice conditions, and compare and contrast their impact on retraining/training of motor skills.
4. Describe the theoretical underpinnings and assumptions of the occupational therapy task-oriented approach (OT-TOA).
5. Describe and apply evaluation and intervention strategies that are consistent with the OT-TOA.

CHAPTER OUTLINE

Introduction
Motor Learning
Occupational Therapy Task-Oriented Approach
Case Study

TERMINOLOGY

Augmented feedback: information about task performance that is fed back to the patient by artificial means; sometimes called extrinsic feedback.

Blocked practice: a practice schedule in which many trials on a single task are practiced consecutively and uninterrupted by practice of other tasks.

Continuous task: a task in which the action is performed without a recognizable beginning or end.

Discrete task: a task that has a recognizable beginning and end.

Distributed practice: a practice schedule in which the duration of rest between practice trials is equal to or greater than the time spent in practice.

External focus of attention: attention directed outside the body to an object or environmental goal.

Inherent feedback: information that is normally received during performance of a task; sometimes called intrinsic feedback.

Internal focus of attention: attention directed to locations inside the body (e.g., motor or sensory information).

Knowledge of performance (KP): augmented feedback about the nature of performance (movement patterns).

Knowledge of results (KR): augmented feedback about the outcome of the performance with respect to the task goal.

Massed practice: a practice schedule in which the amount of rest between practice trials is relatively short, often less than the length of the practice trial.

Serial task: a task consisting of several discrete tasks strung together to make a whole; order of the actions is usually critical for successful performance.

Introduction

As indicated in Chapter 16, task-oriented approaches (i.e., task-specific training, repetitive task practice, functional task practice) are considered the most current approaches used to address occupational performance deficits related to impaired motor function and motor control for those

living with neurological impairments as a consequence of brain damage.¹ These approaches are guided by current understandings of motor control, motor development, recovery of function, and contemporary motor learning principles. In these approaches, it is assumed that movement emerges from a dynamic interaction between multiple systems in the brain, is organized around a specific goal, and is constrained by the environment.²

Task-oriented approaches assume that people learn or relearn motor skills by actively attempting to solve motor problems during the performance of functional tasks. Thus, effective movement strategies and patterns emerge from the interaction of persons with the environment as they attempt to achieve a specific task goal.^{1,2} The occupational therapy task-oriented approach (OT-TOA), originally developed by Mathiowetz and Bass-Haugen in 1994, is an example of one such approach.³ This chapter provides an overview of motor learning theories and key motor learning principles, as they are generally regarded as a common component of task-oriented approaches. Afterwards, the theoretical base, and evaluation and intervention principles associated with the OT-TOA are highlighted to provide specific examples of task-oriented approaches.

Motor Learning

Practitioners are faced with the challenge of assisting patients to learn or relearn motor skills that facilitate engagement in occupation. Motor learning is defined as “a set of processes associated with practice or experience leading to relatively permanent changes in the capability for skilled movement.”⁴ The notion of a relatively permanent change in skilled movement distinguishes learning from changes in motor performance, which are temporary changes in motor behavior seen during practice.⁴ It is the retention of motor skills and the transfer of these skills to novel situations, known as generalization, that indicates learning.^{2,4} The field of motor learning has provided valuable insights about how skilled actions are acquired, modified, retained, and transferred as the result of practice. These insights can guide practitioners as they assist patients to both reacquire motor skills that were lost due to disease or injury and acquire new motor skills in order to compensate for lost function.

Motor Learning Theories

Overtime, various motor learning theories have been proposed. These theories were informed by current theories of motor control and were developed based on the current knowledge of the structure and function of the nervous system.^{2,4} Table 34-1 provides a brief overview of common motor control and motor learning theories. It should be pointed out that no one motor control or motor learning theory accounts for all experimental evidence compiled to date. Nonetheless, key principles related to the promotion of skill acquisition and generalization of learning have emerged from these theories and motor learning research. The following sections highlight key motor learning principles and provide examples of the practical application of these principles.

Table 34-1. Summary of Motor Control and Motor Learning Theories

THEORY	KEY COMPONENTS OF THEORY
Motor Control Theories^{2,4}	
Reflex theory	<ul style="list-style-type: none"> • Stimulus–response view of motor control • Complex patterns of movement are the result of combining individual reflexes.
Hierarchical theory	<ul style="list-style-type: none"> • Top–down organizational control of movement with higher levels always exerting full control over lower levels
Motor programming theory	<ul style="list-style-type: none"> • <i>Central motor program</i> contains the “rules” for generating an action. • Program can be activated by sensory input or by central processes.
System theory	<ul style="list-style-type: none"> • Describes the body as a <i>mechanical system</i> that is subject to both external (e.g., gravity) and internal forces (e.g., inertial forces) • <i>Self-organization</i>: movement emerges from an interaction of multiple systems—no need for “higher centers” or “central motor program” • <i>Nonlinearity</i>: motor output is not proportional to input—variability expected and needed in the system • <i>Control parameters</i>: a variable that regulates a change in behavior (e.g., velocity may be considered the control parameter that shifts the action of walking to running) • <i>Attractor states</i>: preferred patterns of movements that are highly stable • <i>Attractor wells</i>: the degree of flexibility to change an attractor state: <i>shallow well</i>—unstable pattern that is easy to change; <i>deep well</i>—stable pattern that is difficult to change
Ecological theory	<ul style="list-style-type: none"> • Motor control evolved so that animals can cope with their environment: <i>perception–action coupling</i>. • Gibson’s theory of affordances—perception of environmental factors that are critical to the task
Motor Learning Theories^{2,4}	

THEORY	KEY COMPONENTS OF THEORY
Schmidt's schema theory	<ul style="list-style-type: none"> • Draws heavily on <i>motor programming theory</i> of motor control • Emphasize on open-loop control processes and the development of the <i>generalized motor program</i> (GMP), which contains the <i>rules</i> for creating the pattern of muscle activity needed to perform the movement • After a movement is made, there are four elements available for short-term memory storage: (1) initial movement conditions, (2) parameters used in the GMP, (3) outcome of the movement (knowledge of results), and (4) sensory consequences of the movement (knowledge of performance). This information is stored as two schemas: <i>recall schema</i> (motor) and <i>recognition schema</i> (sensory). • <i>Recall schema</i> is used to select a specific set of responses and the <i>response schema</i> is used to evaluate the responses. • <i>Learning</i> occurs as a result of the updating of the two schemas each time a movement is attempted, and it is augmented by the amount of practice and variability of practice.
Ecological theory	<ul style="list-style-type: none"> • Draws heavily on <i>systems</i> and <i>ecological theories</i> of motor control • During practice, there is a search for <i>optimal strategy</i> to solve the task problem—search for most salient perceptual cues and optimal motor response. • <i>Learning</i> occurs as a performer searches for the optimal solution; this process strengthens perception–action coupling, and is augmented by helping the learner understand the nature of the perceptual/motor workspace, identifying the natural search strategies employed by the learner, and using augmented feedback to aid the search for the optimal solution.
Fitts and Posner three-stage model	<ul style="list-style-type: none"> • <i>Cognitive stage</i>: learner is figuring out what is to be done; determining appropriate strategies to complete the task. Effective strategies are maintained and ineffective ones are discarded. Performance is variable, but improvements are large. High cognitive demands are placed on the learner. The therapist uses instructions, models, feedback, etc., to assist in learning the task at hand. • <i>Associative stage</i>: learner determines the best strategy for the task and is now refining it. Performance is less variable and improvements are slower. Cognitive demands decrease. • <i>Autonomous stage</i>: skill is performed automatically requiring little attention.
Bernstein's three-stage model	<ul style="list-style-type: none"> • Draws heavily on the <i>systems theory</i> of motor control and solving the <i>degrees of freedom</i> problem • <i>Stage 1</i>: reduction in the number of degrees of freedom that must be controlled—learner will constrain the degrees of freedom and develop an <i>effective strategy</i> for task performance, but the <i>strategy is not energy-efficient or flexible</i>. • <i>Stage 2</i>: release of additional degrees of freedom and muscle synergies are used across multiple joints resulting in <i>well-coordinated movement</i> that is more efficient and flexible. • <i>Stage 3</i>: release of all the degrees of freedom needed for task performance; performer has <i>learned to exploit external and internal forces</i> acting on the system to produce the most coordinated and efficient movement pattern.
Gentile's two-stage model	<ul style="list-style-type: none"> • <i>Initial stage</i>: learner develops an understanding of the task and generates a movement pattern that enables some degree of success; key element of this stage is learning to discriminate between <i>regulatory features</i> (characteristic of environment that determine movement requirements) and <i>nonregulatory features</i> in the environment; high cognitive load. • <i>Later stage</i>: (aka: <i>fixation/diversification</i>) learner is refining the movement so that it can be performed to meet the demands of any situation, and so that it is performed consistently and efficiently. • <i>Closed tasks</i>: environmental conditions are stable and little variability is needed—<i>fixation</i>. • <i>Open tasks</i>: environmental conditions are changing requiring multiple movement patterns—<i>diversification</i>.
OPTIMAL (optimizing performance through intrinsic motivation and attention for learning) theory	<ul style="list-style-type: none"> • Goal-action coupling: learning is associated with structural brain changes and task-specific neural connections across brain regions (functional connectivity). • Evidence demonstrates strong motivational and attentional focus influences motor performance and learning—enhances goal-action coupling. • Key motivational variables include enhanced expectancies for future performance (need high expectancies of success) and learner autonomy (choices and a sense of control). • External focus of attention (concentration on task goal) is critical during practice.

Note: No single theory accounts for all of the experimental evidence to date.

Key Principles

Generally speaking, key motor learning principles include taking into account the type of task to be learned (task specificity), the stage of the learner, the type of feedback provided during the learning process, and how best to structure practice conditions to optimize learning. Each of these are considered in turn and summarized in Table 34-2.

Table 34-2. Key Motor Learning Principles

PRINCIPLES/CONSIDERATION ^{2,4}	EXAMPLE
Stage of the Learner: How Practice is Structure Is Dependent of the Stage of the Learner	

PRINCIPLES/CONSIDERATION ^{2,4}	EXAMPLE
<ul style="list-style-type: none"> • Early stages of learning: focus is on understanding the action goal in a functionally relevant context, identifying key regulatory features in the environment, and attempting to generate a movement strategy that leads to goal attainment. • Later stages of learning: focus is on developing skill; cognitive demands are lower; the general movement strategy is refined through practice so that there is consistency in goal attainment and efficiency in the movement. 	<ul style="list-style-type: none"> • During retraining of drinking from a cup, the therapist uses a cup filled with a desired beverage and makes sure the patient is aware of the task goal (i.e., drinking a cup of coffee using his or her right hand); prior to initiating an attempt to drink from the cup, the therapist asks the patient to describe the size, shape, and weight of the cup, as well as its location on the table surface. The therapist then models the performance of the activity for the patient and asks the patient to perform the task. Feedback is provided (see below) and task attempts are repeated. • During retraining of drinking from a cup, the therapist now uses multiple types of cups that are placed in various locations on the table surface and the patient is encouraged to practice drinking from the various cups. Feedback is provided as needed (see below).
Task Specificity: Learning is Contingent on the Type of Task Being Learned	
<ul style="list-style-type: none"> • Discrete tasks: tasks with a recognizable beginning and end. • Continuous tasks: tasks without a recognizable beginning or end; the task is performed until arbitrarily stopped. • Serial tasks: tasks that contain a series of movements linked together to make a “whole”. • Closed tasks: performed in predictable and stable environments; movements can be planned in advance. • Open tasks: performed in constantly changing environments that may be unpredictable. • Variable motionless tasks: involve interacting with a stable and predictable environment, but specific features of the environment are likely to vary between performance trials. • Consistent motion tasks: involve interacting with environmental features that are in motion, but the motion is consistent and predictable between trials. 	<ul style="list-style-type: none"> • Kicking a ball, pushing a button, standing up from a chair, writing your name • Walking, swimming, driving <p>Playing an instrument, dressing, making a sandwich, lighting a fire Oral care, signing a check, bowling Driving in traffic, walking down a busy street, playing a game of soccer Performing ADLs outside of the home environment Stepping onto an escalator, assembly line work, retrieving luggage from an airport carousel</p>
Feedback: Information Learners Receive about Their Attempts to Learn a Skill can Enhance Learning	
<ul style="list-style-type: none"> • Inherent (intrinsic) feedback: information that is normally received during performance of a task. • Augmented (extrinsic) feedback: information about task or motor performance that is fed back to the patient by artificial means; supplements intrinsic feedback (can be verbal or nonverbal). • Concurrent feedback: information that is provided during task performance. • Terminal feedback: information that is provided after task performance. • Immediate feedback: information that is provided immediately after performance. • Delayed feedback: information that is delayed by some amount of time. • Accumulated feedback: information that represents an accumulation of past performance. • Distinct feedback: information that represents each performance separately. • Knowledge of results: information about the outcome of the task performance. • Knowledge of performance: information about the nature of the task performance. 	<ul style="list-style-type: none"> • Seeing and feeling water spill from a cup as you are attempting to drink • Therapist provides verbal information to a patient “you need to lock your wheelchair brakes before standing up” or nonverbal information (e.g., using a mirror to show the patient their sitting posture). • While the patient is reaching for the toothpaste, the therapist says, “Don’t hike your shoulder.” • After the patient reaches for the cup the therapist says, “You didn’t open your hand wide enough.” • Right after the patient attempts a tub transfer, the therapist says, “That was perfect.” • At the end of the day the therapist says to the patient, “Your transfers were better today, keep checking your wheelchair brakes.” • The therapist says, “Your feet were placed perfectly during 3 out of 5 of your transfers today.” • The therapist says, “Your feet were placed perfectly during that transfer.” • The therapist says, “Your shirt is on backwards.” or “You dropped the cup.” • The therapist says, “Next time dress your right arm first.” or “Your elbow was bent.”
Practice Variables: Learning is Contingent on the Amount and Type of Practice Provided	

PRINCIPLES/CONSIDERATION ^{2,4}	EXAMPLE
<ul style="list-style-type: none"> • External focus of attention: learner’s attention is directed outside the body to an object or environmental goal. • Internal focus of attention: learner’s attention is direct inward toward body movements. • Massed practice: practice time is greater than rest time. • Distributed practice: practice time is equal to or less than rest time. • Blocked practice: repetitive practice of the same task, uninterrupted by practice of other tasks. • Random practice: tasks being practiced are ordered randomly; attempt multiple tasks or variations of a task before mastering any one of the tasks. • Whole practice: task is practiced in its entirety and not broken into parts. • Part practice: task is broken down into its parts for separate practice. • Motivational influences: <ul style="list-style-type: none"> • Enhancing learner’s expectancy of success; practice conditions that enhance self-efficacy or confidence enhance learning. • Autonomy: giving the learner control over certain aspects of practice conditions enhances learning. 	<ul style="list-style-type: none"> • Therapist instructs the patient to focus on keeping his or her cup straight prior to practicing the task of drinking. • Therapist instructs the patient focus on his or her wrist position prior to practicing the task of drinking. • Patient practices the task of typing on a computer for 15 minutes, takes a brief rest for 2 minutes, and then practices typing again for 15 minutes. • Patient practices transferring to and from a commode for 10 minutes, takes a rest for 10 minutes, and then practices transferring again for 10 minutes. • Patient practices moving from sit to stand multiple times in a row. Practice sequence of tasks “A,” “B,” and “C”: AAAAABBBBBBBBCCCCC. • Patient practices transferring to multiple surfaces (couch, toilet, bench, chair, stool, car) in one occupational therapy session. Practice sequence of tasks “A,” “B,” and “C”: ACBACABCCBACABCACABBACCACB. • Patient practices dressing. • Patient practices donning/doffing shirt. • Therapist sets up a just-right-challenge task, highlights the learnability of the task and provides information that helps reduce the perceived difficulty of the task. • Therapist provides the patient with choices over tasks to be practiced, when feedback is provided, or choices over irrelevant aspects of the task (e.g., color of a cup).

ADL, activity of daily living.

Adapted from Table 57-8 in: Gillen G, Nilsen DM. Motor function and occupational performance. In: Schell B, Gillen G, eds. *Willard and Spackman’s Occupational Therapy, Centennial Edition*. 13th ed. Philadelphia, PA: Wolters Kluwer; 2018.

Task Specificity

Discrete, Continuous, and Serial Tasks

Different types of tasks pose different constraints with respect to the information that must be processed, as well as the movement strategies or patterns that must be organized for the patient to be successful.^{4,5} There are multiple ways in which tasks can be categorized. When considering how tasks are organized, tasks can be categorized as discrete, continuous, or serial in nature (Fig. 34-1).^{4,5} Tasks that have a recognizable beginning and end (e.g., kicking a ball or writing one’s name) are considered **discrete tasks**. Discrete tasks are often very brief in duration.^{4,5} Tasks that do not have a recognizable beginning and end are considered **continuous tasks**. Tasks that are rhythmical or repetitive in nature, such as walking and driving, are examples of continuous tasks.^{4,5} **Serial tasks** consist of a series of discrete tasks that are linked together to make a “whole.” Serial tasks are longer in duration and more complex, and the precise ordering of the discrete tasks is an important element of successful task performance.^{4,5} Getting dressed in the morning or cooking a family meal are examples of serial tasks.

Figure 34-1 Examples of tasks categorized based on their organization. A. Discrete task: writing one's name. B. Continuous task: driving. C. Serial task: cooking a meal.

Closed versus Open Tasks

When considering the level of predictability in the environment during task performance, tasks can be categorized along a continuum with the end points being designated as closed or open (Fig. 34-2).^{4,5} Closed tasks are performed in environments that are stable (lacking motion) and predictable (little variability between trials). When performing closed tasks, patients do not have to cope with moment-to-moment variability in the environment. Under these conditions, environmental demands can be evaluated in advance and movements are self-paced.^{4,5} Brushing one's teeth or signing a check are examples of closed tasks. Conversely, open tasks are performed in environments that are variable and unpredictable. When performing open tasks, patients often need to adjust their movement to changing environmental demands.^{4,5} Walking down a busy street or playing a game of soccer are examples of open tasks.

Figure 34-2 Examples of tasks categorized based on predictability in the environment. A. Closed task: brushing one's teeth. B. Open task: walking down a busy street.

Variable versus Consistent Motion Tasks

When the task involves interacting in a relatively stable and predictable environment, but specific features of the environment are likely to vary between performance trials, the task is classified as a variable motionless task.⁵ Performing activities of daily living (ADL) outside the normal home environment are an example of variable motionless tasks. When a task involves motion in the environment, but this motion is consistent and predictable between one trial and the next, the task is

classified as a consistent motion task.⁵ Stepping onto an escalator or assembly line work are examples of consistent motion tasks.

Practitioners should be cognizant of the type of task they are attempting to retrain (e.g., open or closed), as research suggests that motor abilities and functional connectivity within the brain are specific to particular tasks.^{2,4} Therefore, training should be task-specific. For example, if a patient's goal is to be able to feed himself, and upper limb function is a barrier to task engagement, the practitioner should focus on retraining upper limb movements within the context of a feeding task (e.g., reaching; grasping; transporting/manipulating utensils, cups, napkins, and food items while seated at a table), rather than stacking cones while seated at the edge of a therapy mat.

Stage of the Learner

Motor learning theorists propose that learners move through distinct stages when practicing a skill (see Table 34-1).^{2,4} When structuring task practice, it is important to consider the stage of the learner.

During the early stages of learning when patients are new to a task or attempting to relearn a task under new constraints, they need to identify an effective strategy to accomplish the task goal. Cognitive demands are considered to be high during this stage of learning as patients are engaged in problem-solving to determine the best approach. As patients work to identify critical regulatory features in the environment and explore various movement strategies/patterns to attain the task goal, effective strategies are retained and ineffective ones are discarded. Through a "trial and error" process, the person identifies a movement strategy that accomplishes the goal. Gains in performance are typically rapid and large during this phase; however, performance is inconsistent and the movement pattern is not refined in terms of efficiency.^{4,5}

During the later stages of learning, the focus is on adjusting how the skill is performed. The general movement strategy is refined through practice so that there is consistency in goal attainment and efficiency in movement. Cognitive demands are considerably lower during the later phases of learning and performance improvements are more gradual. Overtime, performance becomes more automatic and attention can be directed to other activities (e.g., listening to music or talking on the phone while preparing lunch).^{4,5}

Practitioners should take into account the stage of learning when deciding how to structure practice. For example, during the early stages of learning, patients may benefit from clear instructions to identify the goal of an action, cueing to identify important regulatory features in the environment, and practice conditions that allow patients to explore task-specific movement strategies.^{2,4} During the later stages of learning, the focus may be on setting up practice conditions that allow the patient to repeat the task performance under varying conditions, so that task performance becomes more consistent and the movement becomes more efficient.^{2,4}

Feedback

Feedback includes all of the information that is available to patients while they are attempting to learn a skill, and it is instrumental to the learning process.⁴ Feedback is generally divided into two broad types: (1) inherent or intrinsic feedback and (2) augmented or extrinsic feedback (see Table 34-2).⁴

Inherent (Intrinsic Feedback)

Inherent feedback is information that is available to patients as a natural consequence of task performance.⁴ For example, when patients attempt to feed themselves breakfast, they receive visual information about whether they successfully scooped their eggs onto the fork, as well as somatosensory information about their arm and hand movements. Injury or disease processes that impact the ability to receive or process sensory information can impose limitations on the type and amount of intrinsic feedback that is available to patients.

Augmented (Extrinsic Feedback)

Augmented feedback is information about some aspect of task performance that is fed back to the patient by artificial means.⁴ It is considered to be supplemental to intrinsic feedback. This type of feedback is provided by sources that are external to the person.⁴ For example, when a therapist tells a patient that she needs to hold the fork tightly when attempting to scoop up eggs, extrinsic feedback is provided. This type of feedback may benefit learning by providing⁴: (1) information about what was wrong with the previous performance and (2) suggestions about how to change

performance to achieve the goal. Augmented feedback can either be verbal (form that is either spoken or capable of being spoken) or nonverbal (form not capable of being spoken).⁴

Additional dimensions of augmented feedback include the following⁴:

- Whether the feedback is delivered during the movement (concurrent feedback) or after the movement has been completed (terminal feedback)
- The timing of delivery (immediate or delayed)
- Whether the feedback describes the average performance over a period of time (accumulated) or represents each performance separately (distinct)

Practitioners should consider each of these dimensions independently.⁴ For example, after completion of a commode transfer the therapist immediately says, “You had your feet in the perfect position,” or “That was a perfect transfer.” Both of these are examples of verbal, terminal feedback that was provided immediately. However, notice that the first statement provides information about the nature of the performance, whereas the second statement provides information about the outcome of the performance. Augmented feedback that targets the outcome of the movement or goal achievement (e.g., “you spilled your juice”) is termed **knowledge of results (KR)**, whereas feedback about the nature of performance (e.g., “you didn’t grip the cup firmly enough”) is termed **knowledge of performance (KP)**.⁴ Research suggests that augmented feedback benefits motor learning in patient populations^{4,6-9}; however, the optimal type and delivery schedule remains unclear (see the Evidence table at the end of the chapter).⁸

Practice Conditions

One of the most important things practitioners do when assisting patients to learn or relearn motor skills is structuring practice sessions to optimize learning.² To do this successfully, it is important to understand the practice variables that influence performance and learning. The subsequent paragraphs and Table 34-2 highlight key practice variables.

Attentional Focus

Whether patients’ attention should be directed toward the intended movement effects (external focus) or whether their attention should be directed inwardly toward their body movements (internal focus) is an important consideration when structuring practice.⁴ When instructing a patient to maintain an **external focus of attention** during task practice, attention is focused outside the body on an object or environmental goal.⁴ Research on healthy individuals suggests that an external focus of attention optimizes learning, leading to greater automaticity and better performance outcomes as compared to an **internal focus of attention**⁴; however, results with patient populations are less conclusive. While several studies have provided evidence supporting the premise that an external focus is optimal,¹⁰⁻¹³ others have failed to find superiority of an external focus over an internal focus of attention.^{14,15}

Distribution of Practice: Mass versus Distributed Practice

Another important consideration is how practice should be distributed with regard to the amount of time spent practicing a task versus rest periods. Researchers investigating the effects of practice-distribution describe two main types of practice: massed and distributed practice.⁴ **Massed practice** is a practice schedule in which the amount of rest between practice trials is relatively short, often less than the length of the practice trial. **Distributed practice** is a practice schedule in which the duration of rest between practice trials is equal to or greater than the time spent in practice.⁴ Generally speaking, research suggests that lots of practice is needed to learn or relearn a skill, and that a distributed schedule may be optimal for learning.^{4,16,17}

Practice Variability: Blocked versus Random Practice

When structuring practice, therapists also need to take into account how much variability should be introduced during task practice. There are two main types of practice described in the literature, blocked and random practice (Fig. 34-3).⁴ **Blocked practice** is when the same task is practiced repeatedly and uninterrupted by practice of other tasks (e.g., practicing drinking from a single type of cup repeatedly). Random practice is when the tasks being practiced are randomly ordered so that multiple tasks or variations of the task (e.g., practicing drinking using multiple types of cups) are attempted before any one task or variation is mastered.⁴ A large body of research suggests that blocked practice improves performance during skill acquisition, while random practice is optimal for learning (retention and generalization).^{4,17,18}

Figure 34-3 Practice variability. **A.** Blocked practice: practicing drinking from a single type of cup repeatedly. **B.** Random practice: practicing drinking from multiple types of cups placed at different locations on the table.

Whole versus Part Practice

Decisions also need to be made with respect to whether a patient should practice a task in its entirety (whole practice) or whether the task should be broken down into smaller parts (part practice).⁴ Generally speaking, if a task cannot be divided into component parts (e.g., discrete tasks like standing up from a chair) and the patient has the requisite motor capacity, the task should be practiced in its entirety. However, if a task can naturally be divided (e.g., serial tasks like making a family meal) into component parts, then part practice is reasonable to consider.^{2,4,5}

Motivation

Finally, motivational influences on learning should be considered. In the past, motivation was thought to have an indirect effect on motor learning. It was thought that motivating practice conditions encouraged a person to practice more and that a greater amount of practice enhanced learning.⁴ However, recent research suggests that motivation may directly influence the learning process as conditions that enhance a learner's performance expectancies or support the need for autonomy have been shown to enhance motor learning. The following have been shown to enhance learning⁴:

- Provision of positive feedback
- Providing information that reduces the perceived difficulty of the task
- Providing information that reduces the learner's concerns about their abilities
- Providing the learner with choices over certain aspects of practice conditions (self-controlled practice)

Occupational Therapy Task-Oriented Approach

In the early 1990s, Mathiowetz and Bass-Haugen argued for a shift away from the traditional neurophysiologic approaches that were commonly used in occupational therapy.³ They proposed the OT-TOA that continues to develop.^{3,19-21} The approach is based on current understandings of motor control, recovery, and development as well as contemporary motor learning principles (see Tables 34-1 and 34-2).²¹

Theoretical Foundation

The theoretical basis of the OT-TOA is the systems model of motor behavior, which according to the authors was heavily influenced by the systems model of motor control and development and contemporary motor learning principles.²¹ The model emphasizes the dynamic interaction between the person (client factors, performance skills, and performance patterns), environment (context and activity demands), the occupational performance task (e.g., basic ADL, instrumental ADL, work), and role performance (social participation), and it suggests that behavior emerges from this dynamic interaction. Changes in any one subsystem can influence changes in any of the other subsystems.²¹ Box 34-1 highlights the major assumptions of the OT-TOA based on a systems model of motor behavior.¹

Box 34-1

Assumptions of the Occupational Therapy Task-Oriented Approach Based on a Systems Model of Motor Behavior

- Functional tasks help organize behavior.
- Personal and environmental systems, including the central nervous system, are heterarchically organized.
- Occupational performance emerges from the interaction of persons and their environment.
- Experimentation with various strategies leads to optimal solutions to motor problems.
- Recovery is variable because patient factors and environmental contexts are unique.
- Behavioral changes reflect attempts to compensate and to achieve task performance.

The sections that follow and Box 34-2 describe the evaluation and intervention principles based on the OT-TOA approach and highlight the evidence related to task-oriented approaches.¹

Box 34-2

Evaluation Procedures and Interventions Based on the Occupational Therapy Task-Oriented Approach

Occupational Therapy Task-Oriented Approach Evaluation Framework

Five Main Areas to Assess

1. Role performance (social participation)
2. Roles: Worker, student, volunteer, home maintainer, hobbyist/amateur, participant in organizations, friend, family member, caregiver, religious participant, and other
 - Identify past roles and whether they can be maintained or need to be changed.
 - Determine how future roles will be balanced.
3. Occupational performance tasks (areas of occupation)
 - Activities of daily living: bathing, feeding, bowel and bladder management, dressing, functional mobility, and personal hygiene and grooming
 - Instrumental activities of daily living: home management, meal preparation and cleanup, care of others and pets, community mobility, shopping, financial management, and safety procedures
 - Work and/or education: employment seeking, job performance, volunteer exploration and participation, retirement activities, and formal and informal educational participation
 - Play/leisure: exploration and participation
 - Rest and sleep: preparation and participation
4. Task selection and analysis
 - What client factors, performance skills and patterns, and/or contexts and activity demands limit or enhance occupational performance?
5. Person (client factors; performance skills and patterns)
 - Cognitive: orientation, attention span, memory, problem-solving, sequencing, calculations, learning, and generalization
 - Psychosocial: interests, coping skills, self-concept, interpersonal skills, self-expression, time management, and emotional regulation and self-control
 - Sensorimotor: strength, endurance, range of motion, sensory functions and pain, perceptual function, and postural control
6. Environment (context and activity demands)
 - Physical: objects, tools, devices, furniture, plants, animals, and built and natural environment
 - Socioeconomic: social supports: family, friends, caregivers, social groups, and community and financial resources
 - Cultural: customs, beliefs, activity patterns, behavior standards, and societal expectations

Intervention Principles

- Interventions are occupation based and client focused.
- Keep clients active during treatment.
- Use natural objects and environments.

- Help patients adjust to role and task performance limitations.
- Create an environment that uses the common challenges of everyday life.
- Practice functional tasks or close simulations to find effective and efficient strategies for performance.
- Provide opportunities for practice outside of therapy time.
- Structure practice of the task to promote motor learning.
- Minimize ineffective and inefficient movement patterns.
- Remediate a client factor (impairment) if it is the critical control parameter.
- Adapt the environment, modify the task, use assistive technology, and/or reduce the effects of gravity.
- For persons with poor control of movement, constrain the degrees of freedom.
- For persons who do not use returned function in their involved extremities, use constraint-induced movement therapy (CI therapy).

Adapted from Box 57-3 in: Gillen G, Nilsen DM. Motor function and occupational performance. In: Schell B, Gillen G, eds. *Willard and Spackman's Occupational Therapy, Centennial Edition*. 13th ed. Philadelphia, PA: Wolters Kluwer; 2018.

Evaluation Principles

According to the OT-TOA, five main areas should be the focus of assessment (Box 34-2).^{1,21} Using a top-down approach to assessment, the beginning steps of the evaluation process involve²¹: (1) determining the roles the patient wants, needs, or is expected to perform and (2) the occupational performance tasks the patient needs to perform, as these are the goals of motor behavior. According to Mathiowetz,²¹ role performance can be assessed by interviewing patients and their significant others, or by administering standardized assessments such as the Role Checklist²² or the Occupational Performance History Interview-II.²³ Likewise, identification of important occupational performance tasks (e.g., ADL, IADL, work education) can be determined by interviewing patients or by administering standardized assessments such as the Canadian Occupational Performance Measure (COPM).²⁴

Once relevant tasks have been identified by the patient, actual task performance should be assessed.²¹ For example, if a patient identifies the desire or need to return to the role of “home maintainer” and he indicates that the tasks of meal preparation and cleanup are instrumental to fulfilling this role, then the tasks of meal preparation and cleanup should be assessed. According to the OT-TOA, when evaluating task performance, the therapist must attend to both the outcome as well as the process to determine which person or environmental subsystems interfere with task performance, as these are considered the critical control parameters that have the potential to shift behavior.²¹ Use of standardized assessments such as the Assessment of Motor and Process Skills²⁵ may assist with this process.²¹

Once critical control parameters have been identified, the therapist may need to perform specific assessments of client factors, performance skills, performance patterns, and the environment as appropriate.²¹ Armed with the results of a comprehensive evaluation, the therapist can target intervention to address these critical control parameters.

Intervention Principles

Mathiowetz (2016) outlined the main intervention principles for the OT-TOA, which are summarized in Box 34-2.²¹

Help Patients Adjust to Role and Task Performance Limitations

It is common for individuals with acquired brain injuries such as stroke to be unable to return to their previous roles or perform meaningful tasks in the same way before injury or event. It is important to discuss this with patients and collaborate to develop strategies to adjust to these limitations. The inability to return to previous roles may be a factor in the development of depression (see Chapter 52).

An individual who previously embraced her role as homemaker may not be able to complete the task of shopping for the family secondary to an acquired inability to drive. The therapist may work with that individual to teach strategies to participate in shopping. This may include teaching online shopping skills, investigating grocery store delivery options, and using prepared food delivery services. A young parent with hemiplegia will likely experience difficulty maintaining a parenting role. The therapist must thoroughly investigate potential assistive devices and durable medical equipment that can allow the parent to independently perform parenting tasks, albeit using new methods and procedures.

Create an Environment that Uses the Common Challenges of Everyday Life

Unless occupational therapists are working in home care or performing onsite work evaluations, they will be working in contrived settings such as hospitals, outpatient clinics, and skilled nursing facilities. Contrived environments are not conducive to occupation-based (task-oriented) interventions. In fact, they most likely lead to the use of contrived activities as main intervention approaches.

Environments where occupational therapy takes place must be creatively configured to support the use of the OT-TOA. Suggestions include²¹:

- Replace contrived activities and objects with naturalistic objects that are found in a patient's home, place of business, or recreational environment.
- Create functional areas within the clinic. These may include an office, mini-apartment, meal preparation area, and leisure station (Fig. 34-4).

Figure 34-4 Creating functional settings in the clinic: simulated grocery store. **A.** Simulated grocery aisles with appropriate food items. **B.** Simulated grocery checkout area.

- In instances where this may be difficult in certain facilities, use other functional environments within the facility. This may include the cafeteria, gift store, office space, and chapel.
- Encourage family members to bring in the client's own clothing, grooming equipment, leisure items, and any other commonly used items such as iPads, diaries, and photo albums.

Practice Functional Tasks or Close Simulations to Find Effective and Efficient Strategies for Performance

The OT-TOA is completely consistent with traditional OT principles. The OT-TOA clearly states that the basis of intervention must be the practice of client-chosen tasks, components of those tasks, or close simulations of those tasks. The research is clear that this approach is effective^{26,27} (see the Evidence table at the end of the chapter). On the other hand, little to no evidence exists demonstrating that rote exercise translates into meaningful changes in task performance and the resumption of life roles.

Provide Opportunities for Practice Outside of Therapy Time

As described above, practice is a potent variable in the development of motor skills and skill acquisition. Unfortunately, it has become clear that the amount of time allotted for therapy by insurance may not be sufficient to make these meaningful changes. Therapists must place as much emphasis on structuring client's time use outside of therapy as they do on developing in-clinic intervention plans. Suggestions include²¹:

- Encouraging homework. This may include practicing specific tasks or parts of specific tasks. Identifying tasks that remain challenging. Continuing to participate in tasks that have been mastered.
- For hospital-based therapists, encourage bedside practice of tasks that are safe in between therapy sessions. Tasks can be brought in by family members or low-cost tasks are provided by the therapist. Tasks may include playing cards, practicing manipulating cutlery, practice of rolling and bridging, and bedside ADLs.

Use Contemporary Motor Learning Principles in Training or Retraining Skills

As described above in this chapter and summarized in Table 34-2, integrating motor learning principles into intervention plans based on the OT-TOA is critical to train or retrain skills after an acquired brain injury. Research also supports the use of these principles^{4,7,17} (see the Evidence table at the end of the chapter).

Minimize Ineffective and Inefficient Movement Patterns

After acquired brain injury, it is common for clients to use ineffective and inefficient movement patterns in the limbs and trunk. Mathiowetz identified several strategies that therapists can use to reduce ineffective and inefficient movement (Table 34-3 and Fig. 34-5).

Figure 34-5 Minimizing ineffective and inefficient movement patterns during feeding: task is modified by using a built-up handled utensil and degrees of freedom are reduced by maintaining the elbow in contact with the table surface.

Table 34-3. Strategies to Reduce Ineffective and Inefficient Movement Patterns Based on the Occupational Therapy Task-Oriented Approach

GENERAL STRATEGY	SPECIFIC EXAMPLES
Remediate a client factor (impairment) if it is the critical control parameter.	Multiple client factors can limit the learning or relearning of tasks. Examples include decreased balance, pain, depression, apraxia, visual impairment, weakness, decreased attention, etc. If the therapist determines that a specific client factor is a critical control parameter, remediation may be in order. See Chapters 8, 9, 11, 12, 14, and 17 for more details.
Adapt the environment, modify the task, use assistive technology, and/or reduce the effects of gravity.	Many examples fall under this strategy: prescription of power wheeled mobility, adapting bathrooms and outfitting them with durable medical equipment (decreasing the degrees of freedom) may include using orthotics in the use of adaptive dressing or feeding devices, using mobile arm supports for upper limb retraining, etc.
For persons with poor control of movement, constrain the degrees of freedom.	When movement is complex and requires the control of multiple joints simultaneously, movements tend to become more difficult, less efficient, and less fluid. Strategies to simplify movement and decrease the number of joints moving simultaneously (decreasing the degrees of freedom) may include using orthotics to stabilize or immobilize joints, providing external postural support, retraining movement patterns such as sliding the hand across a surface as opposed to reaching in space, increasing the diameter on the handles of daily living equipment, etc. See Chapters 21, 22, 25, 26, and 27 for more details.
For persons who do not use returned function in their involved extremities, use constraint-induced movement therapy (CIMT).	CIMT is an evidence based upper limb training approach that includes restraint of the unimpaired upper limb, repetitive massed task practice and shaping of the involved limb, and a transfer package to assure carryover of training in real world situations. See Chapters 16 and 36 for more details.

Evidence

When the principles of the OT-TOA approach were first developed and disseminated, several case studies were published demonstrating the early success of this approach and the practical clinical application. Flinn successfully demonstrated the use of the approach to improve occupational performance for an adult living with hemiplegia.²⁸ Gillen published two separate case studies demonstrating how the approach could be utilized to improve ADL²⁹ and functional mobility³⁰ for individuals with ataxia. More recently, Preissner³¹ published a case study demonstrating the use of the OT-TOA for a person with significant cognitive limitations after stroke in which the client successfully met her personal goals.

Almhdawi et al.^{20,32} present the strongest evidence to date regarding the OT-TOA. Their study evaluated functional and impairment efficacies of the OT-TOA on the more-affected upper extremity (UE) of persons post-stroke. The authors used a randomized single-blinded cross-over trial and recruited 20 participants post-stroke (mean chronicity = 62 months) who demonstrated at least 10° active more-affected shoulder flexion and abduction and elbow flexion-extension. Participants were randomized into immediate ($n = 10$) and delayed intervention ($n = 10$) groups. Immediate group had 6 weeks of 3 hours per week TOA intervention followed by 6 weeks of no-intervention control. The delayed intervention group underwent the reverse order. The authors utilized functional measures (Canadian Occupational Performance Measure [COPM], Motor Activity Log [MAL], and Wolf Motor Function Test [WMFT]) as well as impairment measures (UE active range of motion and handheld dynamometry strength). Measurements were obtained at baseline, cross over, and study end. The OT-TOA intervention showed statistically higher functional change scores. COPM performance and satisfaction scores were 2.83 and 3.46 units greater, respectively ($p < 0.001$), MAL amount of use and quality of use scores were 1.1 and 0.87 units greater, respectively ($p < 0.001$), WMFT time was 8.35 seconds faster ($p = 0.009$). The OT-TOA impairment outcomes were not significantly larger than control ones. The authors concluded that the OT-TOA appears to be an effective UE post-stroke rehabilitation approach inducing clinically meaningful functional improvements.

CASE STUDY

Patient Information

Angelina is a 70-year-old Italian-American female who is a retired seamstress. She lives with her husband, Giovanni, in a three-bedroom, single-level home in a suburban area. They have two adult children and four grandchildren. Angelina and Giovanni babysit for their eldest daughter's children, ages 5 and 7, after school 3 days per week. Angelina also performs the majority of the daily household duties, such as cooking, cleaning, and doing laundry.

Angelina was discharged home after receiving intensive inpatient rehabilitation for residual deficits associated with a left-middle cerebral artery stroke. Home occupational therapy services were recommended to assure that Angelina was safe and that she was beginning to generalize strategies she had learned in inpatient rehabilitation to the home environment. Eventually, Angelina would transition to outpatient services.

Assessment Process and Results

Following the evaluation framework of the OT-TOA, the occupational therapist used the Role Checklist to determine what roles Angelina performed prior to the stroke, what roles she feels she is currently capable of performing, and what roles she would like to perform in the future. Angelina identified the roles of “home maintainer” and “caregiver” as being the most important to her and her family. The therapist also administered the Canadian Occupational Performance Measure (COPM) to identify the important occupations that Angelina associated with those roles. She identified the following five occupations as being most important: (1) preparing meals, (2) doing laundry, (3) grocery shopping, (4) getting her grandchildren a snack after school, and (5) playing catch with her 7-year-old grandson. Out of a possible score of 10 (higher scores indicate better performance and greater satisfaction), she scored her present performance in and satisfaction with these five occupations as follows:

- Preparing meals: performance = 3, satisfaction = 2
- Doing laundry: performance = 3, satisfaction = 1
- Grocery shopping: performance = 2, satisfaction = 1
- Getting her grandchildren a snack: performance = 3, satisfaction = 2
- Playing catch: performance = 2, satisfaction = 1

Guided by the COPM results, the therapist evaluated Angelina's ability to engage in the identified tasks using direct observation of task performance focusing on both the performance outcome and the process in order to identify motor behaviors used to accomplish the task goal and to identify environmental supports and barriers to task performance.

The following client factors were identified as significant limiting factors during task performance:

- Sensorimotor: weakness and impaired joint coordination impacting the right dominant upper extremity resulting in reduced upper limb motor skills and impaired dynamic standing balance
- Cognitive: mild word finding deficits impacting verbal communication
- Psychosocial: easily frustrated by limitations

The following environmental factors were identified as barriers to task performance:

- Location of items in the kitchen and in the laundry room—outside of Angelina’s current motor capabilities (e.g., reaching and balance abilities)
- Uneven terrain in the backyard where Angelina typically plays catch with her grandson—creates further demands on postural control
- Family’s limited understanding of Angelina’s challenges
- Angelina’s belief that she should be able to do everything just as she has always done in the past without assistance from anyone.

Occupational Therapy Problem List

- Weakness and difficulty combining joint motions of the right UE resulting in inefficient forward, side, and overhead reaching and a reduced ability to transport and manipulate objects with the right hand
- Decreased dynamic standing balance resulting in the upper limbs being yoked to the postural system during upright activities
- Decreased verbal communication impacting her ability to communicate with family members
- Decreased coping skills

Occupational Therapy Goal List

- Angelina will be able to prepare a simple family meal with minimal family support by 6 weeks.
- Angelina will be able to assist her husband with unpacking the groceries by 6 weeks.
- Angelina will be able to fold the laundry while seated at the kitchen table by 6 weeks.
- Angelina will be able to play a modified game of catch with her grandson by 6 weeks.

Intervention

As Angelina was receiving occupational therapy services in her home, two guiding principles of the OT-TOA were embedded into the intervention plan: (1) create an environment that uses the common challenges of everyday life and (2) practice functional tasks or close simulations to find effective and efficient strategies for performance. What follows is an example of the implementation of the OT-TOA intervention principles with reference to one of Angelina’s goals.

Angelina was initially treated in her kitchen to work on her meal preparation goal and to attempt to remediate her decreased standing balance and dominant upper limb weakness that the therapist identified as critical control parameters.

In her first session, the therapist allowed Angelina to select, out of a choice of three, which simple meal preparation task she would like to perform. Angelina selected making a pitcher of iced tea from powder and a bowl of ramen noodles. The therapist had Angelina standing at her kitchen counter with a chair behind her to begin the simple meal preparation activity. While standing, Angelina was taught to use her impaired upper limb as a stabilizer to compensate for her poor balance. Angelina was provided with an adapted one-handed scissors with suction cups, an adapted cutting board, and a rocker knife. She was taught to open the ice tea powder and ramen package with the adapted scissors and to cut lemons with the adapted cutting board and rocker knife. The therapist instructed Angelina to focus her attention on the closure of the scissors when cutting open the packages, and the position and direction of the movement of the rocker knife when cutting the lemons. The therapist instructed Angelina to cut one of the lemons in half for squeezing and the other lemon into slices and wedges that would be used for garnishing. This allowed Angelina the opportunity to practice using the rocker knife in several different ways. After this simple meal preparation task, the therapist encouraged Angelina to use her impaired arm to wipe down the counter. The therapist provided verbal feedback regarding Angelina’s task performance after the session. As Angelina progressed, she was able to stabilize the lemon with her impaired limb without the cutting board and was able to bilaterally squeeze the juice out of the lemon using a standard juicer. The first meal that Angelina prepared for her family was a

garden salad and traditional pizza from premade dough. Angelina was able to make both the salad and the pizza while in the standing position. She utilized her impaired limb to stabilize the vegetables while slicing and dicing them in preparation of making the salad, and she rolled out the premade pizza dough with both arms using a rolling pin with one built-up handle. For safety, Giovanni transferred the pizza to the oven and eventually to the table. Angelina was able to walk to the table to serve the salad with a rolling kitchen cart.

Evidence Table of Interventions Studies

Intervention	Description	Participants	Dosage	Research Design	Benefit	Statistical Significance
Contextual interference can facilitate motor learning in older adults and in individuals with Parkinson disease (PD). ¹⁸	Study evaluated the effects of blocked practice (BP) versus random practice (RP) conditions on the learning of a peg sequencing task using a Nine-Hole Pegboard. Three patterns were practiced under BP conditions and three patterns under RP conditions. Time to complete the patterns (MT) and the number of errors were recorded. After completing the acquisition phases, participants completed a free and cued recall test as well as a transfer test 24 hours and 1 week later.	Fourteen people with PD (M age = 62.1 years, SD = 7.7 years) and 14 healthy age-matched control participants (M age = 63.2 years, SD = 6.6 years). Participants with PD had a Hoehn and Yahr stage of I–III, and a unified Parkinson Disease Rating Scale average motor score of 19.14. Participants were excluded if they had any neurological disease other than PD, a musculoskeletal problem of their dominant arm, color blindness, a Mini-Mental State Examination score of <24 of 30.	Both for BP and RP acquisition phases, participants completed 18 trials in each of three movement patterns for a total of 54 trials in each practice schedule. BP: the same movement pattern was practiced for 18 trials in a block for each of the three patterns. RP: in each block of 18 trials, 6 trials of each of the patterns were presented in a random order.	Nonrandomized controlled trial with follow-up. Level 2	For both groups, performance during skill acquisition was superior during BP rather than RP; however, RP was superior to BP for delayed recall and transfer of training to a novel task. Thus, both patients with PD and elderly healthy controls may benefit from RP conditions.	Acquisition phase: mean MT during BP was significantly shorter than that observed during RP ($p = 0.006$). Delayed recall: main effect of schedule: MT was significantly shorter following acquisition that consisted of RP as opposed to BP ($p < 0.001$) MT during the cued recall test was essentially unchanged from the 24-hour to 1-week delay, whereas mean MT for free recall decreased from 24 hours. Fewer errors were committed following RP than following BP ($p < 0.001$). Delayed transfer tests: MT was significantly less following RP as opposed to after BP ($p = 0.001$). In all conditions, MT was significantly slower for the group with PD as compared to controls.

Intervention	Description	Participants	Dosage	Research Design	Benefit	Statistical Significance
Does provision of extrinsic feedback result in improved motor learning in the upper limb (UL) post-stroke? A systematic review of the evidence ⁸	Review evaluated the effects of extrinsic feedback as opposed to no feedback on UL motor learning in adults post-stroke.	Included nine studies: six randomized controlled trials (RCTs), two pre-post designs, and one cohort study.	Varied in each study	Systematic review of published RCTs and pre-post designs. Studies were evaluated for methodological quality and the overall strength of the evidence was graded. Level 1	Stroke survivors are able to use explicit feedback to improve motor performance of both the more-affected and less-affected UL; KP may produce greater long-term benefits. However, further research is required to determine optimal type, delivery medium, and schedule of feedback.	Strong (Level 1) evidence for the effectiveness of feedback for motor learning using more-affected limb and Level 2b evidence using the less-affected limb.
Influence of task-oriented training (TOT) content on skilled arm-hand performance in stroke: a systematic review ⁷	Review evaluated the underlying training components currently used in TOT and assessed the effects of these components on skilled arm-hand performance in patients after a stroke.	Included 16 RCTs; total of 528 patients, all adults post-stroke.	Interventions ranged from 20 to 120 minutes per day; frequencies of sessions per week ranged from 3 to 7; intervention lengths ranged from 3 to 20 weeks.	Systematic review of RCT published through 3/2009. Studies were evaluated for methodological quality. Level 1	The total number of components used in an intervention was not associated with the posttreatment ES. "Distributed practice" and "feedback" were associated with the largest postintervention ES. "Random practice" and "use of clear functional goals" were associated with the largest follow-up ES.	Fifteen TOT components thought to contribute to motor learning were identified. All but three components were associated with large postintervention and follow-up MESs ($d > 0.533$). Components that were associated with the largest postintervention ES are "distributed practice" (MES = 2.39), "feedback" (MES = 1.95), "within task exercise variability" (MES = 1.72), "random practice" (MES = 1.72).

Intervention	Description	Participants	Dosage	Research Design	Benefit	Statistical Significance
Efficacy of OT-task-oriented approach in UE post-stroke rehabilitation ³²	Individualized, client-centered approach applying motor learning and motor control principles; Canadian Occupational Performance Measure (COPM) results guided task selection for practice. Tasks were intensively practiced for 70% of therapy time. Remaining 30% of time was spent on supplemental exercises. Log book was used to monitor compliance.	<i>N</i> = 20, adults, <i>M</i> = 62.1 ± 46.11 months post-stroke with some movement in affected UL	Task-oriented intervention was provided in two 1.5-hour sessions/week for 6 weeks. Plus, homework functional and impairment exercises (1–1.5 hours day on average)	Randomized cross-over trial. Level 1	Clinically, significant improvements in UE function noted postintervention and significant improvements noted in perceived performance and satisfaction with performance of client-chosen tasks	Mean change scores (SD) favored the treatment group for five out of six functional measures as follows: COPM: performance = 2.83 (1.70), <i>p</i> < 0.001; <i>d</i> = 1.66. COPM: satisfaction = 3.46 (2.17), <i>p</i> < 0.001; <i>d</i> = 1.59. Motor activity log: AOU = 1.11 (0.79), <i>p</i> < 0.001; <i>d</i> = 1.41; HW = 0.87 (0.65), <i>p</i> < 0.001; <i>d</i> = 1.34. Wolf motor function test: time = -8.35 (12.46) <i>p</i> < 0.009; <i>d</i> = -0.67. Function: 0.20 (0.52), <i>p</i> < 0.126; <i>d</i> = -0.39. No significant differences noted on impairment outcome measures.

Intervention	Description	Participants	Dosage	Research Design	Benefit	Statistical Significance
Repetitive task training (RTT) to improve functional ability after stroke ²⁷	Review evaluated the effects of RTT on the primary outcomes of upper limb (UL) function and lower limb (LL) function/balance, and secondary outcomes of activities of daily living (ADL), global motor function and quality of life of adults post-stroke.	Included 33 studies (32 RCTs) with 1,853 participants. All adults post-stroke. Studies included a wide range of tasks to practice, including lifting a ball, walking, standing up from sitting, and circuit training with a different tasks at each station.	The number of hours of task practice varied from <10 hours of training to >40 hours of training and intervention lengths ranged from 2 to 20 weeks.	Systematic review of RCTs or quasi-RCTs published through June 2016. Studies were evaluated for methodological quality and the overall strength of the evidence was graded. Level I	In comparison to usual care, people who practiced functional tasks showed small improvements in UL function and walking. Improvements in UL and LL function were maintained up to 6 months. Further research is needed to determine the best type of task practice, and whether more sustained practice could show better results.	Low-quality evidence that RTT improves arm function (standardized mean difference (SMD) 0.25, 95% confidence interval (CI) 0.01–0.49); hand function (SMD 0.25, 95% CI 0.00–0.51), and lower limb functional measures (SMD 0.29, 95% CI 0.10–0.48). Moderate-quality evidence that RTT improves walking distance (mean difference (MD) 34.80, 95% CI 18.19–51.41) and functional ambulation (SMD 0.35, 95% CI 0.04–0.66). Small effect size that was statistically significant (SMD 0.28, 95% CI 0.10–0.45) suggesting RTT improves ADL.

Functional Uses of Neurological Approaches: Rood, Brunnstrom, Proprioceptive Neuromuscular Facilitation, and Neuro-Developmental Treatment

Kris M. Gellert and Karen Halliday Pulaski

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the following sensorimotor frames of reference that shape evaluation and treatment for clients with neurological insults: Rood, Brunnstrom, Proprioceptive Neuromuscular Facilitation (PNF), and Neuro-Developmental Treatment (NDT).
2. Demonstrate an appreciation for the historical impact and the evolution of these four major frames of reference.
3. Compare and contrast the frames of reference and how they guide occupational therapy practice.
4. Apply the principles of Brunnstrom, PNF, and NDT to the evaluation process.
5. Formulate a basic treatment plan based on PNF and NDT.

CHAPTER OUTLINE

Introduction
Rood Frame of Reference
Brunnstrom Frame of Reference
Proprioceptive Neuromuscular Facilitation Frame of Reference
Neuro-Developmental Frame of Reference
Case Study

TERMINOLOGY

Associated reactions: movements on one side of the body that are facilitated by providing resistance on the other side of the body; for example, resistance to the arm in flexion on the intact side will facilitate flexion in the arm on affected side; Brunnstrom used this as treatment technique.

Facilitatory: treatment that increases increase muscle tone/activation.

Inhibitory: treatment that reduces tone/decrease muscle activation.

Limb synergies: patterns of movement acting as a “bound” unit in a primitive, reflexive manner in both the upper extremity (UE) and the lower extremity (LE); in this chapter, we focus on the UE (e.g., UE extension limb synergy and UE flexor limb synergy).

Proprioception: the ability to sense the position and location and orientation and movement of the body and its parts.

Introduction

Occupational therapy (OT) is in part defined, supported, and explained by the various frames of reference in which the profession is grounded. This chapter provides a review of four major sensorimotor frames of reference that have shaped and continue to shape the practice implemented currently with clients with neurological impairments. OT has its own unique way of translating, understanding, and using these frames of reference to guide assessment and treatment. For OT, the overall goal is always to assist our clients to engage in meaningful

activities tied to the roles that define who the client is and what the client values. Because of this, for OT, these frames of reference are far more encompassing than the goal of restoring more normal movement. The occupational therapist should always be asking “why” the patient needs to move better—in order to do what? In other words, the goal isn’t for more normal movement in and of itself; the goal is to move more normally in order to allow the client to do something meaningful. It is the meaningful activities that are the structure of the client’s life roles. These roles take place within a psychosocial and temporal context. These approaches for OT should always be embedded in this concept.

The individuals who developed these frames of reference were able to begin to define and give structure to a new model of assessment and/or intervention for helping clients with stroke or brain injury. They were pioneers in their respective fields, and many of the concepts that they initiated in the 1940s and 1950s are still used today. Many of the earlier frames of reference were based on hierarchical and reflexive theories of motor control. As the body of scientific research has grown for motor control, motor learning, and motor development, the profession has moved to using dynamic systems theory (DST) to understand in part the complexity of motor mastery. The reflex hierarchy refers to the belief that normal motor development was attributed to the refinement of cortical networking in the central nervous system (CNS). This hierarchical system results in the emergence of higher levels of control over lower level reflexes. The belief at the time was that when CNS damage occurred, an individual would revert to reflexive over cortical processing. Today, in rehabilitation, many of the techniques are supported by DST, which recognizes a constant interplay and interaction among many systems in the body (e.g., sensory, motor, cognitive, pulmonary, perceptual) and with the external world (e.g., gravity, inertia, fear, excitement).^{1,2} When there is interference in one system, other systems have some ability to adapt or compensate for that change.

In practice, occupational therapists use many frames of reference for assessment and/or treatment and do not limit themselves to any one frame of reference.³ Some of these frames of reference are used far less frequently today. As our understanding of neuroplasticity and recovery from a neurological insult grows, rehabilitation efforts have shifted toward inclusion of remediation of the impairments to restore as much functional ability as possible rather than just focusing on compensation. Although these frames of reference are applicable to children, adolescents, and adults, the scope of this chapter focuses primarily on the rehabilitation of the adult client. This chapter provides an overview of the following frames of reference: Rood, Brunnstrom, Proprioceptive Neuromuscular Facilitation (PNF), and Neuro-Developmental Treatment (NDT). A more in-depth review is provided for PNF and NDT because these frames of reference are more widely used today.

Rood Frame of Reference

Background and Historical Significance

Margaret Rood (1909–1984) was a pioneer in providing one of the earliest attempts at developing a formal, systematic way to understand and organize rehabilitation efforts and interventions with children and adults with neurological impairment.⁴ She was trained initially as an occupational therapist and then earned her degree in physical therapy as well. She was considered a master clinician and educator and has been formally recognized by both the physical and OT professions.

Much of Rood’s approach, developed in the 1950s, is not currently practiced in clinics today as the growing body of motor learning research does not necessarily support many of her early assumptions; however, it is important to understand the impact that Rood has had on the development of the rehabilitation profession as well as to recognize that other major frames of reference evolved out of her initial efforts.

Evaluation and Intervention Principles

Key Concepts

1. Normalized muscle tone (which is influenced by sensory input) is required in order to develop motor control and mastery of a desired movement. Rood's original approach emphasized the importance of normalizing muscle tone first before there could be an ability to elicit a specific motor response.
2. Flexion and extension patterns of movement are evident in our daily occupations. Rood emphasized the importance of using a specific developmental sequence of movement in order to achieve these patterns of movement.
3. Repetition of muscular responses is crucial to learning movement patterns.
4. The ability for clients to engage in occupations or meaningful functional activity is required for development of normal movement. In other words, clients need to learn motor patterns within the context of functional activity, not just in isolation of a learned movement pattern.

Rood's approach was employed predominantly as a preparatory approach used before the client engaged in purposeful activities. She used a variety of sensorimotor techniques that she believed influenced tone and, therefore, the development of normal movement. She identified two types of sensorimotor techniques—**facilitatory** (those that would increase muscle tone/activation) and **inhibitory** (those that would reduce tone/decrease muscle activation).

Facilitatory Techniques

1. Heavy joint compression
2. Manual resistance to a body part
3. Quick stretch
4. Tapping
5. Vibration
6. Fast brushing
7. Vestibular stimulation (fast movement)

Inhibitory Techniques

1. Neutral warmth
2. Slow stroking
3. Light joint compression
4. Vestibular stimulation (slow movement)
5. Tendon pressure
6. Prolonged stretch

Four Components of Motor Control

Rood described four main components of motor control that she considered essential for movement during purposeful, directed activity:

1. **Reciprocal innervation:** Simply put, this implies that whereas the agonist muscle is contracting, the antagonist muscle is relaxing (e.g., to bend your elbow to wash your face, the biceps would contract, whereas the triceps would relax).
2. **Co-contraction:** The agonist and antagonist muscles co-contract at the same time to provide stability (e.g., the biceps and triceps co-contract to allow you to lean on your arm while putting on your mascara at a mirror with your other hand). This provides a basis for postural control.
3. **Heavy work:** This allows for mobility to be superimposed on stability.⁵ Proximal muscles co-contract, whereas distal segments (i.e., arm, legs, hands, and feet) are fixed. Examples Rood provided were lifting, moving, pulling, and pushing.
4. **Skill:** Rood considered this the most advanced level of controlled movement. This requires that mobility and stability be combined. Proximal muscles (i.e., trunk) act as stabilizers, whereas distal segments are allowed to move freely (i.e., arms, legs, hands, and feet). Examples Rood provided were painting on an upright canvas, writing on a blackboard, and dancing.

Developmental Sequence

Finally, Rood believed that the way to master these four components of movement was through the progression of a developmental sequence. She based this assumption on her observations of how an infant develops and masters movement and theorized that clients with neurological impairment could also master movement in the same way. She used the previously identified facilitatory and inhibitory techniques to assist a client in progressing through this sequence. She theorized that each developmental sequence allowed the client to master various specific movement patterns and thus becomes a building block for the next posture. Because she viewed this as sequential, she believed each step must be mastered to allow the achievement of the next level of control. This sequence consisted of:

1. Supine withdrawal/flexion (total flexion in supine)
2. Rollover
3. Prone extension (prone with upper trunk/head extension)
4. Neck co-contraction (prone with isolated head extension)
5. Prone on elbows
6. All fours (quadruped)
7. Static standing
8. Walking

Use of the Rood Frame of Reference Today

Several assumptions and assertions in Rood's frame of reference are no longer empirically supported. Current motor theory suggests:

1. Neuromuscular function is complex and constantly changing, not linear. It is no longer viewed as simply a system where sensorimotor input leads to motor output.⁶⁻⁸
2. Tone is only one variable that impacts movement, and tone is constantly changing due to various factors such as demand of the task, temperature, and a client's emotional response.
3. In general, many of the facilitatory and inhibitory techniques are viewed as unpredictable. Therapists still use some of the techniques, and the reader will note this in other frames of reference. However, many of the initial techniques Rood discussed are no longer embraced in today's clinics. While Rood and others established guidelines for the use of many of these techniques, the sensorimotor input described is generally considered relatively passive in nature, short lasting, and unpredictable.⁸ With today's current health care climate and its emphasis on short lengths of stays, efficiency, and efficacy, many of these techniques are no longer used in clinics.
4. Motor development for an adult following a neurological insult does not require a sequential developmental progression for mastery of a motor skill.⁹ Many of these postures are still used today to develop specific motor control. For example, a therapist may choose to use prone on elbows to encourage development of neck extension, head control, and upper thoracic extension required for postural control in sitting and standing, as well as proximal shoulder stability. The position of kneeling may be used to facilitate trunk control, address postural control, and develop balance reactions. It is, however, no longer used in today's clinic with adult rehabilitation as a sequential progression. Adults have a mature system that has already "learned" these skills; and as such, an adult system differs from that of an infant.

There are several important assertions developed by Rood that do still impact the delivery of rehabilitation services today. It is important to keep in mind that Rood developed this frame of reference without the benefit of current research:

1. Rood was one of the first therapists to see the importance of having a theoretical-based approach for evaluation and treatment.
2. Rood identified the importance of engaging in purposeful, meaningful activity to promote motor learning. This is a cornerstone belief in the profession of OT for many

reasons, not just motor learning.

3. Rood recognized the importance of repetition as being critical to motor learning. Repetition of a motor response for learning is empirically supported,^{10,11} and this concept is widely used in physical rehabilitation today. Research helps to guide therapists on the types of repetition (such as blocked or random), as well as the need for variation within that repetition, frequency and intensity of repetition/practice, and how to cue and guide clients.^{8,12-18}
4. Rood also recognized a deep connection between the sensory system and skilled movement.
5. Rood discussed the importance of the “art” of OT, which we now refer to as the therapeutic use of self.
6. Rood articulated the premise that therapists have the ability to influence the variables that impact movement, which is a one of the basic building blocks for neuromuscular education.
7. Rood developed a systematic way to begin to categorize movement that influences the language still used today (i.e., stability, mobility, postural control, and skill).

Brunnstrom Frame of Reference

Background and Historical Significance

The Brunnstrom approach was initially developed by Signe Brunnstrom (1898–1988), a physical therapist, in the 1950s. She was also one of the first therapists and researchers involved in developing a comprehensive approach to understanding stroke recovery and rehabilitation of the stroke survivor. Her approach encompassed both evaluation and treatment interventions and was based on her numerous years of providing care to survivors of stroke as well as the early work of Twitchell¹⁹ who first described patterns of recovery following stroke. She designed a framework that describes what she viewed as a common progression or stages of motor recovery poststroke as well as a systematic approach to assessment and treatment based on her understanding of stroke recovery patterns. Brunnstrom theorized that effective and meaningful evaluation and treatment is based on understanding what she viewed as a “normal” motor response to a cerebral vascular event. This is often also called movement theory.²⁰

Evaluation and Intervention Principles

Brunnstrom theorized that normal development of motor control in infants is first dominated by primitive reflexive movement patterns (e.g., tonic neck reflex, righting reflex, stepping reflex). These are involuntary mass patterns of movement that are in response to a specific stimulus. Gradually, as the brain and CNS develop, these reflexive movement patterns are modified by higher control centers of the brain and result in the development of isolated, voluntary control of motor movement (e.g., as a baby develops, she can flex her right arm when her head is turned to the right, thus overriding the tonic neck reflex). Brunnstrom theorized that when a client suffers a stroke, it results in damage to the CNS and thus disrupts the higher centers of CNS control. This disruption then causes the client to undergo what she termed revolution in reverse. In other words, without higher level central control to modify the primitive reflexes, the client reverts back to movement dominated by primitive reflexive movement patterns. The clients lose the ability for isolated, voluntary, controlled movement. While others viewed the loss of volitional control as abnormal, Brunnstrom viewed this reversal to primitive reflexive movement as a “normal response” relative to the damage caused to the CNS by the cerebral vascular event. Based on this belief, she theorized that movement dominated by reflexive, synergistic movement patterns and other supposed “abnormal” motor responses were actually a part of the normal process or progression that a client must go through to regain normal movement. She believed that the overall goal of rehabilitation, and therefore the role of the therapist, was to enhance the progression through very specific, predictable stages of recovery to achieve the ability for more normal and complex movement patterns. She developed a scale of stages of recovery for the upper extremity (UE) and the lower extremity (LE) based on the presence of **limb synergies** as well as the amount of isolated controlled movement at any given time in stroke recovery. She

also developed very specific treatment goals and interventions based on each stage to facilitate the client's progression from one stage to the next.

Additional Assumptions of Brunnstrom Theory

1. Motor return is always proximal to distal.
2. Progress can be slow or rapid through stages, and progress can cease at any stage.
3. Clients gain flexion of primitive movement patterns first, then extension.
4. Clients first recover reflexive movement and then progress to isolated movement.
5. Clients achieve gross motor movement and then progress to isolated, selective movement.
6. Use of cutaneous (skin) and proprioceptive stimulus as well as reflexes will help facilitate a client as he or she progresses through the stages of recovery.
7. Stages of recovery are not necessarily discrete—a client may show movement patterns of two different stages at once.
8. Practice of movement patterns within the context of daily activities promotes motor recovery.

Assessment Based on Brunnstrom

Assessment should include, but is not necessarily limited to:

- **Sensory testing:** Specifically, **proprioception** and light touch as Brunnstrom advocated the use of these stimuli in particular to influence motor recovery. A therapist would need to understand the client's ability to use these inputs during treatment.
- **Associated reactions and reflexes** (tonic reflexes in particular): Brunnstrom also used these as a way to promote progression through the stages of recovery (e.g., she may use a tonic neck reflex stimulus or **associated reaction** to facilitate flexion in the affected UE).
- **Presence of limb synergies:** Brunnstrom assessed this both to determine stage of recovery and to assess if they could be used in treatment (both to facilitate progression to the next stage and during functional activity by the client).
- **Amount of voluntary movement a client can generate:** This would provide information to allow the therapist to identify the stage of recovery as well as for use in treatment for functional use.
- **Tests of motor speed** (i.e., bring hand to chin, then down to opposite knee rapidly)
- **Prehension ability in the hand** (e.g., wrist stabilization, mass grasp, prehension, fine motor)

Table 35-1 outlines a general description of the stages of recovery for both the UE and LE.

Table 35-1. Brunnstrom: Stages of Recovery for the Upper/Lower Extremity

STAGE	GENERAL DESCRIPTION
I	Tone is flaccid, no voluntary movement, muscle or reflexive responses.
II	Synergies can begin to be elicited reflexively, spasticity is developing.
III	Begin voluntary movement but only in synergy, spasticity may be significant.
IV	Spasticity begins to decrease; movement starting to deviate from synergy patterns.
V	Further decreased tone, increased ability to perform more complex movement patterns independent of synergy patterns
VI	Tone nearly normal with ability to do complex combinations of isolated movement
VII	Normal speed and coordination of motor function

Intervention Based on Brunnstrom

Clinicians today employ a limited use of Brunnstrom's approach because rehabilitation professionals try to prevent the development of abnormal and synergistic movements; reflexive movement is no longer considered a precursor to isolated, volitional movements.²¹ Therefore, only a brief review of treatment approaches based on the stages of recovery are included in the scope of this chapter. The intention of the review is to briefly familiarize the

therapist with the historical significance and impact of this frame of reference from a treatment intervention standpoint. Treatment goals and techniques are outlined in Table 35-2.

Table 35-2. Brunnstrom: Treatment Goals by Stage

STAGES	TREATMENT GOALS
Stages I–II	Goal: To try to facilitate increased muscle tone as well as promote the beginning development of limb synergies. Tone should be increasing during these stages.
Stages II–III	Goal: To assist the client in achieving full voluntary control of limb synergies and to learn to use these in functional activities. Tone will be at its peak at the end of stage III. For example, to use a flexion synergy pattern to bring a washcloth to the face.
Stages IV–V	Goal: To assist the client in beginning to break away from limb synergies and to begin to move to more isolated and complex patterns of movement. Tone should be decreasing. For example the ability to extend the elbow when doing shoulder flexion to reach into a cabinet.
Stages V–VI	Goal: Continue to assist the client in developing more complex isolated movements as well as increase the speed of movement. For example, to be able to use normal isolated movement to bring a washcloth to the face.
Stage VII	Client demonstrates normal isolated complex movement.

Early Stage of Recovery (Stages I–III)

The goal of therapy is to aid the client in developing and gaining full control over limb synergies; clients are encouraged to use this limb synergies within the context of functional activity. For example, a client may use a UE flexion pattern to carry a bag, attempt to brush his or her hair or drink from a cup.

Middle to Late Stages of Recovery (Stages IV–VI)

Once the client reaches the ability to fully perform and use limb synergies in functional ways (stage III), the goal of therapy is to aid the client in learning to modify these synergies and to work toward the development and use of simple and complex movement that deviates from synergistic movements. For example, the focus for a client moving from a stage III (control of full flexion synergy) to a stage IV (beginning to break away from synergistic movements) may include encouraging extension patterns in the UE via functional activity (such as wiping a table) through the use of facilitatory techniques. Assuming the client progresses through each stage, this would result in the client being able to perform isolated, voluntary movement of the UE and LE.

The following are some of the treatment interventions Brunnstrom used:

1. Tonic reflexes (e.g., having a client turn his head toward or away from his affected arm will facilitate different movement patterns)
2. Associated reactions
3. Cutaneous and stretch (proprioceptive) stimuli such as skin stimulation and weight bearing of the extremity
4. Positioning (e.g., side-lying on the affected side to discourage excessive tone in the extremities)
5. Facilitation of balance reactions and use of trunk rotation to either encourage or discourage limb synergies.

Use of Brunnstrom Frame of Reference Today

Much of Brunnstrom's assumptions are no longer believed to be absolutes for every client as clients recover from cerebral vascular events in a multitude of ways:

1. Motor recovery is not always proximal to distal.²² For example, clients can demonstrate movement in their hand while having little to no movement proximally. Clients often present with mixed patterns of return in the affected UE.
2. Depending on the location and size of the stroke, clients may not exhibit any reflexive movement at all.
3. Current research would not support facilitation of progressing a patient through the stages of recovery.⁹ Clients may use compensatory limb synergies to complete tasks if

they do not have isolated control (e.g., UE flexion synergy to hold an object). However, this is no longer the “goal” of neuromuscular re-education.

4. As stated before, cutaneous and proprioceptive inputs can be unpredictable, passive in nature, and short lived. There are no real guidelines empirically developed for the use of many of Brunnstrom’s interventions. This does not mean that therapists never use them but rather that there may be a need for further research to guide best practice.

Perhaps, the most widespread influence of Brunnstrom’s work is the recognition that survivors of stroke have a unique recovery course; this course is individualized and varies from client to client. There are general patterns of movement, however, that clients with stroke may exhibit. These stages of recovery have allowed for the development of standardized assessment tools that are widely used today. Although current treatment approaches no longer embrace the concept of encouraging the development of reflexive, synergistic movement patterns, research is focusing on the assessment tools relative to consistent categorization, prognosis, and prediction for functional outcomes for motor recovery and independence with functional activities. One of the most commonly used tools today is the Fugl-Meyer assessment,²² which is based on Twitchell’s original work regarding motor return following hemiplegia¹⁹ as well as Brunnstrom’s stages of recovery.²⁰ This assessment tool is widely supported by research in terms of inter-rater reliability and validity.^{23–28} This tool also allows therapists to “speak” a common language when discussing clients and their recovery from stroke. This assessment tool thus influences the treatment approach and goals that therapists may choose when developing a plan of care.

Proprioceptive Neuromuscular Facilitation Frame of Reference

The term Proprioceptive Neuromuscular Facilitation (PNF), in its literal sense, means techniques that use an awareness of body position and movement, through specific commands and cues directed at muscles and nerves, to help a client achieve new movement patterns. PNF is a useful tool to assist with both the assessment and intervention for clients with orthopedic or neurological diagnoses, which lead to movement problems.²⁹

Background and Historical Significance

Developed initially by neurophysiologist and physician, Dr. Herman Kabat, the underlying philosophy of PNF is that all human beings, including those with disabilities, have untapped existing potential.³⁰ Kabat’s goal was to develop a hands-on treatment approach that enabled therapists to analyze and assess a client’s movement while at the same time facilitating more efficient strategies of functional movement, thus untapping the existing potential.

Dr. Kabat’s early work was influenced by the work of Sister Kenny, a nurse who worked with clients with polio, and who used unique stretching and strengthening techniques. Kabat was also familiar with the work of Dr. Charles Sherrington relating to the functioning of the neuromuscular system; concepts of the reflex hierarchy, facilitation, and inhibition and the phenomenon of irradiation, which will be defined later in this chapter. Dr. Kabat, influenced by these abovementioned practitioners, also believed intervention directed at encouraging combinations of movements would be more effective than the traditional interventions of moving one joint at a time. When a person performs daily living skills, he or she moves with many combinations of movements, through many planes of movement, using rotational and diagonal movement components. Therefore, Kabat’s frame of reference is based on functional human anatomy, as well as neurophysiology. Dr. Kabat combined the manual techniques used by Sister Kenny and the scientific concepts of Dr. Sherrington and began his Proprioceptive Facilitation. It was in the mid- to late 1940s that Dr. Kabat began his search for physical therapists, thus Margaret Knott, and later Dorothy Voss, became the first physical therapists to work closely with him. Voss later completed the current moniker by adding Neuromuscular to the title to highlight the emphasis on sensory input and motor output. Kabat, Knott, and Voss combined their analysis of functional movement with theories from motor development, motor control, motor learning, and neurophysiology in the development of the PNF approach.

Initially, the techniques were used to treat those with poliomyelitis and multiple sclerosis, but it soon became clear that these techniques could be applied to a much broader group. Today, the PNF frame of reference is widely used throughout the world,³¹ and it has shown to be effective for clients with orthopedic, traumatic, and neurological insults or injuries.²⁹ Intensive postgraduate training courses are available in many countries today.

Evaluation and Intervention Principles of PNF

Dr. Kabat believed that all human beings, including those with disabilities, have untapped existing potential,²⁹ and as such, a therapist using the PNF approach would structure his or her therapy interventions in a manner to maximize that potential as related to human occupation. We know today that as human beings, we use movement as way to interact with our surroundings, and movement is critical to our ability to engage in daily occupations. The PNF approach encourages the treatment of the entire human being, not just the problem areas. This approach is always positive with an emphasis on what the client is able to do and building from that point. The goals of PNF treatments are developed to help a client perform at his or her highest functional level.

PNF assessment and treatment strategies are based on specific diagonal and rotational patterns of movement throughout the entire body, including the head/the neck (as vision is always combined with diagonal patterns), the trunk, and the limbs. Those using the PNF frame of reference understand that the trunk is the foundation for limb movement and function. The patterns of movement encouraged with the PNF frame of reference incorporate all three planes of movement (sagittal, frontal, and horizontal) simultaneously.

The clinician using PNF employs a multisensory approach:

- **Visual:** Vision assists in initiation and coordination of patterns of movement.
- **Auditory:** Tone of voice and specific verbal commands. A calm, quiet voice may soothe; whereas a loud, direct tone may excite.
- **Tactile:** Manual contacts and client's own touch provide tactile stimulation for movement. The facilitation of specific movement patterns provides consistent proprioceptive input to improve functional movement patterns for each client.

Critical PNF Concepts

- **Resistance:** Resistance is used to improve muscle contraction. Older terminology was "maximal" resistance, but this created confusion. Current literature suggests using the right amount of resistance for the desired muscle contraction. This will vary for each client, and even within one body may vary among different muscle groups. Resistance may be used to guide or strengthen movement patterns and can help to reinforce the specifics of each pattern, so eventually the client can replicate movements without (or with less) facilitation.
- **Stretch:** In PNF, the use of quick stretch is applied to all three elements of the movement pattern with emphasis on the rotational components. This may be applied in the client's available range of motion, even in the absence of full range of motion. Using the PNF quick stretch technique, the application of quick stretch is done using therapist's entire body, not just the arms and hands. This delivers a safer experience for the client.
- **Irradiation:** Also referred to as overflow or the spread of a response to stimulation—can be excitatory or inhibitory.
- **Traction or approximation:** The elongation or compression of the limbs and trunk to facilitate motion or stability.²⁹
- **Body position/mechanics:** The therapist using PNF considers a starting position that will initially offer the most stability to the client, advancing to more challenging positions as skills are mastered. Therapists must also consider their own body positions relative to the movement sequence being facilitated.

Examples of PNF Techniques for Strengthening

- **Rhythmic initiation:** Cue “relax and let me move you” passive range of motion (PROM) repeat movement active assisted range of motion (AAROM) several times, then cue “Now you do it.” Active range of motion (AROM)³²
- Repeated contraction
- **Slow reversal:** The reverse of the diagonal movement. If D1 flexion is desired movement, reversal is D1 extension.
- Slow reversal hold
- **Rhythmic stabilization:** mid-range isometric contraction of the agonist followed by an isometric antagonist (co-contraction). No movement occurs. Effective for static strengthening and for clients with pain³²

Examples of PNF Techniques for Stretching

- Contract relax
- Hold relax

PNF Movement Patterns

In all PNF patterns, movement occurs in a straight line with diagonal direction and rotational component. Each pattern is comprised of three movement components: flexion/extension, abduction/adduction, and rotation, as shown in Figures 35-1 through 35-5.³²

Figure 35-1 D1 Flexion: The final position of D1 flexion is shoulder flexion, adduction, and external rotation; elbow flexion; and supination so that the hand passes close to the ear on the opposite side of the head. Wrist, fingers, and thumb flex; and fingers and thumb adduct. (Used with permission of Voss DE, Iota MK, Myers BJ. *Proprioceptive Neuromuscular Facilitation: Patterns & Techniques*. 3rd ed. New York, NY: Harper & Row; 1985 and Rust K. Managing deficits of first level motor control capacities using Rood and proprioceptive neuromuscular facilitation techniques. In: *Occupational Therapy for Physical Dysfunction*. 7th ed. Philadelphia, PA: Lippincott Williams and Wilkins; 2014.)

Figure 35-2 D1 Extension: The final position of D1 extension is shoulder extension, abduction, and internal rotation; elbow extension; and pronation so that the hand passes the hip on the same side of the body. The wrist, fingers, and thumb extend; and fingers and thumb abduct. During range of motion exercises, D1 extension is combined with its reciprocal D1 flexion. (Used with permission of Voss DE, Iota MK, Myers BJ. *Proprioceptive Neuromuscular Facilitation: Patterns & Techniques*. 3rd ed. New York, NY: Harper & Row; 1985 and Rust K. Managing deficits of first level motor control capacities using Rood and proprioceptive neuromuscular facilitation techniques. In: *Occupational Therapy for Physical Dysfunction*. 7th ed. Philadelphia, PA: Lippincott Williams and Wilkins; 2014.)

Figure 35-3 D2 Flexion: The final position of D2 flexion is shoulder flexion, abduction, and external rotation; elbow flexion; and supination so that the hand comes close to the ear on the same side of the head. Wrist extends, and fingers and thumb extend and abduct. (Used with permission of Voss DE, Iota MK, Myers BJ. *Proprioceptive Neuromuscular Facilitation: Patterns & Techniques*. 3rd ed. New York, NY: Harper & Row; 1985 and Rust K. Managing deficits of first level motor control capacities using Rood and proprioceptive neuromuscular facilitation techniques. In: *Occupational Therapy for Physical Dysfunction*. 7th ed. Philadelphia, PA: Lippincott Williams and Wilkins; 2014.)

Figure 35-4 D2 Extension: The final position of D2 extension is shoulder extension, adduction, and internal rotation; elbow extension; and pronation so that the hand moves past the opposite hip. Wrist flexes; fingers flex and adduct; and thumb opposes. During range of motion exercises, D2 extension is combined with its reciprocal, D2 flexion. (Used with permission of Voss DE, Iota MK, Myers BJ. *Proprioceptive Neuromuscular Facilitation: Patterns & Techniques*. 3rd ed. New York, NY: Harper & Row; 1985 and Rust K. Managing deficits of first level motor control capacities using Rood and proprioceptive neuromuscular facilitation techniques. In: *Occupational Therapy for Physical Dysfunction*. 7th ed. Philadelphia, PA: Lippincott Williams and Wilkins; 2014.)

Figure 35-5 (A) Bilateral symmetrical D2 with shoulder extension, adduction, and internal rotation. (B) Bilateral symmetrical D2 with shoulder flexion, abduction, and external rotation.

- **Chopping:** Bilateral asymmetrical D1 extension. One arm performs the chop, and the other hand is placed on the lateral extensor surface of the distal forearm. The reversal of this pattern is the reverse of the chop.³²
- **Lifting:** Bilateral asymmetrical D2 flexion. One arm performs the lift, whereas the other arm maintains contact on the lateral flexor side of the forearm. The opposite of this pattern is called the reverse of lift.³²
- **Controlled mobility:** The ability to perform fluid reversing motions necessary to perform skilled activity.³²
- **Reciprocal inhibition:** The mechanism whereby contracture of an agonist muscle produces inhibition of its antagonist.³²

PNF Positions

When using PNF, careful consideration is given to the choices for starting and subsequent positions for intervention (e.g., side-lying, prone on elbows, long sitting, tailor sitting, hands and knees, kneeling, half kneeling, short sitting, plantigrade). Positions are chosen when starting a treatment session to determine where the client will be supported, but also

challenged to complete a task. Movement in and out of these positions may also be stressed within a treatment session because clients need to be able to adjust and change positions within a functional activity. For example, when getting out of bed in the morning, an individual may roll from supine to side-lying, then to side sitting and finally to short sitting at the edge of the bed. When putting on his or her pants, the individual may sit to don clothing over feet and pull up to thighs before transitioning to standing to pull up over hips.

Use of the PNF Frame of Reference Today

It is necessary to learn movement by breaking it down into its simplest parts. A novice therapist initially learns which movements and which directions for movement are available at each joint. However, in function, an individual moves at multiple joints, in multiple planes of motion simultaneously, and often at great speed. Functional movement is typically a combination of movements versus movement in one plane at a time. Consider being seated and reaching down with both hands to place a sock on the left foot. This functional activity uses a D1 flexion and extension pattern of the UE, with significant flexion at the hips and rotation in the trunk.

The therapist using PNF considers that patterned movement allows the stronger muscles in that pattern to influence the weaker muscles, a term known as irradiation. It is also important to note that in the PNF frame of reference, all patterns have a reversing pattern. Therefore, in a functional context, one may consider that when lifting an arm to reach overhead to pull the chain of a ceiling fan, it is also necessary to return that arm back to its starting position. This functional reversal requires a balance between the agonist and antagonist muscles for smooth, controlled movement in both directions.

The PNF frame of reference highlights the importance of the role of the trunk as a basis for limb movement and function. In the case of an individual with hemiplegia following a stroke, this is an important concept because recovery after a stroke or brain injury often includes muscle imbalances between prime movers (agonists and antagonists) that should be relaxed when the agonist is active. This muscle imbalance leads to an inefficient, ineffective, and limited movement repertoire. Shinde et al. outlined how PNF treatment directed at improving trunk control for clients with stroke demonstrated favorable results in both static and dynamic trunk skills needed for functional activity.³³

In training for improved motor control, the occupational therapist using PNF needs to prioritize the goals for intervention. Consideration must be given to the stages of recovery. Consider a continuum of available ROM, stability, and controlled mobility.

- First, it is necessary to determine the client's available motion as well as the movements required for the desired task (PROM/AROM).
- The next step is to determine the client's stability needs: Does client need more stability or mobility to be able to engage in the activity? To determine this, the therapist must understand the stability requirements for this task.
- Finally, the therapist must identify if the client demonstrates sufficient controlled mobility to meet the demands to engage in this activity.

Box 35-1 is an example of using PNF in a patient with a stroke.

Box 35-1

PNF Treatment

Susan is 40-year-old homemaker who is eager to return to cleaning her kitchen after meal time. Since her recent stroke, Susan has left-sided hemiparesis, poor ability to sustain activity in her left shoulder, reported "heaviness" in her left leg, and profound sensory loss in her left hand. Susan is able to walk with a walker, although she relies heavily on her arms for support when walking; she has full PROM and AROM in her left arm, although she rarely uses this arm functionally, reporting "she forgets about it." Her occupational therapist starts with a standing activity where Susan is emptying the

dishwasher. The therapist positions Susan at the counter to the left of the dishwasher to allow her to rotate and reach with her left hand, forward and downward to the right in front of her body to obtain dishes, and then place them up and to the left side of her head to place them in the over counter cabinets. (She is encouraging and facilitating a D2 flexion/and reversing D2 extension pattern.) She encourages Susan to turn her head and locate the dishes visually, then reach downward to grasp lightweight saucers, then move items upward prior to releasing them onto the shelf. The therapist guides Susan by standing behind and placing hands on Susan's pelvis on either side to help her shift weight from left to right foot and then back as activity requires. She allows Susan to keep her right hand on the countertop throughout this movement sequence to help provide balance stability.

Occupational therapists have specialized training in task analysis. Understanding the movement requirements and the timing of movements in a given activity is a critical skill in developing interventions to address the client's ability to participate. Much of the therapist's challenge is to determine where intervention is warranted and to prepare for the next stage of recovery. Individuals with hemiplegia following stroke need muscle length and joint mobility to ensure motion is possible. Then, the treatment focus shifts to begin to develop stability, tonic holding of a muscle in a shortened range and co-contraction—isometric power in lengthened range.

Neuro-Developmental Frame of Reference

Background and Historical Significance

Neuro-Developmental Treatment (NDT) originated in the 1940s by husband and wife team, Dr. Karel and Berta Bobath, for treatment of individuals with neurological disorders of posture and movement, such as stroke, brain injury, or cerebral palsy. Berta Bobath was a remedial gymnast who studied dance and movement, later became a physiotherapist, and worked with clients with CNS damage that leads to posture and movement problems.

Berta rejected the widespread belief that people with upper motor neuron lesions could not regain function. She would assess a client's asymmetrical postures and place him or her into a more neutral alignment. By putting her hands on the client at key points, and by moving him or her in a way that could encourage (facilitate) or discourage (inhibit) aspects of the movement, she helped to create more natural movement patterns. These early concepts still exist today. Specific key points of control encourage the therapist to contact the client's body purposefully and specifically to produce changes in alignment before a movement sequence, or to control the speed direction or effort the client uses during movement.³⁴

Berta observed that by positioning and using various handling techniques, she could alter muscle tone. A client who demonstrated a significant amount of spasticity may experience a reduction of the hypertonicity in his or her limbs, more so than the current passive stretching techniques used at the time. Berta took her results from the clinic and shared them with her husband, Karel, who was a physician, to learn why she was able to influence movement in this way. Karel provided the scientific rationale to support her clinical experiences. Thus, the clinical practice of NDT preceded the scientific support for its intervention.

The Bobaths were frequently quoted for the idea that this theory was a "living concept." They recognized that in the mid-1900s, medical science was evolving, and health care was changing. They had expectations that their theory, initially called the Bobath approach, would also evolve as more scientific evidence became available.³⁵ The current model of NDT is supported by advances in the areas of neuroscience and motor learning, as well as DST. It requires an in-depth knowledge of the way movement is controlled and executed, the way in which feedback is used,³⁶ and the way our body systems interact with each other internally and with the outside world.

Definition of Neuro-Developmental Treatment

"NDT is a holistic and interdisciplinary clinical practice model informed by current and evolving research that emphasizes individualized therapeutic handling based on movement

analysis for habilitation and rehabilitation of individuals with neurological pathophysiology. The therapist uses the International Classification of Functioning, Disability, and Health (ICF) model in a problem-solving approach to assess activity and participation, thereby to identify and prioritize relevant integrities and impairments as a basis for establishing achievable outcomes with clients and caregivers. An in-depth knowledge of the human movement system, including the understanding of typical and atypical development, and expertise in analyzing postural control, movement, activity, and participation throughout the lifespan, form the basis for examination, evaluation, and intervention. Therapeutic handling, used during evaluation and intervention, consists of a dynamic, reciprocal interaction between the client and therapist for activating optimal sensorimotor processing, task performance, and skill acquisition to enable participation in meaningful activities.”³⁷

There are not prescribed movement patterns with NDT. NDT is a problem-solving approach, with an emphasis on helping clients improve motor control to restore movement and participation in meaningful activities. Therefore, interventions are developed based on the very specific and unique needs of the client. Every client has his or her own personality, motivations, fears, goals, body type, prior level of activity, and supportive resources, and each has had a unique neurological event (no stroke or brain injury is alike—each has its own compilation of sequelae). The NDT frame of reference guides the clinician to identify, prioritize, and specifically address the underlying impairments that affect the client’s ability to move and engage in meaningful life skills.

Key concepts of the NDT frame of reference that have stood the test of time include:

- Treating the individual as a whole: Since its inception, the NDT approach has stressed the importance of treating the whole person and the whole body.
- Individualized intervention
- Human movement is organized around functional activity.
- Hands-on intervention process to enhance functional outcomes
- Interdisciplinary approach
- Active participation: Passive motion, although helpful as a preparatory step, will not suffice for NDT intervention. Active participation by the client is necessary to improve motor performance and participation in life skills.

Evaluation and Intervention Principles for NDT

Assessment: Skilled Observation as well as Handling

The *International Classification of Functioning, Disability, and Health (ICF)* is a framework that organizes and categorizes biological and social aspects of health and disability.³⁸ The NDT model for assessment is based on the *ICF* with an added domain to guide the clinician to carefully analyze posture and movement as it directly relates to the client’s level of participation, functional abilities, and body system strengths or impairments.

In the *ICF* framework, the clinician asks the following questions to determine an individual client’s disability and health:

- **Who** the client is. What is his or her level of *participation* in life roles?
- **What** is the client able to do or not do? *Functional abilities/limitations*
- **Why** does he perform these tasks, or struggle to perform these tasks following a stroke or brain injury? *Body system integrities and impairments*

For the NDT model, the clinician also considers one additional question to determine the posture and movement abilities and limitations of the client:

- **How** does the client perform the functional task? The clinician uses an in-depth knowledge of the *human movement system* and understands movement problems that may develop following a stroke or brain injury.

This question of HOW precedes the question of WHY which identifies particular body systems that are intact or have been disrupted.

When assessing a client who has had a stroke or brain injury using the NDT frame of reference, the occupational therapist will use both skills of observation as well as handling to gather needed information regarding the manner in which he or she completes functional activities.

During assessment, through the use of skilled clinical observation, the occupational therapist can note:

- Alignment of whole body, or body part—symmetrical/asymmetrical
- Position of body parts relative to each other
- Coordination or fluidity of movement
- Direction of movement relative to the task
- Facial expressions (attention, fear, effort, frustration, etc.)

From these observations, the occupational therapist begins to appreciate the client's posture and movement abilities, and challenges.

One of the hallmarks of the NDT frame of reference is the use of individualized therapeutic handling for assessment of both client's typical and atypical movement patterns, and also for intervention to facilitate change in these patterns of movement.

The occupational therapist can further enhance the assessment using handling to gather information such as:

- **Amount of muscle recruitment:** Too active, not active enough for task
- **Quality of muscle contraction:** Flickering or sustained contraction
- **Timing of movement:** What moves first and what follows?
- **Client's reaction to being moved:** Passive, resistive
- **Breathing:** Breath holding, coordinating breathing with movement

Combining observation skills and handling skills, and comparing how client moves in contrast to the understanding of normal movement, helps the therapist identify specific strengths and impairments that lead to a direct plan for treatment.

Intervention: Hands-on and Problem-Solving Approach

Assessment and intervention are closely interwoven in every interaction when using the NDT frame of reference. When an NDT trained occupational therapist observes and feels how a client is controlling posture and movement to complete a particular functional task, he or she begins to determine whether the client's movement patterns differ from normal movement. From this, the therapist begins to prioritize the treatment interventions. When providing treatment interventions, it is essential to assess the effectiveness of each aspect of intervention and make further modifications. In this way, assessment and intervention have constant interplay within a session.

Using the NDT frame of reference, the occupational therapist's goal for intervention is to improve the client's postural control and movement to allow more efficient and effective patterns during activities of daily living (ADLs). The therapist will use a hands-on approach using either proximal or distal key points of control to facilitate new motor patterns at times within a functional activity, and at times separate from the activity itself. Putting hands on the client allows the therapist to realign the base of support, and the segments of the body to prepare for the task. The client's poorly aligned position places some muscles in an ineffective shortened or over-lengthened position. Realigning the base of support and body parts specific to the task allows optimal joint position and muscle length for best motor recruitment. It helps prepare the joints and muscles of the body to work at their greatest biomechanical advantage. Keeping hands on the client allows a dynamic interplay between gathering immediate feedback about the movement (assessment) and guiding and facilitating new patterns of movement (intervention).

Weight bearing is an important consideration for treating the individual with CNS dysfunction. An intervention applying weight bearing into a body part is directed at regaining muscle length, normalizing muscle tone whether it is too high (hypertonic) or too low (hypotonic), and/or creating a demand in the muscles to work.³⁹ Weight bearing to neutralize muscle tone happens naturally through the LEs when a client is assisted to stand on his or her legs. In the UE, this becomes more challenging, and the occupational therapist needs to explore options to safely allow the client to accept weight on the arms. This may begin by having client accept weight on forearm, while seated at table, or as a greater challenge, to facilitate the client to accept weight through an extended arm. In the NDT frame of reference, weight bearing is a dynamic, not passive, process with the goal of increasing muscle activity in the trunk as well as in the UE.

Individualized handling is a key concept used to change the way each client manages his or her body, but the ultimate goal is to teach the individual to move more naturally with less input from the therapist. The therapist is frequently considering changing the amount of support and the level of cueing to give the client the experience of moving more of himself or herself. With all of the emphasis on improving alignment and motor control, the occupational therapist must keep in mind that the overall goal for the client is to improve his or her functional abilities and help to restore participation in life roles.

Occupational therapists using the NDT approach need to have an appreciation and an excellent understanding of typical posture and movement. People who have not had a neurological insult develop thousands of movement patterns that are common. For example, when moving from a seated position to a standing position, there is a need to have weight shift forward at the hip joint to move the base of support from the backs of the thighs, to the feet on the floor. Once the body weight is shifted forward, there is an element of bilateral knee and hip extension to rise up from the sitting surface. The body stays fairly symmetrical throughout this motion. Most people would perform this movement using these common components of movement (see Fig. 35-6).

Figure 35-6 Sitting posture and sit to stand with normal subject. (A) Sitting; (B) Sit to stand and (C) Standing.

The occupational therapist also needs to understand how movement patterns are altered after a neurological event, such as a stroke or brain injury. When a neurological insult impedes a client's ability to maintain a posture or to move as he or she did prior to the event, the body adapts with its best attempt to solve the motor problem. In Figure 35-6, the individual first shifted weight forward onto the feet and then extended knees and hips nearly simultaneously to transition to stand. An individual who has had a stroke, which has affected his or her ability to move and control the entire left side of the body, left hemiplegia, and diminished somatosensory awareness on the left side, may use an atypical pattern of movement to rise from a seated position. This individual may first attempt to shift his or her trunk backward and not forward and then may shift the majority of his or her weight to the right leg, which he or she can feel and can control, as seen in Figure 35-7.

Figure 35-7 Ineffective sitting posture and sit to stand pattern as may be seen in client with stroke. (A) Asymmetrical sitting; (B) Dorsal leaning; and (C) Asymmetrical sit to stand.

The occupational therapist needs to be able to recognize that this is an ineffective and potentially unsafe movement pattern and create interventions to directly influence the specific components of the asymmetry, and the weight shift forward to help the individual achieve a more natural transition to standing. The therapist would facilitate a more normal pattern using his or her hands to realign the body parts and by matching his or her own body's transition from sitting to standing with that of the client (see Fig. 35-8).

Figure 35-8 Facilitation of more effective transition from sit to stand. (A) Facilitation of sitting; (B) Facilitation of sit to stand and (C) Facilitation of standing.

Use of the NDT Frame of Reference Today

Today, the NDT approach is one of the most commonly used interventions for individuals with cerebral palsy, stroke, or brain injury and is used internationally. Although this frame of reference was initially developed in the 1940s, the theory has evolved over the years as has science relating to motor development, motor control, motor learning, and neuroplasticity.

Occupational therapists using the current NDT frame of reference add a strong understanding of movement patterns both typical and atypical—after a neurological event, to their expert analysis of task performance to help clients learn to move and perform daily-life functions in a more effective way.

CASE STUDY

Patient Information

Lisa is a 38-year-old married mother of two who was working part time as a radiology technician. Her children are 7 years and 5 months of age. Lisa suffered a significant stroke 3 days after giving birth to her son. She had significant medical complications, including

having two major seizures, resulting in a prolonged hospital stay that included inpatient rehabilitation. Lisa has returned home where she is living with her husband and her children. Her mother has also moved in to assist Lisa, provide care for her children, and manage her home. Lisa has a history of anxiety that she has actively managed with counseling and medication. She has no other significant medical history. Prior to her stroke, Lisa enjoyed running, spending time with her family, boating and water activities, and volunteering at her children's school.

Assessment Process and Results

Use of patient interview, skilled observation of movement during functional activities related to life roles, Fugl-Meyer assessment, and other formal and informal OT assessments including ROM, sensation, trunk control, balance, cognition, perception, and visual assessments.

Impairments in Client Factors/Performance Skills

1. Spastic dominant right hemiplegia
2. Brunnstrom stage IV for right upper extremity (RUE) and stage IV/V for right lower extremity LE (RLE)
3. Absent sensation on right side to midline
4. Impaired perception of body in space
5. Impaired postural alignment, trunk control, and postural control in sitting and standing
6. Impaired attention and memory
7. Decrease PROM/AROM and pain of the RUE
8. Mild expressive/receptive aphasia
9. Anxiety

Occupational Therapy Problem List

Lisa and the occupational therapist choose to focus primarily on these areas:

- Decreased ability to perform ADL, such as bathing, toilet hygiene, and donning her bra.
- Decreased independence in functional mobility such as shower transfers, functional ambulation, and transitioning from sit to stand without losing her balance. Lisa is currently using a wide based quad cane and is falling frequently in her home.
- Decreased ability to care for her 5-month-old son; in particular unable to pick him up from a crib, walk and carry him, and assist him in and out of the bathtub.

Lisa verbalizes that while she appreciates her mother's help, it is "time for my mom to move out."

Occupational Goal List

- Patient will be independent with shower transfers.
- Patient will be independent with toilet hygiene.
- Patient will demonstrate the ability to lift her son in and out of the bathtub from a kneeling position.

Intervention

1. Postural alignment/control in sitting and standing to improve balance, reduce spasticity in the RUE and RLE, reduce pain in the RUE, and facilitate voluntary combinations of functional patterns of movement in the trunk and extremities.

Techniques: Stability (maintain and recover a posture)—slow rhythmic weight shifts initially in sitting progressing to standing. Head and trunk with emphasis on rotational and diagonal movement patterns. Focus on alignment over the base of support (sitting and standing) with emphasis on progressing small controlled weight shifts in all directions. Practice unloading the dishwasher.

2. PROM/AROM and pain in the RUE in preparation for low to mid-reach during functional activities, such as holding a grab bar while entering shower, reaching for toilet paper, reaching behind body, and bilateral low reach to pick up items.

Techniques: PNF D1 flexion/extension, D2 flexion/extension, asymmetrical progressing toward bilateral symmetrical pattern to facilitate low reach. As client progresses, incorporate diagonals into functional tasks as listed in goals.

3. Ability to weight shift in standing initially to midline and then right to left with ease and without fear to improve balance, trunk control, alignment, and use of the extremities for activities such as stepping over the tub edge or leaning over to pick something up.

Techniques: Handling with an emphasis on assisting the client in active, aligned weight shifting on to her hemiplegic leg in preparation for single leg stance for shower transfers. Emphasis on larger controlled weight shifts in standing. Start with slow speed given client's fear of shifting on to hemiplegic side because of absent sensation. Therapist positions himself or herself to move with the patient for smoother, more controlled normal movement. Practice stepping over ledge of shower and picking up laundry off the floor.

4. Build strength in core and extremities to allow for increased demand with functional mobility, lifting, and caregiving.

Techniques: Quadruped: Tonic holding transitioning to side sitting (static to dynamic) to allow RUE to initially stay in weight-bearing progressing toward more controlled mobility that allows client to use RUE out of weight bearing against gravity in smooth controlled manner. Practice getting on and off the floor to play with the baby. Starting in supine and moving toward sitting and then standing, resistance through the UE into the trunk with dynamic weight shifting. Practice picking up the baby.

Summary of Results

At discharge from OT services, Lisa had met all three goals. Her mother has moved out and only helps with driving, grocery shopping, and more difficult home management tasks. Lisa is able to fully care for her children and is no longer experiencing falls. She has decided not to return to work but is volunteering at school in a limited manner. She and her family recently enjoyed a vacation at a lake where Lisa participated in boating and lake activities.

These results indicate that trunk stabilizing exercises using PNF performed by stroke patients were effective at improving FRT and the muscle activities of the soleus and quadriceps.</p>	<p>Paired t-tests $p < 0.05$ for FRT and soleus and quadriceps</p>

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Does physiotherapy based on the Bobath concept, in conjunction with a task practice, achieve greater improvement in walking ability in people with stroke compared to physiotherapy focused on structured task practice alone ⁴¹	To compare the short-term effects of two physiotherapy approaches for improving ability to walk in different environments following stroke: (i) interventions based on the Bobath concept, in conjunction with task practice, compared to (ii) structured task practice alone.	Twenty-six participants between 4 and 20 weeks poststroke able to walk with supervision indoors.	Both groups received six 1-hour physiotherapy sessions over a 2-week period. One group received physiotherapy based on the Bobath concept, including 1 hour of structured task practice. The other group received 6 hours of structured task practice.	Level 1 evidence Randomized controlled trial	This pilot study indicates short-term benefit for using interventions based on the Bobath concept for improving walking velocity in people with stroke.	Walking velocity showed significantly greater increases in the Bobath group (26.2 [SD 17.2] m/minute vs. 9.9 [SD = 12.9] m/minute, $p = 0.01$) A sample size of 32 participants per group is required for a definitive effect size.
Concept vs. constraint-induced movement therapy to improve arm functional recovery in stroke patients ⁴²	To compare the effects of a Bobath intervention and constraint-induced movement therapy on arm functional recovery among stroke patients with a high level of function on the affected side.	A total of 24 patients were randomized to constraint-induced movement therapy or Bobath intervention group.	The Bobath intervention group was treated for 1 hour, whereas the constraint-induced movement therapy group received training for 3 hours/day during 10 consecutive weekdays.	Level 1 evidence Single-blinded randomized controlled trial.	Constraint-induced movement therapy and the Bobath intervention have similar efficiencies in improving functional ability, speed, and quality of movement in the paretic arm among stroke patients with a high level of function. Constraint-induced movement therapy seems to be slightly more efficient than the Bobath intervention in improving the amount and quality of affected arm use.	There were no significant differences in Wolf Motor Function Test "functional ability" ($p = 0.137$) and "performance time" ($p = 0.922$), Motor Evaluation Scale for Arm in Stroke Patients ($p = 0.947$) and Functional Independence Measure scores ($p = 0.259$) between the two intervention groups. Significant improvements were seen after treatment in the "amount of use" and "quality of movement" subscales of the Motor Activity Log-28 in the constraint-induced movement therapy group over the Bobath group ($p = 0.003$; $p = 0.01$, respectively).

Section 6 Guidelines for Physical Dysfunction Diagnostic Categories

Chapter 36

Cerebrovascular Accident

Dawn M. Nilsen and Glen Gillen

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the etiology and risk factors associated with cerebrovascular accidents (CVA, stroke).
2. Describe the classic signs and symptoms associated with stroke.
3. Identify common impairments in client factors and performance skills that impact engagement in occupation after stroke.
4. Describe how impairments in body function (e.g., motor impairments) impact daily functioning.
5. Apply a client-centered approach to evaluation and treatment.
6. Describe evaluation procedures to assess limitations after stroke.
7. List and describe standardized assessments that are commonly used to assess impairments in body functions and performance skills after stroke.
8. Describe evidence-based treatment approaches commonly applied during stroke rehabilitation.
9. Develop targeted occupation-based treatment plans designed to remediate or compensate for underlying impairments.
10. Describe health promoting behavioral changes designed to prevent secondary strokes.

CHAPTER OUTLINE

Introduction
Stroke Epidemiology
Stroke Etiology
Common Stroke Syndromes
Medical Management
The Impact of Stroke on Daily Occupation
Evaluation and Intervention of Functional Skill Deficits Secondary to Stroke
Case Study

TERMINOLOGY

- Acalculia/Dyscalculia:** the inability or impaired ability to perform simple mathematical calculations previously mastered.
- Agnosia:** the inability to recognize objects, persons, smells, or sounds despite having normal sensory functions (e.g., vision or hearing).
- Apraxia/Dysgraphia:** the inability or impaired ability to produce written language.
- Alexia/Dyslexia:** the inability or impaired ability to read written language despite preservation of other aspects of language.
- Aneurysm:** a weakening of an artery wall, resulting in a bulge or distension of the artery.
- Anomia:** the inability to name objects or persons.
- Anosognosia:** an unawareness or denial of a neurological deficit that is clinically evident.
- Aphasia:** an acquired multimodality language disorder that results from damage to the language centers of the brain.

Apraxia: the inability to perform purposeful actions despite having normal muscle function.

Arteriovenous malformation: a tangle of abnormal blood vessels connecting arteries and veins without an intervening capillary bed.

Contracture: an abnormal shortening of muscle tissue, rendering the muscle highly resistant to passive stretching; typically results in permanent restrictions in joint motion.

Contralateral homonymous hemianopia: an ocular condition in which vision has been lost in the same field halves of both eyes.

Dysarthria: a speech disorder resulting from paralysis, weakness, or incoordination of the muscles involved in speech production.

Dysphagia: an eating disorder involving difficulty manipulating and transporting solids/liquids from the oral cavity to the pharynx.

Hemianesthesia: a loss of sensation in either half of the body.

Spasticity: a velocity-dependent increase in tonic stretch reflexes; also denotes a form of muscular hypertonicity with exaggeration of tendon reflexes.

Subluxation: an incomplete or partial dislocation of a joint.

Introduction

A cerebrovascular accident (CVA) or stroke is an acute neurological event of vascular origin that impacts brain functioning. According to the World Health Organization (WHO), a stroke is an “acute focal neurological dysfunction lasting more than 24 hours (or leading to death in <24 hours).”¹ A stroke in one hemisphere of the brain often results in upper motor neuron dysfunction, leading to contralateral weakness (hemiparesis) or paralysis (hemiplegia) of the body, and possibly the face and oral motor structures. For example, a left hemisphere lesion (left CVA) may result in right hemiplegia, whereas a right hemisphere lesion (right CVA) would result in left hemiplegia. In addition to motor deficits, a variety of other impairments may result from stroke. These include the following:

- Sensory impairment
- Cognitive and perceptual impairment
- Visual disturbances
- Behavioral changes
- Difficulty swallowing
- Speech and language function impairment

These client factor deficits can significantly impact an individual’s ability to engage in chosen occupations, limiting participation and quality of life.

This chapter provides an overview of (1) stroke epidemiology, (2) common stroke syndromes, (3) medical management of stroke, (4) the impact of stroke on occupational engagement, and (5) evidence-based assessment and intervention for individuals sustaining stroke. Although the focus of this chapter is on patients with stroke, it should be noted that other types of brain injuries and disease processes, such as head injuries, neoplasms, and infectious diseases, can produce similar impairment patterns. Thus, some treatment approaches presented in this chapter may apply to other diagnoses.

Stroke Epidemiology

According to the American Heart Association/American Stroke Association (AHA/ASA),² stroke continues to be the number one cause of long-term disability in the United States. AHA/ASA stroke statistics indicate that 795,000 individuals sustain a new or recurrent stroke each year. An estimated 7.2 million Americans over the age of 20 self-report having had a stroke. Projections show that an additional 3.4 million Americans aged greater than or

equal to 18 years will sustain a stroke by 2030, representing a 20.5% increase in prevalence from 2012.²

The incidence of stroke is 1.25 times higher in men than in women, although women have a higher lifetime risk of stroke. More than half of all patients hospitalized for acute neurological disease have sustained a stroke, and the impact of stroke on function is compelling. Among long-term patients who sustained a stroke, 50% have hemiparesis, 30% are unable to walk without assistance, 26% are dependent in activities of daily living (ADLs), 19% are aphasic, 35% are clinically depressed, and 26% require home nursing care.²

In addition, evidence suggests that long-term health-related quality of life is decreased in patients having sustained stroke.^{3,4} Given the scope and long-term nature of the problems resulting from stroke, it is clear why stroke rehabilitation is an important practice area within occupational therapy.

Stroke Etiology

The vascular syndromes that cause stroke can be divided into two broad categories: ischemic and hemorrhagic. Ischemic strokes account for approximately 87% of all strokes.² Age, gender, race, ethnicity, and genetic factors are considered nonmodifiable risk factors for stroke²; however, there are several modifiable risk factors that are often targeted in stroke prevention and education programs. Important modifiable risk factors include²:

- Hypertension
- Diabetes mellitus
- Disorders of heart rhythm such as atrial fibrillation
- High blood cholesterol and other lipids
- Cigarette smoking
- Obesity
- Lifestyle factors such as physical inactivity, and poor diet and nutrition

Ischemia

Ischemia results when there is insufficient blood flow to meet metabolic demands. The most common cause of an ischemic stroke is an obstruction of the blood vessels supplying the brain.^{2,5} Obstruction may result from a thrombus (blood clot) or an embolism.⁵ A cerebral thrombosis is a blood clot that forms within a cerebral vessel. An embolism is a blood clot that originates in the heart (cardiac source) or arterial sources outside the brain.⁵ These clots become dislodged from their origin sites and subsequently block vessels supplying the brain. While vessel obstruction is the most common stroke cause, ischemia can also result from systemic blood flow reduction (such as occurs during cardiac arrest).^{2,5}

Hemorrhage

Hemorrhagic strokes are caused by rupture of a weakened blood vessel and include intracerebral (within the brain) and subarachnoid (within the subarachnoid space) hemorrhages.⁵ The most common causes of weakened vessels are **aneurysms** and **arteriovenous malformations**.⁵ Intracerebral hemorrhages account for approximately 10% of all strokes, whereas subarachnoid hemorrhages occur less frequently.²

Transient Ischemic Attack

A transient ischemic attack (TIA) is an event that results in neurological symptoms resembling a stroke.² Although these symptoms develop suddenly and may last up to 24 hours, they resolve completely, leaving no discernable symptoms or deficits.² TIAs are considered a “warning sign” of an impending stroke and precede approximately 12% of all strokes.²

Common Stroke Syndromes

Based on location, strokes are broadly categorized as either cortical or subcortical⁵ and involve either the anterior (internal carotid artery and its branches) or posterior (branches of the vertebrasilar system) circulations of the brain⁶ (see Fig. 36-1). As the name suggests, cortical strokes impact areas of the cerebral cortex, such as the frontal, parietal, temporal, or occipital lobes. Subcortical strokes impact structures below the cortex, such as the internal capsule, basal ganglia, thalamus, brainstem, and cerebellum.^{5,6} Strokes may also occur at the junction between two main arteries. These types of strokes are known as border zone or watershed infarcts.⁶ Stroke outcomes largely depend on lesion size and location.⁵

Figure 36-1 The anterior and posterior circulations of the brain. Note the internal carotid artery, the vertebral arteries, basilar artery, and the distribution patterns of the anterior (green), middle (purple), and posterior cerebral (orange) arteries. **A.** Right lateral view of right cerebral hemisphere. **B.** Medial view of left cerebral hemisphere. **C.** Inferior view.

Diagnostic imaging assists in determining stroke cause and location. Techniques such as computed tomography, magnetic resonance imaging, positron emission tomography, and single-photon emission computed tomography can provide information (e.g., lesion size and location) that may be used to assist with assessment and intervention planning.⁵ Diagnostic testing results are usually accessible in the medical record and can be obtained during the information-gathering stage prior to patient evaluation.⁵ A brief overview of common stroke syndromes is presented in the following section, and a summary of common impairments resulting from anterior and posterior circulation strokes is presented in Tables 36-1 and 36-2.

Table 36-1. Anterior Circulation Strokes: Areas Supplied and Common Impairments

ARTERY	LOCATION	KEY FUNCTIONAL AREAS ⁶	POSSIBLE IMPAIRMENTS ⁵
--------	----------	-----------------------------------	-----------------------------------

ARTERY	LOCATION	KEY FUNCTIONAL AREAS ⁶	POSSIBLE IMPAIRMENTS ⁵
Anterior cerebral artery (ACA)	Medial and superior surfaces of frontal and parietal lobes; majority of the corpus callosum	Primary motor and sensory cortices for the leg and foot; motor planning areas; prefrontal cortex	<ul style="list-style-type: none"> • Contralateral hemiparesis—greater involvement of the leg and foot • Contralateral somatosensory loss—greater involvement of the leg and foot • Left unilateral apraxia • Behavioral disturbances • Mental changes • Inertia of speech or mutism
Middle cerebral artery (MCA)—complete	Lateral surfaces of the hemisphere; penetrating branches supply the basal ganglia and portions of the internal capsule	Primary motor and sensory cortices for the face, trunk arm, and hand; frontal eye fields; Broca and Wernicke areas; parts of the frontal and parietal lobes important for motor planning, lateralized attention, visuospatial analysis and emotional expression; optic radiations; subcortical white matter (corticobulbar and corticospinal tracts); basal ganglia	<p>Damage to Either Hemisphere</p> <ul style="list-style-type: none"> • Contralateral hemiplegia • Contralateral somatosensory loss • Contralateral homonymous hemianopia • Strong gaze preference toward lesion side (acutely) <p>Damage to Right Hemisphere</p> <ul style="list-style-type: none"> • Neglect, visuospatial impairments, emotional lability, behavioral disturbances <p>Damage to Left Hemisphere</p> <ul style="list-style-type: none"> • Apraxia • Global aphasia

ARTERY	LOCATION	KEY FUNCTIONAL AREAS ⁶	POSSIBLE IMPAIRMENTS ⁵
MCA— superior division	Lateral surfaces of frontal and parietal lobes	Primary motor and sensory cortices for the face, trunk, and UE; Broca area; frontal eye fields; parts of the frontal and parietal lobes important for motor planning, lateralized attention, visuospatial analysis, and emotional expression	<p>Damage to Either Hemisphere</p> <ul style="list-style-type: none"> • Contralateral hemiparesis: greater involvement of the face, arm, and hand • Contralateral somatosensory loss: greater involvement of the face, arm, and hand • Visual field impairment • Poor contralateral conjugate gaze • Ideational apraxia • Lack of judgment • Perseveration • Impaired organization of behavior • Depression • Lability • Apathy <p>Damage to Right Hemisphere</p> <ul style="list-style-type: none"> • Left unilateral body neglect • Left unilateral visual neglect • Anosognosia • Visuospatial impairment • Left unilateral motor apraxia <p>Damage to Left Hemisphere</p> <ul style="list-style-type: none"> • Bilateral motor apraxia • Broca aphasia • Frustration
MCA— inferior division	Lateral surfaces of temporal lobe, and portions of parietal and occipital lobes	Wernicke area; parts of temporal and parietal lobes important for visuospatial analysis and emotional expression; optic radiations	<p>Damage to Either Hemisphere</p> <ul style="list-style-type: none"> • Contralateral visual field deficit • Behavioral abnormalities <p>Damage to Right Hemisphere</p> <ul style="list-style-type: none"> • Visuospatial dysfunction <p>Damage to Left Hemisphere</p> <ul style="list-style-type: none"> • Wernicke aphasia
Internal carotid artery— source of the ACA and MCA	Combination of the anterior and middle cerebral artery distributions	Combination of the key functional areas supplied by the ACA and MCA	Impairments as indicated above for both ACA and MCA

UE, upper extremity.

Table 36-2. Posterior Circulation Strokes: Areas Supplied and Common Impairments

ARTERY	LOCATION	KEY FUNCTIONAL AREAS ⁶	POSSIBLE IMPAIRMENTS ^{5,8-10}
Posterior cerebral artery (PCA)	Medial and inferior surfaces of temporal and occipital lobes; posterior corpus callosum; penetrating branches to midbrain and thalamus	Primary visual areas; optic radiations; parts of the temporal lobe important for memory formation; multimodal association areas important for visuospatial analysis, writing, reading, and so on	<p>Damage to Either Hemisphere</p> <ul style="list-style-type: none"> • Contralateral hemiparesis • Sensory loss • Homonymous hemianopia or quadrantanopia • Visual agnosia • Memory impairments <p>Damage to Right Hemisphere</p> <ul style="list-style-type: none"> • Cortical blindness • Visuospatial impairment • Impaired left-right discrimination <p>Damage to Left Hemisphere</p> <ul style="list-style-type: none"> • Finger agnosia • Anomia • Agraphia • Acalculia • Alexia/Dyslexia

ARTERY	LOCATION	KEY FUNCTIONAL AREAS ⁶	POSSIBLE IMPAIRMENTS ^{5,8-10}
<p>Vertebral-Basilar Artery System <i>Branches of the vertebral arteries:</i></p> <ul style="list-style-type: none"> • Anterior and posterior spinal arteries • Posterior inferior cerebellar artery (PICA) <p><i>Branches of the basilar artery:</i></p> <ul style="list-style-type: none"> • Anterior inferior cerebellar artery (AICA) • Pontine arteries • Superior cerebellar artery • PCA (terminal branch) —see above 	<p>Majority of the thalamus; hypothalamus; brainstem (BS) structures; cerebellum</p>	<p>Cranial nerve (CN) nuclei and CN roots (refer to Chapter 20); ascending and descending tracts as they travel through BS; areas important for balance, coordination, and motor learning; areas important for the regulation of vital functions (e.g., wakefulness, cardiorespiratory activities, swallowing)</p>	<p>Damage involving this system can produce specific BS syndromes that often produce crossed motor and sensory deficits and a complex set of signs and symptoms secondary to the involvement of multiple areas of the brain. See above for PCA strokes.</p> <p>The following select BS syndromes are presented as examples:</p> <p>Wallenberg Syndrome (aka lateral medullary syndrome) vascular territory of the PICA:</p> <ul style="list-style-type: none"> • Contralateral loss of pain and temperature sensation—body • Ipsilateral loss of pain and temperature sensation—face • Dysphonia, dysphagia, and deviation of the uvula to the opposite side of the lesion on phonation • Vertigo, nystagmus, nausea, vomiting • Ataxia <p>Dejerine Syndrome (aka medial medullary syndrome) vascular territory of the vertebral artery/anterior spinal artery:</p> <ul style="list-style-type: none"> • Contralateral hemiplegia • Contralateral loss of touch, vibration, and proprioception—body • Ipsilateral deviation of the tongue on protrusion <p>Millard-Gubler Syndrome (aka ventral pontine syndrome) vascular territory of the basilar artery</p> <ul style="list-style-type: none"> • Contralateral hemiplegia • Contralateral impairments in pain and temperature sensation—body • Ipsilateral impairments in pain and temperature sensation—face <p>“Locked-in” Syndrome: vascular territory of the basilar artery impacting the pons</p> <ul style="list-style-type: none"> • Quadriplegia • Paralysis of all muscles innervated by CNs, except for the muscles of the eye. • Anarthria with preservation of consciousness • Dysphagia • May require assistance with ventilation <p>Weber Syndrome: vascular territory of the penetrating branches of the PCA impacting the midbrain</p> <ul style="list-style-type: none"> • Contralateral hemiplegia • Contralateral Parkinson tremor, akinesia • Contralateral weakness of the lower muscles of facial expression, deviation of the tongue to the contralateral side on protrusion, and ipsilateral weakness of the trapezius and sternocleidomastoid muscles • Ipsilateral oculomotor palsy (down and out position of the eye), dilated pupil, and diplopia

Anterior Circulation Strokes

The internal carotid arteries and their two main branches, the anterior cerebral arteries and middle cerebral arteries, supply approximately two-thirds of the brain, constituting the brain's anterior circulation.⁶ Stroke in the territory of the middle cerebral artery is the most common type of anterior circulation infarct, accounting for approximately 70% of all first strokes.⁷ The clinical presentation of anterior circulation strokes will vary depending on the branches involved and the extent of the occlusion.

Occlusion of the internal carotid artery commonly results in contralateral hemiplegia, **hemianesthesia**, homonymous hemianopia, changes in mental functions, and behavioral disturbances.⁵ If the stroke occurs in the dominant hemisphere (i.e., hemisphere containing the representation of speech and controlling the extremities used to perform skilled movements such as writing and kicking a ball; the left hemisphere in the majority of individuals), the patient may also present with **aphasia**, **agraphia** or **dysgraphia**, **acalculia** or **dyscalculia**, and **apraxia**.⁵ If the nondominant hemisphere is involved, the patient may present with visual perceptual impairments, unilateral body or spatial neglect, **anosognosia**, and dressing apraxia.⁵

An occlusion of the anterior cerebral artery typically produces contralateral hemiparesis and somatosensory loss, impacting the leg to a greater degree than the arm.⁵ Behavioral disturbances, apraxia, and mental changes—such as confusion, disorientation, decreased initiation, and impairments in attention and short-term memory—are often present.⁵

An occlusion of the middle cerebral artery typically produces contralateral hemiplegia, impacting the upper extremity (UE), trunk, face, and tongue; contralateral somatosensory loss; and **contralateral homonymous hemianopia** with a strong gaze preference toward the lesion side observed acutely.⁵ If the stroke involves the dominant hemisphere, aphasia is common. If the stroke involves the nondominant hemisphere, perceptual disturbance—such as unilateral neglect, anosognosia, and visual-spatial deficits—are common.⁵ In addition, different patterns of deficits will be seen with a stroke involving the superior or inferior divisions of the middle cerebral artery (see Table 36-1).

Posterior Circulation Strokes

The vertebrobasilar artery system (i.e., vertebral and basilar arteries and their many branches) constitutes the posterior circulation of the brain, which supplies the brainstem, diencephalon, cerebellum, parts of the temporal lobe, and the majority of the occipital lobe.⁶ Strokes involving the posterior circulation are less common, accounting for approximately 20% of all ischemic strokes.⁸ The clinical presentations of these strokes vary considerably, and specific subcortical stroke syndromes, such as Weber, Dejerine, and Wallenberg syndromes, are well described in the literature^{8,9} (see Table 36-2). Common presenting signs and symptoms of posterior circulation strokes include vertigo, impaired balance, slurred speech, double vision, headache, nausea, vomiting, unilateral limb weakness and numbness, gait and limb ataxia, **dysarthria**, **dysphagia**, and nystagmus.^{5,8,9}

Occlusion of the posterior cerebral artery may result in a variety of deficits depending on the extent of occlusion and the involved arterial branches. Possible deficits include sensory and motor impairments, visual field deficits (contralateral hemianopia or quadrantanopia), cortical blindness, **agnosia**, memory impairments, and **alexia/dyslexia**.^{5,8,10}

Boarder Zone (Watershed) Infarcts

Border zone infarcts are thought to be the result of hemodynamic failure produced by repeated episodes of hypotension in the presence of severe arterial stenosis or occlusion, microemboli originating from the heart or atherosclerotic plaques in major arteries, or a combination of hypoperfusion and embolization.¹¹ They account for approximately 10% of all strokes and are classified as cortical (external) or subcortical (internal).¹¹ Common locations of cortical watershed infarcts are along the borders of the anterior and middle cerebral arteries, and the middle and posterior cerebral arteries.^{6,11}

The clinical presentation of border zone infarcts will vary according to the involved vessels and areas of compromised cerebral tissue. Typically, damage to the anterior and

middle cerebral artery border zone will result in LE contralateral hemiparesis, expressive language impairments, and behavioral disturbances. Damage to the middle and posterior cerebral artery border zone will typically result in partial visual loss and a variety of language impairments.⁶

Medical Management

The medical management of stroke will depend on multiple factors, including, but not limited to, lesion type, location, and extent; neurological deficits and associated medical problems; availability of technology; access to trained medical personnel; and ability and willingness of patients and their supportive network to cooperate with treatment recommendations.

According to the *AHA/ASA 2018 Guidelines for the Early Medical Management of Patients with Acute Ischemic Stroke*,¹² acute medical management should encompass prehospital care, urgent and emergency evaluation, treatment with intravenous (IV) and intra-arterial therapies as appropriate to restore blood flow, and in-hospital management focused on prevention measures instituted within the first 2 weeks after stroke onset.

The guidelines indicate the need to enhance public awareness of stroke warning signs and access medical care in a timely manner. It is recommended that first aid providers use a stroke assessment system and that emergency medical personnel begin initial stroke management in the field, including use of valid and standardized stroke screenings such as the FAST (Face, Arm, Speech Test) scale. Patients with a positive stroke screen and/or a strong suspicion of stroke should be transported to the nearest Certified Stroke Center, or health care facility capable of administering IV alteplase (aka IV tPA: tissue plasminogen activator), a medication that dissolves blood clots.¹²

Emergency evaluation and treatment should focus on determining the type and location of stroke and preventing mortality and/or progression of the brain lesion. The guidelines recommend the following¹²:

- Use of a stroke severity rating scale, preferably the National Institutes of Health Stroke Scale (NIHSS), to quantify the degree of neurological deficit
- Brain imaging evaluations to determine the type and location of stroke
- Additional diagnostic tests, as needed, to determine the cause of stroke
- Establishment of an open airway, maintenance of breathing, and appropriate oxygenation
- Maintenance of appropriate blood pressure, body temperature, and blood glucose levels
- Administration of IV alteplase or mechanical thrombectomy (i.e., removal of blood clots) as appropriate

After emergency management and treatment, in-hospital management should include the following¹²:

- Dysphagia screening before the patient begins eating, drinking, or taking oral medications
- Establishment of appropriate nutrition, which may necessitate the placement of a nasogastric tube (feeding tube that is placed through the nose and into the stomach)
- Continued maintenance of appropriate blood pressure, body temperature, and blood glucose levels
- Cardiac evaluation and monitoring as needed
- Treatment of any acute complications that may arise (e.g., edema, pneumonia)

Treatment of bowel and bladder incontinence; assessment, prevention, and treatment of hemiplegic shoulder pain; fall prevention; skin integrity maintenance; and prevention of deep vein thrombosis (DVT) (clots that form in the deep veins, frequently in the LEs) are also important during the acute phase.^{12,13} Prolonged bed rest and immobilization place patients at risk for the development of decubitus ulcers (skin breakdown) and DVTs. Proper positioning and early mobilization may prevent the development of these secondary

complications. In immobilized patients without contraindications, intermittent pneumatic compression in addition to routine care is recommended to reduce DVT risk.¹²

Finally, the guidelines recommend routine screening for poststroke depression, that patients diagnosed with depression be treated with antidepressants in the absence of contraindications, and that early rehabilitation for hospitalized patients be provided by trained personnel at an intensity appropriate to anticipated benefit and tolerance.¹² High-dose very early mobilization (within 24 hours of stroke onset) should be avoided because it can reduce the odds of favorable long-term outcomes.¹²

The course and prognosis for each patient will vary based on residual deficits, but the majority will require postacute care. In fact, more than two-thirds will receive rehabilitation services after initial hospitalization.¹³ Rehabilitation services are typically delivered by a multidisciplinary team consisting of physicians, nurses, occupational therapists, physical therapists, and speech language therapists. Social workers, psychologists, psychiatrists, and counselors may also play a role in the rehabilitative process. Rehabilitative treatment intensity will vary depending on the setting. The most intensive treatment is provided in inpatient rehabilitation facilities (occupational, physical, and speech language therapy administered at a minimum of 3 hours per day, 5 days per week), followed by skilled nursing facilities delivering subacute care.^{13,14}

For patients with continued needs who are discharged directly home after hospitalization, therapy is often provided in the community by home health agencies or outpatient clinics.^{13,14} Although formal rehabilitation commonly ends 3 to 4 months after stroke, unmet needs persist in areas such as social reintegration, health-related quality of life, maintenance of activity, and self-efficacy.¹³ Therefore, patients may require continued monitoring for needed therapy services for years after stroke onset.

The Impact of Stroke on Daily Occupation

Each patient having sustained stroke will have a unique set of impairments as a result of lesion location and extent (see Tables 36-1 and 36-2). These impairments can impede the patient's ability to engage in chosen activities. Hemiparesis is the most common consequence of stroke,¹⁵ resulting in decreased ability to effectively move one side of the body. These motor impairments can pose significant barriers to occupational engagement. For example, impairment in trunk and postural control may limit the patient's ability to perform functional activities in sitting or standing, whereas UE weakness may limit use of the arm and hand in daily activities. Likewise, concomitant somatosensory impairment, cognitive and perceptual deficits, language production and comprehension impairment, visual impairment, and psychosocial limitations can negatively impact occupational engagement. The following sections and Table 36-3 highlight the most common problems experienced after stroke.

Table 36-3. Impact of Stroke on Occupational Engagement

COMMON LIMITATIONS	EXAMPLES OF IMPACT OF LIMITATIONS ON FUNCTION
Trunk and Postural Control	
<ul style="list-style-type: none"> • Multidirectional trunk weakness • Impairments in appropriate activation of trunk and postural control muscles • Assumption of abnormal static sitting postures (i.e., posterior pelvic tilt, kyphosis, lateral flexion) • Asymmetrical weight bearing in sitting and standing • Decreased ability to shift weight through the pelvis and legs • Inability to perceive the midline as a result of spatial relationship dysfunction 	<ul style="list-style-type: none"> • Increased risk of falls • Decreased independence in ADL and IADL • Inability to use the more functional arm during chosen activities secondary to the arm being used for postural support • Visual dysfunction secondary to malalignment of the head and neck in sitting and standing • Swallowing difficulties secondary to poor proximal alignment
Upper Extremity	

COMMON LIMITATIONS	EXAMPLES OF IMPACT OF LIMITATIONS ON FUNCTION
<ul style="list-style-type: none"> • Weakness • Loss of selective motor control • Changes in muscle tone • Contractures • Joint subluxation • Pain • Somatosensory loss 	<ul style="list-style-type: none"> • Decreased ability to reach, grasp, transport, and manipulate objects during ADLs • Decreased independence in ADL and IADL • Development of pain syndromes that can impact sleep patterns and decrease motivation to engage in activity
Cognition and Perception	
<ul style="list-style-type: none"> • Apraxia • Unilateral neglect • Memory loss • Attention deficits • Executive dysfunction • Spatial dysfunction 	<ul style="list-style-type: none"> • Inability to use or manipulate utensils correctly • Difficulty locating a clock on the left side of the room • Forgetting a shopping list • Not able to sustain the task of reading a recipe • Difficulty multitasking • Difficulty aligning/orienting clothing to the body
Vision	
<ul style="list-style-type: none"> • Diplopia • Decreased acuity • Visual field cut • Strabismus 	<ul style="list-style-type: none"> • Double vision impairs reading, mobility, and so on • Difficulty with medication management • Will require mobility options other than driving • Poor depth perception results in spilling milk when pouring into cup
Psychosocial	
<ul style="list-style-type: none"> • Depression • Anxiety • Lability 	<ul style="list-style-type: none"> • Decreased engagement in leisure activities • Fearful to leave the home • Not able to maintain social relationships

ADL, activity of daily living; IADL, instrumental activity of daily living.

Trunk and Postural Control Impairments

Appropriate trunk and postural control (the ability to maintain equilibrium in a gravitational field by maintaining or returning body mass center over its base of support¹⁶) are needed for engagement in a broad range of activities, such as walking and wheelchair propulsion, morning self-care routines, work-related tasks while seated at a desk, and meal preparation. It is common for patients having sustained stroke to exhibit impairments in trunk and postural control.

Specific deficits related to stroke include:

- Multidirectional trunk weakness¹⁷
- Reduced and delayed activation of trunk muscles on the paretic side in anticipation of limb movements^{18,19}
- Reduced and delayed activation of postural control muscles on the paretic side in response to postural perturbations^{20,21}
- Loss of automatic postural reactions such as ankle, hip, and stepping strategies during standing²²
- Asymmetrical trunk movements during walking²³
- Asymmetrical weight bearing in sitting²⁴ and standing (favoring the nonparetic LE)²⁵
- Soft-tissue **contractures** that limit spine mobility²⁶
- Inability to perceive midline as a result of spatial relationship dysfunction²⁶

These impairments may manifest as an inability to sit or stand in proper alignment, an inability to engage the upper limbs in functional tasks, an inability to reach beyond arm's length while sitting or standing, gait impairments, an inability to transfer or climb stairs, and balance loss and fall risk during functional activities. In fact, studies have found trunk and postural control to be strongly associated with poststroke UE function,²⁷ gait, and balance²⁸; and trunk control to be a predictor of comprehensive ADL function (as measured by the Barthel Index and Frenchay Activities Index)²⁹ and gait recovery.³⁰

Upper Extremity Impairments

The majority of the daily activities in which we engage require interaction with objects in the environment. Thus, the ability to use the arm and hand to reach, grasp, transport,

manipulate, and release objects is critical for daily functioning. A majority of patients experience UE dysfunction poststroke, with the most common impairment being paresis.¹³ In addition to weakness, loss of selective motor control, changes in muscle tone, and somatosensory loss can impact the patient's ability to engage the UE during functional activities.^{31,32}

Also problematic are secondary complications that may develop as a consequence of abnormal muscle activity. For example, profound muscle weakness and loss of muscle tone (flaccidity) during poststroke early phases, coupled with the dependent nature of the arm and hand, may cause the following³³:

- Edema (predominantly in the hand)
- Overstretching of the glenohumeral joint capsule
- Establishment of muscle imbalances caused by shortening of some muscle groups and overlengthening of others (e.g., shortening of shoulder internal rotator and overlengthening of external rotators)
- Shoulder joint subluxation
- Risk of joint and soft-tissue injuries during the performance of daily tasks

After the initial period of profound weakness, hypertonia (increased muscle tone), stereotypical limb posturing, hyperactive stretch reflexes, and **spasticity** may develop. If spasticity is not appropriately managed, complications such as joint deformities and contractures, skin breakdown on the palmar hand surface, and the development of pain syndromes may arise.^{32,33}

In fact, according to the *AHA/ASA Guidelines for Adult Stroke Rehabilitation and Recovery*,¹³ shoulder pain is common after stroke, with a reported incidence of up to 22% within the first year after the onset. The development of pain is commonly associated with shoulder **subluxation** and motor weakness; however, spasticity is also thought to contribute to shoulder pain in some patients. Other predictors of shoulder pain include¹³:

- Older age
- Left hemiplegia
- Presence of tactile extinction (i.e., impaired ability to sense sensory stimuli applied to the affected limb when stimuli are simultaneously applied to the unaffected limb) and reduced proprioception
- Reduced passive abduction and external rotation at the shoulder joint
- Shoulder pain with passive shoulder abduction with the arm internally rotated
- Tenderness to palpation over the biceps and supraspinatus tendons

Few patients make a full recovery, and the vast majority must contend with UE limitations. It is estimated that approximately 65% of patients cannot incorporate their affected hand into daily activities at 6 months poststroke onset.³⁴ This decreased ability to use the arm and hand during ADLs results in activity limitations and participation restrictions that impact quality of life.^{13,35}

Cognitive and Perceptual Impairments

Most patients having sustained stroke present with some deficits related to cognitive and perceptual processing.³⁶ Deficits can range from mild to severe and substantially impact activity and role performance. It is generally agreed that patients with cognitive and perceptual deficits have suboptimal outcomes compared to those without such deficits.³⁶ It is common for deficits to appear in clusters based on the stroke lesion site. For example, those with left hemispheric strokes may present with ideational apraxia, motor apraxia, poor organization, decreased ability to sequence, and impaired judgment. Those with right hemispheric strokes may present with unilateral spatial neglect, unilateral body neglect, decreased attention, and spatial dysfunction.

Depending on the type and severity of cognitive and perceptual deficits, multiple aspects of daily life can be impacted including:

- Decreased independence in basic ADLs and functional mobility³⁷
- Decreased independence and efficiency performing instrumental activities of daily living (IADLs)³⁸
- Inability to return to work³⁹
- Inability to drive⁴⁰

Language Impairments

Deficits in speech and language functions are common problems, particularly in strokes involving the left hemisphere. Disorders of aphasia, dysarthria, and speech apraxia can impair an individual's ability to communicate impacting engagement in daily occupations and overall quality of life.⁴¹ The speech language therapist is the member of the rehabilitation team who evaluates and treats speech and language disorders. These therapists provide valuable information to the treatment team and members of the patient's social network regarding the best methods for communicating with the patient. Practitioners should incorporate these recommendations when working with their patients. Common disorders of speech and language functions are described in the subsequent sections. It is important to note that these disorders may range in severity and may occur in isolation or in combination with each other.

Aphasia is an acquired multimodality language disorder that results from damage to the brain's language centers.⁴¹ As such, it can impair the understanding and expression of both oral and written language modalities. Aphasias are frequently classified according to verbal fluency, auditory comprehension, and repetition ability. According to Cherney and Small,⁴¹ "non-fluent aphasia is characterized by output that is slow, labored, and effortful." Phrase length (i.e., number of words produced continuously without a pause) is short, and normal grammar is lacking. Conversely, fluent aphasia is characterized by speech that is easily produced and prosody (i.e., patterns of stress and language intonation) that is normal. Phrase length is adequate, and sentences are grammatically correct. The most common types of nonfluent and fluent aphasias are described as follows.⁴¹

Broca Aphasia

Nonfluent aphasia is characterized by speech that is slow and effortful, with disrupted prosody. Phrase length is short (<4 words), and sentences are simplified. Apraxia of speech may also be present. Comprehension is relatively intact, and repetition ability is poor.⁴¹

Wernicke Aphasia

Fluent aphasia is characterized by speech that is well articulated, but often produced at an increased rate. Phrase length is greater than four words. Oral expression contains paraphrasing (i.e., sound substitutions), neologisms (i.e., newly coined word), or often lacks content words. Comprehension and repetition ability are poor.⁴¹

Anomic Aphasia

Fluent aphasia is characterized by word-finding pauses that may interrupt speech flow. Phrase length is within normal ranges and sentences are grammatically correct. Circumlocution or use of nonspecific words to cope with word-finding difficulties is noted. Comprehension and repetition ability are good.⁴¹

Global Aphasia

Nonfluent and severely impaired aphasia are characterized by stereotypical utterances that may be present. Comprehension and repetition ability are severely impaired.⁴¹

Dysarthria is a term used to describe speech disorders that result from paralysis, weakness, or incoordination of the muscles involved in speech production.⁴¹ These deficits impact various dimensions of speech, including articulation, pitch, loudness, vocal quality

(e.g., harsh, hoarse, breathy, strained/strangled, hyponasality or hypernasality), ventilation, and prosody. Overall, speech intelligibility is affected to varying degrees from mildly impaired to unintelligible.⁴¹

Speech apraxia is a disorder of motor programming or planning impacting speech articulation and prosody.⁴¹ Common symptoms of speech apraxia include difficulty producing correct sounds, inconsistent or variable errors in sound production with more consonant than vowel errors, difficulty producing consonants that are adjacent to each other (e.g., str, bl), incorrectly using sounds or words that approximate the target sound or word, and disruptions in prosody. Clients with speech apraxia are aware of their errors and may be frustrated by them.⁴¹

Visual Impairments

Approximately 25% of patients present with visual impairment poststroke.⁴² Visual impairment after stroke is associated with older age, higher NIHSS scores on admission, higher modified Rankin Scale scores, and lower Barthel Index scores at day 7.⁴² As compared to patients without visual impairment, those with such impairment present with lower quality of life, higher levels of depression and anxiety, higher fatigue severity, and lower levels of ADL and mobility function.⁴²

Specific examples of occupations impacted by visual impairment include:

- Inability to drive secondary to visual field cut or impaired depth perception
- Impaired functional mobility and potential fall risk
- Inability to read or balance a checkbook
- Inability to access electronic communication methods
- Difficulty locating objects in the environment required to perform basic ADL and/or IADL

Psychosocial Impairments

Psychosocial impairments are common after stroke. Depression and anxiety are frequently observed and are associated with increased mortality and suboptimal functional outcomes.¹³ It is important for occupational therapists to monitor and screen for signs and symptoms of psychosocial disorders. The impact of these disorders can be substantial and may include:

- Decreased or inability to participate in the rehabilitation process
- Suboptimal functional recovery
- Decreased overall social participation
- Interference with social relationships
- Altered sex drive
- Altered appetite

Evaluation and Intervention of Functional Skill Deficits Secondary to Stroke

Evaluation and intervention procedures will vary depending on the impairment pattern resulting from stroke, the recovery stage (i.e., acute, subacute, or chronic), and the treatment setting (e.g., hospital, inpatient rehabilitation facility, home environment). During the acute recovery stage, the patient is considered medically stable, the lesion is nonprogressing, and residual impairments are typically most severe. For example, a patient with a left hemisphere lesion may exhibit little or no movement of the right body side because of profound weakness, little or no response to sensory information from the right body side, and severe language impairment.

Over time, it is anticipated that the patient will improve both neurologically and functionally; however, the extent and course of improvement are difficult to predict. Some patients make only slight improvements slowly over time, whereas others regain almost full function. It is generally accepted that the majority of improvement occurs within the first 3

to 6 months^{13,15} poststroke onset (acute to subacute stages of recovery). As indicated earlier, stroke should be considered a chronic condition because >30% of patients continue to report participation restrictions 4 years poststroke onset and evidence suggests that patients can make functional improvements several years after onset (chronic stage).¹³

When determining which specific evaluations and interventions to use, and how best to implement them to address a given patient's needs, therapists should use evidence-based practice principles. To determine the best evidence available from systematic research, practitioners must remain up to date with occupational therapy and related professional literature. Systematic reviews and meta-analyses provide a synthesis of evidence related to a specific topic. Evidence-based libraries and search engines, such as the Cochrane Library, are excellent resources for locating these types of reviews.

In addition, published practice guidelines and comprehensive evidence-based reviews are available to aid therapists in the selection of appropriate evaluations and interventions when working with patients having sustained stroke. The *American Occupational Therapy Association's Occupational Therapy Practice Guidelines for Adults with Stroke*¹⁴ (AOTAPG), *AHA/ASA Guidelines for Adult Stroke Rehabilitation and Recovery*¹³ (AHA/ASA Guidelines), and *Evidence-Based Review of Stroke Rehabilitation*⁴³ are highly recommended resources. These resources provide an overview of the care continuum and provide comprehensive recommendations regarding evidence-based evaluations and interventions that address patient needs. The following sections provide an overview of evidence-based evaluations and interventions that are commonly used with patients having sustained stroke.

Evaluation Approaches

The concepts of client-centered assessment and care have been discussed in occupational therapy for over 30 years⁴⁴ and are considered best practice. Client-centered approaches are particularly useful owing to patient variability in the presentation of poststroke function. The completion of an occupational profile, collaborative goal setting, and establishing a therapeutic partnership are important client-centered care components.

When evaluating a patient having sustained stroke, therapists may use a top-down, bottom-up, or combination approach.⁴⁵ A top-down approach begins with inquiry into role performance after stroke, followed by an evaluation of the activities required for desired roles, and finally determination of which client factors support or limit occupational performance. In contrast, a bottom-up approach begins with an evaluation of patient skill impairment, followed by an evaluation of daily activities, and finally inquiry into role performance limitations resulting from stroke.⁴⁶ Although both approaches are potentially useful, the authors recommend beginning with a top-down approach followed by bottom-up evaluations as needed. Beginning with a top-down approach ensures client-centeredness, individualized goals and is consistent with performance-based assessment.

Evaluation of Areas of Occupation

Stroke may impact a patient's ability to engage in a variety of desired occupations. Guided by a top-down approach, occupations that have been identified by the patient as desired and important should be the target of evaluation. Areas of occupation evaluated may include ADLs (e.g., grooming, bathing, toileting, dressing, feeding, functional mobility), IADLs (e.g., care of others, home management, meal preparation), rest and sleep activities, educational and work activities, leisure activities, and social participation.

Direct observation of task performance and use of activity analysis allow the therapist to determine those activities for which the patient is having difficulty and to identify the factors interfering with occupational performance. Both standardized and nonstandardized methods of evaluating areas of occupation may be useful depending on the context. Standardized assessments provide reliable and valid data that can be used to guide treatment planning and evaluate changes in performance over time. Examples of standardized assessments that can be used to evaluate areas of occupation include the Activity Card

Sort,⁴⁷ the Canadian Occupational Performance Measure,⁴⁸ the Barthel Index,⁴⁹ and the Functional Independence Measure.⁵⁰

Evaluation of Performance Skills and Client Factors

Residual deficits in performance skills and client factors that limit occupational performance are common after stroke. For example, impairments in arm and hand function, balance and mobility, processing skills, communication, and emotional expression are common performance skill deficits observed after stroke. These deficits typically occur secondary to underlying client factor impairments. As indicated earlier, neuromusculoskeletal impairments, sensory impairments, and changes in mental functions are common stroke consequences. Key skills and factors to be evaluated, and common instruments used to evaluate these areas, are presented in the sections that follow. In the case of strokes impacting the brainstem, cranial nerve assessment may be needed (see Chapter 20).

Balance and Mobility

Impairment in trunk and postural control limits a client's ability to assume and maintain balance in sitting and standing positions, and reduce overall functional mobility (e.g., bed mobility, transfers, walking). Trunk and postural control can be assessed during observation of task performance in sitting (see Fig. 36-2) and standing positions. This allows the therapist to determine the patient's isometric, concentric, and eccentric trunk muscle control; symmetry of weight bearing through the pelvis and LEs; limits of stability; and the use of postural strategies (ankle, hip, and stepping strategies) to maintain balance.^{22,26} There are several standardized assessments available that can be used by occupational therapists to evaluate trunk control, balance, and functional mobility after stroke. Examples include the Postural Assessment Scale for Stroke Patients (PASS),⁵¹ Timed Get Up and Go,⁵² Berg Balance Scale,⁵³ Functional Reach Test (see Chapter 15),⁵⁴ Trunk Control Test,⁵⁵ and Tinetti Test.⁵⁶

Figure 36-2 Observation of the patient reaching for a cup with the noninvolved upper extremity, while seated at the edge of the bed. Note the asymmetrical weight bearing through the pelvis favoring the intact (*right*) side.

Upper Extremity Function

As indicated earlier, the ability to integrate the UE in ADLs is a significant problem after stroke. A comprehensive evaluation of motor skills and client factors that may limit UE engagement during function should be undertaken. The main focus of this evaluation should be to determine the capacity to use the arm and hand in daily activity performance.

There are a variety of valid and reliable performance-based and self-report measures to evaluate the capacity of the arm and hand after stroke. Performance-based measures involve the therapist rating and/or timing UE movements during the performance of simple tasks (e.g., pouring water, transporting items from one location to another, flipping cards) or more complex activities (e.g., sentence copying, shoe tying, sandwich making, or laundry folding).³² Standardized performance-based measures such as the Action Research Arm Test (see Fig. 36-3),⁵⁷ Jebsen-Taylor Test of Hand Function,⁵⁸ Wolf Motor Function Test,⁵⁹ Functional Test for the Hemiparetic UE,⁶⁰ and the Assessment of Motor and Process Skills⁶¹ can provide objective measures of arm and hand function after stroke (see Chapter 15).

Figure 36-3 A and B. Action Reach Arm Test. This test consists of 19 items grouped into four subscales: grasp, grip, pinch, and gross movement. **A.** Patient performing hardest item of grasp subsection—moving a 10-cm block from the brown square to the top of the board. **B.** Patient performing easiest item of the pinch subsection—moving a marble (using the thumb and index finger) from the brown square to the top of the board.

Conversely, self-report measures are typically semi-structured, Likert-scale questionnaires through which the therapist queries the patient or caregiver about the client's UE use during common daily activities.³² Such self-report questionnaires provide important subjective information that can be used to compliment the objective findings of performance-based measures. Examples of self-report measures that can be used to evaluate UE function poststroke include the 30-, 28-, and 14-item Motor Activity Log (see Chapter 15)⁶²⁻⁶⁴; the hand and ADL subsections of the Stroke Impact Scale (SIS)⁶⁵; the 36-item Manual Ability Measure⁶⁶; and the 23-item ABILHAND.⁶⁷

Once UE capacity for engagement in daily activities has been determined, it may be necessary to evaluate specific client factors to gain a clearer understanding of the underlying factors limiting functional arm and hand use. For example, the inability to effectively reach, grasp, and transport objects from one location to another may be due to several factors, including, but not limited to, decreased hand sensation, restricted joint mobility, insufficient grip strength, or an inability to selectively control and coordinate distal and proximal limb segment movement. Evaluations of sensation, joint alignment and mobility, muscle tone and strength, and the ability to isolate and coordinate various joint movements should be selectively performed if the therapist suspects that deficits in these areas may underlie difficulty using the arm and hand during functional activities. Each of these is discussed as follows.

Somatosensory Function

Standard procedures for assessing somatosensory functions (e.g., ability to sense touch, vibration, temperature, pain, and proprioception) are outlined in Chapter 12. The majority of these procedures can be used to assess UE sensation in patients having sustained stroke. It is important, however, to note that most of these tests require attention and the ability to follow directions, which may be impaired after stroke. It is, therefore, important to determine the patient's ability to follow assessment procedures prior to testing. Patients with language impairments impacting expressive abilities (e.g., Broca aphasia) may require modification of testing procedures (e.g., head nod or an agreed-upon gesture to indicate yes/no responses). In patients with severe language or cognitive impairments, standard testing is not possible. In these cases, gross information may be obtained via observation of limb movements (i.e., withdrawing of a limb) or facial grimacing in response to pinprick. Conversely, in patients with very mild impairments, more comprehensive sensory testing may be required to determine subtle deficits, such as impairment of two-point discrimination or the ability to distinguish light touch on the finger tips (see Chapter 12).

Joint Alignment and Mobility

It is important to assess the integrity of the shoulder joint because it is estimated that 50% of patients have inferior subluxation of the glenohumeral joint poststroke.⁶⁸ Alignment can be assessed by palpating the subacromial space while the patient is in a seated position with the arm hanging freely at the side. In this position, the therapist determines the location of the

humeral head with respect to the glenoid fossa. Subluxations are typically classified according to the position of the humeral head with respect to the glenoid fossa as (a) inferior: humeral head is below the glenoid fossa; (b) anterior: humeral head is anterior to the fossa; or (c) superior: humeral head is superior to the fossa and lodged under the acromion.³³ To determine whether there are joint mobility restrictions, passive range of motion (ROM) measurements can be obtained via goniometric measurements as needed (see Chapter 13).

Muscle Tone, Strength, and Selective Motor Control

Changes in muscle tone should be assessed to determine the presence of hypotonicity or hypertonicity/spasticity (see Chapter 15). Muscle tone can be assessed by passively moving the limb to determine its resistance to passive stretch, coupled with use of the Modified Ashworth Spasticity Scale (MASS),⁶⁹ which provides a method of quantifying spasticity using a six-point ordinal scale. Traditional tests of strength such as manual muscle testing (MMT) and dynamometry (see Chapter 13) can be used to quantify strength deficits after stroke. An alternative to traditional methods of measuring strength is the use of the Motricity Index,^{55,70} which is similar to MMT in that it involves grading strength on the basis of the patient's ability to activate muscles, move a limb segment against gravity, and tolerate resistance given by an examiner.⁷⁰

The ability to isolate and coordinate UE joint movements can be objectively measured using the UE motor section of the Fugl-Meyer Assessment⁷¹ (FMA-UE, see Chapter 15). The FMA-UE has been used to reliably measure change in UE motor impairment in a variety of stroke intervention trials⁷² and has clinical utility.⁷³ It was developed from Brunnstrom stages of motor recovery and consists of 33 items that progress from reflexive muscle activity to the ability to selectively combine and fractionate movements. Evidence suggests that scores on the FMA-UE are valid and reliable indicators of motor impairment severity across poststroke stages of recovery. Scores on the FMA-UE have been correlated with spontaneous use of the UE in a variety of common daily activities.⁷⁴ In addition, a key form recovery map was developed for use with the FMA-UE.⁷³ Use of the form allows therapists to quickly identify those movements for which the patient is having difficulty. This information can then be used to tailor UE training to target missing motor components in the context of patient selected activities.⁷³

Cognition and Perception

Because of the variability in cognitive and perceptual deficit presentation, occupational therapists must be familiar with a variety of instruments that measure the impact of these deficits on daily living skills. This approach differs from interprofessional colleagues who tend to assess cognitive skills outside the context in which they are typically performed.

The Kettle Test⁷⁵ is an example of a performance-based assessment that uses an IADL task (making two hot beverages with varying ingredients using an electric kettle) to assess cognitive skills within a functional context. Practitioners can then use this information for discharge planning. Similarly, the ADL-focused Occupation-based Neurobehavioral Evaluation (A-ONE; formerly, Árnadóttir OT-ADL Neurobehavioral Evaluation)⁷⁶ identifies specific cognitive and perceptual impairments (e.g., apraxia, unilateral neglect, spatial dysfunction, memory loss, poor organization and sequencing, decreased insight) during basic ADL and functional mobility.

There are also domain-specific performance-based assessments. Executive dysfunction is common after stroke and requires specific attention during the evaluation process. The Executive Function Performance Test⁷⁷ examines components of executive functioning such as initiation, organization, judgment, and safety while observing a patient performing IADL tasks such as cooking, money management, and bill paying. The Multiple Errands Test⁷⁸ examines the impact of executive dysfunction during a multitasking situation. The task can be performed in the community or in a public area such as a hospital lobby. Finally, the Weekly Calendar Planning Activity⁷⁹ examines executive functions performed as clients

insert multiple appointments onto a weekly paper calendar using specific rules (e.g., “Do not schedule appointments on Wednesday”).

The Catherine Bergego Scale⁸⁰ (CBS) is a standardized behavioral assessment of unilateral neglect. It is based on direct observation of the patient’s behavior in 10 everyday situations such as grooming, dressing, eating, and wheelchair mobility. More recently, the Kessler Foundation Neglect Assessment Process (KF-NAP)⁸¹ was developed based on the CBS. Because the authors found that additional instructions were needed for reliable CBS administration, they developed the KF-NAP, which provides detailed administration instructions and a scoring chart for the original 10 CBS behavioral categories (for further information regarding cognitive and perceptual evaluation, see Chapters 9 and 10).

Vision

Examples of visual screening components include near and far acuity, visual field testing, ocular ROM or control, ocular alignment, and contrast sensitivity. These skills are often considered the foundation skills for visual processing. Specific visuomotor abilities that should be assessed include fixation, pursuits, saccades, accommodation, and convergence (see Chapter 7). The Brain Injury Visual Assessment Battery for Adults (biVABA)⁸² is an example of a standardized assessment of vision and perceptual processing, including visual acuity (distant and reading), contrast sensitivity, visual field function, oculomotor function, and visual attention and scanning.

Psychosocial

As mentioned earlier, a variety of psychosocial disorders can occur after stroke and negatively impact occupational performance. Similar to other domains, therapists should be familiar with a variety of psychosocial instruments based on individual patient needs. The Beck Depression Inventory⁸³ is one of the most widely used screening instruments to measure depression severity in both adults and adolescents over the age of 13. Items relating to depressive symptoms include hopelessness, irritability, cogitations such as guilt or feelings of being punished, as well as physical symptoms such as fatigue, weight loss, and lack of sexual interest. The Patient Health Questionnaire (PHQ)-2 and PHQ-9⁸⁴ are also commonly used instruments for those with psychosocial impairment. The 9-item PHQ is based on the *Diagnostic and Statistical Manual of Mental Disorders* criteria for major depression. Sample items include little interest or pleasure in doing things; feeling down, depressed, and hopeless; and poor appetite or overeating.⁸⁵ The Hospital Anxiety and Depression Scale⁸⁶ (HADS) is a self-administered measure used to screen for the presence of depression and anxiety. The HADS includes 14 total items that ask patients to reflect on their mood in the past week. Seven items assess depression, and two concern appearance and feelings of slowing down. Seven items assess anxiety, of which two assess autonomic anxiety (panic and butterflies in the stomach), and the remaining five assess tension and restlessness.

Intervention Approaches

As indicated earlier, intervention procedures used with patients having sustained stroke will vary depending on impairment pattern, recovery stage, and treatment setting. The general focus of occupational therapy intervention during the three primary recovery phases (acute, rehabilitation, and subacute-chronic) is outlined as follows.

Acute Stage

In the acute stage (hospital setting), therapists should address:

- Appropriate positioning to prevent secondary complications such as subluxation, muscle imbalances, joint contractures, skin breakdown, and the development of pain syndromes (see subsequent section on motor impairments)
- Dysphagia management (see Chapter 19)
- Fall prevention (see Chapter 30)
- Early mobilization and the beginning of self-care activity retraining (see Chapter 27)

- Initial remediation of client factor impairments that interfere with activity engagement (see subsequent sections on intervention and Chapters 8, 9, 11, 12, 14, 16, 17, and 20)

Rehabilitation Stage

In the rehabilitation stage (inpatient rehabilitation setting):

- The focus of treatment shifts to restoration of or compensation for performance skill deficits that continue to interfere with daily occupations (e.g., limitations in UE function, balance and mobility, and mental functions) (see subsequent section on intervention).
- Maximizing independence in ADLs and IADLs for discharge to the community is a key focus of treatment during this recovery stage (see subsequent section on intervention and Section 4, Restoration of Independent and Community Living Roles).

Subacute-Chronic Stage (Home and Community Environments)

In this recovery phase, therapists should focus on:

- Maximizing independence in IADLs (see Chapter 28)
- Addressing skills needed for return to work (see Chapter 29)
- Resumption of driving (see Chapter 31)
- Promoting engagement in leisure activities and socialization (see Chapters 28 and 29).

When selecting appropriate interventions, therapists should be guided by evidence-based practice principles. Intervention approaches that use task-specific training or functional task practice to promote change in patients having sustained stroke are supported by both research and clinical perspectives.⁸⁷ For example, both the *AOTAPG*¹⁴ and the *ASA/AHS Guidelines*¹³ recommend practicing functional tasks to improve balance and mobility, UE function, and ADLs/IADLs.

Motor learning and intervention principles espoused in the Occupational Therapy Task-Oriented Approach⁸⁸ (OT-TOA) can serve as useful guidelines for developing appropriate treatment interventions for patients poststroke. These principles are discussed in detail in Chapter 34 and are briefly presented as follows:

- Assist patients to adjust to role and task performance limitations by exploring alternative ways to perform tasks associated with desired roles.
- Create a treatment environment that mirrors the common challenges that patients experience in daily life.
- Practice functional tasks (identified by the patient) or close simulations to identify effective and efficient strategies for task performance.
- Provide opportunities for practice outside therapy sessions.
- Use contemporary motor learning principles in training or retraining skills, including minimizing ineffective and inefficient movement patterns, the use of random and variable practice conditions, providing decreasing amounts of physical guidance and verbal feedback, and developing task analysis and problem-solving skills in patients so they can find their own solutions to occupational performance problems.

In addition to the OT-TOA, components of other approaches may help guide treatment of patients having sustained stroke. For example, application of a biomechanical approach may be useful for addressing impairments such as decreased strength, muscle imbalances, decreased joint mobility, edema, and pain (see Chapter 32). In contrast, the rehabilitative approach can guide the use of adaptation, compensation, and environmental modifications to maximize independence in daily activities when residual impairments continue to interfere with performance (see Chapter 33). The remainder of this section highlights evidence-based interventions that can be used with patients to address ADL and IADL impairments; motor impairments; cognitive, visual, and perceptual impairments; and psychosocial impairments poststroke.

Interventions that Address ADL and IADL Impairments

Evidence suggests that activity- and occupation-based interventions improve ADL and IADL performance after stroke.¹⁴ According to the *ASA/AHA Guidelines*,¹³ all patients with stroke should receive ADL and IADL training tailored to individual needs and the eventual discharge setting. This functional training should be task specific, repetitive, graded to challenge the patient's individual capabilities, and progressed as appropriate.^{13,14}

For example, in the acute recovery phase, a patient may indicate a desire to self-feed without assistance from significant others or staff. In this case, the patient should be engaged in self-feeding activities to allow for learning and practice of such tasks (e.g., drinking from a cup, using a spoon, or cutting food). Grading of this task-specific training may begin with the relatively simple task of sandwich eating or drinking from a cup, progress to the appropriate use of utensils with a variety of food types (cereal, vegetables, meats), and finally advance to eating a variety of full meals unaided. In later recovery phases, this same patient may wish to prepare his or her own meals when discharged home. In this case, the patient should be engaged in meal preparation activities that are graded in complexity.

Depending on the degree of impairment, recovery stage, patient preferences, and the anticipated discharge environment, it may be appropriate to teach compensatory strategies (e.g., one-handed techniques performed with the intact UE, energy conservation, work simplification techniques) or introduce adaptive equipment during ADL/IADL training. According to the *ASA/AHA Guidelines*, adaptive and assistive devices should be used for safety and function when other methods of activity performance are unavailable or cannot be learned, or when patient safety is a concern.¹³ For example, in patients with severe sensory and motor impairment impacting the arm and hand, remediation of UE function to allow independent daily activity performance may not be possible. In this case, instruction in one-handed techniques and/or the use of adaptive equipment for engagement in daily activities would be needed. See Figure 36-4 for an example of one-handed dressing techniques and Table 36-4 for adaptive equipment commonly used with patients poststroke.

Figure 36-4 A to C. Sequence for one-handed dressing technique. **A.** Pulling shirt sleeve over affected arm. **B.** Pulling the shirt sleeve over the affected shoulder and swinging the shirt over back until the other sleeve hangs down over the back. **C.** Reaching to the back with unaffected arm and placing unaffected arm into the opening of the sleeve and pushing unaffected arm through sleeve.

Table 36-4. Examples of Commonly Used Adaptive Equipment

ADL/IADL	ADAPTIVE EQUIPMENT/DURABLE MEDICAL EQUIPMENT
Feeding	<ul style="list-style-type: none"> • Nonskid mats to hold plates/bowls steady on the table surface • Plate guards and scoop dishes to eliminate food spillage off plate when using utensils • Rocker knife to aid with cutting foods • Built-up handled utensils to aid weak grasp
Grooming	<ul style="list-style-type: none"> • Toothpaste dispenser • Electric toothbrush • Suction denture brush for one-handed cleaning of dentures • One-handed finger nail clipper • Long-handled brushes or combs to extend reach

ADL/IADL	ADAPTIVE EQUIPMENT/DURABLE MEDICAL EQUIPMENT
Bathing	<ul style="list-style-type: none"> • Nonskid mats for inside and outside tub/shower for safety • Handheld shower head with control of water flow • Tub or shower seat to allow bathing in the seated position • Grab bars • Long-handled sponge to extend reach • Bath mitt with soap pocket to aid weak grasp
Dressing	<ul style="list-style-type: none"> • Reacher for clothing retrieval or to aid LB dressing • Dressing stick to aid LE and UE dressing • Long-handled shoe horn • Elastic shoe laces • Button hook
Toileting	<ul style="list-style-type: none"> • Commode • Raised toilet seat • Toilet safety frame • Toilet tissue aids to extend reach for wiping
Kitchen activities	<ul style="list-style-type: none"> • Jar opener to aid weak grasp • Box toppers to allow for opening of boxes one-handed • Pan/pot holders to stabilize pots on the stove top • Adapted cutting boards to allow for one-handed cutting, peeling, chopping, and spreading • Suction bottle brushes that allow for one-handed cleaning of glasses

ADL, activity of daily living; IADL, instrumental activity of daily living; LB, lower body; LE, lower extremity; UE, upper extremity.

Interventions that Address Motor Impairments

There are a variety of interventions that can improve occupational performance of patients with motor impairment after stroke. The majority of these interventions target UE and balance and mobility retraining within the context of activity performance.⁸⁷ The following is a brief description of various interventions found to effectively improve UE function, balance and mobility, and activity and participation in patients with motor impairment after stroke as reported in a recent evidence-based review,⁸⁷ the *AOTASPG*,¹⁴ and/or the *AHA/ASA Guidelines*.¹³

- **Task-oriented training:** Are interventions that involve practicing functional tasks that are graded to challenge the patient's current motor capabilities. Tasks are practiced repeatedly and progressed in difficulty so that the patient is continuously challenged as gains are made.¹⁴ Researchers and clinicians use a variety of names to describe this type of training:
 - Repetitive Task Practice
 - Repetitive Task Training
 - Task-specific Training
 - Meaningful Task-specific Training
 - Task-related Training

Evidence suggests that this type of training can improve UE function, balance and mobility, and activity and participation after stroke^{14,87} (see Evidence table). Training can be tailored to various impairment levels and administered in a variety of practice settings (see Fig. 36-5 and Chapters 16 and 34).

Figure 36-5 A and B. Example of task-oriented training targeting upper extremity (UE) function and standing balance. **A.** Using involved UE to place dishes in the cabinet, while noninvolved UE helps support balance. Note that dishes differing in size, shape, and weight are placed in various locations on the countertop to encourage variability in movement patterns. **B.** Graded up version of the activity.

- Constraint-induced movement therapy (CIMT) or modified CIMT (mCIMT):** Is a form of task training that involves (1) restraint of the unimpaired limb, forcing use of the impaired limb during daily activities; (2) repetitive task practice with the affected limb in the form of whole task practice and “shaping” for approximately 6 hours a day for 2 weeks⁸⁹ (see Fig. 36-6). mCIMT is a modification of the original protocol in which the restraint time of the unimpaired limb, and/or the amount of time for intensive training of the impaired limb, is reduced and/or distributed over a longer period of time.⁹⁰ Evidence suggests that both forms of training improve UE function in patients that have some residual wrist and hand function.^{14,87} mCIMT appears to have similar efficacy (see Evidence table), and given the reduced practice schedule, greater clinical utility as compared to CIMT.⁹⁰

Figure 36-6 A and B. Constraint-induced movement therapy. **A.** Eating a meal. **B.** Shaping activity: using a spoon to transfer grapes between bowls with the impaired upper extremity, while the unimpaired hand is restrained in a mitt.

- Bilateral upper limb training:** Involves the patient engaging both limbs in the simultaneous execution of identical activities. Evidence suggests that this type of training can improve UE function.¹⁴

Interventions that Combine Task Practice with Cognitive Strategies

Interventions that combine task practice with cognitive strategies, or use alternative methods of delivering task practice, are appropriate for use as adjuncts to task-oriented training.^{14,87} These interventions can be tailored to various impairment levels (which may be especially useful for low functioning patients), and the majority of them can be administered in a variety of practice settings. Examples are:

- **Mental practice (MP):** In which the patient cognitively rehearses an activity (e.g., drinking from a cup, folding laundry, standing up from a chair) in the absence of actual movements. MP can be performed prior to a treatment session as preparation for the physical performance of an activity, or embedded within repetitive task practice sessions. Evidence suggests that MP improves UE function,^{14,87} balance and mobility, and activity and participation after stroke.¹⁴
- **Mirror therapy (MT):** In which the patient performs movements and simple activities with the unimpaired limb while watching its mirror reflection superimposed over the (unseen) impaired limb. Evidence suggests that MT can improve UE function, and activity and participation after stroke.¹⁴
- **Virtual reality (VR):** In which the patient participates in goal-directed activities in a computer-based, interactive, simulated environment designed to replicate the real-world environment. These environments can be immersive or nonimmersive. Evidence suggests that VR training can improve UE function¹⁴ and can be used as a method for delivering UE movement practice.¹³ Evidence also suggests that VR training may improve gait,¹³ and activity and participation after stroke.¹⁴
- **Action observation (AO):** In which the patient first watches another person perform an activity (most often on a prerecorded video) and then performs the activity himself or herself. Evidence suggests that AO may improve UE function.¹⁴
- **Robotic therapy:** There is evidence that robotic training can provide some benefit for UE motor abilities and activity participation and can be used to deliver intensive UE practice for patients with moderate-to-severe UE paresis.¹³
- **Strengthening and exercise:** Evidence suggests that strengthening exercises can be considered as an adjunct to functional task practice for improving UE function, balance and mobility, and activity and participation after stroke.^{14,87}
- **Neuromuscular electrical stimulation (NMES):** Evidence suggests that NMES may improve UE function and can be considered for patients with minimal voluntary movement after stroke or for individuals with shoulder subluxation.¹³

In addition to the abovementioned interventions, it may be necessary to incorporate adjunctive treatments that prevent the development of secondary complications, such as edema, joint contractures, shoulder subluxation, and pain.

According to the *AHA/ASA Guidelines*,¹³ interventions to prevent the onset of and treatment for hemiplegic shoulder pain include proper positioning, maintenance of shoulder ROM, and motor retraining. The patient and all involved caregivers should be educated in proper bed positioning (see Box 36-1), self-ROM exercises (see Fig. 36-7), and proper handling of the hemiparetic UE (see Box 36-2) during ADLs. Positioning devices such as wheelchair lap trays and arm troughs may help UE positioning during wheelchair mobility.^{13,33} The use of a sling can be considered to support the UE both when the patient is upright and during transfers^{13,33}; evidence for preventing or reducing long-term shoulder subluxation, however, is unclear.³³

Figure 36-7 Example of self-range of motion exercises for the hemiplegic upper extremity. Patient places the affected arm on a towel and pushes the affected arm toward specific target locations (items located on the table) to encourage shoulder range of motion.

Box 36-1

Procedures for Proper Bed Positioning of Patients with Hemiplegia

Supine Positioning

- Head and neck slightly flexed
- Trunk straight and aligned
- Involved upper extremity supported behind scapula and humerus with a small pillow or towel, shoulder protracted and slightly flexed and abducted with external rotation, elbow extended or slightly flexed, forearm neutral or supinated, and wrist neutral with hand open
- Involved lower limb with hip forward on pillow, nothing against soles of feet

Lying on the Unaffected Side

- Head and neck neutral and symmetrical
- Trunk aligned
- Involved upper extremity protracted with arm forward on pillows, elbow extended or slightly flexed, forearm and wrist neutral, and hand open
- Involved lower extremity with hip and knee forward, flexed, and supported on pillows

Lying on the Affected Side

- Head and neck neutral and symmetrical
- Trunk aligned
- Involved upper extremity protracted forward and externally rotated with elbow extended or slightly flexed, forearm supinated, wrist neutral, and hand open
- Involved lower extremity with knee flexed
- Uninvolved lower extremity with knee flexed and supported on pillows

Based on information from Carr EK, Kenney FD. Positioning of the stroke patient: a review of the literature. *Int J Nurs Stud.* 1992;29:355-369.

Box 36-2

Procedures for Proper Handling of the Hemiparetic Upper Extremity

- Teach the patient as early as possible to be responsible for the positioning of the arm during transfers, bed mobility, and other activities involving change of position.
- Use gait belts or draw sheets, rather than the affected arm, to assist the patient in moving his or her body.
- Avoid shoulder range of motion beyond 90° of flexion and abduction unless there is upward rotation of the scapula and external rotation of the humerus.
- Avoid overhead pulley exercises, because they appear to increase the frequency of pain in the shoulder because neither scapular nor humeral rotation occurs, and the force may be excessive.

Finally, it may be necessary to use orthotic devices to properly position the hemiparetic hand to maintain appropriate biomechanical alignment and to prevent injury, particularly in patients that do not have the cognitive and perceptual abilities required to maintain ROM or properly manage their hemiparetic UE.⁹¹ A variety of orthotic devices can be considered (see Chapters 22 and 23) for use with patients having sustained stroke. The type of device chosen and the device wearing schedule will vary according to the patients' individual needs. Regardless of the type of orthotic device used, wearing tolerance should be assessed and the need for continued use of the device periodically reevaluated.⁹¹ In addition, the patient and caregiver should be educated regarding the goals of the device (e.g., maintain proper joint alignment, prevent hand injury, maintain palmar skin integrity), how to properly don and doff the device, how to care for the device, and the wearing schedule.⁹¹

Interventions that Address Cognitive, Visual, and Perceptual Impairments

Recent reviews³⁶ and practice guidelines^{13,14} have examined the existing research literature to determine which interventions effectively improve function in patients with cognitive, visual, and perceptual impairments. Suggestions from these evidence-based reviews follow.

Apraxia

The Cognitive Strategy Training intervention is a compensatory method that teaches patients with apraxia internal and external strategies to overcome daily challenges. Internal strategies may consist of verbalizing the activity steps and internal rehearsal. External strategies include viewing pictures illustrating task performance and using listed instructions.^{14,36}

Gesture Training has also been recommended for this population and consists of three categories: (1) transitive gesture training using common objects such as a spoon or comb, (2) intransitive symbolic gesture training such as the gesture of eating, and (3) intransitive nonsymbolic gesture training including imitating meaningless gestures.^{14,36}

Executive Dysfunction

Time Pressure Management interventions have been used for those with mental slowness. This intervention provides patients with strategies to overcome daily challenges experienced secondary to external time pressure. The intervention consists of three stages: (1) identifying the problem, (2) teaching the strategy (analyzing the task for time pressure, making an emergency plan), and (3) generalization to other situations.^{14,36}

There is limited but emerging evidence for interventions such as exercise and recreation programs, and training patients within VR environments to improve executive functioning and daily activity participation.^{14,36}

Memory Loss

Interventions are limited for those with memory loss after stroke. While computer-based training has been evaluated with some success, this intervention should be monitored to determine whether memory gains actually generalize to everyday activities. Based on

available evidence, remediation of memory has not been successful with the exception of very mild memory loss cases. Compensatory strategies such as memory books, diaries, checklists, and alarm systems may result in better outcomes.⁹²

Unilateral Neglect

Several interventions have been identified to decrease the negative impact of unilateral neglect on daily life. These include^{14,36}:

- **Visual scanning training:** Which involves teaching systematic and organized visual scanning patterns (see Fig. 36-8 and Evidence table)

Figure 36-8 Example of visual scanning training. Red tape is used as a marker to aid the patient in locating the left side of space, and the patient is instructed in the use of an organized and systematic scanning strategy to locate and turn over cards of a specific suit.

- **Limb activation:** Involving active or passive limb movements contralesional to the brain lesion
- **Prisms/prism adaptation:** Involving the use of prismatic lenses to induce an optical shift (see Evidence table)
- **Vibration:** In which vibratory stimulation is provided to the neck muscles

Visual Field Deficits

There is general consensus that visual field deficits are not amenable to remediation. Therefore, compensatory approaches such as head/trunk turning and using wider saccades are encouraged in conjunction with environmental adaptations.

The reader should note that many of the identified evidence-based interventions for patients with cognitive and perceptual deficits after stroke fall under the category of strategy training. In order to successfully use strategy training approaches, the patient must have insight into his or her deficits, as well as the functional implications of these deficits. Therefore, awareness training should start early and be used consistently. If a patient does not respond to awareness training, the intervention approach must shift to environmental modification. Environmental modifications are usually taught to caregivers to apply in home and community settings (for more details on cognitive interventions, see Chapter 11).

Interventions that Address Psychosocial Impairments

A body of research has demonstrated the effectiveness of psychosocial intervention after stroke.^{13,93} Several studies have examined the effect of exercise training on psychosocial impairments such as anxiety and depression. These programs may be single or multiple component and include interventions such as resistance training, tai chi, walking, and early mobilization in acute care. Behavioral therapy programs and stroke education programs

have been used in isolation and in combination. Specific interventions in these categories include problem-solving therapy, motivational interviewing, and cognitive-behavioral therapy. Finally, there is emerging evidence that community-based programs led by occupational therapists may have a positive impact on mental health after stroke. These programs focus on leisure and recreation, community mobility, and/or community integration.

Prevention of Future Strokes

It is estimated that the annual risk for future stroke after an initial ischemic stroke or TIA is between 3% to 4%.⁹⁴ Given the morbidity associated with recurrent brain ischemia, preventing a future stroke is important for all patients having experienced a TIA. Education targeting modifiable risk factors should be considered as an important component of a patient's overall treatment program (refer to the section on Stroke Etiology of this chapter).

According to Schmid and colleagues,⁹⁵ prevention of a second stroke requires identification and control of modifiable risk factors—the majority of which are best managed through a combination of medication management and changing unhealthy lifestyle choices. Although all members of the health care team can play a role in the prevention of secondary strokes, occupational therapists can make a unique contribution by helping patients to understand and identify the facilitators and barriers to health promotion behaviors.⁹⁵ The *AHA/ASA Guidelines for the Prevention of Stroke in Patients with Stroke and Transient Ischemic Attack*⁹⁴ is an excellent resource that contains evidence-based recommendations that practitioners can use to develop preventive education programs.

Generally speaking, education programs should include identification of modifiable risk factors; teaching patients appropriate medication management; discussing the importance of a healthy diet, regular exercise, and the need for sufficient sleep; the need to eliminate or reduce unhealthy lifestyle choices such as smoking and the use of drugs and alcohol; and identifying perceived supports, facilitators, and barriers as they relate to engagement in healthy promotion behaviors.⁹⁴ In addition, preventive education should include increasing awareness of the signs and symptoms of stroke (i.e., FAST: **F**ace asymmetry, **A**rm weakness, **S**peech impairments, **T**ime to get to the hospital) and be designed to reach racially, ethnically, and age-, and sex-diverse populations.¹²

CASE STUDY

Patient Information

Jorge is a 45-year-old Hispanic man who owns a dog-walking business with two employees. He lives with his male partner, Luis, in a two-bedroom elevator-apartment in an urban area. Although Jorge and Luis have no children, they have a large social network. Jorge was transferred from the acute care floor to the inpatient rehabilitation unit with a diagnosis of right middle cerebral artery stroke. His past medical history is significant for hypertension. Jorge and Luis indicated that discharge to the current home environment is desired and that their extended support network can provide assistance as needed.

Assessment Process and Results

The occupational therapist used the Canadian Occupational Performance Measure (COPM) to identify occupations that were meaningful and important to Jorge. He identified the following five occupations as being most important: (1) bathing and dressing, (2) taking care of bathroom needs, (3) preparing simple meals, (4) returning to work, and (5) socializing with friends during their regular monthly poker game. Out of a

possible score of 10 (higher scores indicate better performance and greater satisfaction), he scored his present performance in and satisfaction with these five occupations as follows:

- Bathing: performance = 5, satisfaction = 2
- Taking care of bathroom needs: performance = 3, satisfaction = 1
- Preparing simple meals: performance = 3, satisfaction = 1
- Returning to work: performance = 1, satisfaction = 1
- Socializing with friends: performance = 2, satisfaction = 2

Guided by the COPM results, the occupational therapist evaluated Jorge's ability to engage in the identified activities using the Functional Independence Measure (FIM) and observation of a simple meal preparation activity. Out of a possible score of 7 (higher scores indicate greater independence), the therapist scored Jorge as follows on the FIM:

- Feeding: 4
- Grooming: 4
- Bathing: 3
- UE Dressing: 4
- LB Dressing: 3
- Toileting: 3
- Bladder/bowel function: 7
- Transfers: 4
- Locomotion: 3

Decreased use of the left dominant UE, impaired standing balance during reaching, and left unilateral spatial neglect were significant limiting factors during task performance. Performance skills and client factors were evaluated using the following assessments:

- FMA-UE motor and sensory sections to assess motor and sensory impairments
- Action Research Arm Test (ARAT) to assess UE capacity
- CBS to assess the impact of unilateral spatial neglect on daily functioning
- PASS to assess balance
- Beck Depression Inventory-II (BDI-II) to assess psychosocial status

Scores on the abovementioned assessments were as follows:

- FMA-UE motor: 39/66 indicating moderate motor impairments of the left UE
- FMA-UE sensory: 8/12 indicating mild sensory impairments of the left UE
- ARAT: 37/57 indicating limited capacity of the left UE
- PASS: 29/36 with limitations noted in standing balance
- CBS: 15/30; self-awareness score: 2/30 indicating moderate left unilateral neglect with poor self-awareness of neglect
- BDI-II: 2/63 indicating minimal evidence of emerging depression

Occupational Therapy Problem List

- Difficulty combining joint motions of the left UE, resulting in inefficient forward, side, and overhead reaching
- Decreased ability to reach, grasp, transport, and manipulate objects with the left UE
- Diminished tactile sensation of the left arm and hand
- Decreased standing balance
- Moderate left unilateral spatial neglect with poor self-awareness of neglect
- Minimal evidence of emerging depression

Occupational Therapy Goal List

- Jorge will be able to bathe, dress, and toilet himself with supervision by 2 weeks.
- Jorge will be able to prepare a simple meal with supervision by 2 weeks.
- Jorge will be able to play a poker game with Luis and friends by 2 weeks.
- Increase left UE capacity to notable (score of ≥ 43 on ARAT) to allow for use of the left UE as a functional assist during self-care, meal preparation, and computer tasks by 2 weeks.
- Increase standing balance as evidenced by a 3-point increase on the PASS to allow for greater independence during self-care, meal preparation, and computer tasks by 2 weeks.
- Decrease left unilateral neglect and increase awareness of neglect as evidenced by a 5-point score change on the CBS to allow for increased independence during self-care, meal preparation, and computer activities by 2 weeks.

Intervention

Applying the principles of evidence-based practice, the following treatment interventions were chosen to address Jorge's needs:

- Occupation-Based Interventions to improve ADL/IADL
- Task-Oriented Training (TOT) to enhance arm and hand function, and improve standing balance to support engagement in chosen activities
- Visual Scanning Training (VST) to improve performance and compensation for unilateral neglect
- MP combined with task practice to promote self-directed independent practice outside regular therapy sessions

Three occupational therapy sessions are presented in the following to illustrate how the abovementioned interventions were implemented.

- Session 1 targeted specific practice of two of Jorge's chosen occupations (bathing and dressing) in his hospital room. The therapist began the session by describing the two activities that would be practiced. After describing the activities, Jorge was asked to predict (awareness training) how long each would take and how much assistance he would need. He predicted that each task would take approximately 8 minutes and that he would need someone close by, but no "real help." The therapist proceeded to engage Jorge in task practice, providing verbal and physical prompting as needed. Prompts were needed to encourage left limb use, locate items on the left side of the environment, and complete tasks. Occasional physical support was required to prevent loss of balance while standing. After task completion, the therapist helped Jorge to reflect on his performance and compare his actual and predicted performance by highlighting discrepancies between the two. It became clear that Jorge needed improved awareness to use strategies such as VST. Therefore, awareness training became an integral part of the overall intervention plan.
- Session 2 took place in the occupational therapy clinic and focused on improving arm and hand function, and VST for engagement in chosen activities. Jorge's interests drove the selection of tasks used for TOT. The goal was to maximize repetitions of reaching, grasping, transporting or manipulating, and releasing various meaningful task objects as follows:
 - Manipulation of a computer mouse while seated at a table: Organizing icons on the screen of Jorge's work laptop, entering data onto a spreadsheet, and accessing email and social media.
 - Manipulation of bathing items and kitchen utensils: Organizing (1) bathing items in a basin while seated at a table and (2) kitchen utensils in a drawer while standing at the countertop.
 - Playing cards: Dealing cards, flipping cards, stacking cards, and manipulating poker chips.

Performance of a high number of repetitions of each task was encouraged, and tasks were graded to challenge Jorge’s current motor skills. Examples of gradation included increasing the number of items manipulated; changing the location of items in the environment to encourage reaching over greater distances and in different planes of motion; changing the size, shape, and weight of objects; and varying speed requirements. VST was introduced, and Jorge was taught a structured scanning strategy to use while engaged in each of the abovementioned activities.

- Session 3 took place in the ADL kitchen and focused on preparing a simple meal while standing. Jorge identified a favorite afternoon meal, and the occupation-based intervention of making a chopped salad was chosen. Awareness building continued to be addressed using task prediction methods and review of discrepancies between predicted performance and actual performance. The task was set up to encourage the use of VST—for example, necessary items were placed on both sides of the table, and Jorge was verbally cued to engage in an organized visual search of the table for specific items. He was also encouraged to use his left arm and hand to assist throughout the session. A vegetable peeler and knife with built-up handles were provided, along with a cutting board with suction cups. Jorge was encouraged to use his left hand to peel vegetables; perform multiple repetitions required for chopping vegetables; place food items into a large bowl; and assist with washing, drying, and putting away meal preparation items.

In addition to individual sessions described earlier, the therapist provided Jorge with specific opportunities for self-directed independent practice. An individualized structured program was designed that Jorge carried out with the help of Luis outside of individual therapy session.

- Mentally practicing (1) manipulation of the computer mouse; (2) manipulation of bathing and grooming items; and (3) kitchen utensil use, followed by actual practice of these activities.
- Provision of an occupation box with items related to Jorge’s identified goals, such as a deck of cards, dog brush, can opener, pen and paper, poker chips, and kitchen utensils that Jorge used to engage in TOT.
- Use of organized visual scanning strategies to locate specific items in a pet catalog, entries on an excel spreadsheet, and cards of specific suits spread out over a table.
- Provision of a practice log to record daily practice sessions that would be regularly reviewed to determine the need to modify the self-directed practice program.

By discharge, Jorge met the majority of his goals as evidenced by improved COPM performance and satisfaction scores, and improved performance scores on the noted selected objective measures. Prior to discharge, the therapist educated Jorge about his increased risk for a second stroke. They discussed common stroke signs and symptoms, the importance of monitoring his high blood pressure, medication management, the need to monitor his diet, and how to engage in regular exercise. In addition, Jorge and Luis were educated about the signs and symptoms of depression and were provided with community resources if depression emerged.

Jorge’s additional occupational performance goals were addressed by outpatient occupational therapy, including community mobility and return to work.⁹⁶

Evidence Table of Intervention Studies for Stroke

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
--------------	--------------------------	--------------	--------	------------------------------------	---------	--

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Meaningful Task-specific Training ⁹⁷	UE task-specific training program involving repetitive practice of meaningful unilateral and bilateral tasks	103 inpatients with hemiparesis after stroke; mean age, 50.93 ± 7.78 years; mean TPS, 12.15 ± 6.54 weeks	Dose-matched training for 1 hour/day, 4–5 day/week for 4 weeks	Assessor-blinded randomized controlled trial (RCT); Level I	Reduction in UE motor impairment as measured by the FMA Improvement in UE capacity as measured by the ARAT and WMFT Improvements in self-perceived UE function as measured by the MAL	FMA: $p < 0.001$ WMFT (time): $p < 0.001$ WMFT (quality): $p < 0.001$ ARAT: $p < 0.001$ MAL-AOU: $p < 0.001$ MAL-QOU: $p < 0.001$
mCIMT ⁹⁰	UE intensive task training with the impaired limb and restraint of the nonimpaired limb	278 patients; age range: 31–83; TPS range: 2 days to 60 who met specific criteria for mCIMT (some residual wrist and hand function)	Intensive training of the paretic UE: 30 minutes to 3 hours a day, and restraint of the nonparetic UE was <6 hours a day in the mCIMT	Systematic review and meta-analysis of 13 RCT; Level I	Reduction in UE motor impairments as measured by the FMA Improvements in UE capacity as measured by the ARAT Improvements in self-perceived UE function as measured by the MAL Improvement in ADL as measured by the FIM	FMA: Mean difference (MD) = 7.8; 95% confidence interval (CI), 4.21–11.38 MAL-AOU: MD = 0.78; CI, 0.37–1.19 ARAT: MD = 14.15; 95% CI, 10.71–17.59 MAL-QOU: MD = 0.84; 95% CI, 0.42–1.25 FIM: MD = 7.0; CI, 0.75–13.26
Cognitive Orientation to daily Occupational Performance (CO-OP) ⁹⁸	A cognitive-oriented intervention that uses client-driven cognitive strategies The Goal-Plan-Do-Check problem-solving strategy is the main global cognitive strategy.	20 stroke survivors with a mean age of 60.4, mean NIHSS of 7. 57.9% were women. The 12 subjects who withdrew had significantly lower scores on a variety of neuropsychological tests.	10 one-hour individualized interventions sessions in which the participant received training in two types of strategies: Goal-Plan-Do-Check and domain-specific strategies	Pilot RCT with a blind assessor; Level I	Improved Performance Quality Rating Scale Improved performance on the COPM	$U = 0.0$ $p = 0.02$ $U = 0.0$ $p = 0.02$

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Visual Scanning Training (VST) and Prism Adaptation (PA) ⁹⁹	VST includes four structured tasks: visual-spatial scanning, reading and copying training, copying of line drawings, and description of scenes. PA consists of the repetition of exercises in which the patient points to targets placed in front of them, while wearing prismatic lenses.	20 subjects with right CVA and documented neglect based on objective testing. Exclusion criteria were as follows: previous brain injury, previous substance abuse or dependence, a history of psychiatric disturbances, the presence of cognitive impairment and dementia, left brain lesion, severe hemianopia, and visual impairment.	20 sessions, 1/day, 5 days a week for 4 weeks	Pre-post design with alternating assignment; Level III	Reduced personal/body neglect (Fluff Test) Reduced peripersonal/near space neglect (Behavioral Inattention Test: Conventional scale)	$p < 0.05$ $p < 0.05$ Note: Both groups presented with significant changes with no difference between the groups, indicating both interventions are effective.

Chapter 37

Acquired Brain Injury

Alicia Flores Lohmann and Asha K. Vas

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the similarities and differences in the typical course of recovery for persons with mild, moderate, and severe traumatic brain injury.
2. Select appropriate assessment tools and strategies for persons with acquired brain injury during acute medical management, inpatient, and postacute rehabilitation.
3. Apply information from related chapters of this text to the treatment of motor, cognitive, behavioral, and emotional aspects of acquired brain injury.
4. Analyze the needs of family members during recovery and occupational therapy's role in the adaptation of life after brain injury.
5. Address occupational therapy's role in the long-term needs of survivors of acquired brain injury.

CHAPTER OUTLINE

Introduction
Incidence, Prevalence, and Causation
Mechanisms of Injury and Clinical Implications
Classifications of Brain Injury
Phases of Recovery
Occupational Therapy Assessments
Occupational Therapy Interventions
Support Systems
Case Study

TERMINOLOGY

Acquired brain injury (ABI): head injury that can include traumatic and nontraumatic injuries caused by cardiovascular defects, tumors, substance abuse, environmental exposure, anoxia, bacteria, viruses, nutritional deficiencies, genetic, congenital, and degenerative diseases.¹

Agitation: excessive behavior including varied degrees of aggression, disinhibition, restlessness, and confusion. Person may present in an altered state of consciousness.

Concussion: a type of traumatic brain injury (TBI) usually caused by a blow to the head, usually reported in sports activities including direct blow, bump, or jolt to the head; effects are usually temporary but can include headaches and problems associated with concentration, memory, balance, and coordination.²

Diffuse axonal injury (DAI): extensive lesions in white matter tracts over a widespread area following traumatic acceleration/deceleration or rotational injuries; DAI often results in loss of consciousness and could result in persistent vegetative state after severe head trauma.³

Disorder of consciousness (DOC): a state of reduced wakefulness and awareness due to brain damage.⁴

Mild brain injury: a traumatically induced physiological disruption of brain function, as manifested by at least one of the following: (i) any period of loss of consciousness; (ii) any loss of memory for events immediately before or after the accident; (iii) any alteration in mental state at the time of the accident (e.g., feeling dazed, disoriented,

or confused); or (iv) focal neurological deficit(s) that may or may not be transient; but where the severity of the injury does not exceed the following: loss of consciousness of approximately 30 minutes or less; after 30 minutes an initial Glasgow Coma Scale (GCS) of 13 to 15; and post-traumatic amnesia (PTA) not greater than 24 hours.⁵

Moderate brain injury: a brain injury resulting in a loss of consciousness from 20 minutes to 6 hours and a GCS of 9 to 12; moderate TBI is characterized by loss of consciousness for 1 to 24 hours, PTA for 1 to 24 hours of the TBI, and abnormal brain imaging results.⁶

Severe brain injury: a brain injury that results in loss of consciousness or coma for more than 24 hours, PTA for more than 24 hours of TBI, and abnormal brain imaging results.⁶

Spasticity: a continuous state of muscular contraction that if left untreated can limit muscle and joint motion.⁷

Traumatic brain injury (TBI): a form of ABI following an external trauma to the head; a TBI occurs when the head suddenly and violently hits an object, or when an object pierces the skull and enters brain tissue.²

Introduction

Acquired brain injury (ABI) can be due to internal or external causes. ABI is a public health problem. It is defined as “Damage to the brain, which occurs after birth and is not related to a congenital or a degenerative disease. These impairments may be temporary or permanent and cause partial or functional disability or psychosocial maladjustment.”⁸ ABIs are caused by one or more of the following: traumatic forces (e.g., traumatic brain injury [TBI], falls, assaults, gunshot wounds), stroke (e.g., hemorrhage, embolus), brain bleeds (e.g., hemorrhage, hematomas), lack of oxygen (e.g., anoxia, cardiac arrest), brain infections (e.g., meningitis), brain tumors, or environmental causes (e.g., toxic exposure).

This chapter focuses on the various levels of ABI that occur as a result of external or internal damages to the brain. Consequently, varying degrees of impairments occur in cognitive, behavioral, emotional, and/or physical functioning. These alterations in functioning result in changes in valued roles, tasks, and activities, which affect virtually every area of life for the survivor and his or her family.⁹ For the many individuals, especially younger adults at the time of injury, changes in physical, cognitive, and psychosocial abilities may affect their occupational functioning for months, years, or decades. The complex interaction of factors associated with impairment, context, and environment requires an interprofessional approach to assessment and treatment. Therefore, occupational therapists who work with patients with ABI must appreciate the contributions and expertise of other team members in the best interest of the patient.

Incidence, Prevalence, and Causation

Each year, **traumatic brain injuries (TBIs)** contribute to a substantial number of deaths (30%) and cases of permanent disability in the United States.¹⁰ In 2013, approximately 2.5 million people sustained a TBI.² Individuals with more severe injuries are more likely to require hospitalization. The estimated economic cost of TBI in 2010, including both direct and indirect medical costs, is estimated to be approximately \$76.5 billion in the United States. Additionally, the cost of fatal TBIs and TBIs requiring hospitalization, many of which are severe, accounts for approximately 90% of the total TBI medical costs.^{11,12} Each year, approximately 1.7 million civilians in the United States sustain a TBI.¹³ Of these, 3% (52,000) die, 16% (275,000) are hospitalized, and 80% (1.4 million) are treated in an emergency room (ER) and released. The Centers for Disease Control and Prevention (CDC) measures incidence by combined emergency visits, hospitalizations, and deaths. The incidence has steadily risen from 2001 to 2010, from 521 to 616 per 100,000 population (between 2001 and 2005) to 824 per 100,000 population.¹⁴ This steady increase is

secondary to TBI-related ER visits that increased by 70% from 2001 to 2010, while hospitalization rates increased by only 11%. In addition, deaths related to TBI decreased by 7% over the same 10-year span.¹⁴

Factors such as automobile safety, seat belt use, helmet use, and better overall treatment for severe TBI in prehospital and hospital settings, although unable to prevent TBIs entirely, have mitigated their severity and thus mortality. In addition, there are an unknown number of individuals with TBI who are not included in these estimates because they are seen in an ER but discharged without a diagnosis of TBI.¹⁵ Between 3.2 and 5.3 million persons (1.1%–1.7% of the US population) live with long-term disabilities that result from TBI.^{16,17}

Estimated average annual numbers of TBI-related ER visits, hospitalizations, and deaths, by external cause, the United States, 2002 to 2010, are outlined in Table 37-1.¹⁸

Table 37-1. Mechanisms of Average Annual Traumatic Brain Injuries

MECHANISM OF INJURY	EMERGENCY DEPARTMENT VISITS	HOSPITALIZATIONS	DEATHS
Falls	658,668	66,291	10,944
Struck by or against an object	304,797	6,808	372
Motor vehicle/traffic	232,240	53,391	14,795
Assault/homicide	179,408	15,032	5,665
Self-inflicted/suicide	*	*	14,713
Other	122,667	25,478	4,990
Unknown	97,018	113,172	0

*Estimate not reported because of small numbers.

Mechanisms of Injury and Clinical Implications

External mechanical forces that cause TBI include blow to head (e.g., fall onto pavement, head impacting windshield in a car accident, assault, baseball striking head), acceleration–deceleration forces, wherein no direct impact is required (e.g., a restrained passenger coming to a sudden stop when a car strikes a tree or telephone pole), projectile missile (e.g., bullet), and concussive forces (e.g., blast waves from an explosion). Neurological events that occur as a result of trauma to the head include bruising (contusion) to surface brain tissue or trauma to the blood vessels of the brain causing bleeding (hematoma). A hematoma can damage the brain tissue it contacts and can increase pressure in the brain. As a consequence of contusions and bleeding, intracranial pressure (ICP) may rise, which can shift and put pressure on brain tissue owing to the confined space of the skull. Adding to the building pressure is the possibility of edema or swelling of brain tissue due to trauma (see Fig. 37-1).

Figure 37-1 Subdural hematoma computed tomography (CT) images. Acute subdural hematoma, CT versus magnetic resonance (MR). A. Acute subdural hematoma in the left frontal region. B, C. Respective sagittal T1-weighted and axial T2-weighted MR images show an extra-axial clot consistent with intracellular deoxyhemoglobin (i.e., acute subdural hematoma). D. The calculated apparent diffusion coefficient map demonstrates marked hypointensity, indicating restricted diffusion within acute hematoma.

Typically associated with acceleration–deceleration injuries, there may be shearing or twisting of axonal fibers (white matter tracts) in the brain. This occurs most often in the frontal and temporal lobes. Midline structures (e.g., corpus callosum, anterior commissure) may also be affected, which can disrupt communication between left and right cerebral hemispheres. Extensive shearing can cause **diffuse axonal injury (DAI)**, a serious condition that may be associated with coma and poor outcome. Changes in neurotransmitter (i.e., chemical communicative agents in the brain) also occur as a result of an ABI. Increase in glucose metabolism in the context of decreased cerebral blood flow leads to an energy deficit in the brain. Hypoxia (i.e., decreased oxygen to the brain) as a result of drug overdose or toxic exposure leads to impaired blood supply to the brain that could lead to brain tissue damage or death. Coup/contrecoup is a common mechanism to explain a TBI. Coup refers to damage occurring at the point of head trauma impact (e.g., where the head hit the ground in a fall) as the brain slides forward within the skull and impacts the inside of the skull. This can occur even if there is no direct external impact to the head (e.g., sudden deceleration in a motor vehicle accident). Contrecoup injury refers to damage occurring when the head/brain rebounds from the initial force and either impacts an object (e.g., headrest in a motor vehicle accident) or simply rapidly moves in the opposite direction and hits the inside of the skull. The frontal lobes rest on bony prominences of the skull just above the eyes. When the brain moves within the skull, these prominences can cause a grating action against the brain tissue, leading to injury (Fig. 37-2).

Figure 37-2 Anatomy of the cerebral cortex with areas of potential damage indicated.

A TBI can be classified as either open or closed based on the biomechanics of the injury.¹⁹ In an open brain injury, an object, such as a bullet, enters the cranial cavity. Some classification systems categorize all open injuries as penetrating injuries.⁶ Other systems differentiate between penetrating and perforating injuries depending on whether the object remains lodged within the cranial cavity (penetrating) or passes through and exits the cranial cavity (perforating). In an open brain injury, the extent of the damage depends on the shape, mass, direction, and velocity of the object.¹⁹

A TBI that results from a direct or indirect impact, without penetration of the brain tissue, is classified as a closed brain injury. Closed head injuries can result from dynamic or static loading.¹⁹ A dynamic loading injury occurs when there is rapid acceleration and deceleration of the brain. A static loading injury, also termed crush injury,⁶ occurs when a slow mechanical force is applied to the brain, for example, if the head were trapped for an extended time under heavy debris after an earthquake. This type of injury is uncommon. The damage from a closed brain injury is directly related to the type (e.g., shear, tensile) and amount of forces generated during the traumatic event. In the case of crush injuries, there tends to be more damage to the skull than to the brain.⁶

Blast injuries have recently been recognized as a specific type of TBI.⁶ A blast injury results from any type of blast explosion, including improvised explosive devices (IEDs). A blast injury can occur in conjunction with an open or a closed brain injury.

Table 37-2 shows criteria used to classify the severity of TBI.²⁰

Table 37-2. Traumatic Brain Injury Severity Classification Criteria

CRITERIA USED TO CLASSIFY TBI SEVERITY	TBI SEVERITY		
	Mild	Moderate	Severe
Structural imaging	Normal	Normal or abnormal	Normal or abnormal
Loss of consciousness	<30 minutes	30 minutes to 24 hours	>24 hours
Post-traumatic amnesia	0–1 day	>1 and <7 days	>7 days

CRITERIA USED TO CLASSIFY TBI SEVERITY	TBI SEVERITY		
	Mild	Moderate	Severe
Glasgow Coma Scale (GCS) score (best available score in 24 hours)	13–15	9–12	3–8
Abbreviated Injury Scale score: head	1–2	3	4–6

Brasure M, Lamberty GJ, Sayer NA, et al. *Multidisciplinary Postacute Rehabilitation for Moderate to Severe Traumatic Brain Injury in Adults*. Rockville, MD: Agency for Healthcare Research and Quality (US); 2012.

Focal Versus Diffuse Injuries

Brain injuries can also be categorized as focal or diffuse injuries based on the extent of the pathology. Focal injuries result from brain contusions, lacerations, and masses of blood called hematomas.²¹ Focal lesions are usually seen at the anterior poles and inferior surfaces of the frontal and temporal lobes. They occur when the brain hits the skull and scrapes over the irregular bony structures at these locations.²² The occipital and parietal lobes, which have smooth surfaces, are less likely to incur damage. Focal lesions to the prefrontal and anterior temporal areas interrupt connections to subcortical limbic structures and affect modulation of memory, emotion, and drive.²³ Damage to the orbitofrontal areas generally results in impulsivity that is greater than with diffuse damage, whereas damage to the frontolateral cortex results in hemiparesis, impulsivity, and attentional impairments as well as decreased mental flexibility.²⁴

Diffuse injuries typically occur in motor vehicle crashes where there is rapid movement of the head.²⁵ Traumatic axonal injury (TAI), previously termed diffuse axonal injury (DAI), is a type of diffuse injury that results when the brain accelerates, decelerates, and rotates inside the skull. The brainstem is more stable than the cerebrum, which rotates around the brainstem during impact. The rotation places a stretch or shear force on the long axons that transmit information throughout the brain and brainstem.²⁶ Although the mechanisms for TAI are not completely understood, contributing factors include altered permeability of the axonal cell membrane, which impedes axonal transport. This results in focal swelling of the axon and, ultimately, detachment of the axon at the point of the swelling.²⁷ These injuries are likely to result in coma.¹⁷

Coma due to axonal injuries may quickly reverse if the axonal damage was mild or may continue as a vegetative state if axons were ruptured. Recovery from coma progresses to a period of confusion with impaired attention and post-traumatic amnesia (PTA). When confusion clears, any cognitive impairments become more evident. Impairments may include diminished mental processing speed and efficiency and difficulty with divided-attention tasks, which require the patient to respond simultaneously to two sources of information. Memory, not only post-traumatic memory, but short- and long-term memory, may be reduced. There may also be a reduced capacity for higher level cognitive functions, including abstract reasoning, planning, problem-solving, organization, and self-awareness. Typical behavioral outcomes range from impulsivity, irritability, and exaggerated premonitory traits to apathy and poor initiative. Diffuse injuries often include damage to the brainstem and cerebellar pathways, resulting in ataxia, diplopia, and dysarthria.²⁴ It is common to find both focal and diffuse damages with a TBI, especially in more severe cases. In both types of injuries, secondary pathogenic events at the cellular, biochemical, and molecular levels contribute to widespread damage beyond the effect of the primary insult.¹⁹

Cranial Nerve Damage Associated with Brain Injury

Cranial nerves can be torn, stretched, or contused. The olfactory nerve (I) is often abraded or torn when the frontal lobes scrape across the orbital surface of the skull.²⁸ The optic nerve (II) may be damaged directly, or vision can be compromised by injury to the eye, the optic tracts, or the visual cortex. Cranial nerves III, IV, and VI, which control eye movements, are all vulnerable to injury. The oculomotor nerve (III) can be stretched when edema or bleeding expands the contents of the skull, causing the uncus of the temporal lobe

to herniate into the foramen magnum and compress the brainstem. The abducens nerve (VI) is very long and consequently vulnerable to injury. The facial and vestibulocochlear nerves (VII and VIII, respectively) may be damaged if the temporal bone is fractured at the base of the skull. Cranial nerves V and IX to XII are rarely damaged.²⁹

Brain Tumors

In the words of Victoria Lynn Johnson, “A diagnosis of brain tumor confirms at some point you WILL need assistance. Asking for assistance has always been difficult; however I soon realized two things: I needed to get over my own interpretation of independence so that I could ask for assistance and that if I expected anyone to assist me I must be an active participant in my own well-being.”³⁰

A tumor is a mass of abnormal cell growth. More than 200,000 people in the United States are diagnosed with a brain tumor each year.³¹ According to the Central Brain Tumor Registry of the United States, nearly 80,000 new brain and central nervous system tumors are expected to be diagnosed in 2018. Over 90% of primary brain tumors are diagnosed in people over 20 years old; people over 85 have the highest incidence. The average age at diagnosis is 57. Family history of brain tumors is not very common. Only a very small number of families have several members with brain tumors.

There are over 100 different types of brain tumors. The World Health Organization (WHO) classifies brain tumors by cell origin and the rate of growth of cells.³² Brain tumors are classified in multiple ways, including benign versus malignant, primary versus secondary, and different stages (0–IV) and grades (I–III).³³ The stage of a cancer describes the size of a tumor and the degree of progression from its original site. The grade describes the appearance of the cancerous cells. Stage 0 indicates that the cancer is at its site of origin (in situ) and hasn’t spread. In stage I, the cancer is small and hasn’t spread either. In stage II, the cancer has grown, but hasn’t spread. However in stage III, the cancer is larger and may have spread to the surrounding tissues and/or the lymph nodes. Spread of cancer to another body organ represents stage IV. This stage of cancer is also known as secondary or metastatic cancer. With regard to cancer grades, a lower grade indicates a slower-growing cancer and a higher grade indicates a faster-growing one. In grade I cancer, cells resemble normal cells and aren’t growing rapidly. In grade II, cells don’t look like normal cells and are growing faster than normal cells. In grade III, cancer cells look abnormal and may grow or spread more aggressively.

Benign brain tumors are noncancerous in nature and usually grow slowly. These tumors do not spread to other organs or surrounding tissues. Most benign brain tumors seldom recur after surgical removal. Benign brain tumors can have an impact on function (or can be life-threatening), especially if the tumor is compressing on vital structures inside the skull. An example of a benign brain tumor is meningioma (tumor arising from the meninges). Meningiomas account for 20% to 30% of brain tumors. The risk of developing a meningioma increases with age, and they occur about twice as often in women.^{34,35} Another example of a benign tumor is schwannoma (tumor of the nerve sheath that grows slowly and pushes nerve fibers aside). Schwannomas can arise from any peripheral nerve containing Schwann cells, including cranial nerves. The cranial nerve VIII is the most susceptible to schwannomas, referred to as acoustic neuroma.³⁶ Schwannoma accounts for about 9% of all brain tumors. Malignant primary brain tumors are cancers that originate in the brain, typically grow faster than benign tumors, and aggressively invade surrounding tissue including other parts of the brain or the spinal cord. Malignant tumors are also sometimes called brain cancer.

Brain tumors are also classified as primary and secondary tumors. Primary brain tumors originate in the brain. In the United States, primary brain tumors are among the top 10 causes of cancer-related death. Some of the more common types of primary brain tumors include:

- **Astrocytomas:** The most common type of cancer brain tumor that affects the astrocytes (star-shaped brain cells)
- **Oligodendrogliomas:** Is a slow-growing transformation of oligodendrocytes, cells that wrap around axons. Oligodendrogliomas account for 3% of primary brain tumors. They usually occur in young adults and range from grade II to grade III. Because oligodendrogliomas are less likely than other gliomas to spread into normal brain tissue, surgery alone is frequently very beneficial, especially for grade II tumors.
- **Medulloblastoma:** A malignant tumor that forms in the cerebellum. It can spread to the spinal cord and cause spinal fluid to back up into the brain (hydrocephalus).
- **Ependymomas:** Tumors formed in the lining around the cerebral ventricles. These tumors account for nearly 6% of intracranial gliomas and about 60% of all newly diagnosed spinal cord tumors.
- **Gliomas:** Brain tumors arising from glial cells. Mixed gliomas have cells and characteristics of more than one type of glioma, usually astrocytomas and oligodendrogliomas.

Secondary (metastatic) tumors start as a cancer in another part of the body, such as the lungs or breast. The cancer then spreads to the brain, where it forms a new tumor. Metastatic brain tumors occur in 20% to 40% of people with cancer. Breast, lung, colon, kidney, and melanoma cancers are the most common cancers to metastasize to the brain. Metastatic brain tumors are more common than primary brain tumors in adults. Numerical grading of brain tumors is based on the growth of the tumors.

- **Grade I:** These tumors are considered benign in nature and are often slow growing. Surgical removal of these tumors is common. Prognosis, with regard to longevity and quality of life (QoL), is favorable.
- **Grade II:** These tumors also grow slowly and are less likely to spread. However, relapse and reoccurrence can happen with grade II tumors even following treatment.
- **Grade III:** These tumors are cancerous and tend to spread to other parts of the brain. Relapse of tumors can happen, as grade IV tumors.
- **Grade IV:** These are the most malignant tumors. They grow and spread most rapidly. Response to treatment is minimal, so prognosis is negative.

Classifications of Brain Injury

Regardless of the cause, the primary goal after a diagnosis of ABI centers on surviving, achieving medical stability, and preventing or minimizing the impact of secondary insults and effects on the injured central nervous system.³⁷ Upon arrival to a medical facility, the patient who has been assessed a score on the Glasgow Coma Scale (GCS) will receive complete examinations including computed tomography (CT) scanning, neurosurgical assessment, ICP monitoring, and procedures to limit thromboembolic complications (Table 37-3).⁴⁴ Assessment of the spinal cord is necessary because spinal cord injury is associated with 4% to 8% of TBIs.³⁸ Airway protection is of utmost importance; therefore, many times, a tracheostomy is performed to secure the airway. The interprofessional team will observe and monitor vital signs and assess neurological function. The primary goals at this stage are to avoid further neurological damage and to stabilize critical extracranial injuries.³⁸ The role of the physician is to prevent secondary medical complications such as sepsis, stress ulcers, and symptoms of “storming,” a result of sympathetic hyperactivity.³⁹

Table 37-3. Glasgow Coma Scale

Eye opening (E)	Spontaneous	4
	To speech	3
	To pain	2
	Nil	1
Best motor response (M)	Obeys	6
	Localizes	5
	Withdraws	

	Abnormal flexion	4
	Extensor response	3
	Nil	2
		1
Verbal response (V)	Oriented	5
	Confused conversation	4

	Incomprehensible sounds	2
	Nil	1
Coma score = $E + M + V$		

Jennett B, Teasdale G. *Management of Head Injuries*. Philadelphia, PA: F.A. Davis; 1981. doi:10.1093/bja/54.3.371-a.

After appropriate evaluation and treatment for life-threatening injuries, the patient with a severe TBI is taken to the intensive care unit (ICU). Medical treatment in the ICU aims to optimize cerebral perfusion and brain tissue oxygenation, minimize brain swelling, and maintain all other physiological variables requiring advanced cerebral monitoring, including seizure prophylaxis.⁴⁰

A physiatrist is typically consulted within the first few days of admission to the ICU to make decisions for appropriate rehabilitative care. Along with occupational therapists, interprofessional members of the rehabilitation team often see the patient for rehabilitative consult and contribute the results of their assessments. The physiatrist orders rehabilitation services, including occupational therapy (OT), for the patient who is in a coma and that treatment may begin in the ICU. Generally, patients with more severe injuries move from the ICU to acute inpatient rehabilitation facilities.⁴¹

Severe Disorders of Consciousness

A person with severe brain injury may exhibit any of a number of altered states of consciousness, depending on the severity of the injury. Various terms are used to describe the continuum from complete consciousness to complete absence of consciousness. These patients begin in coma as a result of loss of consciousness, which is characterized by the inability to open their eyes in response to any stimuli and absence of the sleep–wake cycle based on electroencephalogram (EEG) readings. Vegetative state is a result of cerebral hemisphere dysfunction and presents with complex reflexive movements such as eye movements, yawning, and withdrawal to noxious stimuli. These patients, however, still do not demonstrate ability to interact with their environment. A minimally responsive state presents with the person emerging from coma. These patients are severely disabled, yet demonstrate inconsistent abilities to purposely interact with their environment depending on the stimuli presented. These interactions are recorded through observation and further testing.⁴² The ability to open eyes and sustain visual pursuit eye movement, along with evidence of a sleep–wake cycle, appears to be the first signs of the transition out of coma according to Coma Recovery Scale–Revised (CRS-R). Medical management goals include improving physical stability of the individual for future participation in daily routines and therapeutic activities.⁴³ Rehabilitation may also occur in acute medical or subacute units, such as long-term acute care or skilled nursing facilities. The decisions for ongoing care are made based on the degree and rate of recovery, as well as logistical factors such as insurance coverage and social factors important to the patient and their support system. During the rehabilitative process, occupational therapists, along with other team professionals, use a number of objective assessments to monitor changes in function as a response to physical, cognitive, pharmacological, environmental, and behavioral interventions.

Moderate Brain Injury

As stated in Table 37-2, a person has sustained a moderate brain injury if loss of consciousness has occurred between 30 minutes and 24 hours, imaging shows either normal or abnormal structures, PTA is greater than 1 day but less than 7 days. The patient has a

GCS of 9 to 12 and an Abbreviated Injury Scale score of 3. Symptoms may consist of headache, nausea, and vomiting, along with increased confusion, restlessness, **agitation**, or increased sleepiness. A patient with moderate brain injury may present with functional impairments in the areas of motor, sensory, and/or cognition.⁴⁴ Interprofessional assessment of cognition and function is important and may include the Rancho Los Amigos Scale of Cognitive Functioning Scale (Table 37-4), Functional Independent Measure (FIM), Berg Balance, and the CRS-R. Outcomes vary depending on the cerebral structures that are injured, and each patient is treated based on his or her individual presentation of symptoms. The rehabilitation treatment provided is similar to that for those with severe injuries; however, prognosis is considered to be better because of original scores at time of injury.

Table 37-4. Rancho Los Amigos Levels of Cognitive Functioning Scale

LEVEL	DESCRIPTION
I	No response: unresponsive to stimuli
II	Generalized response: nonspecific, inconsistent, and nonpurposeful reaction to stimuli
III	Localized response: response directly related to type of stimulus but still inconsistent or delayed
IV	Confused—agitated: response heightened, severely confused, may be aggressive
V	Confused—inappropriate: some response to simple commands, but confusion with more complex commands; high level of distractibility
VI	Confused—appropriate: response more goal directed but cues necessary
VII	Automatic—appropriate: response robot-like, judgment and problem-solving lacking
VIII	Purposeful—appropriate (with standby assistance): response adequate to familiar tasks, subtle impairments require standby assistance with acknowledging other people’s needs and perspectives, modifying plans
IX	Purposeful—appropriate (with standby assistance on request): responds effectively to familiar situations but generally needs cues to anticipate problems and adjust performance; low frustration tolerance possible
X	Purposeful and appropriate (modified independent): responds adequately to multiple tasks but may need more time or periodic breaks; independently employs cognitive compensatory strategies and adjusts tasks as needed

Rancho levels I to VIII are widely used in brain injury rehabilitation. The addition of levels IX and X in 1998 describes higher level cognitive, behavioral, and emotional barriers to optimal functioning.^{45,46}

Mild Brain Injury

Mild brain injuries can occur without hospitalization and are often referred to as **concussions**. According to Levin and Diaz-Arrastia,⁴⁷ the terms concussion and mild TBI are considered interchangeable. Impact on the cranium from any type of mechanical force can result in mild TBI.¹³ Mild TBI is estimated to account for the majority of all TBI cases in civilian and military populations.⁴⁷ The American Congress of Rehabilitation Medicine (ACRM) defines mild TBI to include at least one of the following: any loss of consciousness up to 30 minutes, PTA lasting no more than 24 hours, any period of confusion or disorientation; transient neurological abnormalities such as focal signs, seizures, and intracranial lesions; or GCS score of 13 to 15. Post-concussion symptoms may be physical, cognitive, or behavioral/emotional in nature. Physical symptoms occurring in mild TBI may include nausea, dizziness, headache, blurred vision, fatigue, and difficulty sleeping. Cognitive deficits may present with decreased memory and executive functioning, whereas behavioral or emotional symptoms may present in the form of anxiety, depression, or agitation. The prognosis of mild TBI is relatively good as patients seem to obtain complete recovery, in approximately 12 weeks after time of injury.

Phases of Recovery

Although management of ABI is typically an interprofessional enterprise, the following description of each level is based on a typical recovery with emphasis on OT evaluation and treatment. Note how the role of OT changes with each level of severity, increasingly

focusing on occupational functioning the further the patient progresses in recovery.⁴¹ Recovery after ABI is lifelong. Depending on the severity, the patient may require several hospitalizations and treatment in a variety of settings throughout this lifelong journey. Care after ABI requires interprofessional collaboration and constant communication in the best interest of the patient.

Table 37-5 explains the possible phases of hospitalization and the recovery process throughout the continuum of care. Movement throughout the system is based on the patient’s medical changes, funding, physician, rehabilitation team recommendation, as well as patient and family advocacy.

Table 37-5. Phases of Hospitalization, Recovery, and Continuum of Care

CARE SETTING	CARE TEAM
Intensive care unit	Follow-up with Primary Care Physician (PCP), Neurologist, Psychiatrist, all specialists, Nursing
Acute medical hospitalization	Follow-up with PCP, Psychiatrist, Neurologist, all specialists, Nursing, Neuropsychology, Occupational Therapy (OT) and Physical Therapy (PT), Chaplin, Social Worker
Acute rehabilitation	Follow-up with PCP, Psychiatrist, Neurologist, Medical Specialists, Nursing, OT, PT, Speech and Language Pathology, Social Worker, Neuropsychologist, Chaplin (Rehab Team)
Acute specialty inpatient rehabilitation	Follow-up with PCP, Psychiatrist, Neurologist, Rehab Team
Skilled nursing facility (SNF)/long-term care facility (LTAC)	Follow-up with PCP, Psychiatrist, Neurologist, Rehab Team
Outpatient rehabilitation	Follow-up with PCP, Psychiatrist, Neurologist, Rehab Team
Residential specific for brain injury	Full team on location with follow-up of PCP, Psychiatrist, Neurologist, Rehab Team
Home health	Follow-up with PCP, Psychiatrist, Neurologist, Rehab Team
Community resources/support groups/advocacy	Respite care, PCP, Neurologist

Occupational Therapy Assessments

The level of severity is determined by the physician and medical team. As occupational therapists, the clinician needs to consider the overarching condition of the patient, estimated prognosis, length of stay, funding, and the lives of both the patient and families in efforts to service the needs of this population after brain injury.⁴⁸ Table 37-6 identifies the areas of concentration during assessment and intervention as a quick guide for occupational therapists. Table 37-7 lists the assessments used by occupational therapists to meet the needs of patients in specific areas of practice. Descriptions of each of the tests follow.

Table 37-6. Occupational Therapy Assessments and Interventions

LEVEL OF INJURY	ASSESSMENTS	INTERVENTIONS
Severe	Coma Recovery Scale–Revised (Interprofessional) Modified Ashworth Scale Assessment of static head control Pain Skin integrity Seating and positioning Assistive technology needs Possible home assessment	Promote sensory stimulation, pain and or motor responses, positioning, muscle re-education, family/caregiver training, home modifications, and equipment trials

LEVEL OF INJURY	ASSESSMENTS	INTERVENTIONS
Moderate	Motor observations Range of motion Rancho Los Amigos of cognition Modified Ashworth Scale Pain Skin integrity ADLs FIM scoring Custom seating and positioning assessment Assistive technology needs Behavioral agitation scale Depression Equipment needs Home assessment	Target basic ADLs, cognition, physical, psychosocial and behavioral goals; equipment trials, family/caregiver training, home modifications
Mild	Motor Cognitive assessments aimed at memory IADLs FIM scoring Executive functioning Self-awareness Pain Depression Behavior Preinjury behavior Home assessment Equipment needs	Target areas with IADLs, higher cognitive skills, family, caregiver training, return to work, driving, sports

ADLs, activities of daily living; FIM, Functional Independence Measure; IADLs, instrumental activities of daily living.

Physical Assessments

Range of Motion

Range of motion (ROM) is a musculoskeletal assessment that addresses the flexibility or range that a joint is capable of moving. The assessment is typically conducted with a goniometer measuring tool. Common joints that are assessed include the shoulders, elbows, neck, wrists, and fingers. ROM assessments can be used to track ranges in joint mobility over time and determine whether an individual's ROM is within the expected range.⁴⁹

Modified Ashworth Scale

The Modified Ashworth Scale (MAS) is used to measure the degree of **spasticity** in individuals with central nervous system lesions. Examples of populations include brain injury, cerebral palsy, stroke, and multiple sclerosis. The MAS is scored on a 6-point scale, ranging from 0 to 4. A score of 0 indicates no increase in muscle tone. A score of 1 indicates a slight increase in muscle tone, manifested by a catch and release or minimal resistance at the end of the ROM when the affected part(s) is moved in flexion or extension. A score of 1+ indicates a slight increase in muscle tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the ROM. A score of 2 indicates more marked increase in muscle tone through most of the ROM, but affected part(s) easily moved. A score of 3 indicates considerable increase in muscle tone, passive

movement difficult. Lastly, a score of 4 indicates the affected part(s) rigid in flexion or extension.⁵⁰

Nine-Hole Peg Test

The purpose of the Nine-Hole Peg Test is to measure finger dexterity. The test is administered by asking the client to take pegs out of a container and place them one by one into holes on the board, as quickly as possible. The client must then remove the pegs after all holes are filled. Clients are scored based on their total time to place pegs in and take pegs out of the board.⁵¹

QuickDASH

Also known as the Quick Disabilities of the Arm, Shoulder, and Hand. This test uses 11 items to measure physical function and symptoms in people with any or multiple musculoskeletal disorder in the upper limb(s). The QuickDASH is a self-report disability measure that asks clients to answer questions on a scale of 1 to 5, with 5 indicating great difficulty. The higher the total score, the more disabled a person reports to be.⁵²

Box and Blocks Test

The Box and Blocks Test measures unilateral gross manual dexterity. The patient is seated at a table facing a box that contains 150 blocks. The goal of the test is to move as many blocks as possible, one at a time, into an empty adjacent compartment in 1 minute. Higher scores indicate better gross manual dexterity.⁵³

Berg Balance Scale

Fourteen-item objective measure used to assess static balance and fall risk in adults. The tester observes the client perform 14 tasks that assess both static and dynamic balance. Items are score on a 0 to 4 scale, with 56 being the maximum score.⁵⁴

6-Minute Walk Test

The 6-Minute Walk Test (6MWT) assesses distance walked over 6 minutes as a submaximal test of aerobic capacity and endurance. Prior to beginning the test, the client should begin in a seated position. The client is allowed to take as many rest breaks as required, but the time should not stop during the breaks. It is ideal to have the test performed in a hallway or open area at least 12 m long with a smooth, consistent surface, and clear pathways at either end.⁵⁵

Activities of Daily Living Assessments

A-ONE

The A-ONE evaluates the impact of neurobehavioral impairment on functional performance of activities of daily living (ADLs). The measure allows observation of ADLs and evaluation of the level of assistance required for ADLs performance. The A-ONE provides the therapist with an ecologically relevant assessment of the consequences of neurobehavioral impairments through clinical observation of ADLs tasks using a “top-down” (occupation-based) approach.⁵⁶

Activity Card Sort

Used by occupational therapists to help clients describe their social, instrumental, and leisure activities. The Activity Card Sort (ACS) can be used to identify lost activities, set goals, and monitor rehabilitation. The test uses 89 photographs of various activities that the client sorts into different categories based on engagement and interest in occupations.⁵⁷

Assessment of Motor and Process Skills

The Assessment of Motor and Process Skills (AMPS-9) is an observational assessment that allows for the simultaneous evaluation of motor and process skills and their effect on the ability of an individual to perform complex or instrumental and personal ADLs. The AMPS is comprised of 16 motor and 20 process skill items.⁵⁸

Barthel Index

The Barthel Index (BI) measures the extent to which somebody can function independently and has mobility in their ADLs (i.e., feeding, bathing, grooming, dressing, bowel control, bladder control, toileting, chair transfer, ambulation, and stair climbing). The index also indicates the need for assistance in care. The BI is a widely used measure of functional disability.⁵⁹

Functional Independence Measure

The Functional Independence Measure (FIM) was developed to offer a uniform system of measurement for disability based on the *International Classification of Impairment, Disabilities and Handicaps* for use in the medical system in the United States. The level of a patient's disability indicates the amount of support needed to care for him or her and items are scored on the basis of how much assistance is required for the individual to carry out ADLs. The FIM consists of 18 items assessing 6 areas of function. The items fall into two domains: motor (13 items) and cognitive (5 items).⁶⁰

Performance Assessment of Self-Care Skills

The Performance Assessment of Self-care Skills (PASS) is designed to measure occupational performance of daily-life tasks. The PASS is a client-centered, performance-based, criterion-reference, observational tool that objectively documents occupational performance and helps plan occupation-based interventions for adolescent, adult, and older adult populations in a variety of settings. The PASS consists of 26 core tasks, categorized in 4 domains. The PASS includes 5 functional mobility (FM) tasks, 3 basic activities of daily living (BADLs) tasks, 4 instrumental activities of daily living (IADLs) tasks with a physical emphasis, and 14 IADLs tasks with a cognitive emphasis.⁶¹

Cognitive Assessments

The Kettle Test

The Kettle Test is used to assess functional cognitive performance. The client is asked to complete a variety of daily tasks, which the clinician observes and assesses. The task assesses 13 areas of performance, whereas the client prepares a drink for the clinician and themselves. Total possible score of 52, with higher scores indicating greater performance deficits.⁶²

Montreal Cognitive Assessment

Screen of cognitive abilities used to detect mild cognitive dysfunction. Sixteen-item measure that screens visuospatial abilities, executive function, naming, memory, language, attention, orientation, and abstraction. Total possible score of 30, with a score of 26 or higher considered normal function.⁶³

Neurobehavioral Cognitive Status Examination

Assessment of neurocognitive functioning in three general domains: (1) consciousness, (2) orientation, (3) simple attention; and five major domains: (1) language, (2) constructional ability, (3) memory, (4) calculation skills, and (5) executive skills.⁶⁴

SELF-AWARENESS Assessment

Interprofessional assessment used to assess a person's degree of self-awareness using guidelines for building a collaborative relationship, and applying intervention, which aims at restoring self-awareness in a confidence and skill-building manner.⁶⁵

St. Louis Mental Status Examination

Administered by the clinician to identify persons who have dementia or mild cognitive impairment. St. Louis Mental Status Examination (SLUMS) is a quick screening that can be completed in approximately 7 minutes.⁶⁶

Lowenstein Occupational Therapy Cognitive Assessment

Used to measure basic cognitive skills needed to perform ADLs/IADLs, including orientation, visual perceptual/psychomotor abilities, problem-solving skills, and thinking operations. Scores on a 1 to 4 scale, with higher scores indicating less impairment.⁶⁷

Rancho Levels of Cognitive Functioning Scale–Revised

This evaluation tool identifies patterns of recovery for people with brain injury. The scale describes behavioral characteristics and cognitive deficits associated with brain injury to help the team understand and focus on the person’s abilities in designing an appropriate treatment program. Scores range from level I to level VIII, with higher levels indicating higher levels of cognitive functioning.⁶⁸

Emotional Assessments

Canadian Occupational Performance Measure

Assesses an individual’s perceived occupational performance in the areas of self-care, productivity, and leisure. The assessment takes place in a semi-structured interview setting. The information obtained can be used to create goals for therapeutic interventions.⁶⁹

Sickness Impact Profile

Assessment of QoL and level of dysfunction that results from disability or illness. Provides a valid and sensitive assessment of outcomes that result from health care–related services. Assesses four areas: (1) behavior, (2) life participation, (3) mental health, and (4) social relationships.⁷⁰

Beck Depression Inventory

The most widely used instrument for detecting depression, takes just 5 minutes to complete, and is clinically sensitive.⁷¹

Behavioral Assessments

Agitated Behavior Scale

The Agitated Behavior Scale (ABS) measures behavioral aspects of agitation during the acute phase of recovery from ABI, including aspects of aggression, disinhibition, and lability. The ABS measures 14 statements on a scale of 1 to 4. The maximum score is 56, and the minimum score is 14. Higher scores indicate greater levels of agitation.⁷²

Motivations for Traumatic Brain Injury Rehabilitation Questionnaire

Designed to assess motivation to participate in postacute rehabilitation, including factors of denial, anger, apathy, compliance, medical information seeking, and excessive enthusiasm. Thirty-one items that are scored by Likert-style scoring, ranging from –2 to 2. Maximum possible score of 62.⁷³

Quality of Life After Brain Injury

Health-related QoL instrument for survivors of TBI that includes the person’s subjective perspective. The scores range from 0 to 100. 0 means worst possible QoL, and 100 means the best possible QoL.⁷⁴

Assessments Used by the Interprofessional Team

Assessments used by interprofessional teams are outlined in Table 37-8.⁷⁵

Table 37-8. Assessments Used by the Interprofessional Team

ASSESSMENT	DESCRIPTION
Abbreviated Injury Scale (AIS)	One-time tool used to measure the severity of brain injury. The AIS differs from other measures in that it represents the threat a brain injury presents to an individual’s life rather than assessing the severity of the injury.
Glasgow Coma Scale	Measures severity of brain injury by objectively measuring conscious state, initially at time of injury and periodically afterward.

ASSESSMENT	DESCRIPTION
Glasgow Outcome Scale–Extended (GOS-E)	Extension of the GOS designed to address the original scale’s insensitivity to changes or progress over time. The GOS-E extends the original five categories in the GOS to eight: ranging from Dead to Good Recovery.
JFK Coma Recovery Scale–Revised (JFK CRS-R)	Used to assess individuals who are emerging from a minimally conscious or vegetative state. The CRS-R addresses 23 items, including auditory, visual, motor, communication, arousal functions, and automatic body functions. It also measures communication and arousal functions.
Galveston Orientation and Amnesia Test (GOAT)	Measures post-traumatic amnesia. The test features 10 questions that assess the patient’s temporal and spatial orientation (<i>Where Am I?</i>), biographical recall (<i>Who Am I?</i>), and memory (<i>What Happened?</i>).
Orientation Log (O-LOG)	Measures post-traumatic amnesia. The O-LOG measures the individual’s orientation to time, place, and circumstance over a period of time.
Westmead Post-Traumatic Amnesia Scale (WPTAS)	Administered at bedside by a member of his or her treatment team. The WPTAS measures the length of post-traumatic amnesia.
Rancho Los Amigos Levels of Cognitive Functioning Scale	Ten levels of cognitive function based on behavioral observations and responses to environmental stimulation.

Functional Impairment in Daily Occupations

“Every day I wake up is a good day. Even the bad days are now good” (Alice Torres, 2018).⁷⁶ ABI is disruptive to a person’s normal routine and interrupts many, if not all, areas of daily life in the context of physical, emotional, cognitive, psychosocial, behavioral, intimacy, and sexuality. The degree of severity and the areas of the brain affected impact overall independence in occupations such as ADLs, work, and social participation; client factors such as vision and cognition; and performance skills in motor control, physical agility, stamina, and mobility.^{42,77} The person with a brain injury must learn a new way and modify his or her approach to living the remainder of life using new strategies to accomplish routine tasks. Some adjustments are temporary, whereas others are permanent and lifelong. Occupational therapists are the professional experts in developing rapport through therapeutic use of self. Through this relationship, occupational therapists gather information using the occupational profile, perform activity analysis, assess and predict the positive functional potential of the patient, and access patient personal motivation to assist in modification of the environment, and/or tasks as needed to enhance daily occupations.

Occupational Therapy Interventions

Many researchers have attempted to assess the predictive power of age; clinical observations such as the GCS, duration of unconsciousness, and length of PTA; and neuroimaging evidence of structural damage in efforts to predict recovery outcomes.^{78,79} Despite all the medical and technological advances, the ability to predict outcomes on an individual basis remains complex. In the writing of new guidelines by the ACRM for managing vegetative and minimally conscious states, Joseph T. Giacino, PhD writes “People are sometimes misdiagnosed due to underlying impairments that can mask awareness. An inaccurate diagnosis can lead to inappropriate care decisions and poor health outcomes.”⁸⁰ Although the occupational therapist does not diagnose or predict outcomes, he or she is a valuable team member in considering predictive factors that contribute to the overall recovery process of the patient. These predictive factors are used to determine goals, length of stay, course of interventions, equipment needs, and ability to move directionally within the continuum of care. It is imperative that occupational therapists use their keen observation skills to report changes and their therapeutic skills to empower changes regarding patient performance. Interventions chosen by the clinician are generally driven by areas of training, evidence-based practice, and the desire to apply new knowledge. As always, interventions chosen are patient centered and occupationally based.

Physical Interventions

Positioning

As an occupational therapist, it is important to work collaboratively with all professions regarding patient positioning. The patient's position must be reevaluated frequently with close monitoring of his or her reactions, including facial expression, changes in muscle tone, and vocalizations. Minor adjustments can make a difference between comfort and discomfort. Assistive positioning supports are to be removed as the patient's neuromuscular status improves.⁴¹ When considering bed positioning, communication between the nursing staff, physical therapy (PT), and the patient's family must be good to make an informed decision regarding desired bed positioning, its purpose, and the schedule. Daily skin assessment is critical to protect from the development of skin breakdown or pressure wounds. Development of pressure wounds will require the occupational therapist to make necessary adjustments in collaboration with the medical team. Patient positioning is dependent on the medical condition of the patient and any precautions that may be on board. Refer to the patient chart, the physician, and the nursing team to guide you during your review for bed positioning. The standard practice in bed positioning is 2 hours on back and then alternate to each side. If the patient has a severe brain injury, swallowing precautions may need to be considered regarding bed of head angle and degree of elevation.

Supine

Lying supine may trigger an extensor response if not properly supported at lower extremities (LEs) with slight hip and knee flexion, feet supported with heels off the bed and in neutral dorsiflexion.⁴⁰ Collaboration with PT regarding LE positioning is in the best interest of the patient. Head is positioned in neutral with only one pillow for support. Depending on the degree of head control, more support may be needed with conscious effort to protect the ears from constant pressure. The trunk is in alignment with shoulders. Upper extremities (UEs) are positioned in partial abduction away from the body, with elbows extended, forearms elevated on pillows or wedges to decrease any edema, wrists are in extension, and hands are open in abduction. Hand splints may be in place to promote functional hand positioning, and the type of splinting used will be determined on whether the tone in the UEs is flaccid or increased. If increased abnormal flexor tone is present in the hand, custom splinting is the best option. Do not use soft towels in the hands because soft materials will elicit abnormal flexion reflexes.

Side-Lying

In side-lying, the head, resting on a small pillow, should be in neutral alignment with the trunk; the bottom UE should be in moderate scapular protraction and humeral external rotation; the top UE should be in scapular protraction, slight shoulder flexion, and resting on a pillow to avoid horizontal adduction; the bottom elbow should be flexed; the top elbow should be extended; wrists should be in extension; and hand splint should be placed to decrease spasticity and maintain thumb web spaces and finger abduction. A pillow between the knees decreases hip internal rotation and adduction. The lower leg also may need pillow support to align it with the thigh. If necessary, place a firm pillow or foam wedge in the space between the thigh and the calf to prevent excessive knee flexion. The foot should not be placed higher than the knee and hip because this can result in torque on the knee and cause the hip to go into internal rotation. Elongation of the lower side of the trunk between the shoulder and the pelvis is desirable. A pillow or foam wedge behind the back and shoulder will assist in maintaining trunk position in side-lying and may also need to be tucked in front of the trunk in maintaining the alignment.⁴⁰ If a long body pillow is used, it can often be positioned to maintain some abduction in the LEs and support the calf and foot of the upper leg. Avoid positioning the feet near the footboards because this may elicit extensor thrust. There are many options for foot orthotic devices used to avoid pressure to the heel of the foot, while maintaining ankle dorsiflexion to 90°, in efforts to prevent foot drop. The orthotic devices may also be used to avoid stimulating an extensor thrust from the foot. If the pelvis is retracted on one side, a small folded towel is placed

behind it, and that leg is positioned in neutral. Some knee flexion should be encouraged with care to avoid prolonged knee flexion to prevent development of a contracture. A semi-recumbent bed position with head-of-bed angle maintained at 45° is recommended for patients on mechanical ventilators, tracheostomies, or swallowing issues, to minimize risk of aspiration and pneumonia.⁸¹

Wheelchair Positioning

Early and correct upright wheelchair positioning helps to facilitate arousal by stimulating the visual and vestibular systems, inhibiting abnormal tone, providing normal proprioceptive input, and reducing the likelihood and/or extent of contractures and complications from prolonged bed rest. The pelvis must be positioned correctly before other areas can be addressed. The pelvis should be in a neutral position or have a slight anterior tilt if needed to decrease extensor thrust. The pelvis should be symmetrical, without one side retracted or elevated.⁴⁰ Custom seating and positioning becomes valuable as equipment trials begin using solid seat inserts, solid backs, and cushions to gain optimal alignment. Because the spine and rib cage are the essential connecting parts between the shoulders and the pelvis, it is important to obtain alignment in these structures to facilitate shoulder and trunk stability. Positioning the trunk with thoracic extension and neutral scapulae is critical for improved function. The trunk should be symmetrical and in midline with shoulders over the pelvis in sagittal, frontal, and horizontal planes. Lateral trunk supports can be used in the wheelchair to better position the trunk in an upright manner and to decrease lateral trunk flexion. Experimentation with the positioning is essential because trunk control varies among patients and is the key to achieving reach. The therapist must not overcompensate with too much trunk support, but rather facilitate and challenge the patient's normal movement and control. With a solid seat, supportive cushion, and solid-custom wheelchair back, the patient may not require additional trunk support. Dependent trunk control may require a chest harness, shoulder straps, or a chest strap to enhance functional potential by keeping the patient from falling forward or limiting forward trunk flexion. Positioning of the extremities is also crucial. Hips, knees, and ankles are flexed to 90°. Heels are slightly behind the knees in sitting, with feet in neutral pronation-supination and inversion-eversion. The footplate should be large enough to support the whole foot. If abnormal tone presents in the ankles, wheelchair accessories such as foot wedges, heel loops, shoe holders, or custom bracing may be required to properly reach 90° of ankle flexion. The ideal UE position for wheelchair propulsion begins with scapulae in slight protraction, and slight shoulder abduction. Elbows are in comfortable flexion, and the forearm is in partial pronation. The wrists are in extension with neutral ulnar-radial deviation, the fingers are relaxed, and the thumb is radially abducted with the mobility coming from the first carpometacarpal (CMC). The height and angle of the solid back for trunk support impacts the shoulder position and must be considered for efficient wheelchair propulsion. In addition, a lap tray may be used to allow for UE weight bearing and serves as a support for an extremity with limited mobility. Head position also needs to be considered. Ideally, the head should be in midline with cervical elongation posteriorly and the chin tucked in slightly. It is important that positioning eliminates chin jutting and neck hyperextension. The position of the patient's pelvis, trunk, and shoulders all influence head position. When prescribing a wheelchair, keep in mind that the wheelchair is an extension of the person. "People are not confined by their wheelchairs. They are in fact liberated by their wheels."⁸²

Passive Range of Motion

Passive range of motion (PROM) programs are used in conjunction with positioning to minimize the development of contractures from abnormal tone and static postures. PROM can be difficult when muscle tone is increased. Inhibitory movements opposite the abnormal tone are performed slowly, holding the stretch until muscles relax. Flexor muscle groups tend to present with higher risk of developing contractures than the extensor group muscles. Sudden quick stretch or noxious stimulation and handling should be avoided. Scapular mobility should be addressed before UE PROM to free the scapula and facilitate

normal scapular and humeral movement during the rest of PROM.⁸³ Awareness of joint limitations along with increased pain and increased spasticity may be a sign of heterotopic ossification. Occupational therapists use PROM and positioning to minimize the development of contractures.⁴³

Splinting and Casting

The goals of splinting and casting are to decrease abnormal tone and increase the patient's functional movement. Custom splinting focuses on inhibiting flexion or extensor patterns as a result of abnormal tone. Splinting can be used as a means to promote or inhibit motion. Plaster or fiberglass serial casting may be indicated when there is severe spasticity in the elbow and/or wrist.⁸⁴ Serial casting along with the use of neurolytic procedures such as BOTOX injections and intrathecal baclofen (ITB) pumps can be very effective in treating ROM limitations or motor issues as a result of spasticity, in the UE.^{82,85} Dropout casts, which leave a portion of the limb exposed; bivalve casts, which are split in two, can be removed during therapy and nursing procedures; and weight-bearing inhibitory casts, which are fabricated to approximate the ideal weight-bearing posture of the foot or hand, can also be used.⁴¹ Casting is contraindicated with uncontrolled hypertension, major open wounds, unhealed fracture, impaired circulation, acute inflammation, a recent episode of autonomic dysreflexia, or if professionals need access to the extremity for lines or monitoring of vital signs.⁸⁶ "When spasticity interferes with comfort, function, ADLs, mobility, positioning, or caregiver assistance, patients should be considered for ITB therapy."⁸⁵

Occupational therapists work collaboratively with other professionals in this decision-making process. The treatment of spasticity is complex and challenging. It requires an investigative and continuous reassessment approach, while tapping into different therapeutic interventions. An interprofessional approach is critical as both occupational and physical therapists join with nurses and physicians in addressing secondary complications, during attempts to prevent risk of contracture and skin breakdown.⁴³ Because OT uses a client-centered approach, remember that the patient and/or supportive persons should be empowered to assist in all decisions in the best interest of the patient.

Sensory Stimulation

Although studies do not present reliable evidence of support regarding sensory stimulation for persons with **disorders of consciousness (DOCs)**, structured use of these techniques is generally accepted as a practice model. The goals of a sensory stimulation programs are to promote arousal from coma while stimulating the reticular activating system, prevent sensory deprivation by facilitating appropriate patterns of movement from prolonged immobility, and interaction with the environment, while facilitating ability to increase responses to stimuli and also encouraging the ability to follow commands.⁴³ Therapists use consistent protocols to standardize the administration of stimuli and data sheets to record observations regarding rate of response and changes in respiration, pulse, blood pressure, head movements, eye opening, eye movements, eye fixations, mimic responses, aimed and non-aimed motor reactions, and articulations in response to tactile, vestibular, olfactory, kinesthetic, proprioceptive, auditory, and visual stimuli. Therapists hope to see an increase in consistent responses, which is an indication of improvement.

Vision and Visual Perception

Vision and visual-perception issues present in most cases of ABI. Vision is another area that is dependent on communication between team members. Occupational therapists should include vision as part of their assessment protocols in identifying visual impairments that can impact function such as ADLs, IADLs, daily life, and QoL.^{87,88} Assessments and interventions should include the areas of visual acuity, oculomotor, visual fields, binocular vision, vergence, and vestibular interactions. Patients with visual deficits will have damage to the areas of occipital and/or parietal lobes. Visual perceptual deficits may occur as a result of sensory interference and the inability to accurately respond to sensory information. Visual perceptual deficits include form discrimination, depth perception, figure-ground perception, topographical orientation, and spatial relations. Due to the fact that visual-

perception difficulties interact with cognition, it is often important to rule out cognitive impairments.⁴³ As an occupational therapist addressing visual deficits, collaboration with other team members such as ophthalmologist, neuro-ophthalmologist, and neurologist is important when distinguishing between a visual function issue and/or a visual perceptual issue.⁸⁹ Mary Warren's Hierarchy Model of Visual Perception states that the foundation of visual function is based on oculomotor control, visual fields, and visual acuity. The highest order of the visual perceptual process is visual cognition. According to Warren, the role of OT in determining appropriate interventions is to identify the functional impairment and to link the presence of the functional impairment to the presence of the visual impairment.^{89,90} Many clinicians today choose to use a combination of remedial, compensatory, and adaptive approaches when treating patients who have visual deficits from ABI. Generalization of cognitive and perceptual rehabilitation techniques has a higher ability to be transferred into function if training is done in a variety of settings.⁹¹

Management of Agitation

Post-traumatic agitation is reported to occur in the acute setting in 33% to 70% of patients with ABI and may last for up to 10 days or less. Agitation is a subtype of delirium in the coma-emerging patient that is associated with frontotemporal injury, disorientation, comorbid medical complications, and/or use of anticonvulsant medication.⁹² Management of agitation is an interprofessional team process. The aggressive behavior may present in bizarre, unpredictable, and impulsive manners.⁴³ The main purpose of the team during this phase is to provide the patient with a safe environment. The role of clinicians is to determine which factors are contributing to the problem, considering client factors, social context, and the physical environment.⁴¹ Interventions such as decreasing stimulation, implementing consistent behavior techniques, psychotropic medications, and one-on-one coaching with continuous supervision, including telemonitoring, may be warranted.⁹³

Cognition

There are currently several million Americans living with long-term disabilities due to ABI.² In today's health care model, patients with ABI typically move quickly within the continuum of care. There has been much discussion in recent years about the role of OT in the assessment and treatment of cognition. Much of the confusion is surrounded by reimbursement issues and billing codes. The profession of OT has been involved in treating cognitive issues since the inception of the profession. Salvador Bondoc informs occupational therapists to justify the use of cognitive rehabilitation by applying clinical reasoning and describing how cognitive deficits influence occupational performance.⁹⁴ Occupational therapists use remedial, compensatory, and adaptive approaches to improve cognition. Activities and exercises combined with functional, client-centered purposeful challenges stimulate primary cognitive domains (attention, memory, and executive function). While past cognitive training methods have consisted of card or board games, puzzles, paper-and-pencil drills, and computer programs, increasing clinician involvement in occupation-based treatments with transfer ability to a variety of contexts is recommended.⁹⁵ During the 2018 AOTA Slagle Lecture, Gordon Giles speaks of evidence-based practice where occupational therapists have a unique role in skill development for patients with ABI. Although many professionals have the capacity to address cognition, the profession of OT has a unique position in assessing functional cognition. Functional cognition is the ability to use and integrate thinking and performance skills to accomplish ADLs and IADLs in both the dynamic clinical environment and the community to which patients will return. Giles discusses the neurofunctional approach to achieving functional cognition. The neurofunctional approach concentrates on incorporating principles of skill learning and promotes the development of routines and competencies in the practical activities required for daily living. Giles goes on to state that occupational therapists must increase confidence in their ability to clearly articulate the profession's unique approach to assessment during collaboration with the interprofessional team. Furthermore, he states, "Our unique vision is needed to improve client care and outcomes. If we fail to meet this need, another discipline will do so."⁹⁶

Self-Awareness

The rehabilitation process is a journey for all those involved. The key to a full recovery includes intact self-awareness. The presentation of impaired self-awareness creates a significant barrier to successful rehabilitation.⁶⁵ The profession of OT emphasizes the importance of consideration between empathy, personal beliefs, dignity, and the interrelationships between the person, the occupations, and the environment.⁹⁷ As occupational therapists, the ability to integrate art and science while fostering self-awareness in an empathetic and dignified manner can be accomplished using the Self-Awareness Enhancement through Learning and Function (SELF) practice guide. This practice guideline is an interprofessional collaborative example merging the latest theoretical perspectives from disciplines such as neuroscience, psychology, computer science, and OT. Use of the SELF for assessment and treatment encompasses clear direction, while demonstrating therapeutic alliance, occupation, belief perspectives, neurological education, and compensatory strategies for the purpose of enhancing self-awareness. The SELF differs from traditional methods of cognitive retraining by providing “occupational therapists with guidelines for building a collaborative relationship with the client, using an intervention that restores self-awareness in a manner that builds confidence and skills,” rather than focusing on poor performance-based feedback.⁶⁵

Functional Training

The ability to develop rapport with a patient is imperative for safety and progression in treatment. Depending on the severity of the injury and the area in the continuum of care, the focus of therapy in the area of daily living begins with reestablishing routine self-care tasks. If the patient has a severe impairment, training is initiated with family or support system. All self-care is simplified until skills are successfully mastered. Activities are client centered, and distractions are minimized. Using the neurofunctional cognitive approach, training is performed by implementing the following steps: (1) task analysis, (2) whole task method, (3) cue experimentation, (4) consistent time delay cuing, (5) self-generation, (6) reinforcement, (7) errorless learning, and (8) overlearning. Practice is essential.⁹⁶ Occupational therapists may need to assist with establishing consistent and automatic self-care routines at home by documenting the sequence of steps for which the patient is successful. Clinicians must consider the patient’s previous knowledge or familiarity with the task prior to attempting to reestablish habits and routines.⁴¹ When choosing interventions, occupational therapists should be leaders in using authentic occupations by engaging patients in purposeful activities. Purposeful activities are meaningful tasks that are part of daily routines, such as personal care, home management, school, and work. Research has shown that using purposeful, occupation-based interventions is an intrinsic motivator for patients.⁹⁸

Psychosocial

The consequences and effects associated with brain injury can be lifelong. ABI sequelae include impairments in the areas of cognition, emotions, behavior, and sensorimotor function. Many individuals experience increased life complexity after ABI. There are many factors such as prior premorbid personality, personal relationships, marital discord, work-related issues, and financial instability that contribute to further development of neuropsychiatric symptoms.⁹⁹ Patients recovering from mild brain injuries tend to experience more symptoms such as headaches, pain, cognitive, emotional, or even personality changes. Additional life stressors may contribute to anxiety or even depression. It is important that after discharge from inpatient rehabilitation services that the patient continue to be followed by neurology and even neuropsychology.⁴³ Ylvisaker et al.¹⁰⁰ recommend focusing on antecedents associated with positive behavior and less on consequences related to problems. The following are examples of strategies that contribute to the patient’s ability to learn effective behaviors during inpatient rehabilitation and beyond:

- Redesign the environment.¹⁰⁰ For example, if noise and distractions seem to contribute to a patient's irritability and aggressiveness, provide treatment and care in areas that are calm and quiet.
- Capitalize on the superiority of procedural over declarative memory after brain injury by helping patients learn context-sensitive routines rather than broader transfer-dependent strategies.¹⁰⁰
- Use of neurofunctional approach by incorporating task analysis with functional activity participation using cues, repetition, and errorless training to encourage success.⁹¹
- Provide successful experiences to reduce frustration-induced maladaptive behavior.

The discharge from inpatient status can often be anxiety producing for both the patient and the individual's support system. Patients will continue to focus on improvement in all areas of cognition, visual and visual-perception, and self-maintenance roles such as ADLs, IADLs, leisure and social participation, work, and behavioral and emotional adaptation. As patients and families attempt to resume and reintegrate into their prior lives, the ability to escape the awareness that change has occurred in some manner is difficult.⁴¹

Support Systems

With changes in health care, more families are assuming a participatory role in caring for individuals affected by brain injury. Patients' families continue to require information and support to understand the recovery and rehabilitation process. This information is to assist in making informed decisions and actively participating in discharge planning. Much has been stated about team and interprofessional collaboration. The support system is part of this collaborative team. Owing to shorter length of stays, family involvement should begin immediately, as allowed, to begin the training process. Families must be provided with information regarding the continuum of care system, home programs, equipment, and community resources to prepare for discharge options as soon as possible. Training should occur over the duration of hospitalization or length of stay in whatever setting the patient is being treated. Many times, occupational therapists are working closely with social work and case managers to provide a smooth transition for the patient and family to the next destination in the recovery process. Family members must consider developing support outside the immediate family unit because caregiver burden is estimated to occur in nearly 90% of caregivers of individuals with ABI.¹⁰¹

The survivorship phase of life for persons with ABI presents opportunities for clinicians to employ all that is truly unique to OT, synthesizing the totality of our education, philosophy, and values to enhance occupational functioning in society. Readers are challenged to consider the following ways to poise themselves for action:

- Recommend that a life care plan be prepared for survivors of moderate-to-severe ABI. A life care plan delineates the services and items required for the current and long-term care of the survivor as well as the costs of these services. A life care plan can be used clinically to plan appropriate long-term care, including intermittent follow-up, and for forensic purposes, such as determination of an appropriate settlement that will provide for the lifetime needs of the injured person.
- Promote to possible referral sources to enhance community integration and QoL for persons with ABI. Join the local brain injury association, connect with the state's vocational rehabilitation division, and become familiar with key personnel supporting disabled students at local colleges and universities.
- Establish the kind of therapeutic relationship with patients and family members that will make them want to return for help. Respecting the patient's readiness for treatment means sometimes not intervening, but making sure that he or she knows that the door is open in the future.

Make sure that the discharge from outpatient OT incorporates plans for follow-up and clear information regarding possible circumstances in the future when further OT services may

be helpful. Provide information to the patient and his or her family regarding mechanisms to reinstate services. Remember that the nature of ABI interferes with patients' ability to advocate for themselves (e.g., lack of initiation, impaired memory), and so the therapist must build in opportunities to discern and respond to their needs.⁴¹

Acknowledgments

With great love and gratitude, I thank my parents Joe and Frances Flores for their belief in the power of education; Candy, whose love and support allows me to accomplish anything life slings at me; Erica, Thomas, Maddi, and Zach, your constant support and tolerance of mountains of paper is remarkable. Thank you for allowing your mother to “just be.” To Dr. Lee Mountain, what an inspiration you always are. Dawn Phillips and Rachel Sieber, your professionalism and collaboration have been invaluable. To the TIRR/Memorial Hermann Brain Injury Team OTs of 2018, thank you for allowing me pick your brain. To Bridget Furlong for your many hours of input. To all the OT students of Texas Woman's University, thank you for your support and inspiration.

CASE STUDY

Patient Information

Nathan is a 16-year-old high school student who sustained a TBI from falling out of the back of a pickup truck after a high school football game. Nathan was previously an extrovert who loved music, worked at a local grocery store on weekends, and was excited about starting high school. Nathan is part of a blended family whose parents are very involved with their children, and who also work full time. Upon arrival to the trauma center, Nathan was still unresponsive. The assessment in the ER revealed the following:

- Initial GCS of 3
- Open wound to the back of the head with large hematoma
- Increased ICP
- Intubation requiring tracheostomy necessary to sustain breathing
- C4–C5 spinal processes hairline fracture
- Right posterior humeral fracture
- Left femur fracture
- Bleeding into all ventricles

Nathan was treated in the ICU for 21 days where he underwent surgery for fractures with internal pinning for right UE (RUE) and left LE (LLE) and was on non-weight-bearing status for both. Surgical placement of gastrostomy tube (G-tube) was also performed for feeding purposes prior to transfer to the acute floor. Nathan remained on the acute unit for 7 days while undergoing medical treatment for pain, continued monitoring of ICP, feeding, and further stabilization procedures. He was to wear a Miami J Collar at all times to protect his cervical spine. OT orders were initiated, along with PT and speech-language pathologist (SLP). OT received orders as part of the interprofessional team to assess and provide ROM, positioning, sensory stimulation, and caregiver education. At the time the patient was transferred to the acute care unit, he presented with abnormal flexor posturing in bilateral UEs (BUEs) and extensor posturing in bilateral LEs. RUE humeral and LLE femur were casted, PROM was still within normal limits at this time. Nathan also presented with spasticity in UEs scoring 0 to 2 throughout BUEs on the MAS. Nathan was still unresponsive to any stimuli, nonverbal, and not moving neither on command or involuntarily. While still on the acute care unit, the patient contracted methicillin-resistant *Staphylococcus aureus* (MRSA) in his urine and was placed on contact-isolation. Once stabilized, although he remained unconscious, he was transferred to acute inpatient rehabilitation for further DOC management. At 5 weeks after onset, Nathan was now receiving rehabilitation on the inpatient brain injury

unit. He was referred to an interprofessional team consisting of OT, PT, SLP, neuropsychology, dietary, social work, and pharmacology. He is being followed by a medical team inclusive of physiatrist, orthopedic surgery, neurosurgery, gastroenterology, and infectious disease. OT received orders to assess and treat for responsiveness to stimuli, cognition, bed positioning, seating and positioning, ADLs, spasticity management, neuromuscular re-education, and caregiver training.

Assessment Process and Results

The CRS-R2 was administered jointly by OT and neuropsychology. Nathan's scores demonstrated emergence of coma in the following areas: eye movement but no eye opening, response to auditory stimuli, and response to pain.

PROM is still within normal limits; however, right elbow was not assessed due to cast from distal humeral fracture. Manual muscle test (MMT) is zero not only because of patient unable to follow commands but also because of spasticity. MAS reported increased tone of RUE shoulder internal rotators, adductors, and wrist and finger flexors bilaterally. He is dependent in all ADLs and mobility. Skin is intact; however, stage I redness is occurring on sacrum. Nathan's parents hope to take him home depending on status at discharge.

Occupational Therapy Problem List

- Decreased arousal and attention
- Inability to visually track
- Decreased ability to follow basic commands
- Poor head control
- Decreased ability to sit unsupported
- Dependent in ADLs
- Increased risk for skin breakdown
- Non-weight-bearing RUE and LLE

Occupational Therapy Goal List

OT goals are set for 4 weeks for long term (LTG) and 2 week for short term (STG). Length of stay varies depending on progress of Nathan and funding source. Discharge options are dependent on status at time of discharge as to whether it will be home or community based. Insurance requires updates every 2 weeks.

- **LTG:** Nathan will improve in level of arousal from severe to moderate level of consciousness.
- **STG:** Nathan will open eyes on command to stimuli 3/5 attempts. Nathan will tolerate sitting upright, with support, for 60 minutes daily.

Interventions

Nathan received inpatient OT for a total of 90 minutes, a day with one session being 60 minutes and another 30 minutes session. Focus of therapy was to increase sensory stimulation and deep pressure through the hips, pelvis, and left UE (LUE) joints while in upright posture to increase level of arousal and physical demands against gravity. Sessions start in supine to perform stretching, abnormal tone inhibitory techniques, and PROM to all UE joints with the exception of right elbow. Patient is placed in a tilt-in-space manual wheelchair that provides good head and trunk support. Patient is then transferred and placed in sitting with total support for trunk and head control. OT co-treats with music therapy to attempt to increase arousal and his ability to follow commands during weight-bearing activities. As Nathan's level of arousal improved to being alert throughout the day, OT continued to focus on head and trunk control, along with consistency in following verbal commands and increased ability to regain the use of UEs for the purpose of BADLs.

Upon discharge from inpatient rehabilitation, Nathan remained alert and could follow basic commands with eye blinks for “yes and no.” Head control was fair, and he could sit upright in his manual wheelchair for 2-hour intervals three times a day with appropriate wheelchair accessories for head and trunk control. The OT was responsible for ordering necessary equipment, training parents on BADLs, PROM and stretching program, tone inhibition techniques, bed and wheelchair positioning splint wear and care, and follow-up care.

Best Evidence for Interventions Used for Acquired Brain Injury in Occupational Therapy

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Neurofunctional approach ¹⁰²	Comparison of randomized controlled trial between cognitive and functional approaches over 10 years	Participants with moderate-to-severe TBI (N = 360)		Systematic Level I	Neurofunctional approach as compared to traditional rehabilitation can improve cognitive performance.	$p = 0.01$
Efficacy of activities of daily living ¹⁰³	ADL retraining was manualized, followed errorless and procedural learning principles with individualized goals.	Participants with severe TBI (N = 104)	Participants received individual ADL skills retraining for nine modules, using a structured format by occupational therapists.	Systematic review Level I	Individuals in PTA can benefit from skill retraining.	$p = 0.001$
Cognitive habilitation ⁹⁵	Various cognitive rehabilitation approaches	Participants (number not specified) with TBI or stroke from 112 studies	Varied by study	Systematic review Level I	Recommendations for practice standard for attention remediation in postacute rehab, metacognition strategy training; practice guidelines for use of memory compensations in severe TBI	Not calculated

Chapter 38

Neurodegenerative Diseases

Susan J. Forwell Lucinda L. Hugos and Setareh Ghahari

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Appreciate the complex considerations when approaching and working with a client with neurodegenerative disease.
2. Describe the epidemiology, etiology, course and prognosis, and medical management of multiple sclerosis (MS), Parkinson disease (PD), amyotrophic lateral sclerosis (ALS), and Guillain-Barré syndrome (GBS).
3. Describe the signs and symptoms of MS, PD, ALS, and GBS and the role of occupational therapy in their management.
4. Synthesize the functional impairment in daily occupation experienced by persons with MS, PD, ALS, and GBS.
5. Select standardized occupational therapy assessment and evaluation tools for clients with neurodegenerative diseases based on individual clients' characteristics and requirements.
6. To achieve client-centered goals, determine interventions for clients with MS, PD, ALS, and GBS based on their individual characteristics, the social context and physical environment, the occupational therapy evaluation, and current research evidence.

CHAPTER OUTLINE

Introduction
Occupational Therapy for Neurodegenerative Diseases
Multiple Sclerosis
Parkinson Disease
Amyotrophic Lateral Sclerosis
Guillain-Barré Syndrome
Case Study

TERMINOLOGY

- Akinesia:** initiation impairment of voluntary and spontaneous motor responses that interrupts performance to engage in voluntary activity.
- Bradykinesia:** slowness or poverty of movement such as lack of facial expression or “mask face” and reduced eye blink, arm swing during walking, and decreased postural stability.
- Cogwheel rigidity:** series of catches through passive range of motion much like a second-hand jerks on a clock face.
- Demyelination:** a process by which myelin, the covering on nerves that enables conduction speed, is lost or damaged and results in an absence or impairment of impulse conduction typically manifesting in functional limitations.
- Festinating gait:** small rapid steps when the posture of the head and trunk involuntarily lean forward ahead of the feet. One's center of gravity (COG) shifts forward and is compensated by small shuffling steps and increased gait resulting in “chase” the COG.
- Intention tremor:** an oscillating tremor that occurs during visually guided, goal-directed movements. Amplitude increases as the target is approached and when increased precision is demanded.

Lower motor neurons (LMN): neurons located in the brainstem and cranial nerves that allow voluntary muscle movement and link to upper motor neurons (UMN) and muscles; damage to LMN can lead to flaccidity, muscle atrophy, loss of swallowing, and vocalization ability.

Rigidity: hypertonicity of agonist and antagonist muscles that offers a consistent, uniform resistance to passive movement.

Upper motor neurons (UMN): neurons located in the brain that function to transmit motor signals to the spinal cord activating LMN to activate muscles; damage to UMN can result in weakness and paralysis, decreased motor control, and spasticity.

Introduction

Neurodegenerative diseases are chronic, potentially progressive, and frequently require coping with disability and the threat of functional loss. The underlying pathologies of neurodegenerative diseases are shown to have mechanisms that attack the peripheral and central nervous system, resulting in impairments and limitations that affect all aspects of life. Although, not curable, research, including rehabilitation interventions, has led to treatments that allow people to live longer, productive lives.

Occupational Therapy for Neurodegenerative Diseases

The unique contribution of occupational therapy (OT) for persons with neurodegenerative diseases is the consistent focus on participation in occupations that are valued in their lives. There is no script, because the nature, type, intensity, and context of these occupations are as individual as each person with the neurodegenerative disease. By listening to each individual coupled with professional expertise in occupation, occupational therapists support individuals and families by providing a repertoire of systematic processes and sensitive diverse solutions.

OT frequently begins at diagnosis and continues throughout the continuum of comprehensive care, taking place in inpatient acute care, inpatient rehabilitation, and in outpatient, in-home, or long-term care settings. Inpatient acute treatment usually follows a major relapse or deterioration in the disease, is short, and is limited to safety considerations and stabilizing symptoms with medical interventions. Inpatient rehabilitation may last one to several weeks, with daily therapy sessions to deal with changing symptoms. Outpatient therapy is usually weekly or biweekly, with 45- to 60-minute individual sessions to maximize independence in the home, minimize the effects of symptoms on chosen occupations, and identify and obtain needed equipment. OT in long-term care facilities may be related to adjusting to changing or deteriorating symptoms to ensure maintenance of function and control over their environment, or developing palliative care plans. Occupational therapists attend to their own coping and maintain objectivity, especially when treating individuals whose disease course portends increasing disability or death.

Occupational Therapy Evaluation

The OT evaluation with persons with neurodegenerative disease begins with an interview to gather information about the client's roles and occupations, relevant history of the neurodegenerative disease, previous and current strategies used to manage daily life, and the nature of present concerns or problems. This interview must be sensitive to the individual's changing function and fear of the unknown and should illuminate areas that clients may not naturally mention such as fatigue, depression, sexual function, and cognitive concerns that impact occupations and social network. With this information, the therapist selects assessments and measurement tools that will provide in-depth information on occupational areas of concern. For persons with neurodegenerative disease, the content of these measures may be limited to a few or cover a broad spectrum of occupational performance areas.

Occupational Therapy Intervention Process

The unplanned and profound impact of neurodegenerative disease frequently makes realistic goal setting and intervention complex and requires thoughtfulness, flexibility, and astute

negotiation skills on the part of the occupational therapist. The therapist frequently helps the client modify behaviors and assumptions of a lifetime while assisting the person and significant others to move toward realistic goals. Given the progressive nature of many neurodegenerative diseases, regular reassessment and reordering of priorities may be necessary as intervention proceeds.

Because of the complexity of disability present with neurodegenerative disease, intervening in one area may affect several other symptoms or problems. Fatigue, for instance, may be related to pain, depression, and weakness. Interventions must be individually appropriate and may involve significant others, especially as the disease progresses. Depending on the setting, occupational therapists are involved with facilitating the maintenance of self-care (activities of daily living [ADLs] and instrumental activities of daily living [IADLs]), as well as employment, social and leisure occupations through the use of adaptations, appropriate planning, and credible websites and recommending new and emerging mainstream technology. For persons with neurodegenerative diseases, many of these advances have erased differences in participation, minimized the need for altered approaches, specialized adaptive equipment and environmental modifications, and have facilitated access to previously unavailable opportunities and personal connections.

Multiple Sclerosis

Epidemiology

Multiple sclerosis (MS) is the most commonly diagnosed neurological disease that can cause disability in young adults. An estimated 900,000 people in the United States have MS,¹ and worldwide that number is 2.3 million.² Onset of MS is typically between 15 and 50 years, although children are increasingly being diagnosed. Women are two to three times as likely to have MS. Caucasians of northern European descent have the highest risk of developing MS, whereas groups like the Norwegian Lapps, Inuit, and New Zealand Maoris who live in similar latitudes have no incidence of MS.³

Etiology

The precise cause of MS remains unknown. Research suggests that an environmental trigger, genetics, and infectious agents are among the factors that initiate the autoimmune response.⁴ The *multiple* in multiple sclerosis refers to dissemination across both time and location of MS lesions and relapses. The *sclerosis* refers to the plaques on the axons and myelin covering that form scar tissue and interfere with nerve conduction.

Demyelinated axons may remyelinate and provide conduction of nerve impulses, though transected axons are permanently destroyed and lose potential for conduction. There is evidence that disease activity continues even during periods that are clinically quiet or when no change in symptoms is apparent.⁵ Inflammation occurs with **demyelination** and axonal damage, which may explain the rapid improvement with corticosteroid anti-inflammatory agents used during relapses. Recent work has demonstrated that functional reserve influences the course (or phenotype) and prognosis of MS, suggesting that functional reserve may be important for future research.⁵

Course and Prognosis

Understanding of the initial neurological event and MS phenotypes has advanced over the past 30 years with imaging, biomarkers, and clinical observations. Currently, these are described as clinically isolated syndrome (CIS) and the phenotypes of relapsing-remitting, secondary progressive, and primary progressive MS.⁶ CIS, or the first neurological episode that may go onto an MS diagnosis, is important to identify and follow so that early treatment can minimize disease progression prior to a confirmed MS diagnosis. The relapsing-remitting course, most common at diagnosis, produces clearly defined relapses of acute worsening followed by partial or complete improvement and then stable periods of remission between attacks. Secondary progressive MS starts with a relapsing-remitting course of up to 10 to 15 years and is typically diagnosed when there is continued deterioration and disability.

People with primary progressive MS have continuously declining neurological function from onset without clear relapses.

Signs and Symptoms

OT intervention may reduce the impact of MS symptoms and ability to maintain desired occupations. Common signs and symptoms include fatigue, weakness, cognitive changes, pain, spasticity, tremor, dysphagia, sensory changes, balance disturbance, visual changes, bowel and bladder problems, vertigo, ataxic gait, sexual dysfunction, and depression.⁴ A few of these are described here to exemplify therapy services.

Fatigue

Fatigue is the most common and pervasive MS symptom and a primary reason for referral to OT. It affects 60% to 80% of people with MS and is a significant contributor to unemployment and overall disability.⁷ Fatigue augments other MS symptoms, varies from mild to severe with worsening typically in the afternoon, and may be related to increased ambient and core body temperature.⁸

Therapists must be aware of both the types and factors contributing to fatigue in MS⁹ and know that multicomponent education programs and single component energy conservation programs have the strongest evidence of benefit for fatigue management.¹⁰

Types of fatigue in MS include the following:

- **Primary MS fatigue:** Fatigue caused by MS disease process, the cause of which is poorly understood.
- **Secondary MS fatigue:** Fatigue resulting from untreated MS problem(s) such as walking difficulties.
- **Physical fatigue:** Fatigue experienced in the limbs, torso, head, and neck such that the body is tired.
- **Cognitive fatigue:** Fatigue that affects one's thinking, planning, memory, word-finding, and decision-making processes such that the brain feels exhausted.
- **Local or focal fatigue:** Motor fatigue caused by inefficient nerve conduction to a selected area of the body, such as progressive foot-drop with extended walking.
- **Generalized fatigue:** An entire body experience; a complete exhaustion that is physical and cognitive.
- **Normal fatigue:** Fatigue experienced by humans after excessive energy output or several hours of being awake (a normal day) that benefits from rest or sleep.

Factors shown to contribute to fatigue in MS include the following:

- Other medical issues such as anemia, arthritis, cardiac problems, respiratory inefficiency, infection, and thyroid problems
- Sleep problems, often related to muscle spasms, depression, or urinary problems
- Depression
- Stress
- Anxiety
- Pain
- Deconditioning
- Side effects to medications
- Nutrition or caloric intake
- Ambulation difficulties

Weakness

Weakness may occur in all parts of the body, resulting in referral to OT. Weakness that increases after repeated muscle contractions is known as nerve fiber fatigue. The cause is unknown but likely related to the conduction impairment of demyelinated nerves. An example is dorsiflexion weakness, resulting in foot-drop that increases stumbling, particularly on uneven surfaces. Coupled with decreased balanced and gait impairment, the

risk of falls is increased by 58%.¹¹ In some situations, with rest, conduction and muscle contraction can improved.

Cognition

Up to 60% of people with MS have cognitive problems that vary in severity and appear related to loss of brain volume, particularly gray matter.¹² It is estimated that 5% to 10% of those with MS have cognitive problems that interfere with participation in everyday occupations and employment in MS.³

Common cognitive problems include memory (acquiring and retaining new information); word-finding; attention, concentration, and executive function; and slowed information-processing speed.³ Visual-spatial impairments may also occur. Cognitive issues do not correlate with physical disability in MS but are influenced by depression, stress, anxiety, and fatigue.¹² Individuals and their families may be unaware that cognitive problems such as reduced self-awareness and inflexible thinking are related to the disease and should not be mistaken for personality or psychological changes. By identifying cognitive impairments, compensation strategies can be recommended to benefit everyday function.

Pain

Pain is estimated to occur in 40% to 60% of people with MS, with 48% reporting chronic pain.³ Pain negatively impacts quality of life (QoL) and independence¹³ and is not related to age, length of time with MS, or degree of disability, although twice as many women report having pain than men. Pain in MS can be localized as in trigeminal neuralgia, Lhermitte sign (a stabbing, electric shock along the spine when neck forward flexes), or pain as a result of spasticity.¹³ Pain directly caused by the neurological lesions is considered primary to MS and is treated with medications. Pain secondary to MS is often due to posture, gait, and positioning problems and can be relieved by therapy and proper mobility equipment.

Spasticity

Spasticity in MS is usually greater in the lower extremities and may be source of pain, interrupted sleep, and activity limitations. Up to 84% of people with MS deal with daily spasticity and 30% eliminate or modify activities because of spasticity.¹⁴ Factors that may precipitate or augment spasticity include infections, distended bladder, and stress and disease progression. The assessment, MS Spasticity Scale with eight subscales, is a client-based measure that accounts for the physical, psychological, and functional experience of spasticity in MS.¹⁵ Therapists should be familiar with standard medical management, particularly medications, such as baclofen and tizanidine, and their side effect of drowsiness. Botox (onabotulinumtoxin), a neurotoxin, results in relaxation of the targeted muscle and can last up to 3 months.¹⁶ The intrathecal baclofen pump has been shown to reduce pain and improve function and QoL for people with MS with moderate-to-severe spasticity.¹⁷ Should a baclofen pump be indicated, the therapist may be involved in assessment prior to and reevaluation following pump implantation. A recent systematic review has suggested that cannabis may reduce spasticity.¹⁸

Tremor and Ataxia

Intention tremor is the most common tremor seen in MS and is one of the most difficult problems to manage.³ As an activity progresses and the extremity approaches the target (where greatest precision is required), the tremor is at its worse. Intention tremor occurs in the upper extremities, lower extremities, torso, and neck.

Ataxia presents in the trunk and lower extremities where postural responses tend to occur before upper extremity movements. The functional challenges of ataxia are further magnified because multiple joints are involved in ataxic movement.

Dysphagia

Research on swallowing problems in MS that did not use videofluoroscopy (VF) suggested that 34% to 43% of the individuals studied experienced dysphagia, although only half of these individuals reported swallowing difficulties.¹⁹ When VF was used, however,

swallowing abnormalities were identified that were not detected on non-VF swallow assessment. These studies suggest that the severity of disease and cerebellar or brainstem involvement are risk factors for dysphagia. Occupational therapists should routinely screen for choking, aspiration, and swallowing difficulties.

Medical Management

Diagnosing Multiple Sclerosis

The diagnosis of MS has evolved with the updated McDonald criteria based on the medical history, neurological examination, magnetic resonance imaging (MRI) results, and analysis of cerebrospinal fluid.²⁰ Additional tests including visual evoked potential and blood tests may be used to corroborate the MS diagnosis or exclude other diseases. Signs of MS include weakness, hyperreflexia, positive Babinski sign, dysmetria, nystagmus, and impaired vibratory or position sensation. The most common rating instruments for both clinical and research uses are the Expanded Disability Status Scale and the MS Functional Composite.

Medical Developments Changing Health Care for Multiple Sclerosis

The most significant medical advances consuming enormous research efforts and impacting clinical practice are the advent of disease-modifying therapies (DMTs).²¹ There are five self-injectable immune-modulating medications approved in the United States²¹: interferon beta-1a (Avonex), interferon beta-1b (Betaseron), interferon beta-1b (Extavia), glatiramer acetate (Copaxone with generic version known as Glatopa), and interferon beta-1a (Rebif). These drugs have been shown to reduce the number of lesions evidenced on MRI and frequency and severity of relapses, although some studies suggest beta interferons do not impact long-term disability.²² A newer interferon beta-1a known as peginterferon beta-1a (Plegridy). Natalizumab (Tysabri), a monthly injectable, is administered by qualified practitioners and is approved for relapsing-remitting MS. Mitoxantrone (Novantrone), an immunosuppressant rather than an immunomodulator, is rarely used because of significant side effects. Fingolimod (Gilenya) was the first oral medication and is generally used when the response to injectable DMTs has diminished. Another oral medication, dimethyl fumarate (Tecfidera), may have allergic and abdominal reactions as well as side effects associated with other immunosuppressant medications. Other immunosuppressant DMTs are teriflunomide (Aubagio) and alemtuzumab (Lemtrada). The first medication approved for progressive MS is ocrelizumab (Ocrevus). Another class of medications, neurofunctional modifiers, targets underlying pathophysiology and MS symptoms.²³ Of these drugs, dalfampridine has been shown to improve walking in any type of MS.²⁴

Clients may want to discuss their medications with therapists, particularly DMTs, because they are designed to slow disease progression, not reverse disability. The therapist's responsibility is to understand and explain the importance of taking medications because the benefits may contribute to controlling the disease, thereby allowing continued employment and participation in priority occupations.

As MS is not curable, unproven remedies emerge periodically. The difference today is the presence of the Internet that enables diverse ideas to capture widespread attention. Occupational therapists must keep abreast of emerging remedies and relevant research. While communicating the evidence in a balanced way, sensitivity to clients' concerns and providing honest, compassionate, accurate responses without diminishing hope is essential.

Functional Impairment in Daily Occupation

A disease that strikes young adults has substantial economic, social, and emotional costs that influence all aspects of life. Between the ages of 20 and 40 years, when MS is typically diagnosed, people are entering the labor market, establishing careers, meeting life partners, and forming families. MS, with its common symptoms of fatigue, weakness, difficulties with prolonged walking, cognitive problems, and depression, can impede productivity at work and home and social engagement.

A body of research is developing that may influence family planning. The relapse rate in MS declines during pregnancy, increases in the first 3 months following childbirth, and

thereafter returns to prepregnancy levels.²⁵ Therapists must be aware of this research to assist clients seeking information and refer as appropriate.

The uncertainty of the MS disease progression may explain an estimated lifetime prevalence of 50% for depression and 35% for anxiety.²⁶ It has been shown that persons with MS who leave employment have greater likelihood for social isolation, psychological distress, and great burden of disease, as well as lower incomes.²⁷

Occupational Therapy Evaluation

OT evaluation begins with an interview about the person's goals for therapy, a brief history of symptoms and treatment since diagnosis, and life experience. This gives the therapist an understanding of the disease course and the person's coping style. Throughout the interview, the therapist listens for hints of cognitive difficulties, being mindful that there may be further hidden impairments. Brief questions regarding dizziness, thinking problems, motivation to engage in occupation, numbness and tingling, dexterity, walking and standing, employment, home physical and social environment, leisure interests, bladder problems, ADL, IADL, energy, sleeping pattern, cramping, pain, fine-motor activities, falls and balance problems, and vision can provide clues to the specific assessments needed.

Analysis of Occupational Performance: Tools and Methods

The initial interview gives the therapist an indication of the type of evaluation tools and methods to use. There are a plethora of assessments that are used and developed for people with MS that are symptom-focused or function-focused or both. Examples include:

- Canadian Occupational Performance Measure
- Modified Fatigue Impact Scale or Fatigue Severity Scale to assess fatigue
- 6-Minute Walk Test to assess endurance
- Activities-specific Balance Confidence Scale
- Multiple Sclerosis Walking Scale or mobility section of the Functional Independence Measure to assess mobility concerns
- Pittsburgh Sleep Quality Index
- Home assessment
- Beck Depression Inventory-Fast Screen to assess depression
- Symbol Digit Modalities Test (SDMT) predictors MS cognitive impairment
- ADL, IADL, and dysphagia assessments
- Nine-Hole Peg Test to assess dexterity
- Semmes-Weinstein Monofilaments to test sensation
- Manual muscle test (MMT), range of motion (ROM) evaluation, and grip strength (dynamometry)

There are also composite assessment batteries that provide detailed or diverse estimation of an individual's ability. Examples include:

- The Brief International Cognitive Assessment for MS (BICAMS). The SDMT (above), one of its measures, is quick to administer and predicts unemployment.
- Comprehensive Fatigue Assessment Battery for MS (CFAB-MS) identifies factors contributing to MS fatigue, the functional implications, and is a guide for clinical decisions.
- Multidimensional Assessment of Tremor measures the severity and functional impact of intention tremor.
- MS Functional Composite measure provides a estimation of walking, hand function, and cognitive ability.

Administering such measures requires the therapist to accurately interpret findings in the context of the client's situation and the interrelationship between functional challenges and symptoms. For example, therapists must differentiate various types of fatigue by considering the results of several assessments. A high score on a depression index may indicate that depression is contributing to fatigue, whereas slow times on the 6-Minute Walk Test may

suggest a nerve fiber or motor fatigue. Information from a sleep questionnaire may indicate that disturbed sleep caused by urinary frequency is a factor in daytime fatigue. Given this complexity, assessment selection must be sufficient to provide a nuanced understanding of the scope of concerns to make prudent clinical decisions.

Occupational Therapy Intervention Process

Client priorities are the cornerstone of goal setting and treatment planning, necessitating a collaborative process to achieve realistic and satisfying outcomes. Frequently, the person with MS and the referring provider mistakenly believe they must live with problems that, in fact, are treatable through therapy. For example, Finlayson²⁸ suggests that, for older adults with MS, the therapist must ensure they feel a sense of control over their future, work with families affected by the MS, and advocate for enhanced community support options. In addition, treatment focusing on isolated symptoms is unlikely to be effective, and thus working with and coordinating intervention of the health care team is often indicated. The first evidence table at the end of this chapter presents a sample of best evidence for OT intervention for MS. Considerations for activity strategies, equipment and environmental modifications, exercise programs, symptom management, and employment issues are discussed later in this chapter.

Self-Maintenance Roles

The occupational therapist assists the client to maintain independence in ADL and IADL priority activities, using specialized equipment, and participating in self-management strategies such as:

- Assisting in setting priorities
- Education about the disease process and effect on motor or cognitive changes
- Environmental modifications at home to promote safety
- Stretching and strength exercises to facilitate occupations like bathing
- Behavior modification strategies such as time management techniques
- Technology to assist many aspects of life, including environmental control, reminder systems, communications, and emergency alerts
- Balancing independence with assistance from others

Self-Advancement Roles

The onset of neurodegenerative diseases may affect employment in or outside the home. Many can and should continue to work rather than pursue disability benefits by seeking advice from an occupational therapist. Continued employment is beneficial for financial independence, access to health care, maintaining social network, and supporting a productive identity and healthy self-esteem. Therapists critically review job expectations; suggest modifications to the environment, behavior and routines, equipment, and resources; and make recommendations to the individual or employer.

Self-Enhancement Roles

Maintaining leisure pursuits as well as involvement in community, neighborhood, and family activities may be a priority but are often the first roles or occupations to be abandoned. Modifying activities, creative transportation solutions, and use of web-based interfaces enable continued involvement in meaningful occupations.

The tasks associated with self-maintenance, self-advancement, and self-enhancement roles are supported by technology, including smartphones, electronic tablets, and environmental controls. With technology, however, there are a number of challenges particularly related to the vast amount of information and misinformation.

Activity Strategies and Energy Conservation

Based on the comprehensive assessment, the fatigue intervention begins with the occupational therapist providing explanations about the underlying types of fatigue and contributing factor impacting the individual. The client then completes a detailed activity

diary that can be done on paper or well-selected apps and identified goals and priorities. The therapist and client use the diary to analyze daily work, home, and leisure activities. Identifying activity and environmental modifications, equipment, and technology to address fatigue issues then follows. Energy conservation strategies and exercise routines will also be incorporated to help the individual perform valued occupations.

Research has demonstrated the effectiveness of a face-to-face OT-led group intervention in energy conservation strategies for MS.¹⁰ The *Managing Fatigue* program²⁹ has shown positive results to improve energy that has both teleconference³⁰ and an online versions.³¹ Further, there is a 6-week group video program called *Fatigue: Take Control* that has been tested with positive outcomes.³² In addition to these programs, occupational therapists should collaborate with physical therapists who treat fatigue through obtaining gait equipment, recommending appropriate aerobic exercise routines, and educating on the difference between energy expenditure during functional activities and exercise to increase endurance. With any of these interventions, written recommendations and summaries should be provided. Clients then return to OT for a 2 to 3 month follow-up or sooner if changes in symptoms present or there are difficulties implementing strategies.

Equipment, Behavioral, and Environmental Modifications

Equipment, environmental, and behavioral modifications help persons with MS compensate for weakness, spasticity, tremor, fatigue, ataxia, and cognitive problems. Many pieces of adaptive equipment are helpful (e.g., scooters, electric wheelchairs, bath benches, shower chairs, bed poles) in limiting fatigue and mitigating functional limitations related to weakness and spasticity. Due to fatigue, self-propelling manual wheelchairs are usually not indicated. Carrying out physical tasks or doing activity that limits energy in the heat of the day may require a cool environment such as pool to do exercise or cooling garment to reduce one's body temperature (Fig. 38.1). Mainstream technology such as computers, motion sensors, and smart devices that have audio options reduce the impact of many MS limiting symptoms. When appropriate, the therapist identifies equipment and facilitates trials of consumer technology and adaptive equipment.

Figure 38-1 Woman in cooling vest vacuuming. Sensitivity to heat when participating in chosen occupation(s) can be mitigated by wearing cooling garments, such as cooling vests (as above) or cooling wraps comfortably worn on the neck or around the wrists.

Behavioral changes, such as moving exercise from lunch to afterwork and incorporating a lunchtime nap, frequently improve productivity. Another example is using the elevator at work (rather than climbing stairs for exercise) to maximize energy for employment and engaging in exercise at another time. Environmental modifications may help in areas as diverse as maintaining independence in ADL to ensuring continued employment and involvement in the community. Home and/or work visits may be necessary to identify modifications. The combination of the right equipment, behavior changes, and environmental modifications depends on the individual's needs, resources, and personal preferences. Follow-ups are recommended to determine the need for new or further modifications as changes occur.

Exercise Programs

Occupational therapists teach clients to monitor the effects of any MS exercise program on both fatigue and their ability to perform priority activities. Two MS symptoms, fatigue and spasticity, often decrease with regular exercise. A structured aerobic program has been shown to reduce fatigue and increase endurance,³³ and spasticity may be managed with rhythmic exercises such as walking or cycling and a stretching program.³⁴ Therapists can be instrumental in assisting the client to integrate exercise into weekly routines so that exercise does not reduce the ability to perform other activities. A realistic exercise program performed regularly is better than an ideal program that is never followed.

Spasticity Interventions

The appropriate intervention for spasticity depends on the severity and the extent to which it interferes with function and QoL. A recent study showed that education and daily stretching had a positive impact on self-reported spasticity, fatigue, depression, and physical health.³⁴

Modifying the approach to occupation should be considered, such as using adapted dressing techniques (using a stool to maintain hip flexion to decrease extensor spasm). Another option may be using dressing sticks to compensate for inability to reach one's feet. A home standing program using a standing frame for 30 to 60 minutes per day may be beneficial. These are examples of modifying options, though the principle applies across occupations.

Cognitive Compensation

OT intervention for MS clients with cognitive problems focuses on education and compensation for deficits to manage everyday life. Education of clients and families is beneficial and brings awareness that these problems are due to MS and not personality, easing stress, and optimizing receptivity to modifications. Treating factors that reduce cognitive ability, such as fatigue, often improves cognitive performance. Caution should be exercised in disclosing cognitive issues to employers, with careful consideration given to each circumstance.

Interventions that include group therapy, stress management, personal digital assistants, electronic memory aids, and cognitive-behavioral therapy have been shown to have positive effects on cognitive function in MS.^{35,36} Examples of cognitive techniques and strategies include:

- Scheduling work responsibilities and cognitively demanding tasks in the morning or after breaks to reduce the influence of the cognitive problems
- Maintaining a paper, smartphone, or electronic diary as a memory aid and to help identify the timing of cognitive and fatigue problems and the environment in which these occur
- Changing the environment to reduce distractions and interruptions and promote organization
- Using problem-solving strategies for decision-making rather than emotion-focused strategies
- Supporting involvement of social network to assist with problem-solving
- Using written step-by-step instructions for home and work routine tasks
- Doing one activity at a time, avoiding multitasking
- Incorporating assistive technology to improve high-order IADL, such as money management, family schedules, and transportation planning
- Increasing time for an activity and reducing the number of activities
- Delegating difficult tasks to others
- Using repetition in the learning process
- Assessing driving safety and recommending appropriate testing and interventions

Pain Intervention

For pain related to weakness or spasticity, interventions such as posture training, ergonomic seating, stretching, supportive splinting, and focal heat modalities on muscle trigger points may be effective. An ergonomic workstation (such as ergonomic chair with armrests, supportive back rest, headsets, and keyboard trays) tailored to the individual can be beneficial. Exercise and mobility equipment to correct gait problems may also minimize pain.

Tremor and Ataxia Intervention

The hallmarks of OT intervention for tremor and ataxia are proximal stabilization or support, modified approach to occupations, and adapted equipment and orthoses. Proximal stabilization includes supporting the trunk and larger joints of the upper and lower extremities. For example, at mealtime, position the client's torso against the table with arms

resting on the table.³⁷ Because the position is sitting, the lower extremities are supported, the trunk is stabilized by leaning against the table, and the shoulders and elbows are supported. A modified approach may be the use of hand-over-hand guidance for writing or dialing a cell phone. If one hand is unaffected by tremor, consider retraining the unaffected hand as tolerated. Orthoses might include a cervical collar to reduce the travel of the head and neck or wrist splints to minimize travel and number of joints in motion. Weights on the wrist, for example, may also serve to dampen tremor³ but may contribute to fatigue. Peripheral cooling of the forearm has been shown to reduce tremor amplitude and frequency and increase function for up to 30 minutes.³⁸ An OT intervention program, the Step-wise Approach to the Treatment of Intention Tremor,³⁷ developed specifically for MS was pilot tested and has shown some promising results.

Employment Modifications

The problems described in the preceding sections may affect the job performance of persons with MS. Additional modifications to maintain employment and satisfaction may include:

- Changing the time at which tasks are performed
- Limiting prolonged walking, standing, and travel using conference calls, Internet, and apps
- Using appropriate gait equipment and powered mobility devices
- Changing to a workspace that is convenient to frequent activities
- Modifying work hours
- Working completely or partly at home
- Arranging a space to rest periodically

Perspective on Intervention

Although referral to OT services can occur across the MS continuum, it is often those with relatively severe disability that are referred. Unfortunately, a tremendous window of opportunity has passed for interventions such as improving ambulation skills (and thereby reducing or delaying the need for wheeled mobility aids), attending to fatigue, and on-the-job modifications to support continued employment. It is essential that therapists educate referring practitioners about the need and benefit for early OT intervention for persons with MS.

It must also be recognized that people with MS, as well as those with other chronic conditions, play an integral role in the self-management of their conditions. Individuals with MS understand their unique circumstances and can provide information that is complementary to the health professionals' knowledge. There is evidence that people with MS with poorly developed self-management skills feel less control and, more uncertainty, have feelings of depression and hopelessness, and experience poor adjustment.³⁹ Self-management decisions for persons with MS involves taking control through planned strategies and routines and balancing the health providers' expectations and advice against the practicality in their lives.⁴⁰ It is for this reason that self-management is an important and critical for those living with MS.

Adjusting to Multiple Sclerosis

Although only a small percentage of people with MS are severely disabled, the diagnosis can be devastating. The need to adjust to changing symptoms and impairments affects self-esteem, relationships, sexuality, physical activities, vocation, and recreation. From questions about pregnancy to cognitive changes influencing competence or safety, MS affects every role and relationship. The variability of the disease and the hidden nature of symptoms such as cognitive changes, pain, and fatigue make it difficult to explain to friends, coworkers, and family.

Each person's reaction to MS varies and has implications for adjustment. Research has shown that emotion-focused coping techniques were used more often by those experiencing an MS relapse, whereas problem-solving and using one's social network were strategies used when in remission.⁴¹ There is MRI evidence that emotional involvement was a marginal

indicator of new MS lesions and that fewer lesions were found in persons who participated in a stress management program.⁴²

Initially, people may be preoccupied with their diagnosis because it represents a change that may challenge assumptions about the future. As time passes, particularly if individuals with MS return to full function, they frequently ignore the diagnosis and MS issues. As long as the inattention does not result in adverse decisions, this may be a healthy attitude. The therapist helps clients process the implications of changes and identifies modifications to minimize their effects. Information about new symptoms may be all a person needs to make a successful adjustment.

Parkinson Disease

Epidemiology

Parkinson disease (PD), a progressive, variable condition, is the most common movement disorder⁴³ and the second most prevalent neurodegenerative condition of aging after Alzheimer disease. The onset is typically between 65 and 70 years and is slightly more frequent in men.⁴³ The incidence of PD is 1,000 per 100,000 persons (or 1%) in people older than 60 years.⁴³

Etiology

The cause of PD is thought to stem from both hereditary and environmental factors. The link between hereditary factors and the condition is particularly marked in individuals with younger onset. A study by Bellou et al.⁴⁴ indicated that environmental factors related to PD included biomarkers, diet, drugs, exposure to toxic environments, lifestyle, and medical history. The authors noted that constipation and physical activity are risk factors for PD⁴⁴ and that gastrointestinal problems that start years before diagnosis are correlated with a lifetime risk of PD.⁴⁵ The pathogenesis is related to the loss of dopaminergic neurons of the substantia nigra that provide input to the corpus striatum and, in part, modulate the thalamus and its connections to the motor cortex.⁴⁶

Course and Prognosis

PD has been described as having either five stages⁴⁷ (Table 38-1) or three stages⁴⁸ (Table 38-2). These stages are broadly described by the presence of symptoms, functional implications, and response to medications. PD is gradual at onset, and symptoms may take years to develop.

Table 38-1. Stages of PD as Defined by Hoehn and Yahr

STAGES	FEATURE
Stage I	Unilateral symptoms, no or minimal functional implications, usually a resting tremor
Stage II	Midline or bilateral symptom involvement, no balance difficulty, mild problems with trunk mobility and postural reflexes
Stage III	Postural instability, mild-to-moderate functional disability
Stage IV	Postural instability increasing, though able to walk; functional disability increases, interfering with ADL; decreased manipulation and dexterity
Stage V	Confined to wheelchair or bed

ADL, activities of daily living; PD, Parkinson disease.

From Hoehn MM, Yahr MD. Parkinsonism: onset, progression and mortality. *Neurology*. 1967;17(5):427-442.

Table 38-2. Stages of PD as Described by Bradley

STAGES	DESCRIPTION
Early	Not disabling; monosymptomatic; responds well to medication; may remain at this level for years
Nonfluctuating	Some disability; levodopa added to medication regimen; 80% of function is restored
Fluctuating	Function limited; side effects to levodopa; difficult-to-control symptoms, postural instability, and gait disturbance become debilitating

PD, Parkinson disease.

From Bradley WE. *Neurology in Clinical Practice*. 2nd ed. Boston, MA: Butterworth-Heinemann; 1996.

Signs and Symptoms

PD is defined by the three cardinal motor signs of Tremor, Rigidity, and Akinesia and Postural instability,⁴⁹ marked by the acronym TRAP. Tremor, often the first complaint, is a resting tremor that increases with stress and may present as pill-rolling. **Rigidity** tends to occur at more advanced stages of PD.⁴⁹ **Bradykinesia**, a type of **akinesia**, causes a lack of facial expression, or “masked face,” and slowed movement of the limbs and occupational engagement. Postural instability begins with reduced arm swing, head and trunk leaning forward, and shorter strides that progress to a shuffling gait. Lack of postural reflexes and **festinating gait** results in 37% increase in falls and akinesia or episodes of motoric “freezing” that impedes spontaneous initiation of walking, turning, and crossing thresholds.

Other symptoms of PD are common, including cognitive impairment, word-finding difficulty, depression, apathy, fatigue, sensory symptoms, pain and paresthesia, urinary and sexual dysfunction, weight loss, and sleep disorders.⁴⁹ Swallowing problems can occur at any point and are unrelated to disease severity. These include delayed swallow reflex and abnormal tongue control that result in residue of food remaining in the mouth. Nonmotor symptoms are “recognized as a major source of disability in PD and treatment focus has shifted to quality of life and maintaining it in advanced disease.”⁴⁹

Dementia occurs in 15% to 20% of persons with PD and tends to be among those who are older at diagnosis, a history of PD, and experience depression.⁵⁰ The cognitive functions most affected are attention, working and episodic memory, executive functions, word-finding, and visuospatial skills.⁵¹ It has been shown that cognitive training using external cues, feedback, and repetition when learning new tasks has small-to-moderate effect on cognition for people with mild-to-moderate PD.⁵²

Medical Management

Diagnosing Parkinson Disease

Diagnosis is based on clinical evidence using diagnostic criteria related to the cardinal signs of tremor, rigidity, bradykinesia, and postural stability and is complex in the early stages.⁴⁹ The clinical presentation can be very different from one person to another. The diagnosis must distinguish PD from other parkinsonian syndromes such as multiple system atrophy and corticobasal degeneration and from secondary causes resulting from drugs and neurotoxins. The presence of tremor predicts a more benign course, whereas older onset and initial symptoms of hypokinesia/rigidity are predictors of early cognitive impairments.⁴⁹

Medical Interventions

Medical treatments can include medication and surgical procedures. Medications are used to compensate for dopamine loss throughout the course of PD and are effective for a limited period followed by “wearing off,” particularly in later stages of PD, and may result in difficult “on/off” fluctuations and side effects. There are four types of medication for PD. L-Dopa, a first-line treatment, has not been shown to alter disease progression, though the standard formulation is efficacious as a monotherapy, whereas the catechol-*O*-methyltransferase (COMT) inhibitors as adjuncts to L-dopa appear to be clinically useful for treating motor symptoms. Monoamine oxidase B (MAO-B) inhibitors, particularly rasagiline, assist in reducing motor symptoms over 6 months in early PD. The numerous dopamine agonists, as an adjunct to L-dopa, are overall useful for controlling motor variability. It is recommended that the choice of medication be based on the person’s lifestyle and choice.⁴⁹ It is essential that OT intervention accounts for fluctuations in medication effectiveness throughout the day to maximize therapeutic benefit. Surgical interventions are typically reserved for those with advanced disease with unilateral pallidotomy or deep brain stimulation deemed to be useful for improving motor challenges, particularly when the response to medications has diminished.⁵³

Functional Impairment in Daily Occupation

In the initial stages of PD, the degree of physical disability is minimal. The emotional burden and social consequences, however, can be marked. Resting tremor, rarely resulting in motor

disability, is a frequent source of distress, and reports suggest feeling embarrassed or self-conscious. In later stages, tremor and rigidity were highly correlated with distress and reduced QoL. Other predictors of poor QoL are depression, cognitive decline, social isolation, sleep disorders, mobility issues, fatigue, urinary incontinence, unpredictable on/off fluctuations, pain, and increasing dependence. Major depression was found in 58% of those with PD, whereas 84% demonstrated cognitive decline, suggesting that early identification and intervention are crucial.⁵⁴

The social consequences of PD are striking. In early stages, handwriting may be shaky and micrographic, reducing legibility. In intermediate and later stages, the voice softens and becomes monotone, limited facial expression and hand gesturing contribute to reduced communication and negative messaging. The person with PD may have waning interest in social and previously enjoyed leisure activities challenging relationships and roles in families. Both the individual and family members, typically an elderly spouse or adult child, may have feelings of guilt, despair, and anger as caregiving increases.⁵⁵

Economic implications of PD are frequently related to medications, wheeled mobility, accessibility modifications, self-care and safety equipment, and in-home support. If employed, increasing limitations may require employment modifications, early retirement, and application for disability benefits that accompany a loss of income.⁵⁶ People with PD stop working 5 to 6 years earlier than the normal population.⁵⁷ The caregiver may require assistance and respite, which has financial implications, and if required, long-term care placement is costly.

Occupational Therapy Evaluation

In the early stages of PD, OT is rarely indicated unless there are functional limitations or psychological issues. At this stage, it is recommended that interests and roles be maintained within and outside the home, including employment, social activities, and driving.⁵⁵ OT is most often required in the intermediate and later stages of the disease.⁴⁷ Evaluation should include a brief history and, in the intermediate stages, should identify occupational performance problems related to reduced mobility, safety, swallowing, incoordination, slowed movements, **cogwheel rigidity**, and depressed affect. A standardized QoL measure, the Parkinson Disease Questionnaire-39, may be a useful screening tool. Its 39 items are clustered into eight dimensions relevant to OT: mobility, ADL, emotional well-being, stigma, social support, cognition, communication, and bodily discomfort.⁵⁸ The therapist should also note occupations that have been eliminated. Examples of occupational limitations that may be included in evaluation are:

- Fine-motor activities at home and work (writing, eating, shaving, and fastening)
- Safe mobility, such as walking, stair climbing, driving, and moving from sit to stand
- Fatigue that affects most activities
- Work evaluation at early stages of PD to reduce the risk of unemployment or early retirement
- Bradykinesia, postural instability, and rigidity that limit participation in ADL and IADL
- Swallowing or other mealtime problems that prolong eating and reduce intake
- Cognitive problems that affect activities associated with usual roles
- Sexual activity limitations related to bradykinesia, fatigue, depression, and psychosocial issues
- Sleep disturbances

Occupational Therapy Intervention Process

When setting goals with the client with PD and significant others, the therapist must balance energy demands with motivation and frustration as well as caregiver time and abilities in the context of the dependence–interdependence–independence continuum. Participation of others in this process is crucial to the viability of interventions that vary, based on priorities and resources, stage of the disease, and occupational difficulties identified through the evaluation. Many of the interventions described in the subsequent section may be

incorporated at home and in other relevant environments. Studies report an overall effectiveness of both OT and other rehabilitation interventions for PD.^{59,60} A meta-analysis showed that 10 of the 15 studies reviewed demonstrated a positive effect for OT intervention, with 63% of persons with PD experiencing improvement as compared to 37% who did not receive therapy.⁶¹ A randomized controlled trial showed the efficacy of a self-management rehabilitation program for persons with PD.⁶² The second evidence table at the end of this chapter lists best evidence for OT interventions for patients with PD.

Interventions Related to Decreasing Isolation and Communication Problems

- Educate about timing activities to synchronize with optimal medication effectiveness.
- Modify leisure activities to encourage participation and decrease isolation.
- Provide information on support and advocacy groups.
- Educate caregivers about modifying communication and activities to support engagement.
- Recommend voice interventions such as the Lee Silverman Voice Treatment (LSVT) or RehabSelfCue-Speech programs to ensure continued social engagement.
- Use writing modifications such as an enlarged felt-tip pen and writing when rested.
- Use communication aids, including smart devices such as electronic tablets (mobile phone may be too small), large-key telephones, and electronic aids to daily living (EADL).
- Provide home exercise program to maintain facial movement and expression for socializing.

Interventions Related to Safety

- Instruct in sit-to-stand and bed mobility using the RehabSelfCue-Speech program.
- Manage motoric “freezing” while walking, including avoiding crowds, narrow spaces, and room corners; reducing distractions and not carrying items while walking; reducing clutter in path; focusing when changing directions; and using rhythmical beat or counting to maintain momentum.
- Recommend equipment to increase independence such as a raised toilet seat and grab bars.
- Prescribe walking aids (walker for festinating gait).
- Recommend, if required, a wheelchair having a proper seating system, cushion, and adjusted foot/leg rests and armrests that are appropriate for transporting within the community.
- Recommend good, uniform lighting, particularly in narrow spaces and at doorways.
- Provide home exercises to maintain mobility, coordination, posture, and tolerance.
- Perform home assessment and recommend modifications that might include alterations to the bathroom (e.g., nonskid surfaces, bath bench/chair) and flooring (e.g., eliminating throw rugs), horizontal strips on the floor where “freezing” episodes occur, and reducing furniture congestion.

Interventions to Maintain Independence and Participation

- Modify eating routine to include smaller portions, reduced distractions, schedule frequent meals that allow adequate time, and provide equipment such as nonslip surfaces for plates and built-up handles.
- Recommend use of adult absorbent underwear to reduce embarrassment should a bathroom be difficult to access.
- Recommend that sexual activity be engaged in following rest and urination and when medications are most effective.
- Encourage movement programs such as LSVTBIG that uses high-amplitude movements to assist in maintaining overall movement.⁶³
- Instruct on energy effectiveness strategies in-home, leisure, and work activities.
- Reduce/eliminate the need for fine-motor control, such as minimal or no clothing fasteners.
- Reduce the impact of perceptual problems using visual cues and rhythmic music in a nondistracting environment; speak slowly using simple instruction.

Amyotrophic Lateral Sclerosis

Epidemiology

Amyotrophic lateral sclerosis (ALS) is most often a fatal motor neuron disease distinguished by changes to **upper motor neuron (UMN)** and **lower motor neuron (LMN)** functions as well as brainstem and multiple spinal cord regions. Amyotrophic is derived from Greek where *a* means no or without, *myo* refers to muscle, and *trophic* means to build or nourish —“No muscle building.” “Lateral” locates the nerve cells signals and controls the muscles on the spinal cord. Sclerosis refers to the scarring that occurs as a result of degeneration.⁶⁴ The incidence of ALS is 2.7 per 100,000 people, with onset generally between the ages of 40 and 70 years and occurring more often in men.⁶⁵

Etiology

The cause remains unknown, and it is widely believed that both genetics (several genes are identified) and environmental factors may play a role. It has been observed that oligodendrocyte degeneration, neuroinflammation, and mitochondrial impairment are implicated in the axonal retraction and cell denervation.⁶⁶ Other factors suggested to correlate with risk of ALS have not been established as causal.⁶⁵

Course and Prognosis

ALS typically presents as either limb onset with a combination of UMN and LMN signs or bulbar onset with speech and swallowing difficulties,⁶⁷ the latter occurring in about 30% of cases. Despite the onset, muscle atrophy is initially focal and asymmetrical, then gradually widespread. It may begin in the hands, with wasting of the thenar and hypothenar eminences, as well as in the shoulders. Finger extension is usually affected earlier than grip strength because of dorsal and palmar interossei wasting. Falling and problems with walking and bed mobility are common because of leg weakness. Increasing difficulties with speech, swallowing, and breathing is common as the disease progresses. Six stages of ALS are recognized and described according to clinical features (Table 38-3). The median survival after diagnosis ranges from 20 to 48 months, although 10% to 20% survive more than 10 years.^{64,68}

Table 38-3. Stages and Rehabilitation for Individuals with Activities of Daily Living

STAGE	CLINICAL FEATURES	ACTIVITIES TO MAINTAIN MOTOR FUNCTION	EQUIPMENT
I	Ambulatory, no problems with ADL, mild weakness	Normal activities, moderate exercise in unaffected muscles, active ROM, and strength exercise	None
II	Ambulatory, moderate weakness in certain muscles, increased fatigue	Modification in living; modest exercise; active, assisted ROM exercise	Assistive devices, use of hands-free devices, electronic tablet
III	Ambulatory, severe weakness in certain muscles, increased difficulty with ADL; marked fatigue	Adaptations to continue active life; active, assisted, passive ROM exercise; joint pain management	Smart technology, adaptive devices, home equipment and environmental controls
IV	Wheelchair confined, almost independent, severe weakness in legs	Passive ROM exercise, modest strength exercise in uninvolved muscles	Smart technology, adaptive devices, home equipment, environmental controls, wheelchair
V	Wheelchair confined, dependent, marked leg and arm weakness	Passive ROM exercise, pain management, decubitus ulcer prevention	Smart technology, adaptive devices, home equipment, environmental controls, wheelchair
VI	Bedridden, unable to perform ADL, maximal assistance required	Passive ROM exercise, pain management, prevention of decubitus ulcers and venous thrombosis	Smart technology, adaptive devices and home equipment to assist caregiver(s), environmental controls, wheelchair

ADL, activities of daily living; ALS, amyotrophic lateral sclerosis; ROM, range of motion.

From Mitsumoto H, Chad D, Piroo E. Amyotrophic lateral sclerosis. *Contemporary Neurology Series*. Philadelphia, PA: Davis; 1998; Sinaki M. Rehabilitation. In Mulder DW, ed. *The Diagnosis and Treatment of Amyotrophic Lateral Sclerosis*.

The two primary forms of ALS are sporadic and familial. Sporadic occurs in 90% to 95% of those with ALS, whereas familial appears to have a genetic link occurring more than once in a family.⁶⁵ Age at onset and the pattern of symptom development are useful for determining an individual's prognosis, with a younger onset of UMN origin having a somewhat better prognosis.⁶⁹

Signs and Symptoms

The primary symptoms of ALS are associated with motor dysfunction such as muscle weakness, spasticity, and dysphagia. Weakness occurs with a pronounced atrophy of muscle groups and leads to falling, dropping items, and difficulty performing self-care. Spasticity is associated to increased pain in ALS and interferes with daily activities. Dysphagia, a distinguishing symptom in ALS, is independent of disease course eventually occurring as a result of weakness and spasticity of the oral musculature with women experiencing greater difficulty.⁶⁹

Although it has been thought that cognition is rarely affected in ALS, recent evidence suggests that up to 50% develop cognitive and/or behavioral difficulties, and 13% experience a frontotemporal dementia.⁶⁶ Of note, vision, bowel and bladder control, and sensation are commonly spared.

Medical Management

There is no single test or procedure to diagnosis ALS. Rather, several diagnostic tests are used in a careful, multistep system of exclusion of other diagnoses.⁶⁴ This may include combinations of a thorough neurological examination, use of electromyography and nerve conduction velocity tests, MRI, blood and urine analysis, spinal tap, and, possibly, muscle biopsy.

There are currently two ALS pharmacological treatments approved by the Food and Drug Administration (FDA). Riluzole (Rilutek), an antiglutamate agent taken in pill form, has been shown to slow the course of the disease though has side effects of dizziness, fatigue, and gastrointestinal and liver problems. In 2017, Edaravone (Radicava) was approved and shown to reduce the difficulty in daily activities associated with ALS and is taken by intravenous infusion. The side effects may include swelling, shortness of breath, walking difficulty, and hives as well as allergic reactions for those with sulfite sensitive.⁷⁰

Medications for symptomatic management of difficulties with spasticity, anxiety, depression, insomnia, and excessive saliva are useful, but do not affect the progression of the disease. Assisted ventilation, tracheotomies, and gastrostomies ease problems with eating and breathing.⁷¹

Because of the disease progression, numerous symptoms, and potential interventions, a multidisciplinary team and clinics dedicate to the care of ALS have been shown to improve the QoL for those with ALS.⁷²

Functional Impairment in Daily Occupation

As a result of the relatively fast progression, ALS is a devastating disease for individuals and their families. Because the disease quickly affects the ability to perform ADL, IADL, and employment, QoL is impacted, and significant depression results. One may feel an external locus of control and hopeless⁷³ and that this is not related to physical function or sociodemographic factors.⁷⁴

People frequently withdraw from work soon after diagnosis and often confront economic instability and health insurance issues. Because those commonly affected are employed and actively involved in family and community activities, the abrupt change is devastating. Acceptance of the ALS diagnosis by family members may affect willingness to be involved in planning, incorporating necessary changes to maximize the independence, and making informed choices for intervention.⁷⁵

Occupational Therapy Evaluation

OT is provided throughout the course of ALS and environments across the care continuum. Assessment is based on clearly defined levels of function and the individual's needs and priorities. It has been demonstrated that clients want to have control over health care services in order to enhance their feelings of control,⁷⁶ and thus, an interview to understand the ALS client and family's goals and changing needs is an essential mainstay throughout the care continuum. Early interventions should target the individual's symptoms as they affect their occupations. For example, facilitating continued employment can be a key contribution of OT to enable continuity with professional identity, meaningful occupation and financial benefits. As ALS progresses, interventions focus on individual function, as well as physical and social environment.

To assist with the evaluation process and to monitor ALS progression, the ALS Functional Rating Scale–Revised (ALSFS-R)⁷⁷ can be used. To determine functional ability, ADL and IADL assessments should be included in all evaluations. Functional limitations may be owing to reduced upper extremity ability; thus, the Purdue Pegboard, nine-hole peg test or other timed upper extremity function tests, and standard ROM and MMT are useful early in the disease to monitor disease progress. Fatigue affects physical activities and QoL and can be assessed with the Multidimensional Fatigue Inventory or other screening measures described earlier in this chapter. It is essential to evaluate mobility, seating, and positioning needs as ALS progresses in order to make appropriate occupational and equipment recommendations. As communication and swallowing decline,⁷⁸ ongoing assessment of social participation and nutritional needs should be maintained. Owing to disease progression, reevaluation at each visit is required.

Occupational Therapy Intervention Process

The progressive nature of ALS necessitates that rehabilitation be compensatory, focusing on adapting to disability and preventing secondary complications. Goals center on maintaining activity level and independence for as long as possible, resulting in interventions that focus on both individual function and physical and social environment. Examples of OT goals in the early stages include:

- Optimizing strength and ROM using home exercise programs⁷⁹
- Maintaining function in ADL and IADL through use of assistive or adaptive devices
- Decreasing fatigue in the neck and extremities through use of splints and orthotics
- Managing pain and energy using joint protection and work simplification techniques

As function declines, mobility and self-care become increasingly difficult. Home evaluations and in-home therapy are important, and intervention focuses on enabling the caregiver to assist the client safely and effectively. The therapist helps the caregiver–client team to:

- Optimize safety and positioning, perform safe transfers, and maintain skin integrity
- Enable communication using augmentative communication equipment⁷⁵
- Assess and manage dysphagia⁷⁸
- Optimize social participation
- Identify and obtain equipment, such as a hospital bed to allow continued mobility and comfort
- Modify the environment to enhance participation, safety, and comfort
- Discuss differences with client and their caregivers about their view of emotional needs, caregiver burden, and QoL to make transparent any issues and allow for resolution of misunderstandings⁸⁰

Throughout the stages of the disease, the occupational therapist must be sensitive to the client, family, and caregiver as physical demands, financial concerns, and transformation of the home into a hospital-like setting produce enormous stress and strain.⁸¹ Despite this, it has been shown that the QoL of a person with ALS who has a supportive family and social

network remains stable over time despite reduced health status.⁸² Open discussions and close collaboration with clients, caregivers, and the ALS team help to address the client and family's changing needs and goals in the face of this devastating illness.

Intervention Implementation

When treating clients with ALS, therapists must be aware of the client's level of gadget tolerance, financial resources, affective response, and social and cultural context. Evidence suggests that multidisciplinary intervention results in higher rates of receiving appropriate assistive devices and a 30% increase in survival as compared to general services. ALS clients also have better QoL and mental health when receiving care from multidisciplinary programs.⁸³

The special considerations for persons with ALS to engage in meaningful occupation through movement programs, obtaining equipment and assistive technology, and with dysphasia management are reviewed in the subsequent sections.

Movement Programs

Moderate exercise of active and passive ROM, strengthening, endurance, stretching, and home breathing programs have been shown to maintain functional level and minimizing secondary complications when compared to a control group as measured by the ALSFS-R at various stages of the disease.⁸³ A client may initially be able to perform an independent home stretching program, but as the disease progresses and the program becomes too fatiguing or difficult, the caregiver may become involved.

Education and discussion about the importance of the client, family, and caregiver unit and perceived understanding about their experience will assist in improving overall QoL. This includes supporting client and caregiver spirituality, as appropriate, which has been shown to positively predict of QoL.⁸⁴

Equipment and Assistive Technology

The therapist's role in providing information and assist with accessing assistive technology and adaptive equipment is essential and supports the client to achieve optimal level of independence at the various stages of ALS (see Table 38-3). Assistive devices such as a neck collar for improved positioning or universal cuff to enhance upper extremity function may be helpful. Mobility equipment, depending on the level of function, may include a foot-drop splint, cane, and/or walker. Because independent walking becomes difficult as ALS progresses, use of a wheelchair may need to be expedited. A study showed that 57% of those with moderate disability used a mobility device in addition to a wheelchair.⁸⁵ Among power wheelchairs users with ALS, there was a 77% satisfaction with comfort and 72% satisfaction with ease of use as well as an overall ability to participate in meaning occupation.⁸³ Other devices that were useful, depending on functional level, were raised toilet seat, shower seat, grab bars, transfer board, and communication boards.

Mainstream technology and environmental controls are extremely useful as the disease progresses. This technology, for example, includes lighting and call-alert systems, motion sensors, and remotes or keyless door (un)locking systems. Use of smart devices with voice activation (that can be adjusted if the voice is weak) to replace the need for touch typing is helpful to conserve energy and to maintain communication. Together, a home assessment and client-caregiver consultation inform selection of mobility and assistive devices for persons with ALS.

Dysphagia

Swallowing difficulties may be present at any stage of ALS, particularly when bulbar involvement is apparent. Depending on the dysphagia problem, interventions may include reducing distractions during mealtime (limit conversation and other activities), altering food consistency (i.e., thicken liquids), small bolus sizes,⁸⁶ teaching manual techniques to swallow, and ensuring adequate time for meals. Early introduction of an alternate route of nutrition may be indicated if nutrition and maintaining weight become issues. Occupational therapists should routinely screen for swallowing function in ALS.

Guillain-Barré Syndrome

Epidemiology

Guillain-Barré syndrome (GBS) or acute inflammatory demyelinating polyneuropathy results in axonal demyelination of peripheral nerves. Its distribution is worldwide, with a median incidence of 1.1 per 100,000⁸⁷ that increases with age such that those over 80 years have an incidence of 2.7 per 100,000. GBS is 1.5 times more common in men, and onset dominants in adults 20 to 24 years and 70 to 74 years.⁸⁸

Etiology

The cause of GBS is unclear. No hereditary or environmental factors are known to increase susceptibility to GBS.⁸⁷ In the 2 to 4 weeks prior to GBS onset, however, most adults report a respiratory, gastrointestinal, or another infection.⁸⁹

Course and Prognosis

GBS has three phases. In more than 95% of people with GBS, the onset, or acute inflammatory progressive phase, manifests as weakness in at least two limbs that progresses and reaches its maximum in 2 to 4 weeks accompanied by increasing symptoms.⁸⁸ Mechanical ventilation is required for 20% to 30% of individuals.⁸⁷ It is during this phase that GBS could be life-threatening; thus, appropriate treatment is essential. This is followed by the plateau phase of no significant change, which lasts for a few days or weeks, when the greatest disability is present. The third phase is progressive recovery, when remyelination and axonal regeneration occur and may last for up to 2 years, although the average length is 12 weeks.⁸⁸ Recovery generally starts at the head and neck and proceeds distally⁹⁰ with approximately 50% experiencing return of function, and another 35% experience some residual weakness that may not resolve. The remaining 15% experience more significant permanent disability,⁹¹ of which fatigue is the most common problem. Subtle cognitive deficits in executive functions, short-term memory, and decision-making may also occur.⁹²

Signs and Symptoms

Characteristics include a quickly progressing, symmetrical ascending paralysis starting with the feet; pain in the legs; the absence of deep tendon reflexes; mild sensory loss in glove-and-stocking distributions; cranial nerve dysfunction with possible facial palsy and swallowing problems; an autonomic nervous system response of postural hypertension and tachycardia; respiratory muscle paralysis; and pain, fatigue, and urinary dysfunction.^{87,92} Cognition typically remains intact. Symptoms vary from being so mild that medical attention is unlikely to so severe that they may cause death in 1% to 10% of cases.⁹³

Medical Management

Diagnosis of GBS entails a history of symptoms and a physical and neurological examination that includes nerve conduction tests and cerebral spinal fluid analysis to detect elevated fluid protein.⁸⁷ Features necessary for a GBS diagnosis include progressive weakness in legs and arms over 2 to 4 weeks and decreased tendon reflexes. The medical interventions for GBS attempt to lessen the severity but do not cure the disease, such that upon initial diagnosis, individuals may be admitted to hospital to monitor breathing and other functions until the GBS has stabilized.⁸⁷ Treatments in the acute phase include intravenous immunoglobulin, plasma exchange (or plasmapheresis), and steroids.⁸⁸ In the plateau phase, close monitoring is undertaken, and, like the recovery phase, symptomatic management along with OT and physical therapy are the treatment of choice.

Functional Impairment in Daily Occupation

Emotional and psychological reactions are in response to the rapid onset of symptoms and the mounting disability. As recovery progresses and improvement is slow, adjustment, impatience, and frustration may persist. At follow-up, GBS was reported to impact confidence and ability to live independently, with 18% having depression and 22% having anxiety.⁹¹

For young adults, the impact of GBS can have educational, employment, and economic implications. This age group is launching careers and may have only small savings. For those who develop GBS in later years, the economic effect may be less. For those returning to work after GBS, there may be a renewed value for work, a need to cope with losing and recovering a work identity, and dilemmas about work adaptations that require coping strategies. Lack of public awareness of GBS may be a barrier for returning to work.⁹⁴

Occupational Therapy Evaluation

Referral to OT is common when the course of GBS is moderate to severe. Approximately 40% of all GBS clients require rehabilitation services.⁹⁵ The types of OT evaluation and intervention changes as improvement occurs through the three phases of GBS.

Assessment during the acute and plateau phases typically occurs in the intensive care unit, when the individual is undergoing extensive medical procedures and pain and abnormal sensations can be significant. Therapists should complete an interview to understand the client's feelings and fears⁹⁶ and evaluate communication, control of the environment, comfort, and level of anxiety and depression. A sensory assessment is essential because hypersensitivity is typical of acute GBS with the guiding principle to ask prior to touching the client.⁹⁶ Functional evaluation should be conducted based on the results of sensory tests, joint range, and muscle strength and may include communication, bed mobility, transfers and self-care during these early phases.

During the recovery phase, therapists evaluate self-care, communication, leisure, as well as mobility, sensation, strength, ROM and, as appropriate, reintegration into the workplace.

Occupational Therapy Intervention Process

Because the natural course of GBS is improvement, clients and caregivers tend to be optimistic about recovery. The long-term goal is full recovery, so that the individual performs at the same level as prior to the GBS onset with or without modification. Goals should focus on achieving optimal function at each level of recovery within tolerated pain levels.⁹⁶

During the acute phase, the client may be actively involved in directing care rather than physically performing, providing the opportunity for educating the client and others about positioning and supports to maintain comfort in bed, protect against bed sores, and future therapy.⁹⁶

In the recovery phase, goals are developed at the just-right challenge to increase involvement in occupation within safe parameters. Examples of goals include:

- Pacing occupations within energy and fatigue tolerance
- Grading therapy to be realistic and supporting continued progression
- Return to independence in self-care and communication with or without aids
- Maximizing mobility skills with or without aids
- Grading return to work with or without modifications
- Increasing re-engagement in leisure and recreational occupations

The therapist helps the caregiver–client team to closely collaborate to address concerns and encourage realistic expectations over the course of recovery.

Intervention Implementation

Modifications during the acute and plateau phases should be considered temporary and may include:

- Communication tools, such a picture board or voice-activated devices, if appropriate
- Access to the nurse call button, TV, and lights by remote control, as appropriate
- Use of hands-free telephone
- Modification of lying and sitting positions for optimal function, comfort, and reduced pain
- Positioning the trunk, head, and upper extremities for stability and comfort

- Introducing strategies to reduce anxiety for both the person with GBS and their families

Recovery-phase interventions are initially completed with few repetitions, punctuated with rest, and expanded gradually as persons with GBS should not be pushed to fatigue.⁹⁶ During this phase, OT services can be provided in an inpatient rehabilitation facility, through an outpatient program, and/or at home or work. It has been shown that with inpatient rehabilitation, individuals with GBS made meaningful improvements from admission to discharge in self-care, mobility, and cognition.⁹⁷

The number and complexity of tasks should be increased gradually.⁹⁶ Examples of interventions include:

- Providing activities and dynamic splints to maintain ROM, particularly of the wrists, fingers, and ankle (hinged drop-foot orthosis)
- Slowly increase involvement in preferred occupations
- Instructing both caregiver and client on safe mobility and independent transfers
- Providing a sensory stimulation or desensitization program, as appropriate
- Training in modified self-care techniques and adapting other daily activities
- Using smart devices to facilitate communication and conserve energy
- Modifying and encouraging re-engagement in routine occupations, as appropriate
- Adapting equipment for home, leisure, and work occupations
- Instructing in energy conservation and fatigue management strategies
- Modifying employment roles, tasks, and environment, as indicated
- Recommending a fine-motor program to enhance strength, coordination, and sensation to engage in functional activities
- Undertaking a home assessment and modifications, as appropriate, to facilitate return to home

CASE STUDY

Client Information

Katie is a 34-year-old woman with relapsing-remitting MS. Two months prior to her first visit to OT, she resigned her position after 11 years as a human resources professional. Katie was distraught about leaving a job she enjoyed but believed she was no longer able to work due numerous problems, including (1) severe fatigue, resulting in her inability to do household tasks without becoming exhausted; (2) memory difficulties; (3) lower extremity weakness, resulting in falls and reduced ability to perform tasks requiring walking or standing; (4) stiffness in extremities, making tasks more difficult; (5) decreased manual dexterity; (6) daily headaches and dizziness; (7) bladder problems; and (8) disturbed sleep. Her adaptive strategies included use of a manual wheelchair and to stop driving. She was taking bladder medication and a DMT. Her husband was very supportive.

Assessment Process and Results

The OT evaluation revealed decreased strength and increased tone in Katie's lower extremities; decreased sensation, strength, and manual dexterity in the dominant upper extremity; severe dizziness with head movement; head, neck, and shoulder trigger points; and marked fatigue. She had no adaptations to reduce energy expenditure in daily activities. Katie was scheduled to have a neuropsychological evaluation to identify her current cognitive function and problems. Her self-selected adaptive strategies were inappropriate. She was not taking medications to manage spasticity or fatigue. Her seating at home and work was not supportive. Katie purposefully climbs the stairs in the morning and had a desk distant from the bathroom to get exercise, as she had no exercise program.

Occupational Therapy Problem List

The problems identified were:

- Minimal use of fatigue management strategies and use of inappropriate equipment

- Did not have cognitive compensation strategies
- Resigned from work without knowledge of options
- Had stopped driving without investigating options
- Is not involved in a home exercise program

Occupational Therapy Goal List

In collaboration with Katie, the goals established were to:

- Obtain appropriate power mobility equipment
- Incorporate energy-saving strategies in her day
- Withdraw resignation notice from employer
- Make changes to her work routines, that is, by taking the elevator
- Modify to work area by obtaining a headset, ergonomic chair, improved computer setup, and moved workstation closer to the bathroom
- Submit a request to her employer for automatic door on bathroom
- Apply to vocational rehabilitation and work with therapist and vendor to install hand controls for driving
- Educate Katie in head, neck, and shoulder exercises to relieve stiffness and reduce the impact of the headaches and dizziness

Occupational Therapy Intervention

The OT intervention included (1) instructing in the adoption of energy conservation techniques at home, work, and in the community³²; (2) identifying and obtaining powered mobility equipment²⁸; (3) identifying equipment to decrease energy expenditure and impact of cognitive issues at home and work; (4) decreasing headaches with head, neck, and shoulder stretching; (5) modifying workstation to decrease pain and energy consumption; (6) facilitating the use of hand controls to drive; (7) continuing full-time or part-time employment; and (8) educating on vestibular, stretching, and strengthening home exercise program to reduce dizziness, stiffness and weakness.³⁴

Following the therapy, Katie withdrew her job resignation, returned initially part time, and made workstation modifications. She planned to resume driving with the appropriate hand control.

By 1 month, Katie had met her goals for energy conservation and felt more confident to manage her fatigue. However, she developed right foot-drop, which impacted her balance when fatigued. With prompting to use energy management strategies (use power chair for distances; managing schedule to reduce periods of extended walking), she was able to mitigate the impact of drop foot.

Best Evidence for Occupational Therapy Practice Intervention Related to Multiple Sclerosis

Intervention	Description	Participants	Dosage	Research Design and Level of Evidence	Benefit	Statistical Significance and Effect Size
--------------	-------------	--------------	--------	---------------------------------------	---------	--

Intervention	Description	Participants	Dosage	Research Design and Level of Evidence	Benefit	Statistical Significance and Effect Size
An online fatigue self-management program for people with chronic neurological conditions ³¹	Online fatigue program facilitated by occupational therapists. Included education, activities and discussions.	Ninety-five adults with MS, PD, and post-polio syndrome with access to the Internet 3×/week for at least 1 hour; minimum baseline score of 4 on Fatigue Severity Scale Excluded if scored >9 on the Memory Orientation Concentration Test.	One 2-hour asynchronous session/week for 7 weeks. Participants had access to the program anytime during the day.	Randomized controlled trial. Level I. Participants were in three groups: receiving the fatigue program, information only, and control (no intervention).	The online fatigue management group and the information-only group showed improvement in fatigue, whereas the control group did not improve.	Repeated-measures analysis of covariance (ANCOVA) ($p < 0.05$) with small effect size (ES)
Nintendo Wii Fit and its effect on physical activity behavior ¹⁰⁰	Exercise program (yoga, balance, strength, aerobic training) using Wii Fit. Participants were telephoned, monitored for adverse events and for duration and frequency of Wii Fit use.	Thirty participants with relapsing-remitting MS: 23 women, 7 men; 18–60 years; able to walk 25 feet with or without a cane. Excluded if doing 2.5+ hours of activity per week, had low vision, lower extremity amputation, severe fatigue or depression, cardiopulmonary disease, or were pregnant.	14-week Wii Fit exercise program for 3 days/week	One-group repeated-measures design with 5-week baseline period and 2-week Wii setup and training followed by 14-week intervention. Level IIIB3b	Balance and strength were significantly improved at week 7. By week 14, physical activity declined relative to week 7, and there was no difference compared with the baseline period.	Using multivariate analysis of variance showed physical activity improved at 7 weeks ($p = 0.001$; ES = 0.65) though declined at 14 weeks; self-efficacy improved to 14 weeks ($p = 0.025$); and no difference in QoL or the level of fatigue.
A self-management program that reduces spasticity in people with MS ³⁴	Spasticity self-management program: two groups sessions viewing and discussing stretching and education DVDs. Then stretches practiced with facilitator input. Participants recorded stretching and exercises for 4 weeks in diaries.	Forty participants with physician-confirmed MS, aged 18 years or older, who walked 25 feet independently with or without devices, lower extremity spasticity that interfered with daily activities, and agreed not to change medications during the study. Excluded if other conditions interfering with participation were present.	Two 2-hour facilitator-led group sessions 1 week apart	Randomized controlled, Level I, single-blinded, two-arm study of those who received the program and controls (usual care)	Mean total score and scores on two subscales of the MS Spasticity Scale-88 showed improvement for the program group compared to usual care ($p < 0.03$).	Signed test was used to evaluate the change following intervention within each group. The Wilcoxon rank-sum test was used to compare changes between groups.

Best Evidence for Occupational Therapy Practice Intervention Related to Parkinson Disease

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Interdisciplinary self-management rehabilitation program for persons with PD ⁶²	Eighteen hours of group sessions included movement and speech exercises; ADL and gait training; discussions of cognitive strategies, stress management, and fall prevention.	One hundred and sixteen persons with PD: 30% were women; mean age of 66 years.	Six weeks of treatment. Participants divided into three groups: 1: 0 hours of rehab; 2: 27 hours having 18 in group and 9 social; 3: 27 hours having 18 in group and 9 in-home and community skill transfer training.	Randomized controlled trial Level: I	The two rehab groups improved in health-related QoL, with communication and mobility gains. There was no difference between intervention groups and no improvement for the untreated group.	Repeated-measures ANCOVA. Post-treatment effect at follow-up: $F = 3.98, p = 0.02$, and moderate ES ($h = 0.26$). A significant response ($p = 0.03$) was shown for the health-related quality of life (HRQOL) domains of communication (2-month follow-up) and mobility (6-month follow-up).
Exercise programs in PD—the Berlin LSVTBIG study ⁶³	LSVTBIG uses intensive high-amplitude movements done 1 hour, 4×/week for 4 weeks with 15 reps/task.	Fifty-eight people with PD at Hoehn and Yahr stages I–III: 36 women, 22 men. Mean weekly exercise time between baseline and final was 2.53 hours; in BIG, 2.10 (2.05) in WALK, and 2.6 (1.12) in HOME.	Participants were divided into three groups: BIG—training 1:1; WALK—Nordic group walking; HOME—nonsupervised exercises.	Randomized controlled trial Level I	LSVTBIG group improved over other groups in motor performance, moving from sit to stand, and walking. No differences for QoL between groups.	ANCOVA for between-group comparison. BIG participants showed significant improvement on Unified Parkinson's Disease Rating Scale (UPDRS) ($F = 11.9, p = 0.001$) and timed up and go (TUG) ($F = 3.64, p = 0.033$), whereas 10-m walk approached significant benefit ($F = 2.97, p = 0.059$).

Spinal Cord Injury

Deborah E. Budash

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Identify and understand the terminology and fundamental concepts related to spinal cord injury (SCI) and rehabilitation.
2. Appreciate the physical, psychosocial, and occupational challenges associated with SCI.
3. Recognize functional expectations of SCI at various neurological levels and the related factors that impact outcomes.
4. List the priorities and goals of the occupational therapist for each treatment phase and injury level.
5. Describe the tests and procedures appropriate for occupational therapy assessment.
6. Understand and adopt the perspective that focuses on the unique abilities of each patient and seeks individualized solutions to achieve goals.
7. Appreciate the long-term implications of SCI on the individual related to participation in valued roles and occupations.
8. Identify occupational therapy interventions for each treatment phase and injury level.
9. Understand how SCI care has evolved as a consequence of changing health care policies and the impact of these changes on the occupational therapy profession.
10. Perceive how the Occupational Therapy Practice Framework and the unique skills and knowledge of the therapist can support function and wellness of patients with SCI throughout the life span.

CHAPTER OUTLINE

Introduction
Description of Spinal Cord Injury
Medical Management
Functional Impairment in Daily Occupations
Evaluation and Intervention of Functional Skill Deficits Secondary to Spinal Cord Injury
Case Study

TERMINOLOGY

Assessment: tool used to gather information during the evaluation process.

Catheterization: a bladder-emptying technique in which a flexible tube (catheter) is inserted into the urethra to drain urine.

Clonus: an alternating involuntary muscle contraction and relaxation in rapid succession, associated with changes in muscle tone as a consequence of neurological injury or disease.

Complete injury: a diagnostic label that represents an absence of sensory and motor function in the lowest sacral segments (S4–S5).

- Crede method:** a manual bladder-emptying technique that involves manual application of pressure superficial to the bladder.
- Dermatome:** the area of skin innervated by the sensory axons within each segmental nerve. A myotome is a group of muscles innervated by a single spinal nerve; myotomes are used in the diagnostic process of identifying the level of the spinal cord injury.
- Ergometry:** the study of physical work activity. In rehabilitation, ergometry often involves the use of a stationary bicycle or treadmill.
- Functional electrical stimulation (FES):** involves the application of electric current to paralyzed muscles in order to cause a muscle contraction.
- Functional level:** the lowest segment at which the strength of important muscles is graded 3+ or above out of 5 on a manual muscle test (MMT), and at which sensation is intact; the functional level has implications to functional rehabilitation outcomes.
- Incomplete injury:** a diagnostic label that represents the preservation of any sensory and/or motor function below the neurological level that includes the lowest sacral segments S4–S5.
- Motor level:** a diagnostic label that quantifies functional outcome expectations; the motor level is identified by the most caudal section of the spinal cord with normal motor function.
- Paraplegia:** the loss or impairment in motor and/or sensory function in the thoracic, lumbar, or sacral segments of the cord, resulting in impairment in the trunk, legs, and pelvic organs and sparing of the arms.
- Sensory level:** identified by the most caudal segment of the spinal cord possessing normal sensation to pin prick and light touch; it has implications for functional outcomes.
- Tetraplegia:** the loss or impairment in motor and/or sensory function in the cervical segments of the spinal cord, resulting in functional impairment in the arms, trunk, legs, and pelvic organs; previously known as *quadriplegia*.
- Tracheostomy:** a surgically created hole in the trachea through which the tracheostomy tube is inserted; the tracheostomy provides the connection to the ventilator for individuals who cannot breathe spontaneously.
- Valsalva maneuver:** method to facilitate a bowel movement; it involves holding one's breath while bearing down or pushing through the abdomen.
- Zone of partial preservation:** refers to the dermatomes and myotomes caudal to the neurological level that remain partially innervated; over time, strength and sensation improve, resulting in better functional outcomes.

Introduction

A spinal cord injury (SCI) is catastrophic and impacts every aspect of an individual's life.¹ Paralysis often results from SCI and is generally well understood, but there is also a corresponding loss of spontaneously occurring body functions that can seriously impact health in less-understood ways.^{1,2} Contemporary medicine has facilitated the survival of SCIs, leaving those injured to cope with overwhelming loss.^{3,4} Although the underlying objectives of SCI care have remained consistent over time—that is, to maximize the patient's abilities and minimize secondary complications—there is hope that future medical advances will achieve greater functional restoration for survivors of SCI and disease.^{1,5,6}

Occupational therapists, with their unique skill set including knowledge of occupational performance, health and wellness, task analysis and adaptation, and psychosocial adjustment, play an important role in SCI rehabilitation.⁷⁻⁹ This chapter provides a foundational understanding of SCI and the vital role that occupational therapists play in returning patients to meaningful occupations, despite the severity of their limitations. The chapter begins with the epidemiology and etiology of SCI. The medical management of SCI is reviewed with a focus on the sequelae that impact function—the primary focus for occupational therapists. An overview of the occupational therapy process with this unique group of patients follows, concluding with considerations for the profession’s evolving role in SCI rehabilitation.

Description of Spinal Cord Injury

Epidemiology

Epidemiology provides information about SCI prevalence and incidence rate and offers insight into the typical characteristics of patients sustaining SCI. Such insights inform treatment, preventative initiatives, and proactive planning for the future of SCI care and rehabilitation.^{3,10}

According to the National Spinal Cord Injury Statistical Center (NSCISC), about 17,500 people per year in the United States experience an SCI, or about 54 of every 1 million Americans.¹¹ The total number of people with SCI alive today in the United States is estimated to be in the range of 245,000 to 353,000. About 90% of SCIs are traumatic in nature, and the epidemiological data are present from the traumatic and nontraumatic perspectives, respectively.

Trends in SCI have evolved over time and generally align to demographic and societal trends.¹⁰ As of 2017, the average age at injury is 42 years.¹¹ By contrast, the average age at SCI was 29 years in the 1970s. Considering SCI incidence from a life span perspective, the lowest incidence of SCI is seen in children at 3% to 5%,⁵ is highest for the age range of late teens and early 20s, and generally declines as adults age.^{5,10,12} Recent trends demonstrate an increasing incidence of SCI in elderly age groups.^{5,10,13} This second peak in incidence is attributed to our aging population and is expected to continue.¹⁰ The age groups most at risk for SCI are those 20 to 29 and 70+.^{3,10}

Males account for about 81% of new SCIs.¹¹ However, SCI in children, the elderly, and of nontraumatic causes are more evenly distributed between genders.^{5,10-12} The primary ethnicities of individuals incurring new SCIs includes non-Hispanic white (63%), non-Hispanic black (22%), and Hispanic (11%).¹¹ There are further trends to be considered within these data; for example, 22% of new SCIs occurring in non-Hispanic black populations is higher than the 12% representation of this group in the general population.

Most new SCIs are diagnosed as incomplete injuries, with 46% incomplete tetraplegia and 20% incomplete **paraplegia**.¹¹ Complete paraplegia is diagnosed in about 19% of SCIs, followed by 13% as complete **tetraplegia**. A recent increase in high cervical (C1–C4) and incomplete injuries has been observed.¹⁰ Nontraumatic SCI (NTSCI) occurs more often in older patients and females and typically does not occur at the cervical level.^{10,14}

The life expectancy of individuals with SCI is less than that of the general population.^{3,10,11} This is particularly so within the first year following SCI. As explored later in this chapter, the nature of the SCI places individuals at risk for a number of life-threatening secondary conditions. As a result, about 33% of SCI patients will be rehospitalized within the first year of injury at least once.¹¹ If these conditions are not

properly managed, they can escalate to become life-threatening. The most common cause of death for individuals with SCI is pneumonia followed by septicemia. These conditions have remained the primary causes of death for individuals with SCI for over 40 years. The mortality rates are higher for older patients with more severe SCIs.¹⁰ One study found that increasing age, male gender, and lower functional independence scores at discharge were significantly related to decreased life expectancy.¹⁵

There are additional pertinent characteristics to consider related to patients with new SCI. Most individuals who experience a new SCI are single, but trends show that the number of individuals who marry over a lifetime increases, as does the divorce rate for those married at the time of injury.^{3,11} Most individuals who incur an SCI (52%) possess a high school education.¹¹ About 11% of new patients with SCI are college or university-educated. The level of education slowly increases over time for those with SCI. Most individuals who experience an SCI are employed (60%) or are students (15%) at the time of injury. The rate of employment declines to 34% at 20 years postinjury.

On a global scale, similar trends are observed, but outcomes vary by country.³ There is a higher incidence of SCI in the United States than throughout the rest of the world, but this may be due to the fact that, in underdeveloped countries, more of those injured do not survive.^{3,10} The World Health Organization estimates that 40 to 80 SCI cases per million, or 250,000 to 500,000, occur annually throughout the world, and 90% are of a traumatic nature.¹⁶ Many of the trends observed in SCI incidence in the United States are also noted throughout the world, with some regional variance. The incidence of SCI is higher for males than females, with a bimodal incidence by age groups, as noted previously.^{3,17} Mortality is highest in the first year following injury and remains higher throughout the life span. Individuals with SCI possess a risk of premature death that is two to five times higher than the average population. As seen in the subsequent section, the causes of SCI are also similar globally.

Etiology

The overwhelming causes of SCIs, about 40%, are attributed to vehicular accidents.¹⁸ Falls account for approximately 30% of incidence, followed by 14% due to violence, and 8% attributed to sports. SCI incurred by these causes are deemed traumatic and account for more than 90% of all SCIs. The remaining 8% are attributed to other causes and are considered nontraumatic. Nontraumatic causes include medical conditions related to the spinal cord, such as spinal stenosis, tumors, surgical complications, and other unclassified occurrences.^{5,17,18} Falls are the leading cause of SCI in the elderly, with sports injuries and violence causing fewer SCIs in this group.¹⁰ The most frequent causes of SCI in children include lapbelt injury, birth injury, and child abuse.^{5,12} Violence is more often a cause of SCI in the African American population.¹³

Globally, the etiological trends are similar to those in the United States. Between the ages of birth and 5 years, the most common cause of SCI is vehicular crashes at a rate of 65%.^{3,12} Violence is the cause of SCI in males more often in every age group.³ Falls are the most common cause of SCI after the age of 60.

The most frequent causes of SCI are observed to be preventable, and successful public health campaigns have been developed to reduce the risk of injury.^{3,10,16} Most remarkable in the United States are those related to sports activities, such as diving, football, and trampoline use.¹⁰

Course

To help guide and support their patients through the initial stage of injury, occupational therapists must be familiar with the usual course of events following SCI, the

diagnostic process, and the factors relevant to prognosis.

SCI, depending on the level of spinal injury and accompanying injuries, can be a life-threatening situation, requiring intensive emergency and acute care.^{13,19} Immediately following SCI, a period of spinal shock begins.^{5,13} During this time, spinal reflexes and motor, sensory, and autonomic function cease below the lesion level.^{13,20} The extremities below the lesion level become flaccid (or lose tone). Spinal shock is more extensive with lesions above T1, but even complete lower thoracic injuries are accompanied by some degree of spinal shock.¹³ This is a temporary and variable phase that can last several days to weeks, during which the true extent of paralysis cannot be determined. Neurogenic shock (a life-threatening medical condition resulting from autonomic instability) can occur simultaneously with spinal shock because of a loss of sympathetically mediated peripheral vascular tone, causing hypotension and bradycardia. Increased bronchial secretions can also be experienced during this time as well as gastrointestinal motility issues, complicating the clinical scenario.¹³ Resolution of spinal shock is characterized by the return of spinal reflexes and hyperreflexia (spasticity) as well as the return of voluntary motor function and sensation.^{13,20}

A baseline neurological **assessment** is conducted during the provision of emergency care to establish the presence and nature of an SCI and thereafter periodically to quantify progress and healing.^{13,19} The American Spinal Cord Injury Association (ASIA) assessment is the international standard for this assessment.²¹ An SCI causes a disruption in the motor and sensory pathways at the lesion site.^{13,21} Because the nerve roots are segmentally routed, a thorough evaluation of motor and sensory function can identify the lesion level, and this is the approach of the ASIA examination. The neurological level is diagnosed by the physician according to the findings.

The **motor level** is determined by testing 10 key muscles on each side of the body using manual muscle test (MMT), graded 0 (total paralysis) through 5 (normal).²¹ The **sensory level** is determined by testing sensation of each of the 28 **dermatomes** at key sensory points on each side of the body (ASIA sensory examination). Sensation is assessed for pin prick and light touch and is graded on a scale of 0 (absent) to 2 (normal). The sensory examination includes the perianal area and external anal sphincter.^{13,21}

Findings are classified in terms of bilateral sensory and motor levels, and neurological level.^{13,21} The neurological level of injury (NLI) is the lowest segment of the spinal cord with preserved bilateral normal sensory and antigravity motor function. The level above must also have normal strength and sensation. The motor and sensory levels can differ; for example, sensory level may be higher than a motor level.¹³ At the injury level, areflexia (loss of reflexes) may remain as the reflex arc is interrupted. The motor levels are identified by the injury location on the spinal cord, be it cervical (C1–C8), thoracic (T1–T12), lumbar (L1–L5), or sacral (S1–S5)²¹ (Fig. 39-1).

Figure 39-1 Spinal cord with segments: cervical, thoracic, lumbar, and sacral, with body areas affected by spinal cord injuries at C4, C6, T6, and L1 levels. (Reprinted with permission of Advancells.)

Further classification of the injury can be made based on the results of the neurological examination.²¹ Tetraplegia refers to a cervical injury causing sensory and/or motor loss in the arms, legs, pelvic organs, and trunk. Paraplegia refers to impairment or loss of motor and/or sensory function in the thoracic, lumbar, or sacral segments of the spinal cord. The upper extremities (UEs) are generally spared in paraplegia, and, depending on the lesion level, the trunk, legs, and pelvic organs are more or less affected¹³ (see Fig. 39-1).

SCIs are further classified by whether they are complete or incomplete.²¹ Complete injuries are those where there is no motor or sensory function preserved in S4–S5. Incomplete injuries can be classified as motor or sensory incomplete, with sparing of sensory or motor function at S4–S5.²¹ The ASIA Impairment Scale is used to clearly classify injuries by letter grade (Table 39-1).

Table 39-1. ASIA Impairment Scale

STAGE	DESCRIPTION
A = Complete	No sensory or motor function is preserved in the sacral segments S4–S5.
B = Sensory incomplete	Sensory, but not motor, function is preserved below the neurological level and includes the sacral segments S4–S5 (LT or PP at S4–S5 or DAP), <i>and</i> no motor function is preserved more than three levels below the motor level on either side of the body.
C = Motor incomplete	Motor function is preserved at the most caudal sacral segments for voluntary anal contraction <i>or</i> the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments [S4–S5] by LT, PP, or DAP), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body. (This includes key or nonkey muscle functions to determine motor incomplete status.) For AIS C—less than half of key muscle functions below the single NLI have a muscle grade ≥ 3 .
D = Motor incomplete	Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the single NLI having a muscle grade ≥ 3 .
E = Normal	If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation when they are unable to be determined based on the examination results.

AIS, ASIA Impairment Scale; DAP, deep anal pressure; LT, light touch; NLI, neurological level of injury; PP, pin prick; SCI, spinal cord injury.

During this assessment, the **zone of partial preservation** and the **functional levels** can be observed.²¹ This information provides clues about functional outcomes and is of particular significance to the occupational therapist because the partially preserved neurological and sensory levels retain some innervation and imply possible strength and sensation improvements with time.^{13,21}

Additional testing is included in the neurological examination, although it does not contribute to diagnosis but rather informs a comprehensive approach to care.² The autonomic assessment considers autonomic control of the heart, blood pressure, and the awareness and management of the bladder and bowel.² The monitoring of joint movement (proprioception, kinesthetic sense), deep pressure, and deep tendon reflexes are also assessed. The testing of deep tendon reflexes permits an appreciation of the evolution through spinal shock and has implications for bowel and bladder function.¹³

There are also a number of clinical syndromes that are not part of the International Standards examination or ASIA classification that should be recognized. All are incomplete injuries²¹:

- **Central cord syndrome** results from damage to the center of the spinal cord.²⁰ This is the most common syndrome resulting in more weakness in the UEs than the lower extremities (LEs). This injury is often caused by falls, occurs mostly to older people, and is often associated with cervical stenosis.²¹
- **Brown-Sequard syndrome** involves damage to one side of the cord, causing ipsilateral proprioceptive and vibratory sensory loss, loss of motor control at and below the lesion, and contralateral loss of pain and temperature sensation.^{13,21} This syndrome is most often caused by a motor vehicle accident, gunshot, or stabbing wound.
- **Anterior cord syndrome** is rare and associated with absent blood supply to the anterior cord, causing loss of motor control, pain, and temperature sensation at and below the injury. Proprioception and light touch are preserved.^{13,21}
- **Cauda equina syndrome** is a lower motor neuron (LMN) injury to two or more of the lumbosacral nerve roots within the spinal canal, but not the spinal cord.^{13,21} It results in areflexic bladder and bowel, and flaccid paralysis (depending on the injury level).^{13,20,21}
- **Conus medullaris syndrome** is similar to cauda equina syndrome but in addition to lesions to the lumbar nerve roots, the cord is also damaged, resulting in a mixed physical picture with some preservation of reflex activity.²¹

Once the patient's medical condition is stabilized, inpatient SCI rehabilitation is recommended to maximize function, strengthen preserved muscles, and teach the patient how to function given the effects of injury.^{5,6,8,22} Active participation in interdisciplinary rehabilitation has been found to improve functional outcomes following SCI. At a minimum, the interdisciplinary team should include a physiatrist, rehabilitation nurse, physical therapist, occupational therapist, psychologist, and social worker/case manager.²³ The lengths of stay for both acute and subacute inpatient care have been greatly reduced.^{11,24,25} Today, inpatient acute care lasts an average of 11 days (reduced from 24 days in the 1970s), and inpatient rehabilitation currently lasts an average of 35 days (reduced from 98 days in the 1970s). Outpatient services can continue from 3 to 12 months following the inpatient rehabilitation stay. This implies that patients may be weaker upon entering rehabilitation and that more of their rehabilitation is conducted in both outpatient and home/community settings than in the past.²⁴

Prognosis

In the 1930s, an SCI was more likely to cause a terminal outcome in 80% of cases.³ Today, an SCI causes great change to an individual's life, but is much less likely to mark the end of life, and many with SCI adapt and find new ways to lead meaningful lives.^{3,26} This disparity in both function and mortality can be appreciated by comparing SCI outcomes in developed countries to underdeveloped countries, where outcomes are less positive.³

The prognosis of SCI can be inferred by the injury level.^{5,13,21} Cervical injuries greatly impact more body functions and thus place individuals at higher risk for medical complications. Patients with lumbar or sacral injuries have better prognoses because they have less motor and sensory loss and lower risk of complications. The NLI is only one metric that impacts prognosis. The age at the time of injury, the extent of injury, the availability and timing of services, and the environment in which the patient lives all contribute to outcomes.³ The patient's environment includes and is impacted by the physical, social, economic, and attitudinal surroundings. In addition, the patient's preinjury level of health and functioning, past medical history and comorbidities, concurrent injuries, and physical build and gender all factor into ultimate outcomes.^{25,27}

Neural recovery during rehabilitation is common and can result in significant improvement in function.⁵ In patients with complete injuries, muscles in the zone of partial preservation strengthen, which may result in significant functional change. Most individuals with tetraplegia regain UE function within one to three motor segments below the initial injury.^{5,6,28} This is true especially if a key muscle, such as extensor carpi radialis, strengthens enough to enable the person to extend the wrist and hold objects. Patients with **incomplete injury** have a better prognosis, but their recovery is less predictable than **complete injury**.²⁸ Most recovery occurs within 3 months of injury, but recovery can continue through 1 year or longer.^{20,22,28} The longer that time passes without improvement generally lessens opportunities for improvement.²⁸ The prognosis for NTSCI is generally less favorable because patients tend to be older with comorbidities and possess less physical reserve.^{10,14}

Functional outcomes resulting from SCI are critically important issues for patients and families. Table 39-2 provides an overview of functional outcomes by neurological level. When clinicians are asked about patient outcomes, it is important to be factual but hopeful and make clear that many factors can impact ultimate outcomes.⁵ The information widely disseminated about SCI outcomes are to be viewed as general guides only, not as final dictates. Best practice in this regard is to encourage open discussion of progress and possible outcomes as often as needed, acknowledge the fear and grief that the patient and families are experiencing, and provide for measured yet realistic hope for the future.⁵

Table 39-2. Functional Outcomes by Neurological Level of Injury

WHAT ARE MY FUNCTIONAL GOALS?
<p>There is a chart on the following pages that outlines common functional goals. These goals are daily activities that most people can manage with the control of muscle movement that they have with a complete injury. You may be able to do additional activities if you have an incomplete injury or if you regain control of more muscle movement. You will work with your rehab team to set your goals and find ways you can reach your goals. The following is a step-by-step guide to using the chart.</p> <ol style="list-style-type: none"> 1. Find your level of injury in the Level of Injury column. 2. The Physical Abilities column shows what muscle movement is common for anyone with a complete injury at that level. 3. The Functional Goals column outlines how people might manage typical daily activities based at that level of injury. 4. The Equipment Used column suggests various equipment options that might be useful in accomplishing those functional goals.

LEVEL OF INJURY	PHYSICAL ABILITIES	FUNCTIONAL GOALS	EQUIPMENT USED
C1–C3	C3—Limited movement of head and neck	Breathing: Depends on ventilator for breathing	Suction equipment to clear secretions, two ventilators with back-up generator and battery
		Communication: Talking is sometimes difficult, very limited, or impossible. If the ability to talk is limited, communication can be accomplished independently, with adaptive equipment.	Mouth stick and assistive technology (e.g., computer, communication board) for speech or typing
		Daily tasks: Full assistance from caregiver for turning in bed, transfers, and all self-care (including bowel and bladder management). Assistive technology can allow for independence in tasks such as reading a book or newspaper, using a telephone, and operating lights and appliances.	Mouth stick, environmental control unit (ECU)
		Mobility: Can operate an electric wheelchair by using a head control, mouth stick, sip and puff, or chin control. Can also operate a power tilt wheelchair for independent pressure relief.	Power or manual lift, electric or semi-electric hospital bed, power wheelchair with pressure-relieving cushion
C3–C4	Usually has head and neck control. At C4 level, may shrug shoulders.	Breathing: May initially require a ventilator for breathing; usually adjusts to breathing full time without ventilator assistance.	Cough-assist device
		Communication: Normal.	
		Daily tasks: Individual requires full assistance from a caregiver for turning in bed, transfers, and all self-care (including bowel and bladder management). Individual may be able to use adaptive equipment to eat independently. May also be able to operate an adjustable bed and perform other tasks, such as painting, writing, typing, and using a telephone with assistive technology.	Eating: Sandwich holder on a gooseneck, feeder, long straw for liquids Other activities: ECU for operating bed (e.g., head or voice activated, mouth stick controller), hands-free devices, mouth stick for typing, etc.
		Mobility: Can operate a power wheelchair using head control, a mouth stick, sip and puff, or chin control. Power tilt function on wheelchair allows for independence with pressure relief.	Power or manual lift, electric or semi-electric hospital bed, power wheelchair with pressure-relieving cushion

C5	Typically has head and neck control, can shrug shoulders, and has some shoulder control. Can bend elbows and turn palms face up.	Daily tasks: Individual can be independent with eating and grooming (e.g., face washing, oral care, shaving, makeup application) after setup from caregiver, with specialized equipment. Individuals will require total assistance from caregiver for bed mobility, transfers, and all other self-care. May be able to assist caregiver with upper body dressing and some bathing, with adaptive equipment.	Eating: Universal cuff for attachment of utensils, scoop plate, plate guard, long straw Grooming: Universal cuff for attachment of tooth brush, comb or brush, adapted or electric razor, makeup applicators; wash mitt for face Bathing: Roll-in padded shower and commode chair, or padded transfer tub bench; wash mitt; adapted loofah
		Health care: Individual will require assistance from caregiver for cough assist. Can perform pressure relief with power tilt in power wheelchair.	Cough-assist device
		Mobility: May have strength to push a manual wheelchair for short distances over level surfaces; however, a power wheelchair with hand controls will be required for daily activities. At this level, the individual may be able to drive with specialized hand controls in a modified van with a lift, but still may require attendant to assist with transportation.	Wheelchair: Power or manual lift, electric or semi-electric hospital bed, power wheelchair with pressure-relieving cushion Bed: Bed ladder, thigh straps, and bed rails used for bed mobility
		Bowel and bladder management: Individual requires total assistance from caregiver for bowel and bladder management. Individual may have indwelling catheter, or the caregiver may perform intermittent catheterization for bladder management. Bowel management can be performed with use of specialized equipment or medication.	Bowel: Roll-in padded shower and commode chair, or padded transfer tub bench Bladder: Leg-bag emptier

C6	Has movement in head, neck, shoulders, arms, and wrists. Can shrug shoulders, bend elbows, turn palms up and down, and extend wrists.	<p>Daily tasks: With use of some specialized equipment and setup from a caregiver, an individual can be independent with most feeding, grooming, and upper body dressing. Will still require some assistance for lower body dressing and will be able to assist with upper body during bathing. Can perform sliding board transfers to padded shower commode chair and/or tub bench for toileting and bathing, with some to total assist from caregiver. Can perform some light meal preparation tasks.</p>	<p>Feeding: Universal cuff, built-up utensils, scoop plate, long straw, plate guard Grooming: Universal cuff, adapted electric razor, or toothbrush Dressing: Dressing stick, leg lifter, thigh straps, dressing hook splints; adapted or specialized clothing Bathing: Adapted loofah, long-handled sponge with universal cuff Transfers: Power or manual lift, sliding board, padded drop-arm bedside commode, padded tub bench with cutout, padded shower and commode chair</p>
		<p>Health care: Can independently perform pressure relief with power tilt and may require some to no assist for forward or lateral lean pressure relief.</p>	
		<p>Mobility: An individual may require some to no assist for turning in bed, with use of special equipment. May be able to perform sliding board transfers on level surfaces with some to no assistance from caregiver. Can use an ultra-lightweight manual wheelchair for mobility, but some may use a power wheelchair for greater ease over uneven terrain. Can be independent driving a vehicle from power or manual wheelchair with specialized equipment.</p>	<p>Bed: Bed ladder, thigh straps, bed rails Wheelchair: Wheelchair pegs, specialized wheelchair gloves, and rubber tubing on wheels. Also, power-assist wheels can be used for independence with manual wheelchair propulsion. Transportation: Modified van with lift, specialized hand controls, tie-downs</p>
		<p>Bowel and bladder management: Some to total assist with adaptive equipment for management of bowel and bladder.</p>	<p>Bowel: Digital stimulation splint device, enema insertion device Bladder: Catheter inserter, penis positioner, thigh spreader with mirror</p>

C7-T1	Has movement similar to C6 level, with the added ability to straighten elbows. At the C8-T1 level, has added strength and precision of hands and fingers.	Daily tasks: Independent with all feeding, grooming, and upper body dressing, with equipment. Individuals may require some to no assistance with lower body dressing and bathing with equipment. Can perform sliding board transfers with some to no assistance to padded shower commode chair and/or tub bench for toileting and bathing.	Feeding: Universal cuff, built-up handles, curved utensils, long straw, plate guard, adapted techniques for grasp Grooming: Universal cuff, splint material to adapt devices Dressing: Leg lifter, dressing stick, zipper pull, hooks-on shoes Bathing: Adapted loofah, long-handled sponge with universal cuff Transfers: Sliding board, padded drop-arm bedside commode, padded tub bench with cutout, padded shower and commode chair
		Health care: Independent with wheelchair pushup or lateral lean for pressure relief.	
		Mobility: Independent with manual wheelchair propulsion and level surface sliding board transfers. Some assistance may be required from caregiver for uphill transfers. Can be independent with driving if able to load and unload wheelchair.	Wheelchair: Rigid or folding lightweight wheelchair, wheelchair pegs, wheelchair gloves Transportation: Hand controls, modified van if unable to perform transfer or load-unload chair
		Bowel and bladder management: Depending on hand function, some to total assist for bowel management, with use of adaptive equipment or medication. Can be independent or need some assist for bladder management with intermittent catheterization or condom catheter.	Bowel: Digital stimulation splint device, enema insertion device, toileting aid Bladder: Catheter inserter household (for men), thigh spreader with mirror (for women)

T2–T12	Has normal motor function in head, neck, shoulders, arms, hands, and fingers. Has increased use of rib and chest muscles, or trunk control. At the T10–T12 level, more improvements in trunk control because of increase in abdominal strength.	Daily tasks: Independent with all self-care, including bowel and bladder management, with adaptive equipment if necessary.	Dressing: Thigh straps, reacher, dressing stick, sock aid Bathing: Long-handled sponge Transfers: Sliding board, padded drop-arm bedside commode, padded tub bench with cutout, padded shower/commode chair Bowel/bladder: Mirror
		Health care: Independent with wheelchair pushup for pressure relief.	
		Mobility: Independent with all bed mobility and transfers, with or without use of equipment. Independent with wheelchair propulsion on uneven and even surfaces and up and down curbs. Able to load and unload wheelchair independently for driving with hand controls.	Wheelchair: Ultra-lightweight wheelchair Transfers: Sliding board, leg straps Transportation: Hand controls
L1–L5	Has additional return of motor movement in the hips and knees.	Mobility: Independent with all bed mobility and transfers with or without use of equipment. Independent with wheelchair propulsion on uneven and even surfaces and up and down curbs. Ambulation possible with use of specialized leg braces and walking devices. Functionality of ambulation depends on strength and movement in legs. Individuals’ ability to ambulate depends primarily on their level household distances. Individuals may use a wheelchair for community mobility. Able to load and unload wheelchair independently for driving with hand controls.	Wheelchair: Ultra-lightweight wheelchair if necessary Walking: Leg braces that extend to the hip, the knee, or just the ankle/foot and varying assistive devices Transportation: Hand controls
S1–S5	Depending on the level of injury, various degrees of return of voluntary bladder, bowel, and sexual function	Mobility: Increased ability to walk with fewer to no bracing or assistive devices	Walking: Braces that support the ankle/foot

Secondary Conditions

There are numerous secondary conditions associated with SCI.^{5,13} The occupational therapist must understand the etiology and effect of these secondary conditions on function, as well as the unique contribution of occupational therapy services provided as part of a comprehensive interprofessional rehabilitation team.

Spinal Stabilization

Spinal surgery is indicated on an individual basis, depending on the level and severity of SCI, the mechanism of injury, and the extent of compression.⁵ Closed reduction is a less invasive option to achieve spinal alignment, and realignment of the cervical spine

is attempted using skeletal traction or via halo ring or cranial tongs.¹³ Traction is typically begun with little weight and is gradually increased.⁵

If closed reduction is not an option, or when a progressive neurological deficit is present, spinal surgery is indicated.¹³ Spinal surgery can involve reducing or realigning the spinal elements, decompressing compromised neural tissue, and/or stabilizing the spine.⁵ Surgical goals include spinal stabilization, decreased pain, and a quicker return to activity.^{1,5} Surgery can also serve to improve neurological recovery.

Following surgery, the use of a spinal orthosis may be ordered.⁵ The spinal orthosis limits spinal motion; stabilizes, supports, and realigns the spine; and protects it after trauma and surgery. The duration of use may vary, but a spinal orthosis is generally worn for 10 to 12 weeks following spinal surgery. Spinal orthoses are named for body regions stabilized. Movement restrictions and discomfort are to be expected as braces and orthoses must be snug fitting. The spinal orthosis may make activities of daily living (ADLs) more cumbersome and should be monitored to ensure that it is not causing pressure areas on insensate skin.

Paralysis and Loss of Sensation

As noted earlier, much of SCI care is directed at the prevention of complications.¹ With the loss of active movement, there is risk of the development of joint stiffness and contractures.^{5,9} Because loss of feeling is often associated with SCI, care must be taken to protect insensate areas at all times. It is possible to incur injury without awareness, which can aggravate other complications and cause needless progression of injury. Osteoporosis or bone loss is a complication of SCI caused, in part, by the lack of weight bearing.⁵ As a result, fractures can occur unexpectedly with routine activities. Great care should be utilized at all times with regard to paralyzed extremities.

Respiration

Many patients with SCI have compromised breathing, but the extent to which breathing is impacted is directly related to the NLI.⁵ Cervical injury, with regard to respiration, is the most involved. Patients with high cervical injuries will undergo **tracheostomy** early in the acute phase of care to provide for mechanical ventilation.¹³ Patients with injuries of C4 or lower may require tracheostomy depending on their age, comorbidities, or the extent of other injuries.

There are many muscles involved in breathing, and their innervations fall at different levels of the spinal column.⁵ As a result, injuries above the level of T12 may involve some degree of respiratory compromise. The diaphragm is innervated at the level of C3–C5. The intercostals are innervated at the levels of T1–T11. The abdominal muscles are innervated at T6–T12, and various accessory muscles are innervated at the cervical or cranial nerve level. Ventilation is primarily as a result of the function of the diaphragm, the cervical accessory muscles, and the external intercostals. Cough is mainly a function of the abdominal muscles and the internal intercostals. When the chest does not expand during inspiration, vital capacity is lessened. With impaired sympathetic function, secretions are increased with accompanying bronchoconstriction. Vocal cord paralysis, tracheostomy, neck orthoses, and anterior surgical approaches can impair swallowing and cause aspiration, which can further impair breathing capacity.⁵

Autonomic Dysreflexia

Autonomic dysreflexia (AD), a sudden dangerous increase in blood pressure, is a possible life-threatening complication associated with lesions at the T6 level or above.^{5,29} AD is brought on by an unopposed sympathetic response to noxious stimuli and does not occur until after spinal shock. Some of the more common causes of AD are distended bladder, urinary tract or other infection, bladder or kidney stones, fecal

impaction, pressure ulcers, ingrown toenails, invasive procedures such as urinary catheterization or enema, and pain.²⁹ This condition qualifies as a medical emergency because of the dangerous elevation in blood pressure. AD may be asymptomatic, or it can be recognized by complaints of a pounding headache, profuse sweating and flushing of the skin above the lesion level, piloerection of the skin (goosebumps), blurred vision or spots in visual fields, nasal congestion, and/or feelings of anxiety or apprehension.^{5,29}

Orthostatic Hypotension

Orthostatic hypotension (OH) is a sudden drop in blood pressure occurring when a person assumes an upright position.⁵ It has been reported that as many as 74% of patients with acute SCIs experience OH, but the condition is less likely in injuries below T6 and incomplete injuries. The cause of OH is believed to be impaired autonomic regulation, specifically related to reflex vasoconstriction. The hypotension is caused by gravitational effects of venous pooling in the LEs and is aggravated by prolonged bed rest (cardiovascular deconditioning). The patient may complain of lightheadedness or dizziness and may faint when transitioning from reclined to upright. OH can be experienced when initially acclimating to a seated position, the tilt table, and/or to standing.⁵

Pressure Injuries

Individuals with SCI are at a high risk for developing pressure injuries.^{5,30} Prolonged pressure, as a result of a lack of spontaneous movement and impaired sensation, compresses the skin and underlying muscles, occluding blood supply. Pressure injuries typically develop over bony prominences. The areas most vulnerable to pressure injuries include ischial tuberosities, sacrum, coccyx, greater trochanters, malleoli, knees, occiput, and calcaneus.³⁰ The causes of pressure injuries include decreased movement, loss or impaired sensation, and changes in the skin as a result of SCI. Prolonged pressure, friction, and shear are forces on the skin that can cause breakdown and ultimately ulceration. Moisture from incontinence and less-than-ideal nutritional status can also contribute to circumstances where pressure injuries can occur. Pressure injuries are a major cause of morbidity, hospitalization, and reduced engagement in activity for individuals with SCI.^{5,30} As such, prevention is the best intervention because significant injuries can require surgical intervention and can be a source of serious infection.⁵

Neurogenic Bladder and Bowel

Bowel and bladder function is controlled in the S2–S5 spinal segments.⁵ Therefore, all persons with complete lesions at and above the S2–S5 levels lose their ability to void and defecate voluntarily. As a consequence, there is a loss of overriding cortical control of these functions, and management of bowel and bladder function must be intentional.⁵ Ultimately, a routine is established, individualized to the needs of each patient, which lessens the impact of these tasks on activities and improves patients' quality of life (QoL).^{31,32} Management of the neurogenic bowel and bladder depends on the level and completeness of the injury.⁵ For injuries above S2–S4, some level of reflex activity remains; this condition is deemed reflexic or upper motor neuron (UMN) bowel and bladder. If the injury is at or below S2–S4, the bowel and bladder are areflexic and referred to as an LMN bowel and bladder. Incontinence can occur in either instance but is lessened by implementation of a care routine (detailed in the section, Neurogenic Bowel and Bladder).^{31,32} The care routine must be continually assessed to assure optimal efficacy for the patient so as to minimize impact on activities and QoL.

Sexual Function

The need for emotional and physical intimacy does not diminish after SCI, but the ways through which an individual with SCI can address these needs do.^{5,33} SCI affects both sexual intercourse and reproduction, both of which are determined by the level of injury and its completeness. Most male patients with complete injuries are unable to have voluntary erections and ejaculations. They can, however, have reflex erections that may be facilitated by sensory stimulation. Patients with complete injuries at S2–S5 lose bowel, bladder, and genital reflexes and have a complete loss of erection. Male fertility is decreased after SCI; however, advances in technology provide ways for male patients to sustain an erection and improve the chances of fathering children.³³ Over 80% of men regain some erectile function within 2 years of their SCI.⁵

Sexual and reproductive functioning is less affected in women.⁵ The menstrual cycle typically resumes between 6 and 12 months after SCI, and fertility is assumed to be unchanged. As pregnancy advances, a higher level of caregiving assistance may be needed. Premature delivery is relatively common, and because of sensory loss, the signs of impending labor should be regularly monitored after 28 weeks of gestation. Blood pressure must be monitored on an ongoing basis because the risk of AD is higher during this time.⁵ Labor is affected depending on the level of injury, particularly with injuries above T10.¹³ Most women with SCI have atypical labor symptoms and deliver by cesarean section with greater frequency.

Temperature Regulation

Related to disrupted autonomic function, particularly with injuries above T8, individuals with SCI have difficulty regulating their temperature, a condition referred to as poikilothermia.^{12,34} As a consequence, their internal temperature acclimates to that of their surroundings, and care must be taken to avoid overheating, core cooling, and exposure to the elements.

Pain

Pain is a significant concern for patients with SCI⁵ and can be related to acute injuries or can be chronic in nature (pain that has endured more than 6 months).¹⁶ There are several causes for pain, and its presence greatly impacts QoL.⁵ Musculoskeletal pain is described as dull and aching and is often caused by overuse in the UEs related to wheelchair propulsion. Visceral pain is described as cramping or tenderness and may be generalized. This type of pain is due to a visceral cause and can include fecal impactions, bowel obstruction, or gallstones. Neuropathic pain feels like burning, tingling, or shocking and can be related to damage to the spinal cord near the injury level. Pain is estimated to affect as high as 80% of patients with SCI.^{5,34} Shoulder pain is estimated in 30% to 70% of individuals with SCI.⁵ Studies vary greatly in estimating the prevalence of chronic pain, with the reported range of pain being 26% to 96%, regardless of SCI completeness and level.³⁵

Fatigue and Sleep Disturbance

Many individuals with SCI experience difficulty with sleep and associated fatigue.^{13,36} This phenomenon is not fully understood because there are many possible causes. Disordered sleep may be associated with the actual SCI and its consequences, or with the associated treatment, such as frequent repositioning for pressure relief, or bowel or bladder care. Additional causes could be infection, respiratory or cardiac failure, medication side effects, or depression.⁵ Fatigue can impact the individual's ability to participate in his or her care and engage in activities. Individuals with SCI also have a higher incidence of sleep apnea.^{5,36}

Changes in Muscle Tone

Spasticity is a motor disorder related to UMN syndrome.^{5,12} It is characterized by a velocity-dependent resistance to passive range of motion (PROM) owing to exaggerated stretch reflexes.¹² Spasticity includes an increase in muscle tone, involuntary muscle spasms, and **clonus**.⁵ The appearance of spasticity follows spinal shock days to weeks following injury, and 50% to 75% of individuals with SCI report spasticity.

Spasticity can be worsened by noxious stimuli, many of the same stimuli that can trigger AD.^{5,37} Spasticity can be painful and limit mobility and ROM. As a result, spasticity can impair independence in ADLs and can make assisting patients difficult. Some spasticity can be functionally helpful, but effective management often proves challenging. Spasticity can lead to complications such as joint contractures, subluxations, and pressure ulcers.^{5,37} By contrast, in LMN (areflexic) injuries, below the level of the spinal cord, the LEs remain flaccid.²¹

Thromboembolism

Thromboembolism (a blood vessel obstructed by a clot dislodged from another region), which includes deep vein thrombosis (DVT) and pulmonary embolus, is a common complication and accounts for significant morbidity and mortality in patients with SCI.¹³ The signs and symptoms of DVT include swelling (typically in the LEs), warmth, and discoloration; patients may also be asymptomatic. DVT can be difficult to detect because chronic leg swelling is common following SCI because of the loss of mobility and venous status, and pain perception impairment due to the spinal injury.³⁸ As a result, the condition can be extensive before it is detected. A pulmonary embolus is a clot that has traveled to the lungs.^{5,13} This condition presents with dyspnea, tachycardia, fever, or chest pain.⁵ Owing to the gravity of this condition, thromboprophylaxis is initiated immediately in the care of SCI.³⁸ Thromboembolism occurs more frequently in paraplegia, older patients with SCI, complete SCI, and when there are concurrent fractures of the LEs and pelvis.

Psychosocial Adaptation

SCI, independent of its severity, is an emotionally traumatic event. In the days following injury and often during acute rehabilitation, paralysis, multiple medical problems, and the need to rely on others for basic functions can be overwhelming.²⁶ Patients and families may experience a myriad of feelings, such as confusion, anxiety, loss, hope, grief, depression, and helplessness.^{19,26} Most people with SCI adapt well with time and reintegrate into their communities.²⁶ Many factors influence SCI psychological outcomes.^{19,26} Premorbid lifestyle and interests, personality and coping styles, fewer medical complications, and the degree of social and economic support all contribute to outcomes. Weaknesses in any of these areas place individuals at risk for developing psychological syndromes, such as anxiety or depressive disorder, substance abuse, and a suicide rate five times higher than the general public.²⁶

Medical Management

This section briefly describes the medical management of the secondary conditions noted in the previous section, with special emphasis on aspects that impact the services and contributions that occupational therapists make to patient care.

Paralysis and Impaired Sensation

Paralysis and a lack of sensation are the most common results of SCI. The therapist must be aware of the implications of these impairments to provide a safe therapeutic environment and educate patients about how to manage these concerns for optimal health maintenance.⁷ Care in this regard involves proper positioning; early mobilization by active, active assisted, or passive means; and splints or orthotics to prevent

contracture and loss of joint ROM.^{5,9} Transitioning to an upright position as soon as medically tolerated conditions the cardiovascular system and permits the patient to engage in activities and socialization.⁵ Daily visual inspection of the skin to identify reddened areas or bruising should be completed to compensate for the loss of sensation.^{5,30} This task should become part of ADL routines, and the occupational therapist is a natural provider to reinforce this practice as a preventative and health maintenance activity.⁷

Respiration

Respiratory complications, specifically pneumonia, have been identified as the leading cause of death in the first year after SCI.¹¹ The occupational therapist typically does not provide care in this area but must be aware of possible difficulties and symptoms and should reinforce breathing interventions in daily routines.²⁰

The goal of respiratory care is to maximize breathing, improve coughing ability, and minimize complications.²⁰ High tetraplegics require mechanical ventilation, and the occupational therapist must become familiar with these devices. Patients requiring long-term ventilator use will likely have a tracheostomy.^{5,36} Suctioning may be required to clear secretions from the airway.⁵ Nebulized medications (breathing treatments) may be used to improve breathing. The use of a rotating bed assists with postural drainage of fluids in the lungs. Respiratory and physical therapists may implement assisted coughs (like the Heimlich Maneuver, a forceful thrust to the abdomen while the patient attempts to cough); chest percussion, vibration, or cupping to break up secretions; or mechanical insufflation or exsufflation that provides for a machine-facilitated deep breath.^{5,20} Physical therapists work with patients to strengthen the muscles associated with breathing and teach self-coughing. Patients may undergo the insertion of a phrenic nerve stimulator that provides an electrical stimulation to cause the diaphragm to contract to improve breathing.^{20,36}

Occupational therapists can contribute to respiratory care by remaining vigilant related to positioning of the patient. The best seated position for breathing begins with an anterior pelvic tilt, an upright trunk, and a neutral head and neck.²⁰ Diaphragmatic breathing should be encouraged, and the patient's pattern of breathing should be noted including chest and diaphragm excursion, and the contraction of neck muscles so that variances can be identified.²⁰ In addition, adherence to proper infection control standards is important for respiratory care to minimize exposure to risks.

Autonomic Dysreflexia

The occupational therapist should be mindful of the symptoms of AD and, if the symptoms appear, respond immediately to this medical emergency.⁵ If the eliciting cause of the AD can be identified, often of a urinary nature, it should be addressed. Medications can be administered to lower blood pressure.¹³ Sitting the patient upright may lower blood pressure by venous pooling in the LEs. Any restrictive clothing should be loosened. Emergency attention should be sought if these interventions do not resolve the AD.

Orthostatic Hypotension

Medically, OH or postural hypotension can be managed by reviewing the medications utilized and their hypotensive effects.⁵ Additional measures can be included in the daily routine to attempt to minimize OH. Simple routine-related interventions such as assuring adequate hydration and attending to the timing of meals related to activity can lessen the risk of OH (blood flow is diverted to the gut for digestion, making OH a higher risk after meals). Exercise later in the day may be tolerated better than early in the morning. Gradual elevation of the bed while sleeping may foster tolerance to the upright position, leading incrementally to longer periods of tilt table use, sitting upright

in a reclining or tilt-in-space chair, using a standard wheelchair, and possible standing. Rapid position changes should be avoided as well as exercise in a hot environment. Abdominal binders and compression stockings are often used to increase venous pressure and decrease venous pooling in the LEs.^{5,38}

Pressure Injuries

One of the main interventions in the prevention of pressure injuries is the implementation of routine positions changes.^{5,30} This is begun in the emergency department with position changes every 2 hours as medical condition allows^{19,30} and can involve pressure reduction mattresses. Efforts should be made to control skin exposure to moisture and heat, for example, changing clothing after incontinence. Shearing forces should be minimized during repositioning. Positioning with the use of pillows and other positioning aids to elevate (unweight) bony prominences should be part of routine care. Patients and their caregivers should be educated to visually inspect their insensate skin daily for areas of pressure.^{5,30} Ideally, there will be no reddened areas enduring more than 15 minutes. If so, adjustment of the pressure redistribution regime may be indicated.

When the patient is strong enough, a weight-shifting schedule should be implemented and trained to be spontaneously completed.³⁰ It is recommended that every 30 minutes, at least 1 to 2 minutes is offloaded or unweighted. This can be done by weight-shifting forward or side to side, or by wheelchair push-ups. For patients who cannot weight shift manually, a tilt-in-space or reclining wheelchair may be indicated to provide pressure relief.

The prescription of a wheelchair seating system, customized to the needs of the individual, is recommended with the goals of redistributing pressure; minimizing shear; and providing comfort, stability, and mobility.³⁰ Specific body measurements are taken to facilitate proper prescription of the wheelchair seating system. Pressure mapping of the seated positions may be conducted to identify areas of high pressure and permit customization of the wheelchair seating system.⁵ Wheelchair cushions are prescribed to assist with pressure distribution, and options include foam, gel, air, and alternating air. Regular assessment of the system's efficacy is important to insure ongoing efficacy of pressure relief.

Neurogenic Bowel and Bladder

Care of bowel and bladder function is generally a primary task of nursing, but the occupational therapist can be involved in training these new habits and adapting techniques to meet patient abilities.^{31,32} Bowel and bladder regimens are individualized to each patient's unique needs and circumstances. The loss of cortical control, dyscoordination of sphincter function, and lack of sensation of the need to void, all imply the use of different techniques as part of the individualized routine. Factors impacting routines include the level and severity of injury, lifestyle, dexterity, caregiver willingness and ability, diet, and activity levels. Diligence to the established routine, and ongoing monitoring for effectiveness and side effects, should be considered as important as all other bowel and bladder care tasks.^{31,32}

There are two bowel function scenarios that relate to the presence of bowel reflexes.³¹ A reflexic bowel is the result of a cervical or thoracic SCI. Cortical control of the elimination process is lost due to the SCI, but the spinal reflexes continue to function. Reflex peristalsis provides for stool movement through the colon to the rectum, which can cause a reflex bowel movement. At other times, the anal sphincter is tight/spastic and requires digital or manual stimulation, or stimulant medications or enemas to relax and permit evacuation. For a UMN or reflexive bowel, a bowel training program includes defecation every 1 to 3 days at the same time each day.^{5,31}

An areflexic or LMN bowel occurs with SCI to the lumbar or sacral sections, or to the nerve roots.³¹ In this case, peristalsis is impaired, and there is no to little reflexive control over the anal sphincter. Here, the need to defecate is not appreciated and must be facilitated by mechanical stimulation and manual evacuation of the rectum. The areflexic bowel requires more facilitating of stool movement using the **Valsalva maneuver**, abdominal massage, seated push-ups, and leaning and forward-bending at the waist. Consistency in routine remains important, and bowel training is implemented daily to minimize incontinence.⁵

Both bowel care routines are ideally completed from a seated position over a commode.^{31,32} Both require stimulation of the rectum to permit stool to pass. This can be done using one or two fingers if the patient has sufficient dexterity, or with a dil stick (a specialized device for this purpose). Mirrors and lighting may need to be arranged to facilitate task completion to compensate for sensory loss, and the occupational therapist can provide support in this area.

As with the bowel program, the goal of the bladder program is to achieve a simple and effective routine that minimizes the risk of complications, reduces incontinence, and permits engagement in valued activities.^{5,32} Recurring urinary tract infection is a frequent complication and the most frequent cause of rehospitalization after SCI.⁵ To avoid complications, patients must empty their bladder fully and routinely, and some of the options below provide for better emptying than other methods.

There are several options for managing the bladder, and the entry-level occupational therapist must have an understanding of each so as to support the patient's successful engagement in the task.³² **Catheterization** can be done intermittently, usually at 4- to 6-hour intervals, or as needed.³² Urine is drained through the catheter into the commode or a collection bag. This method is associated with fewer complications and is more convenient than indwelling catheterization where the catheter can remain in place for 2 to 4 weeks, but a collection device for the urine is needed (such as a leg bag). Indwelling catheters are associated with higher rates of infection. Reflex voiding (spontaneous voiding) is an option for males and utilizes a condom catheter that is connected to a leg or other type bag to collect urine. The **Crede method** and **Valsalva technique** can assist with bladder emptying, but are not effective at completely emptying the bladder. There are additional surgical and pharmacological interventions to assist with managing bladder function, but are beyond the scope of this chapter. The advanced options are generally utilized if traditional methods are chronically ineffective. With bowel and bladder training, the occupational therapist may assist in the management of clothing, practicing the bowel or bladder care routine in varied environments and circumstances, and modifying activities if the patient has additional needs caused by cognitive or perceptual deficits.³²

Bladder care is classified in a similar manner, UMN (reflexive) and LMN (areflexive).³² Intermittent catheterization is the preferred method of managing urinary function, but this implies that the patient has sufficient hand function to self-catheterize or has a caregiver willing to complete the task.

Diet and fluid intake and activity levels impact bowel and bladder care.^{31,32} Complications related to bowel care include constipation, fecal impaction, diarrhea, rectal bleeding, and hemorrhoids.⁵ For complicated and persistent bowel and bladder issues, medications, injections, and surgical options may be considered.^{31,32} **Functional electrical stimulation (FES)** involves electrical stimulation of the nerve roots to cause contraction of muscles involved in bowel and bladder function and is also an option to improve routines.²⁰

Sexual Function

The entry-level occupational therapist likely does not possess sufficient expertise to educate patients in the area of sexual function, but certainly can be alert to patients' readiness to learn more in this area.⁵ Experienced occupational therapists may function as part of an interdisciplinary team specializing in sexual functioning and can facilitate candid discussion about the topic. If this expertise is not readily available, a referral for specialized providers may be appropriate. In this context, the role of the occupational therapist is to address varied individual needs such as grooming activities to improve appearance or to find equipment to either compensate for lack of hand function or to help with position to facilitate physical contact.³⁹ When addressing sexual function issues, the therapist must be particularly sensitive to the needs of the individual and discuss issues in a factual and nonjudgmental way.^{5,33} In the ideal situation, counseling is offered to couples, the patient and the partner, to help both work through the complex issues related to intimacy.³³

Temperature Regulation

The occupational therapist has a natural role in educating patients and caregivers to be aware of environmental conditions that can impact patients' impaired ability to regulate their internal temperature.⁷ The occupational therapist provides education about the selection of clothing appropriate to environmental conditions, the importance of avoiding temperature extremes, and the protection of skin from environmental exposure (heat or cold).

Pain

Musculoskeletal pain is managed in a similar manner to individuals without SCI.¹³ Joint protection, rest, flexibility, and strengthening exercises are prescribed for overuse injuries.^{5,26} Splinting, home modifications, and alternate techniques may be introduced to facilitate healing.⁵ Medications are utilized for neuropathic pain, but efficacy is inconsistent.^{5,26} Visceral pain is also addressed by treating the underlying cause. Pain can impact function and the patient's ability or willingness to engage in rehabilitation.

Fatigue and Sleep Disturbance

Rest and sleep are identified as part of the occupational therapy scope of practice.⁷ The occupational therapist can help to facilitate restorative rest and sleep by considering activity levels; modifying behaviors to facilitate restful sleep such as limiting screen time or liquid intake prior to bed time; and by evaluating the sleep environment for variables such as temperature, noise, and interruptions.

Changes in Muscle Tone

An injury to the spinal cord often results in an increase in transmission within the synaptic stretch reflex, causing spasticity.⁵ Spasticity develops into clonic or tonic spasms triggered by sensory stimuli, such as sudden touch, infection, or other irritation. Management of spasticity is important in maximizing a patient's functional independence. Severe spasticity may hinder function.³⁷ For example, the hypertonicity of the hip and knee adductors can make donning pants difficult.

Medications are prescribed to manage spasticity and often include baclofen, dantrolene, and benzodiazepines, such as diazepam or clonazepam.³⁷ An intrathecal pump, a method of continual baclofen administration into the spinal canal, or motor point/nerve blocks (which provide temporary reduction in spasticity in specific muscles) may be used in severe cases.^{12,37} Spasticity can lead to contractures necessitating attention to proper positioning in bed and in the wheelchair. Additional interventions can include ROM exercise, splinting, and weight-bearing activities.^{5,13,37}

Thromboembolism

Thromboembolism is treated with blood thinning medications (heparin and warfarin).^{5,38} Mobilization should occur as soon as is feasible after the SCI to lessen the risk of thromboembolism.¹³ Compression stockings and pneumatic compression sleeves are used to improve venous return and limit venous pooling.^{5,13,38} Combining the abovementioned methods has been found to be effective in the prevention of thromboembolism.³⁸ The use of vena cava filters is an option for patients with anticoagulation medication contraindication.^{5,38}

The occupational therapist can contribute to the care of DVTs by observing for asymmetry in the LEs in color, size, and/or temperature. It is also noteworthy that an anticoagulant side effect is blood thinning, which can cause excessive bleeding in even minor injuries.³⁸

Heterotopic Ossification

Heterotopic ossification (HO) is the pathological formation of bone in the soft tissues around the joints.⁵ HO has been recorded in 25% to 30% of patients with SCI. HO typically appears 1 to 4 months after injury and presents as localized swelling and redness, fever, and/or loss of ROM. HO is most often seen in the hip (80%–90%), knee, elbow, and shoulder joints. Preventative interventions include nonsteroidal anti-inflammatory drugs (NSAIDs), attention to positioning in bed and in the wheelchair, and daily ROM.

Psychosocial Adaptation

The complexity and ramifications of SCI can leave the patient at risk for depression, post-traumatic stress disorder (PTSD), anxiety, substance abuse, and suicide.²⁶ Routine and ongoing screening is indicated and should include attention to biological, social, and psychological factors.⁴⁰ An antidote to these risks is active engagement in rehabilitation and social activities, as participation fosters mastery of new skills, growth, and self-efficacy, including better rehabilitation outcomes.^{4,6,26}

Antidepressant medications may be used to manage psychological conditions when function is impaired.⁴⁰ The occupational therapist can share valuable observations about the efficacy of the prescribed pharmacological interventions and provide guidance and support to patients as their new reality is realized.^{4,6} The occupational therapist may also reinforce cognitive-behavioral therapy strategies during patient interactions, help to educate families and caregivers, and work with patients in groups to foster socialization with peers.^{5,26} When environmental or social concerns are identified in the patient with SCI, the occupational therapist may facilitate referrals for social work, rehabilitation counseling, or case management for additional support.

Polytrauma

Given the violent nature of traumatic SCI, it is common that the patient may have additional injuries that complicate outcomes.⁵ The occupational therapist must pay particular attention to precautions and activity restrictions related to injuries. About 15% to 60% of patients with SCI have a concomitant traumatic brain injury (TBI). A TBI adds medical complexity and heightens issues with frustration, concentration, memory, and behaviors that can impair new learning.

Functional Impairment in Daily Occupations

SCI is incurable, and treatment is limited to minimizing secondary complications and maximizing remaining functional capabilities.¹ The SCI levels have been mapped to the functional expectations of injury at those levels. Although the mapping is generally accurate, functional outcomes ultimately depend on several variables including the completeness of the injury, the patient's age, preinjury function and health, past

medical history and comorbidities, concurrent injuries, and psychosocial well-being.²⁵ For more detailed explanation of functional outcomes, refer to the section on Evaluation and Intervention of Functional Skill Deficits Secondary to Spinal Cord Injury and Table 39-2.

Evaluation and Intervention of Functional Skill Deficits Secondary to Spinal Cord Injury

The occupational therapy evaluation permits an understanding of the patient's baseline functional level, goals, and values.⁴¹ The evaluation process also provides a method for measuring progress and gathering information to project outcomes.⁴¹ Inherent to this process is the establishment and cultivation of the therapeutic relationship between the client and occupational therapist, where the occupational therapist leverages "therapeutic use of self" to facilitate the client's understanding of the implications of injury to his or her personal goals, valued activities, and roles.⁷

The Initial Occupational Therapy Evaluation

Completion of the comprehensive occupational therapy initial evaluation may require multiple interactions with the patient owing to the chaotic nature of transition in care.⁷ If the client is not able to fully participate, valuable information may be gathered from caregivers or family members. In general, all evaluation follows a basic process, including a review of the medical record, meeting and interviewing the client to gather data about problems of concern, observation of functional activities with an evaluation of component skills, and analysis and summarization of the data.⁴² Special attention must always be given to identify and adhere to prescribed activity or medical precautions, which are typically identified in the medical record.

Occupational therapy evaluations consider similar content areas, but the specific characteristics of focus vary by the needs of the client, the practice setting, and the therapist's practice model.⁴³ Areas of concern to the occupational therapist include ADLs, instrumental activities of daily living (IADLs), occupations (noted later), client factors, and body functions; client habits, roles, and routines; the impact of culture, spirituality, social support, and the environment on function; and specific performance skills.⁴³ The evaluation process may include the use of standardized and/or nonstandardized assessments.⁷ Evaluation may proceed formally or informally. These considerations are encompassed in the two-part occupational therapy evaluation process that includes the occupational profile and the analysis of occupational performance.

Occupational Profile

The occupational profile section of the assessment provides information about the patient's occupational history, activity patterns, interests, values, and needs.⁷ These data inform the client-centered perspective by acknowledging the client's priorities and providing a picture for the therapist of what the client's life was like prior to injury. With time, a deeper appreciation of the client's occupational profile is gained, prompting ongoing evaluation and refinement of goals throughout the occupational therapy process. There are many assessment instruments that can guide the gathering of this information, and use varies by facility and guiding philosophies.⁴³ Commonly noted assessments include the Canadian Occupational Performance Measure (COPM)⁴⁴ and the Occupational Performance History Interview Second Version (OPHI-II).⁴⁵

Evaluation of Performance Skills

Occupational performance is the completion of occupations within the context of client factors, the occupational setting or environment, and the activity itself.⁷ Client factors include the client's beliefs, values, and spirituality; and his or her body structures and

functions. Body structures include vision and cardiovascular status (and the impact of these on the client's functional ability). Body functions include memory, ROM, and cognition. The client's contexts and environments are viewed from multiple perspectives, including the physical environment (architecture and accessibility), cultural influences (role in family structure), personal or demographic aspects (education level), temporal context (life span development issues), and virtual context (interactions that occur absent from physical contact). Activities or occupations within the scope of occupational therapy practice include ADLs, IADLs, rest and sleep, education, work, play, leisure, and social participation.⁷

The assessment of client factors includes UE ROM, strength, muscle tone, and sensation.⁷ The therapist also observes the patient's endurance, transfer ability to and from varied heights and places, trunk balance, bed mobility, sensation, muscle tone, and pain. The MMT⁴⁶ is most widely used to measure strength. The Functional Independence Measure (FIM)⁴⁷ is often used for grading the level of assistance required for ADLs. The Spinal Cord Independence Measure (SCIM) is a similar tool that provides sufficient sensitivity to demonstrate progress toward goals.⁴⁸

The assessment of hand function is of special interest in tetraplegia levels C5–C8 because the ability to use the hands implies a higher level of independence.^{22,27} A dynamometer and pinch meter may be used to measure strength, but some patients will need more sensitive tools to quantify strength and dexterity. Dexterity and grasp ability can be observed through manipulative tasks and the use of assessments such as the Sollerman Hand Function Test⁴⁹; Graded Redefined Assessment of Strength, Sensibility, and Prehension (GRASSP)⁵⁰; or the Jebsen Test of Hand Function.⁵¹ Readers are encouraged to refer to assessment indices for a comprehensive index of assessments utilized in occupational therapy evaluation as utilization choices vary.⁴¹

The connection between evaluation and intervention is the identification of goals.⁵² The hallmark of client-centered care is collaborative goal setting between the occupational therapist and client.^{25,52} Goals guide the progression in therapy, foster positive coping skills and participation, and yield functional gains.^{26,52}

Occupational Therapy Intervention

The manner in which occupational therapy intervention proceeds is client centered and designed to address the results obtained from the evaluation.^{7,9} Intervention is influenced by the patient's level and severity of injury, support available, the phase of care (acute care, rehabilitation, outpatient/community), and the phase in the life span.^{24,53} For example, a pediatric patient with SCI will need little rehabilitation time addressing home management tasks. Finally, each phase in the life span impacts the nature of SCI rehabilitation. SCI occurring during adolescence heightens the issues of personality development and puberty, and complicates transition to adulthood.^{12,54} Patients incurring SCI in their 30s may have a high-priority goal of resuming their parenting role.⁷ The greater frequency of SCI in the elderly presents concerns related to slower recovery and discharge planning.¹⁰

It is now estimated that more than half of SCI rehabilitation is conducted in the outpatient or community setting.^{24,55} This shift of care setting implies that certain occupations may or may not be addressed in the early phases of rehabilitation. Medical stabilization, basic ADLs, and preventative measures are the main focus of acute care.¹³ Often, occupational therapy in the acute care phase are of short duration and may serve to prepare the patient for the rehabilitation phase. Inpatient rehabilitation will likely explore more ADLs, IADLs, and discharge planning including a home evaluation.³⁹ Outpatient rehabilitation and beyond will address the occupations of education and work, leisure and play, and community reintegration and accessibility (in addition to those noted earlier). In areas where outpatient services are not available, ongoing

rehabilitation services may be conducted through home care or in a transition placement (skilled nursing facility) prior to returning to the home environment. Social participation should be addressed throughout this continuum, but appropriate to the situation. For example, social engagement in the community may be appropriate postrehabilitation once the patient's status has stabilized and new functional routines have been established.

Another way to characterize occupational therapy intervention is by the underlying objective. Five strategies have been identified in all occupational therapy intervention: health promotion, remediation and restoration, maintenance, compensation and adaptation, and prevention. Each of these strategies means different things in each phase of the rehabilitation process. For example, promoting health and preventing isolation by fostering engagement with the environment and care providers in acute SCI rehabilitation is vitally important, and this intervention looks very different when addressing these same objectives in outpatient therapy sessions.

The following sections provide a brief overview of the occupational therapy intervention process addressing the functional capabilities of patients and the key tasks and interventions of therapy at these levels.

Patient with High Tetraplegia: C1–C4

Patients with SCI at C1–C3 have intact functionally relevant musculature of the sternocleidomastoid, cervical paraspinal, and neck accessory muscles.¹³ As a consequence, active movement is limited to neck flexion, extension, and rotation. Patients with complete C1–C3 SCI require an external breathing device because their diaphragm is either paralyzed or only partially innervated (C3).^{5,13} The most common device for assisted breathing is the ventilator, a pneumatic electric machine that forces room air into the lungs. This device is attached to the patient via tracheostomy.

Patients with SCI at the level of C4 possess function in the upper trapezius and diaphragm musculature, meaning that they can generally elevate the scapula and breathe in.¹³ They require support with ventilation during acute care, but typically can be weaned eventually.

People with complete high tetraplegia are paralyzed from the neck down and require a high level of specialized care.^{5,9,13} The occupational therapist who works with this population must be comfortable with nursing procedures and ventilators. The rehabilitation team must also be well coordinated, simultaneously caring for the patient and family while providing education in preparation for discharge.

The role of the occupational therapist is limited in the traditional sense because of the involved nature of this injury. Patients with these injuries are dependent in ADLs.^{9,28} Occupational therapy may consist of teaching how to direct care, educating and engaging in decision making related to equipment, training in the use of a mouth stick, and exploring assistive technologies for environmental control¹³ (Fig. 39-2). Tilt-in-space power wheelchairs are required at this level for mobility and pressure relief and are fitted with high back supports and a chest strap to provide positional security.⁹

Figure 39-2 A 6-year-old girl with cervical spine injury using a mouth stick–paintbrush to engage in age-appropriate activities. Note the tracheostomy and attachment of portable ventilator and also the head rest on the electric wheelchair.

Positioning and ROM are important interventions at this phase for the monitoring and prevention of secondary issues, particularly the maintenance of skin integrity and joint mobility.^{5,22} To prevent ROM limitations, therapists use positioning techniques and ROM exercises. In bed, most persons with tetraplegia tend to lie with their arms adducted, internally rotated, and with elbows flexed and, over time, are at risk for contracture.⁵⁶ Positioning the UEs in either some abduction or external rotation, with elbow extension, within the patient’s tolerance, provides passive stretch to the shoulder and UE joints (Fig. 39-3). Hands are fitted with resting hand splints.^{9,13} There is also evidence in the literature of using FES with **ergometry** to maintain range, minimize muscle atrophy, and improve cardiovascular health.²²

Figure 39-3 Positioning in bed (*top image to bottom*). Views of prone and supine lying with shoulder abduction and external rotation. Side-lying with alternate upper extremity in shoulder abduction and external rotation with pelvic rotation. (Adapted and reprinted with permission from Paralyzed Veterans of America, Washington, DC.)

ROM to the hand of the patient with tetraplegia is performed in a special way to facilitate tenodesis grasp.²² Specifically, this includes passive opening of the fingers when the wrist is flexed and closing of the fingers when the wrist is extended (Fig. 39-4A and B). The patient and all caregivers should be taught how to perform ROM exercises to the UEs and hands, and positioning methods to hinder loss of joint mobility.

Figure 39-4 Tenodesis grasp. **A.** When the wrist is flexed, the fingers are extended. **B.** When the wrist is extended, the fingers are flexed. (Images courtesy DiSepio Institute, Saint Francis University.)

Patient with Lower Cervical Injuries: C5–C8

The lower the cervical injury, the more strength and function will be preserved in the UEs.¹³ Patients with a complete C5 injury possess function in the deltoids, biceps, brachialis, brachioradialis, rhomboids, and part of the serratus anterior. This musculature permits active shoulder flexion, extension, and abduction; elbow flexion and supination; and scapular adduction and abduction. Patients with C5 tetraplegia lack elbow extension, pronation, wrist and hand movement, and trunk and LE movement. Patients with C6 tetraplegia possess scapular protraction, some horizontal adduction, forearm supination, and radial wrist extension. Wrist flexion and elbow extension are absent. At C7–C8, elbow extension, ulnar wrist extension, wrist flexion, finger and thumb flexion and extension, and thumb abduction are present. Dexterity and grasp release are limited, but greater function is possible by virtue of active hand and wrist motion.¹³

Occupational therapy intervention includes positioning, splinting, and exercise as noted earlier, with the addition of strengthening exercises as proximal strength is increased.²⁸ Strengthening can be performed by weights, pulley systems, tabletop skateboards, suspension slings, and mobile arm supports.^{20,57} The mobile arm support, also called a ball-bearing feeder, is a mechanical device attached to the wheelchair that carries the weight of the arm and allows distal use of the UEs for task completion.^{13,57}

Research has demonstrated that corticomotor reorganization or neuroplasticity can be fostered through mass practice task training, somatosensory stimulation (SS) (low-level continuous electrical stimulation), and FES.^{22,58,59} Regimens of intense repetitive UE training using external FES devices or implants (“neuroprosthetic”) can facilitate reach-and-grasp activities.^{57–59}

Occupational therapists can effectively address patient functioning in the virtual realm and achieve functional goals through mass practice.⁷ Video games can be used to provide repetitive motion with the aim of increasing function, particularly in the hands of patients with tetraplegia.⁶⁰ Another example is the implementation of compensatory interventions to permit use of a smartphone in patients with tetraplegia.⁶¹ By modifying the environment (setup for phone use), adjusting phone settings, exploring wrist and hand compensatory techniques, using splints, and adapting styli, participation and socialization can be facilitated.^{27,61}

Patients with C5 Tetraplegia

Initially, the deltoids and biceps—key muscles for this level of injury—are weak, so upper limbs require support to function.¹³ The mobile arm support can assist the patient in driving the wheelchair, feeding, hygiene and grooming, and carrying out tabletop activities, such as writing.⁵⁷

Patients with C5 complete tetraplegia need a way to grasp and hold objects because their wrists and hands are paralyzed.²⁸ A stable wrist is required for grasp, and this is achieved with a splint or orthosis.^{13,20} A universal U- or C-shaped cuff can be secured to items (such as a phone or electric razor) to permit placement on the splinted hand for use^{28,39}(Fig. 39-5). Experimentation with alternate grasp patterns should be conducted to permit gross utilization of the hands²⁷ (Fig. 39-6A to C). To maximize functional gain with any device, the patient must have adequate time and repeated training sessions to strengthen musculature and adopt new movement patterns. Most patients with C5 tetraplegia can master tabletop activities, basic grooming tasks, and can assist with upper body ADLs.^{25,28}

Figure 39-5 Universal cuff to type: using devices to compensate for lack of ability to point and isolate finger movements. (Image courtesy DiSepio Institute, Saint Francis University.)

Figure 39-6 Hand compensatory techniques of an individual with incomplete C6 tetraplegia. **A.** Pressing one hand against the other to lift a bottle. **B.** Alternate grasp pattern to pick up coins. **C.** Dragging the coin to the edge of the table in order to pick it up. (Images courtesy DiSepio Institute, Saint Francis University.)

Patients with C6 and C7 Tetraplegia

Patients with C6 and C7 tetraplegia may attain significantly higher levels of independence than those with C5 injury.^{5,13,28} The addition of radial wrist extensors allows patients to close their fingers with a tenodesis grasp. A tenodesis grasp allows patients to pick up and hold light objects—a critical functional movement. The wrist-driven wrist–hand orthosis (also called the flexor hinge splint or tenodesis splint) is a metal device that transfers power from the extended wrist to the radial fingers, allowing a stronger pinch.^{13,25}

More fully innervated proximal scapular and shoulder muscles, such as the rotator cuff, deltoids, and biceps, allow for an increase in upper limb strength and endurance.¹³ Patients can use their arms to cross the midline forcefully and roll in bed with the addition of the clavicular pectoralis muscle.²⁸ The ability to use the triceps, the key muscle for C7 tetraplegia, allows the patient to reach for objects above head level, transfer with greater ease, and push a manual wheelchair on level surfaces. Generally, upper body ADLs can be completed, but assistance is required for lower body ADLs.

Patients with C8 Tetraplegia

Hand function is significantly improved with the addition of extrinsic finger muscles and thumb flexors, but still lacks dexterity and strength because of the absence of intrinsic finger and thumb muscles.¹³ A patient with complete C8 tetraplegia grasps objects with the metacarpophalangeal joints in extension and the proximal interphalangeal and distal interphalangeal joints in flexion. This is called a claw hand or intrinsic minus hand.¹³ Depending on the individual, lower body ADLs, transfers, and bowel and bladder care may require no assistance.²⁸ Wheelchair propulsion is functional on level surfaces.

Surgical Options for the Upper Extremities

The restoration of hand function is a top priority for all patients with tetraplegia.^{22,58,59} Patients with C5, C6, C7, or C8 injuries may have surgical options to provide improved function in the hands.^{22,62} Tendon transfer surgeries can be explored after all strength, and recovery has been realized following the SCI. These surgeries involve attaching a tendon from a functioning muscle to one that acts on the hand that is not functioning.^{22,62} This is often accompanied by the stabilization of the interphalangeal joint of the thumb and can provide improved use of the hands. The procedure changes the anatomy and function of the hand and requires muscular retraining for grasp and release. The best outcomes are a result of multiple characteristics including target range of SCI level, patient and surgeon characteristics, an absence of spasticity, and investment in postsurgical rehabilitation. It is believed that surgical options are underutilized in SCI rehabilitation.^{22,62}

Patient with Paraplegia

Typically, patients with paraplegia have fewer medical complications than those with tetraplegia.¹³ The lower the injury level, the greater the trunk strength and ease in resuming ADLs. Discharge from inpatient rehabilitation comes quickly, and ongoing support is offered from and within the community (outpatient services).²⁴ These interventions often include reassessing routines such as ADLs/IADLs within the context of broader functional environments, facilitating return to school or work, and exploring leisure interests and mobility in the community⁷(Fig. 39-7).

Figure 39-7 Vehicle transfer of an individual with incomplete C6 tetraplegia. (Image courtesy DiSepio Institute, Saint Francis University.)

Ambulation

Foremost in the minds of many with SCI is whether the ability to walk will be restored.^{13,20} Viewing the SCI as a whole, the simple answer is that very few individuals with SCI will be able to walk again without restriction.¹³ Walking potential is mainly determined by the level and completeness of the injury.^{13,25} For example, at 1-year postinjury, no patients with ASIA level A (complete) tetraplegia and about 5% of patients with paraplegia can ambulate. The opposite extreme are patients with ASIA level D injuries, 95% of whom achieve community ambulation at discharge from rehabilitation services.¹³ Additional factors that impact the ability to walk following SCI include body weight, age, prior ambulation status, UE involvement, and pain.¹³

Ambulation training with patients with complete SCI requires a great deal of effort, expense (orthoses), and energy on the part of patients, and many find the effort unreasonable for function.²⁰ Ambulation for those with incomplete SCI depends on the motor function below the lesion level; sensory sparing; strength and motor control in the UE, LE, and trunk; age; and the pattern of injury. Gait training may proceed in a more traditional manner utilizing FES, or utilizing robotics to support body weight while on a treadmill, and typically involves orthotics and assistive devices.²⁰

The ability to ambulate has been classified in four ways, which is also pertinent to this discussion.¹³ Community ambulators can ambulate 250 feet in a functional manner, with or without a device, and transfer from sit to stand independently. Household ambulators are able to ambulate within a safe structured home environment. Exercise ambulators walk short distances as a form of exercise and are not functional ambulators. Household, exercise, and nonambulators have progressively less ability to ambulate. The latter three categories require a wheelchair for mobility, in particular community mobility, and prescription of the right wheelchair is an important part of rehabilitation and discharge planning.

Ambulation carries unique challenges for the occupational therapist.⁷ To properly inform treatment planning, the occupational therapist must clearly understand ambulation goals, and this requires collaboration with the physical therapist.²⁰ Clarity in terms of the type of ambulation expected, whether the UEs will be needed to use an

ambulatory device, and whether LE braces will be utilized all have important implications on functional activities under the purview of occupational therapy (Fig. 39-8). Considerations related to falls and fall prevention should also be part of ambulation education and training.^{13,20}

Figure 39-8 Ambulation with equipment and assistance for an individual with incomplete C6 tetraplegia. This individual is not a functional ambulator, but rather ambulates for exercise and other health benefits. (Image courtesy DiSepio Institute, Saint Francis University.)

There are some additional tasks that are addressed at every level of occupational therapy in SCI rehabilitation, including patient and family education, wheelchair and equipment selection, and protecting the UEs.

Education and Personal Advocacy

Education is a vital part of SCI rehabilitation and should be prominent in every phase.⁶³ Education begins with the injury and should involve the patient and significant others. The patient with SCI should be trained to give explicit instructions to caregivers because most caregivers do not possess requisite experience with SCI. But there are many factors that hinder learning. Shortened hospitalizations restrict the time available to learn a vast amount of information. The stress of the injury limits readiness to learn and with time, when readiness improves, patients have been discharged to community settings where access to SCI expertise is often lacking.^{55,63}

It remains, however, that education is vital to maintaining health, improved QoL, and community integration.⁶³ Suggestions to facilitate learning in this fractured environment include the utilization of peer and group learning experiences, problem-based learning, using multiple teaching methods, and providing multiple opportunities to learn.^{55,63,64}

Education is also key to personal development, empowerment, and self-advocacy for individuals with SCI.⁶⁴ The nature of SCI places patients and caregivers in a position in which they must depend on others and can foster feelings of helplessness.^{4,64} Engagement has proven critical in successful outcomes for patients with SCI and must be part of the rehabilitation process.^{26,64} Engagement can begin by offering simple choices, encouraging the expression of preferences, and involving patients in problem-solving. Rehabilitation should focus on the patient's individual strengths and empower patients to attend to what they can do and adapt to what they cannot. The patient will

also need to weigh the value of activities and roles and identify those that provide the most personal gratification.⁴ This can mean accepting assistance with ADL tasks in order to conserve energy for other more valued activities.³⁹ Working through this process, and with time, most patients grow to develop effective coping skills and achieve mastery navigating the lifelong care needs related to SCI.^{4,26,55,64}

Wheelchair Use

Most patients with SCI require the use of wheelchairs for mobility.^{13,20} Selection of the best wheelchair requires expertise and has important implications for mobility, accessibility, and participation. Often, a medical equipment vendor is involved in this process. The therapist, patient, and family/caregivers must consider many factors when weighing the advantages and disadvantages of specific chairs.⁵⁶ How and where the wheelchair will be used must be identified. The appearance of the wheelchair is a consideration as is its weight. The patient's endurance, posture, availability of assistance, and means of transportation are factors that must all be addressed in the selection of a manual or power wheelchair (Fig. 39-9).

Figure 39-9 Individual with incomplete C6 tetraplegia in power wheelchair. The utilization of the power wheelchair saves wear and tear on shoulder joints. (Image courtesy DiSepio Institute, Saint Francis University.)

Shoulder Overuse

Because patients with SCI rely on their UEs for mobility through manual wheelchair propulsion, preventative care of the shoulders and UEs has great implication for function, well-being, and independence.^{22,56} Routine care, and patient and caregiver education, should address both frequent inspection of equipment to assure working order, and ergonomic review of transfers and the environment. Best practice dictates that risk of overuse be minimized by limiting the frequency of repetitive tasks and avoiding UE joint extreme position. Other recommendations include arranging for level transfers whenever possible—varying the technique so as to not stress one UE more than the other—and propelling the wheelchair using long, smooth strokes of the UE. For high-risk patients, consideration of a power wheelchair may be prudent.

Many trends are merging at this time in history related to the ability of the disabled to fully participate in society and live productive, meaningful lives. At the same time, shortened rehabilitation stays and access to and funding for care in the community

remain real obstacles to optimal outcomes.^{24,55,64} These factors, coupled with the philosophy of occupational therapy, provide exciting opportunities for our profession.⁷ As experts in the science of occupation, therapists possess the knowledge and understanding that can inform public policy and lifelong wellness initiatives for our clients. With ongoing advances in SCI research and technology, new opportunities will continue to present themselves, facilitating both the growth and evolution of occupational therapy, and the empowerment and full participation of our clients in the world in which we live.^{6,55}

CASE STUDY

Patient Information

Sheniqua is a 21-year old, African American college student who was involved in a violent altercation resulting in a fall down a flight of stairs. She reportedly lost consciousness at the scene. When she awoke at the hospital, she could not feel or move her LEs, and she reported pain in her left wrist. Diagnostic testing showed a spinal fracture at T10 with an ASIA grade A SCI and a left Colles fracture. In addition, Sheniqua was diagnosed with a concussion. She underwent spinal stabilization surgery, and her left wrist was casted. She began occupational and physical therapy in the hospital, but did not initially tolerate either well. Sheniqua experienced headaches and had difficulty concentrating, presumably due to the concussion.

Reason for Occupational Therapy Referral

Sheniqua is right-hand dominant. Upper body ADLs were impeded by the fracture and cast; transfers were also difficult for this reason and the T10 SCI. She required maximal assistance for lower body ADLs, and bowel and bladder care. Attention to task was impaired, and Sheniqua was easily frustrated.

Assessment Process and Results

Two weeks following her injury, Sheniqua was transferred to a nearby inpatient rehabilitation hospital. Her occupational therapy assessment found Sheniqua to require full set up for grooming and UE ADLs. She required maximal assist with lower body dressing, bathing, and level transfers. Bowel and bladder care required maximal assistance due, in large part, to the casted wrist. Her headaches subsided, and her concentration, memory, and follow-through were within functional limits. She experienced fatigue with minimal activity and was fearful about her future. Sheniqua required education related to all aspects of the SCI. The discharge plan was to return home with her family with her mother serving as her primary caregiver, and a long-term plan of returning to campus to complete her final year of undergraduate studies.

Occupational Therapy Problem List

- Requires assistance for wheelchair propulsion indoors (throughout facility, during ADLs, etc.).
- Requires full setup with grooming and UE dressing tasks.
- Requires maximal assist with lower body dressing from a seated position.
- Requires maximal assist with managing LEs during transfers.
- Transfers require maximal assistance.
- Activity tolerance is fair.
- Easily frustrated with current limitations, particularly with the restricted use of her left hand.

Occupational Therapy Goal List

- Propel wheelchair indoors within facility with modified independence.
- Complete grooming and UE ADLs with modified independence.
- Complete level transfers with a transfer board and minimal assistance.
- Don and doff pants with minimal assistance.
- Complete shower ADL with equipment and minimal assistance.

Intervention

- Daily ADLs with emphasis on bed mobility, bed transfers, and LE dressing.
- Progress to shower ADL using durable medical equipment likely to be used in the home environment.
- Modify wheelchair push rims to permit easier propulsion.
- Practice wheelchair propulsion particularly negotiating indoor barriers (small spaces, door thresholds, etc.).
- Transport self within facility from room to therapy department and back, and throughout facility.
- Practice shower transfers using shower chair.
- Educate Sheniqua and mother about durable medical equipment needed for discharge to home, precautions and secondary conditions, and preventative measures.
- Prescription and ordering of wheelchair.
- Training in use and care of wheelchair.
- Schedule overnight stay in facility's training apartment for Sheniqua and her mother prior to discharge to identify any concerns and have time to problem solve.
- Schedule and complete home evaluation and make recommendations to improve accessibility.

Best Evidence for Intervention for Spinal Cord Injury Used in Occupational Therapy

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Impact of clinical practice guideline for preservation of upper limb function on transfer skills of persons with acute spinal cord injury ⁶⁵	Participants were educated in transfer skills using structured protocol or provided standard care in these activities.	Volunteer sample of 70 full-time wheelchair users	Standard care or parallel training using structured protocol	Randomized controlled trial; Level I	Participants trained using the protocol performed higher quality transfers for stand pivot transfers and all dependent transfers.	At 1-year postdischarge, intervention group participants performed higher quality assisted sitting pivot transfers (mean \pm standard error [SE]: 9.43 \pm 0.55) compared with standard care group (mean \pm SE: 7.81 \pm 0.46) ($p = 0.026$).

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Effectiveness of group wheelchair skills training for people with spinal cord injury: a randomized controlled trial ⁶⁶	Use of group training to train wheelchair mobility skills	114 manual wheelchair users with SCI	Six 90-minute group wheelchair skills sessions vs. two 1-hour active control group sessions	Randomized double-blind controlled trial; Level I	Group training can lead to improvement in wheelchair skills, particularly in those having attended more classes and possessing lower baseline skills.	Compared with control group, the wheelchair skills group improved in performance ($p = 0.02$).
A synthesis of best evidence for the restoration of upper extremity function in people with tetraplegia ²²	Electrical stimulation and surgical intervention to improve grasps function	43 studies	Dosage unspecified	Review; Level I	Both electrical stimulation (with assistive technologies) and surgical intervention enhance functional abilities for individuals with tetraplegia.	NA
Effects of practice combined with somatosensory or motor stimulation on hand function in persons with spinal cord injury ⁵⁸	FES, SS, and task training to improve hand function and cortical excitability	24 participants with chronic tetraplegia	Control group assignment or assignment utilizing FES or SS	Randomized controlled trial; Level I	Hand training associated with SS or FES was associated with improved hand use and cortical excitability.	Control group did not improve as demonstrated by an increase in time (mean [standard deviation or SD] change = 9.52 [45.55] seconds); the intervention group improved as demonstrated by a decrease in time (mean [SD] change = -71.63 [100.16] seconds); effect size = -81.14 seconds.

Chapter 40

Cardiac and Pulmonary Diseases

Midge Hobbs

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the most common cardiac and pulmonary diagnoses, including clinical presentation and symptoms.
2. Identify the role of occupational therapy in evaluating, planning, and treating individuals with cardiac and/or pulmonary disease.
3. Describe the common risk factors for cardiac and/or pulmonary disease and determine the most appropriate educational strategies to ameliorate their effect.
4. Define common terminology and procedures, including diagnostic tests, pertaining to cardiac and pulmonary rehabilitation.
5. Recognize the signs and symptoms of exercise/activity intolerance and its impact on occupational performance.
6. Determine the most appropriate interventions to maximize an individual's functional independence.

CHAPTER OUTLINE

Introduction

Description of Cardiac Disease

Functional Impairment in Daily Occupation Resulting from Cardiac Disease

Evaluation and Intervention of Functional Skill Deficits Secondary to Cardiac Disease

Description of Pulmonary Disease

Functional Impairment in Daily Occupation Resulting from Pulmonary Disease

Evaluation and Intervention of Functional Skill Deficits Secondary to Pulmonary Disease

Case Study

TERMINOLOGY

Angiogram: diagnostic imaging technique used to evaluate arterial blockages and typically conducted under sedation; the most common interventions provided during an angiogram are stent placement and balloon angioplasty.¹

Arterial blood gas (ABG): test to provide information about the acidity (pH) and the partial pressures of specific gases such as oxygen (PaO₂) and carbon dioxide (PaCO₂) in the blood.²

Atherosclerosis: slow progressive disease typified by arterial thickening and hardening commonly caused by hypertension, high cholesterol, tobacco use, diabetes, or obesity; atherosclerosis is a form of arteriosclerosis that specifically refers to increased lipids, cholesterol, or other substances that restrict arterial blood flow.³

Coronary artery bypass graft (CABG): cardiothoracic surgical procedure used to improve blood flow to the heart by diverting blood around narrowed or restricted arteries; a healthy artery or vein is harvested from the body and used as a graft to bypass blockages in the coronary arteries; surgery can be performed for multiple vessel disease.⁴

Dyspnea: shortness of breath or difficulty breathing that is commonly an indicator of airway, lung, or heart dysfunction.

Echocardiogram (echo): noninvasive test that uses sound waves to produce images of the heart and determine the cause of heart disease; often used to assess overall cardiac performance as well as more specific concerns such as unexplained chest pain, arrhythmias, or heart valve function.⁵

Ejection fraction (EF): measurement of the percentage of blood leaving the ventricles during each contraction, often used to diagnose and track heart failure; a normal EF reading is typically between 50% and 70%; an EF under 40% may be evidence of heart failure.⁶

Electrocardiography (ECG/EKG): painless diagnostic test used to measure the heart's electrical activity via electrodes attached to specified areas of the body; commonly performed to assess unexplained chest pain; to check the condition of the heart in the context of disease such as hypertension, high cholesterol, smoking, and diabetes; and to diagnose heart disease.⁷

Gas exchange: the primary role of respiration or gas exchange is to deliver oxygen from the lungs to the bloodstream; the process occurs via simple diffusion and takes place in the alveoli in the lungs and the surrounding capillaries; as oxygen moves from the alveoli to the blood, carbon dioxide is transferred from the blood in the capillaries to the alveoli and is breathed out via the lungs.⁸

Hypoxemia: abnormal low levels of oxygen (O₂) in the blood, typically below 90%, indicative of breathing or circulatory disorders; without sufficient O₂, the brain, liver, and other organs may be damaged.

Interstitial: lace-like network of supportive tissue that extends throughout both lungs; chronic inflammation of the interstitium changes the lung's ability to function well, impacting gas exchange.⁹

Noninvasive positive-pressure ventilation (NIPPV): a means of delivering ventilation without the need for invasive procedures like intubation or a tracheostomy; bilevel positive airway pressure (BiPAP) and continuous positive airway pressure (CPAP) are the most common options that deliver pressurized air via a tube to a nasal or facial mask worn over the nose and mouth.¹⁰

Oxygen saturation (O₂ sat): measurement of the amount of oxygen carried by the hemoglobin in the blood; a normal O₂ sat is greater than 95%.¹¹

Percutaneous coronary intervention (PCI): nonsurgical reperfusion procedure, also known as coronary angioplasty, that uses a catheter to open an occluded vessel or place a stent in order to improve blood flow to the heart; most commonly used with an ST-segment elevation myocardial infarction (STEMI).¹²

Pneumothorax: accumulation of air, gas, or blood in the pleural space causing the lung to collapse or partially collapse causing chest pain and difficulty breathing.¹⁴

Pulmonary function test (PFT): an assessment of gas exchange, typically via a spirometer; lung volume measurements indicate lung elasticity and respiratory muscle strength; flow rates indicate the degree of airway narrowing or obstruction.¹⁵

Pursed-lip breathing: technique used to slow breathing rate by prolonging exhalation in order to manage shortness of breath; clients are encouraged to breathe in slowly and normally through the nose for a count of two before exhaling through pursed-lips while counting to four.⁸

Sternotomy: procedure used in open heart surgery; the sternum is split in two allowing the surgeon access to the chest cavity and is wired back together postsurgery.¹⁶

Introduction

Cardiovascular disease is an umbrella term that includes conditions affecting the blood vessels such as coronary artery disease (CAD), heart rhythm issues such as arrhythmias, and congenital defects. Although hospitalizations and deaths associated with heart disease have declined in the United States over the past decade—because of an increase in evidence-based practice and medications, as well as initiatives to promote heart-healthy lifestyles—it remains the number one cause of death for both men and women, killing more than 600,000 Americans annually and spanning most racial/ethnic groups.¹⁷ Advancing age remains one of the most significant factors for increased risk of heart disease.¹⁸ Although many occupational therapists may not work primarily in cardiopulmonary rehabilitation, many therapists working in physical medicine settings will encounter adults with limitations associated with cardiac or pulmonary disease; it is important to understand occupational therapy's (OT) role in these clinical areas and be prepared to provide appropriate services.¹⁹

Description of Cardiac Disease

Hypertension

Hypertension (HTN), or high blood pressure, is a common condition determined by a resting systolic blood pressure of 140 mm Hg or more, and/or a diastolic pressure of 90 mm Hg or more, on repeated examination. Without appropriate medical management, the persistent high force of blood pumping through the blood vessels places significant stress on the heart, increasing the risk of serious health problems such as CAD, myocardial infarction (MI), and stroke.²⁰ HTN is either the primary or contributing cause of almost 1,000 deaths each day in the United States²¹ and is commonly called the silent killer because it is typically asymptomatic; a high blood pressure measurement is often the first indication of the condition. HTN is classified by its degree of severity, which guides treatment, but family history and additional risk factors, such as stress, sodium intake, obesity, excessive alcohol consumption, overuse of nonsteroidal anti-inflammatory drugs (NSAIDs), and corticosteroids must also be considered.²⁰ Treatment focuses on lowering blood pressure and includes a medication regimen and lifestyle changes.²²

Coronary Artery Disease

CAD is one of the most common cardiac-related disorders. In the United States, approximately 370,000 deaths are attributed to the disease annually, with the majority of individuals affected over the age of 65.²³ CAD is an ischemic disease, commonly attributed to **atherosclerosis**, a buildup of fatty, fibrous plaque in the arteries that can progressively narrow vessels over time and occlude blood supply to the heart muscle, increasing the risk of significant health-related issues, including angina pectoris, MI, and heart failure. Restricted blood flow or blockage may also trigger a heart attack, and if blood supply is not restored promptly, cardiac tissue will begin to die, which may result in death. Genetic predisposition or a family history of heart disease may increase the likelihood of developing CAD, but additional risk factors include HTN, high cholesterol, diabetes mellitus, obesity, and smoking. Stress and the ability to manage stress may also contribute to the development of CAD—not only do these increase workload on the heart muscle, but they may also lead to unhealthy behaviors.²⁴

CAD is commonly diagnosed through a detailed medical history, physical examination, and diagnostic tests that may include an **echocardiogram** (echo) to assess the heart's effectiveness, a stress test to determine the heart's response to increased activity demand,

and/or cardiac catheterization or **angiogram** to determine potential blockages.^{1,5} Individuals may be asymptomatic during the early stages of the disease, which is commonly treated by controlling risk factors.²⁵ Angina pectoris is a complication of CAD that may develop as arteries continue to narrow over time reducing blood supply. This causes the heart muscle to constrict with increased activity demand, such as exercise, eating, or stress, causing discomfort or pain in the chest or left shoulder, arms, neck, back, or jaw. Other symptoms include shortness of breath, nausea, a rapid or irregular heartbeat, diaphoresis, or a feeling similar to indigestion.²⁶ Typically, women's angina symptoms are less easily identified and may include significant fatigue, sleep disturbance, and anxiety.²⁷

Angina is commonly classified as either stable or unstable. Stable angina occurs more predictably during periods of exertion or stress. Episodes last approximately 2 to 15 minutes and resolve with rest or medication. Unstable angina typically occurs when more than 70% of arteries are occluded, and symptoms can occur at rest without any notable cardiac demand. Treatment includes nitrates or beta-adrenergic blockers that dilate vessels. Symptoms of angina are similar to those of a heart attack, and immediate medical attention is imperative if symptoms persist longer than 15 minutes or there is no response to prescribed medication. With significantly narrowed or blocked vessels, a more invasive treatment may be indicated to alleviate angina and minimize the risk of MI. Treatment includes **coronary artery bypass graft (CABG)** surgery to circumvent blocked vessels. Alternately, **percutaneous coronary intervention (PCI)**, also known as coronary angioplasty, with or without stent placement may be indicated to open the artery.¹⁶

Acute Coronary Syndrome

Acute coronary syndrome (ACS) is an umbrella term that includes unstable angina and acute MI, which is the irreversible damage to heart muscle as a result of coronary artery obstruction or prolonged lack of oxygen to cardiac tissue (see Fig. 40-1).²⁸ If blood flow is not restored quickly, cardiac muscle begins to die and the infarction may be fatal.²⁹ In the United States, someone has a heart attack every 43 seconds. One in five infarctions is asymptomatic, and around 50% of individuals experiencing an MI die within an hour after onset before they reach the hospital. Men are more likely to experience an MI than premenopausal women, although the risk increases after menopause. About half of all Americans have at least one of the three risk factors that may contribute to heart disease and increase the possibility of an MI. These include HTN, high cholesterol, and smoking.³⁰

Figure 40-1 Coronary artery circulation. Lower inset shows a myocardial infarction resulting from coronary arterial blockage. AV, atrioventricular; SA, sinoatrial.

Infarction is tissue death that occurs in response to one or more coronary occlusions. Infarction may occur as a result of an atherosclerotic rupture that leads to thrombus formation, which, in turn, plugs the artery and obstructs blood flow to the heart. In many cases, the vessels may already be narrower if there is underlying atherosclerosis. Classification of an acute MI is designed to assist rapid decision-making and is based on the presence of serum markers in the blood, symptoms of ischemia, and imaging results. The three classifications include unstable angina and two types of MI: non-ST-segment elevation MI (NSTEMI) and ST-segment elevation MI (STEMI), which are determined by the presence or absence of ST-segment elevation or Q waves on an electrocardiogram (ECG/EKG) (see Fig. 40-2). In cases of NSTEMI, there may be ST-segment depression and/or T-wave inversion, and blood tests will show cardiac markers, troponin I or troponin T and creatine kinase-muscle/brain (CK-MB), to be elevated. In cases of STEMI, ECG changes will show ST-segment elevation as well as elevated cardiac markers.³⁰ The severity of an infarction depends on several factors, such as the extent of the arterial occlusion, the duration of the blockage, and whether there is collateral circulation. Typically, the more proximal the blockage, the more likely there will be extensive myocardium tissue necrosis.³¹ Although the immediate prognosis is better for individuals with an NSTEMI, they are often at higher risk for further cardiac events owing to the extent of the underlying heart disease.³¹

Figure 40-2 Electrocardiogram (EKG/ECG).

Some individuals are asymptomatic during a heart attack, but there are several characteristic warning signs associated with an infarction, although these often differ between men and women. Symptoms include significant chest pain often described as pressure, fullness, or a squeezing sensation that may radiate into the jaw, shoulders, left arm, and/or upper back. Additional symptoms may include **dyspnea**, diaphoresis, epigastric discomfort with nausea or vomiting, syncope, and impaired cognition. Evaluation begins with serial **electrocardiography (ECG/EKG)** that shows the electrical activity of the heart, identifies the location of damaged cardiac muscle, and helps to determine whether or not an individual is having a heart attack. An ECG will also help doctors differentiate between unstable angina, NSTEMI, or STEMI, in order to provide appropriate medical care.^{30,31}

Treatment focuses primarily on restoring coronary blood flow and recovering functional myocardium. Once diagnosis is confirmed, intervention is determined by the clinical picture and prognosis. Medication is most often the mainstay of therapy. Typical drugs include thrombolytic agents to revascularize tissue, antiplatelet drugs to prevent new clots forming or existing clots from growing larger, and beta-blockers to relax cardiac muscle, decrease blood pressure and myocardial demand, and minimize heart muscle damage. Additional medications include angiotensin-converting enzyme (ACE) inhibitors to lower blood pressure and minimize the stress on the heart, antiarrhythmics to manage ventricular arrhythmias, and pain medication such as morphine to ease discomfort. Surgical interventions include PCI and stenting. PCI is the preferred reperfusion intervention for individuals with STEMI, provided it can be performed within 90 minutes of admission to the hospital. For others, CABG may be indicated when arterial disease is severe and an individual cannot undergo PCI.¹²

Even if blood flow is successfully restored, individuals who have experienced MI may remain in the hospital until medically stable. Additional treatment focuses on minimizing complications, restoring normal function, and exploration of lifestyle modifications to reduce risk factors. Once discharged, treatment may include cardioprotective medications, cardiac rehabilitation, and ongoing dietary/lifestyle education.³² Several lifestyle modifications have been shown to strongly decrease risk for recurrent MI and minimize the progression of cardiac disease, including adoption of a low-fat and low-sodium diet, smoking cessation, and increased physical activity. However, prognosis varies according to age and clinical picture, including the presence or absence of risk factors. Many individuals continue to live full active lives with appropriate lifestyle changes and medical management.

Congestive Heart Failure

Congestive heart failure (CHF) is a complex diagnosis that results from impaired structure and/or function of the ventricles and affects the heart's ability to pump. The heart muscle becomes stretched beyond its ability to contract efficiently, resulting in the collection of fluid in the lungs or the extremities, hence the term congestive heart failure (CHF). The condition often affects both sides of the heart; however, one side may be more affected than the other. Although both left-sided and right-sided dysfunction share similar clinical traits, left ventricular dysfunction typically presents with increased fatigue, shortness of breath, and pulmonary edema; right-sided dysfunction is notable for peripheral and/or abdominal edema. Left-sided or right-sided heart failure may be the result of either systolic dysfunction, whereby the heart is unable to contract efficiently, or diastolic dysfunction when cardiac muscle is unable to relax.³³

Seventy-five percent of individuals with CHF have a history of HTN that leads to diastolic dysfunction; as the heart pumps more forcibly at a higher pressure, the cardiac walls thicken, leading to ventricle hypertrophy, which makes oxygenating the heart

muscle even more difficult and may lead to ischemic damage. Additionally, an acute ischemic event such as an MI may destroy tissue, contributing to cardiac inefficiency. The most common etiology for systolic dysfunction is CAD, typically caused by a combination of factors; as vessels narrow over time limiting the flow of oxygenated blood to the heart, cardiac muscle weakens impacting its ability to contract. Unhealthy lifestyle factors may also increase the risk for developing heart failure. Approximately 5.7 million American adults have a diagnosis of CHF, and each year, 1 million hospitalizations are attributed to the disease.³⁴

Under stress, the body releases hormones designed to increase cardiac output. However, with sustained response to the stress of chronic conditions such as CAD or HTN, the heart ultimately becomes weaker with a notable impact on stroke volume and a further decrease in cardiac output. The body responds by triggering compensatory mechanisms that include structural changes to the heart muscle wall. As the heart works harder, its walls thicken and enlarge in order to contract more forcefully. Although this measure may increase stroke volume in the short term, the tissue ultimately stiffens with effort, thereby decreasing its effectiveness over time. Additionally, decreased renal perfusion causes a release of the renin–angiotensin–aldosterone–vasopressin system (antidiuretic hormone [ADH]), which promotes sodium and water retention, ultimately leading to volume overload. Initially, retaining salt and water instead of excreting it into urine helps to increase heart function and regulate blood pressure and organ perfusion, but chronic activation is detrimental to cardiac efficiency. Over time, the effort weakens cardiac muscle, worsening the heart failure.³⁴

Heart failure may begin with an acute onset or progress slowly and become chronic, although many cases are initially asymptomatic. Heart failure symptoms are classified in stages from mild to severe. Even when both left and right sides of the heart are compromised, one side will likely dominate in terms of presentation. In the majority of cases, left-sided heart failure will lead to right-sided dysfunction. Although both right-sided and left-sided heart failure produce different symptoms, the most common symptoms associated with the disease are shortness of breath, fatigue, and muscle weakness. In severe cases, individuals may also experience a rapid or irregular heart rate, which should be considered a medical emergency requiring immediate help. Diagnosis is typically determined through a complete medical history with a thorough physical examination. Additional procedures are used to support the diagnosis, which typically includes an ECG to determine heart rhythm irregularities, ascertain whether there are structural changes in the ventricles, or assess valve function. An ECG may also help determine if heart failure is the result of systolic or diastolic dysfunction by assessing the thickness and stiffness of the heart wall and the **ejection fraction (EF)**. A normal ventricle ejects approximately 60% of its blood. An EF below this percentage confirms systolic heart failure. A normal EF suggests diastolic dysfunction.³⁴

Although CHF is considered a chronic condition that can be managed long term with appropriate medical care and lifestyle changes, much depends on the severity of the condition and which treatment options are applicable. Medications and lifestyle changes are often the cornerstone of treatment plans, while surgical interventions may also be indicated. In acute heart failure, such as the development of pulmonary edema, individuals commonly require supplemental oxygen alongside diuretics to decrease edema. Lifestyle changes can also help minimize symptoms and slow disease progression.³⁴

Functional Impairment in Daily Occupation Resulting from Cardiac Disease

Whether cardiac disease presents as an acute health crisis or a chronic condition, symptoms can often limit function, leading to loss of independence and a decline in

confidence.³⁵ Structural changes, or increased workload to the heart, are often characterized by the clinical symptoms of shortness of breath and fatigue, which may significantly impact an individual's ability to perform self-care activities, participate in instrumental activities of daily living (IADLs), including work and leisure activities, as well as fully engage in social relationships. In addition, edema, commonly associated with volume overload and CHF, may impact general mobility and sleep, particularly with increased fluid in the lungs. In the elderly, research indicates that heart failure also has an impact on memory and recall, attention, and the capacity for new learning. The effects on function may include an inability to manage the disease appropriately, or problem-solve daily routines and challenges. A decline in function may also lead to anxiety, decreased self-esteem, and depression.⁹ In cases of open heart surgery or CABG where a **sternotomy** is performed, individuals may also be limited by precautions impacting function. These include weight-bearing restrictions, no excessive twisting or turning, and a lifting limit, all of which affect participation and ability to perform self-care tasks and IADLs, including driving.³⁶

Evaluation and Intervention of Functional Skill Deficits Secondary to Cardiac Disease

Individuals with cardiac disease benefit from an interprofessional approach that may include physicians, nurses, occupational and physical therapists, dietitians, chaplains, psychologists, and social workers, depending on the availability. Collaborative practice is integral to providing safe, quality, accessible, and client-centered care and includes four competencies:

1. Understanding one's role and those of other professionals to assess and address the needs of clients and populations served
2. Maintaining a climate of mutual respect based on shared values and ethical principles
3. Providing responsible and timely communication with clients, caregivers, communities, and other health care providers
4. Applying relationship-building values to maintain healthy team roles in order to plan and deliver effective client-centered health care¹⁰

OT plays a distinct role in interprofessional practice to address cardiac disease across the continuum from acute care to inpatient rehab to home care.³⁷

In order to understand an individual's performance strengths and limitations, an occupational therapist will use his or her clinical reasoning skills to perform an evaluation that may include a synthesis of formal standardized assessment tools, such as the Functional Independence Measure (FIM), to evaluate activities of daily living (ADLs) and medical data. Informal observation and interview of patients, along with information obtained through interprofessional communication, will also be used in evaluation. Many individuals who have experienced a life-threatening cardiac event or disease progression and undergone lifestyle changes also benefit from OT intervention to help with psychosocial adjustment to their new situation. Therefore, in addition to performance skills impacting motor, cognitive processing, and/or social interaction, it is also important to address client factors and performance patterns—such as values and beliefs, and roles and routines—as well as environmental and contextual factors to reflect OT's holistic approach to caring for the client with a history of cardiac disease.³⁸

By synthesizing all pertinent data, the therapist is able to develop an occupational profile that will guide the plan of care. This includes collaborating with the client and/or caregiver to determine his or her priorities regarding outcomes in order to develop objective and measurable goals that are meaningful and client centered. Once goals have been established, interventions may be determined to execute the plan of care.¹¹ The

occupational therapist's expertise in the rehabilitative process across the continuum, as well as knowledge of comorbid diseases, is extremely important when evaluating and adapting treatment for the individual needs of patients with cardiac disease.

The goals of inpatient cardiac rehabilitation are to prevent muscle loss from bed rest, monitor and assess the patient's ability to function, instruct the patient in appropriate home activities, educate the patient about individual risk factors, and teach methods to minimize risks.

Evidence indicates that limited mobility is a significant contributor to long-term health issues, including muscle weakness, delirium and cognitive impairments, and joint shortening. Research suggests that safe and appropriate early mobility can significantly improve functional outcomes.³⁹ Therapists treat each patient at least once a day as soon as the patient's medical status has stabilized, often within the first 24 to 48 hours after admission, and hospital stays for cardiac events have declined significantly in the past 10 years. The average hospital stay is 1 day for the uncomplicated NSTEMI, 2 to 3 days for STEMIs, and 3 to 7 days for open heart surgery. During any activity, physical measurements of heart rate, blood pressure, EKG response, and symptoms are noted. Many occupational therapists working in acute care or cardiac rehabilitation participate in training courses to read EKGs.³⁹

Despite finding their ability to perform basic ADLs compromised by fatigue, dyspnea, and decreased activity tolerance, individuals with cardiac conditions are encouraged to participate in self-care re-training that will include energy conservation techniques and recommendations to modify tasks, such as adjusting body mechanics to minimize fatigue and work of breathing. Additionally, altering the environment to reduce extraneous effort and decrease activity demand, or using adaptive equipment to maximize functional independence, may be indicated. Dressing equipment may include items such as a long-handled shoe horn or sock aide, while a tub seat may be recommended to minimize time standing during a shower. In addition to encouraging participation in functional activities, an exercise routine may also be introduced. For example, individuals following bypass or with a diagnosis of CHF may begin with a program of mild calisthenics consisting of 2-minute bouts interspersed with 1-minute rest. As the patient progresses, the amount of exercise time typically increases to 8 to 10 minutes. For individuals who have had NSTEMIs, STEMIs, or PCI with stents, the therapist may incorporate hall walking or treadmill use in addition to ADLs. Regardless of the modality used, activity demand progression is based on the patient's tolerance and diagnosis with continued monitoring of vitals.

Upon discharge from the hospital or rehab facility, each patient is given a tailored home program based on diagnosis, individual needs, and circumstances. The general components of a home program are activity and exercise guidelines for all meaningful activities, including IADLs such as home management, shopping, meal preparation, leisure tasks, transportation, social activity, and sexual relations. Signs and symptoms of exercise intolerance and a discussion of disease risk factors are included in the educational process. Examples of recommendations include making larger meals to freeze, letting dishes air dry, grouping task items together to minimize unnecessary searches, sliding items on countertops rather than carrying them, shopping with someone who can carry bags, or using grocery home delivery services.

Individuals who have had open heart surgery, a diagnosis of CHF, or experienced an STEMI are often provided with more specific instructions. For example, individuals who have undergone a CABG often have pain and require analgesics, which may impact retention and application of new information. Postoperative patients will have specific precautions defined by the surgeon, which typically include avoiding lifting, pushing, or pulling greater than 10 lb for 6 to 12 weeks. Therapists should make recommendations for alternative ways of performing activities to avoid breaking sternal precautions, such

as opening a heavy door or lifting objects such as a coffee pot with two extremities versus one (see Fig. 40-3). Patients who complain of feeling sternal shifting or clicking are told to avoid the activity that causes it and to stop any upper extremity (UE) exercises. In addition to the potential physical responses postsurgery, such as sternal discomfort and fatigue, individuals are also given information to highlight the possible emotional responses they may expect during the healing process, such as depression. Education may also address affection and intimacy. After open heart surgery, it is generally suggested that patients wait 6 to 8 weeks before resuming sexual intercourse and then begin with alternate positions to minimize strain on the sternum, such as side-lying or sitting in a chair facing each other.⁴⁰

Figure 40-3 Sternal precautions: Lifting with two hands.

Patients with a diagnosis of CHF often experience significant endurance limitations. Consequently, home programs emphasize energy conservation strategies and work simplification in addition to light exercise programs. Education also includes daily monitoring signs and symptoms of worsening medical status, such as increased edema and shortness of breath.

A home program for a patient who has had an STEMI typically focuses on evaluating activity/exercise tolerance and determining the correct energy expenditure during recovery. Depending on the amount of damage sustained, heart muscle healing takes about 2 to 4 weeks, and patients are asked to restrict activities to the 2 to 4 MET range during this time. METs, or metabolic equivalents, are a unit of measure used to describe the amount of oxygen the body needs for a given activity. Values are approximate and do not include environmental factors or skill level. Generally, the more the body moves and has to work against resistance, the higher the MET (see Box 40-1).⁴¹ Energy conservation and work simplification strategies are the cornerstone of cardiac education, which includes prioritizing tasks, reorganizing the environment to access necessary items with minimal exertion, and using adaptive equipment. Depression and sexuality are discussed because certain cardiac medications can significantly impact mood as well as sexual function and desire. The American Heart Association suggests that post-MI patients who can tolerate activities between 3 and 5 METs without symptoms are ready to resume sexual relationships.⁴⁰

Box 40-1

MET Values for Various Activities

Home	Leisure and Vocational	Exercise and Sports

1.0–2.5 METs		
Sweeping floors Dusting Straightening up Serving food Table setting Knitting and crocheting Putting away groceries Making bed Standing quietly in line Mowing lawn with a riding mower Sexual activity (general, moderate effort) Dressing and undressing Sleeping Watching TV Dish washing Bathing-sitting Changing light bulbs Hairstyling–Standing	Power boating Fishing from boat Pumping gas Typing, computer Sitting for light office work Card playing, sitting Board games Playing piano or organ Driving tractor Sewing with a machine Driving an auto or truck Sitting to study, read, or write Casino gambling–standing	Walking at slow pace Playing catch with a baseball or football Horseback riding, walking
2.6–4.0 METs		
Child care bathing and grooming Walk, run, and play with children (moderate) General house cleaning Walking downstairs Sweeping garage or sidewalk Raking lawn Walking and carrying load of 15 pounds	Pitching horseshoes Home auto repair Planting seedlings and shrubs Playing the drums Home wiring or plumbing Feeding small farm animals Standing doing light-to-moderate effort. Bartending–standing Walking and picking up yard Sailing Motorcycle riding	Very light stationary biking Weight lifting of light-to-moderate effort. Stretching, yoga Golf using a cart Snowmobiling Walking at moderate speed Water aerobics Walking pushing a wheelchair Bicycling (<10 mph) Activity videos moderate effort (i.e., Wii Fit™ aerobics and weight training) Curves™ exercise for women
>4.0–6.0 METs		
Major house cleaning, such as washing windows, vigorous effort Moving furniture Scrubbing floors on hands and knees Cleaning gutters Painting the outside of house Painting and wallpapering inside of house Weeding or cultivating Walking carrying a 15-pound load	Laying carpet or tile Slow wood chopping Farming, feeding cattle Carpentry on outside of house Carpentry, refinishing surfaces Hunting-general Road building, carrying heavy loads Roofing Golf, carrying clubs	General calisthenics, moderate effort Shooting hoops Softball, fast or slow pitch Low-impact or dance aerobics Dodgeball or hopscotch Bicycling (10-11.9 mph) Walk/jog (with jogging part less than 10 minutes) Elliptical, moderate effort.
6.0–10 METs		
Carrying groceries upstairs Moving household items in boxes Shoveling more than 16 pounds per minute (heavy) Walking or standing with objects weighing 50–74 pounds	Farming, bailing hay Concrete masonry Moving heavy objects such as furniture Firefighter carrying hoses	High-impact aerobics Running 10–12 minutes/mile Basketball game Jump roping Race walking Swimming laps at a moderate pace Bicycling at moderate pace (> 12 mph)

From Ainsworth, B. W., Haskell, W. L., Herrmann, S.D., Meches, N., Bassett, D. R., Jr., Tudor-Locke, C., Greer, J.L., Vezina, J., Whitt-Glover, M. C., & Leon, A. S. (2011). Compendium of physical activities: A second update of codes and met levels. *Medicine & Science in Sports & Exercise*, 43, 1575–1581; Ainsworth, B. W., Haskell, W. L., Leon, A., Jacobs, D., Jr., Montoye, H., Salis, J., & Paffenbarger, R. (1998). Compendium of physical activities: Classification of energy costs of human physical activities. In J. Roitman (Ed.), *ACSM's resource manual for exercise testing and prescription* (pp. 656–667). Baltimore, MD: Williams & Wilkins.

Many patients who have experienced a PCI, MI, CABG, or valve replacement/repair are often referred to outpatient cardiac rehabilitation to continue skilled monitoring of exercise, risk factor education, and modifications. Individuals may also benefit from

home OT to support a safe transition as well as to ensure appropriate application of educational strategies for identified lifestyle changes. Goals vary according to individual needs and are often dependent on heart function, physical condition, and circumstances.

Stress and anxiety are common by-products of cardiac disorders and life-threatening events such as MI. Providing education to help individuals manage their symptoms in the context of daily routines is an important step in lessening anxiety and promoting participation in the treatment program, as well as improving outcomes.⁴² Interventions include strategies to help clients prioritize activities and create a balanced lifestyle, increase awareness of body-and-mind interaction to manage stressors and perform daily activities with more confidence, and provide education on a variety of relaxation methods (e.g., guided imagery, progressive muscle relaxation, and diaphragmatic breathing). Many therapists use standardized questionnaires to determine depression or anxiety such as the Beck Depression Inventory or the Center for Epidemiological Studies Depression Scale.⁴³ Testing results will indicate whether a referral to a chaplain, social worker, or psychologist is needed based on patient circumstance or preference.

Cardiac rehabilitation education may also include medication management training, exploration of healthy leisure pursuits to promote lifestyle balance, and information regarding community resources. Emphasis should also be placed on managing controllable risk factors, such as smoking, hyperlipidemia, HTN, sedentary lifestyle, and obesity. Smoking is a major modifiable risk factor that contributes to heart disease in multiple ways. The incidence of heart disease is two to four times higher in people who smoke than in nonsmokers.⁴⁴ Smoking damages the endothelial lining of the coronary arteries, making them more susceptible to plaque formation. Nicotine causes arterial vasoconstriction and increases heart rate. Smoking makes the heart more susceptible to lethal ventricular arrhythmias and predisposes it to coronary artery spasm.⁴⁵ Carbon monoxide in cigarette smoke binds with hemoglobin faster than oxygen, resulting in decreased oxygen distribution to tissues. Nicotine alters the metabolism of fats, increasing the levels of atherogenic low-density lipoprotein (LDL) cholesterol and decreasing the levels of the heart-protective high-density lipoprotein (HDL) cholesterol. Smoking also causes the blood to coagulate more quickly and promotes thrombus formation.⁴⁵ Even those who are regularly exposed to secondhand smoke at work or home have a 25% increase in their risk of cardiovascular disease. However, the benefits of smoking cessation accrue quickly and the risk of heart disease may significantly decline over time.⁴⁵

Hyperlipidemia or a high lipid level is also a major risk factor for cardiac disease. Cholesterol levels may be lowered through a low-fat diet, regular aerobic exercise, and weight loss. If these options are unsuccessful, the physician will place a patient on a lipid-lowering drug. A sedentary lifestyle is also a risk factor for heart disease and its impact is comparable with smoking, hypercholesterolemia, and high blood pressure.⁴⁵ Regular physical exercise assists with weight control, lowers blood pressure, and improves lipid profile and glucose tolerance.⁴⁶ In the United States, more than 37% of adults are considered overweight or obese.⁴⁶ Obesity is now the second leading preventable cause of death in the United States and negatively influences a number of risk factors for heart disease such as HTN, diabetes, hyperlipidemia, and physical activity. The distribution of body fat is important in disease promotion. For example, abdominal obesity is linked to increased risk of CAD. Even 5% to 10% weight loss, however, can have a positive influence on risk factors such as HTN, lipid levels, and sleep apnea.⁴⁷ Stress is also a significant risk factor for heart disease, but its effect is difficult to quantify. Several studies have shown that depression, limited social support, and stress increase an individual's risk for developing CAD and other adverse life events.⁴⁸

Description of Pulmonary Disease

According to the Centers for Disease Control and Prevention, 15% of adults in the United States live with chronic lung disease, such as asthma or chronic obstructive pulmonary disease (COPD). While approximately 10% of those adults report mild symptoms, more than one-third report persistent moderate-to-severe symptoms that greatly impact quality of life.¹² Each year, more than 614,000 inpatient admissions are attributed to chronic and unspecified bronchitis. Additionally, chronic lung disease greatly increases the risk of developing pneumonia, with critical episodes accounting for approximately 1.1 million inpatient admissions annually.¹³ Critical illness or acute lung injury, such as acute respiratory distress syndrome (ARDS) commonly associated with sepsis, trauma, and severe pulmonary infections, account for approximately 15% to 18% of all ventilated patients in inpatient care.¹⁴ Lung disease is now the third highest cause of mortality in the United States.⁴⁹

Chronic Obstructive Pulmonary Disease

COPD is an umbrella term used to describe progressive lung diseases that include emphysema and chronic bronchitis. Although COPD is considered preventable, it is also a progressive, life-threatening disorder in which the lungs are irreparably damaged, making it difficult to breathe. Multiple factors may contribute to its onset and progression, including smoking, exposure to environmental pollutants, and a history of asthma. Prolonged exposure to toxic agents over time may result in increased mucous production (chronic bronchitis) and tissue breakdown (emphysema).¹⁵ COPD is characterized by irreversible airflow obstruction impacting **gas exchange** and causing dyspnea, as well as limited reserve lung capacity with an increased risk of developing **hypoxemia**.⁵⁰

Worldwide, 64 million people live with COPD with an estimated 3 million deaths attributed to the disease each year. According to the World Health Organization, 80% of deaths are a result of long-term smoking, which explains why COPD typically affects older adults who may have had a long-standing history of tobacco use. Additionally, more women than men are now being diagnosed with the disease as a result of increased tobacco use over the past 30 years. In 2010, the cost of hospital admissions attributed to COPD exacerbations was estimated at \$32.1 billion dollars annually and was projected to reach \$49 billion by 2020.⁵¹

Dyspnea with minor exertion is the most common symptom associated with COPD, along with a persistent cough, expiratory wheezing, and fatigue.⁵² However, symptoms of COPD typically do not manifest until significant lung damage has already occurred. A diagnosis may be confirmed through a **pulmonary function test (PFT)**, chest x-ray, computed tomography (CT) scan, or **arterial blood gas (ABG)** analysis. Management of the disease focuses on lifestyle changes, including smoking cessation, and prescribed medication such as bronchodilators that relax the muscles around the airways and relieve coughing and dyspnea.¹⁷ For more severe symptoms, inhaled corticosteroids may be prescribed to reduce airway inflammation and minimize the risk of worsening symptoms known as an exacerbation. In cases of moderate-to-severe COPD, doctors may also prescribe supplemental oxygen.¹⁸ Immediate medical care is indicated for an acute exacerbation to minimize the risk of lung failure.⁵²

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is defined as an acute life-threatening inflammatory reaction to illness or trauma affecting approximately 200,000 people each year in the United States.¹⁹ In many cases, ARDS is a complication of severe pneumonia, sepsis, or major trauma, with severity greatly influenced by age, comorbidities, and alcohol consumption. The inflammatory response causes injury to the lungs and fluid to build up in the alveoli, compromising gas exchange, making breathing difficult, and increasing the risk of respiratory failure.²⁰ Up to 40% of ARDS cases are

fatal.²¹ Lung injury associated with ARDS is characterized by tissue damage and narrowing of air space with fibrotic changes in the lungs, which is commonly a predictor of outcomes.^{22,53}

Signs and symptoms vary in severity depending on the cause and presence of underlying heart or lung disease; however, the most common early symptoms include significant dyspnea, increased respiration rate, low blood pressure, extreme fatigue, and confusion.²³ Diagnosis is usually determined via a complete physical examination and diagnostic testing. These include an ABG test, a chest x-ray to assess fluid levels in the lungs, a chest CT scan to look for signs of pneumonia or tumors, a complete blood count (CBC), and a sputum culture to clarify the cause of the infection.^{24,53}

Owing to its life-threatening nature, treatment is most commonly conducted in an intensive care unit (ICU) with the primary aim of improving oxygen levels and treating the underlying cause. Oxygen may be initially provided via nasal cannula or face mask, but if breathing is significantly difficult, **noninvasive positive-pressure ventilation (NIPPV)** may be trialed or mechanical ventilation may be required. Additional treatment focuses on fluid management and minimizing further complications such as **pneumothorax** and pneumonia. Medications may include vasodilators to improve gas exchange, as well as anti-inflammatories. Owing to the severity of ARDS, recovery from the condition may be protracted, and it is commonly associated with residual physical and cognitive challenges requiring additional pulmonary rehab or support for depression.⁵⁴

Interstitial Lung Disease

Interstitial lung disease (ILD) is a group of disorders that share a similar clinical profile. The chief characteristic is scarring of the pulmonary **interstitium**, which includes the walls of the alveoli and the microscopic spaces around the blood vessels. Scarring causes progressive lung stiffness impacting the ability to breathe.⁹ Disorders associated with ILD may be of known or unknown etiology.²⁵ It has not been possible to accurately estimate the prevalence of ILD given the diverse number of associated diseases and variation in etiology.⁵⁵

ILD may be the result of exposure to toxic agents through occupation, such as asbestos and coal dust, or prolonged radiation as in cancer management. ILD may also develop as a complication of systemic disease, including rheumatoid arthritis, scleroderma, and systemic lupus erythematosus. Sarcoidosis, a multisystem inflammatory disease, is the most common ILD in the United States. In some cases, individuals with ILD belong in the idiopathic interstitial pneumonia (IIP) category. The most common IIP is idiopathic pulmonary fibrosis, a crippling disorder with minimal treatment options most commonly affecting individuals over the age of 60. Idiopathic pulmonary fibrosis has a poor prognosis because of rapid progressive scarring.⁵⁵

Regardless of etiology and type, the clinical signs and symptoms of ILD are similar. These include dyspnea and a nonproductive cough. Additional symptoms, such as increased sputum production, hemoptysis associated with microscopic hemorrhages, and wheezing, as well as non-respiratory-related symptoms, such as myalgia and joint pain, may help to further classify the disease. A thorough physical examination is imperative to determine an accurate diagnosis.²⁶ Upon auscultation, many individuals with ILD will have bilateral respiratory crackles with inhalation indicating excess fluid in the lungs. Imaging, PFTs, and a lung tissue analysis are used to make a definitive diagnosis. Given that lung scarring is irreversible, treatment is typically associated with disease management—for example, minimizing exposure to known toxic agents, providing oxygen to assist breathing, and prescribing anti-inflammatory or immunosuppressing medications. In some cases, a lung transplant may be considered, although mortality risk is high.⁵⁶

Functional Impairment in Daily Occupation Resulting from Pulmonary Disease

Common symptoms associated with lung disease include increased shortness of breath, deconditioning with general loss of muscle mass and strength impacting activity tolerance, chronic cough and increased sputum production, as well as anxiety and depression. Persistent shortness of breath and an inability to increase ventilation to meet physiological demand can greatly impact function, leading to a gradual loss of independence and a downward spiral in confidence based on the understanding that quality of life has been permanently compromised. Studies have indicated that individuals with a diagnosis of chronic disease, such as COPD, typically experience higher rates of depression than other comparable chronic conditions.⁵⁷ Eating is another necessary activity that individuals find challenging with compromised breathing due to lung disease. This may lead to inadequate nutrition and weight loss, which will, in turn, further impact endurance and function. In contrast, long-term use of steroids to manage inflammation associated with pulmonary disease may lead to weight gain requiring increased energy expenditure during functional tasks.

Evaluation and Intervention of Functional Skill Deficits Secondary to Pulmonary Disease

Interdisciplinary pulmonary rehabilitation is generally designed to alleviate and/or manage symptoms, increase strength and endurance to optimize function, and maximize quality of life.²⁷ Occupational therapists can be key members of the interprofessional team with our focus on providing client-centered care to maximize individual functional capacity through education and individual lifestyle recommendations, improve activity tolerance, and enhance psychosocial support.⁵⁷ Although many occupational therapists may not choose to specialize in pulmonary rehabilitation, therapists will encounter adults with limitations associated with lung disease in any setting, from acute rehabilitation to home care, and it is important to understand the occupational therapist's role and be prepared to provide appropriate services across the continuum.²⁸

Individuals are typically admitted to acute care hospitals with significant or life-threatening health concerns requiring immediate medical diagnosis and/or intervention, as well as a 24-hour physician and nursing care. An ICU is indicated for those who require advanced medical support, which may include ARDS, respiratory arrest, threatened airway, and significantly low oxygen saturations, causing hypoxemia and risk of brain injury. Occupational therapists are increasingly assuming more active roles in acute care settings with an emphasis on early mobilization, monitoring of vitals with activity, client and caregiver education, restoring function, and performing evaluations to assist with the coordination of care and determine appropriate discharge recommendations. As successful critical care intervention increases and mortality rates decline, the number of individuals surviving, but experiencing long-lasting complications, is on the rise. In many instances, individuals who have experienced a prolonged and/or complex hospital course may remain significantly impaired requiring 24-hour care. In these cases, a long-term acute care facility may be indicated as a bridge between acute care and rehabilitation or home. Regardless of setting, the primary focus of OT is to (1) promote strength, endurance, and mobility within the context of ADL and IADL re-training and (2) provide client/caregiver education, including energy conservation strategies and stress management, to manage conditions at home and in the community.

Upon evaluation and throughout the intervention process, it is vital that oxygen levels are monitored via pulse oximetry, as well as an individual's respiratory pattern to determine work of breathing at rest and with increased activity demand. Often, individuals with chronic pulmonary disease will present with poor ventilation strategies

such as shallow or fast breathing, as well as increased use of accessory muscles, which may further compound dyspnea and anxiety. Occupational therapists provide education that includes strategies to regulate breathing with activity, self-assess dyspnea with exertion, and independently apply appropriate techniques to minimize work of breathing as well as perform recovery breathing, if applicable. The most common technique employed to minimize shortness of breath in cases of COPD is **pursed-lip breathing**. Strategies are commonly embedded into ADL/IADL tasks and mobility.²⁹ Use of supplemental oxygen may also be necessary if **oxygen saturation (O₂ sat)** falls below 90% during activity. Clients should be provided with adequate education to manage O₂ equipment, including the O₂ cord, to increase functional independence, build confidence, and maximize safety.

Individuals experiencing respiratory disorders commonly find their ability to perform even basic tasks, such as bathing and dressing, compromised by dyspnea and decreased activity tolerance; energy conservation techniques are often incorporated into self-care re-training. Recommendations may include the modification of tasks, such as adjusting body mechanics to minimize the work of breathing, or altering the environment to reduce extraneous effort and decrease activity demand. Therapists will also educate clients in the use of adaptive equipment to maximize functional independence (e.g., long-handled sponge or dressing stick) or the use of durable medical equipment (e.g., tub seat for seated showers) (see Fig. 40-4). Similarly, recommendations are made to maximize participation and satisfaction in IADLs, such as home management, meal preparation, driving, leisure tasks, and social participation. Education emphasizes prioritizing, planning, and organizing tasks. This may include eliminating unnecessary steps, sitting versus standing if possible, setting up equipment in advance to minimize extraneous effort, and using lightweight tools or utensils. Additionally, clients are encouraged to self-assess dyspnea, pace themselves through activities, and take rest breaks before experiencing fatigue.

Figure 40-4 Tub seat for seated showers.

Stress and anxiety are common by-products of respiratory disorders. Educating individuals to manage dyspnea is integral to lessening anxiety and promoting participation in the treatment program. In addition to prioritizing activities, interventions include strategies to create a balanced lifestyle, increase awareness of body-and-mind interaction to manage breathing, identify stressors and perform daily activities with more confidence, and provide education on a variety of relaxation methods. These include guided imagery, progressive muscle relaxation, pursed-lip breathing technique, and diaphragmatic breathing.^{30,31}

Prolonged hospitalization and chronic respiratory conditions frequently impact muscle strength and, in turn, may limit participation and/or performance in activities. Clients with a diagnosis of COPD, for example, often experience pain in the neck and shoulder region associated with overuse of accessory muscles, whereas individuals who have experienced critical illness may have significant muscle weakness. Providing education for body mechanics, stretching, and an appropriate exercise program can be invaluable to the process of improving aerobic capacity, reducing O₂ requirements, minimizing pain, and increasing performance in functional tasks. A tailored education plan may also include medication management training, exploration of healthy leisure pursuits to promote lifestyle balance, information regarding community resources (e.g., fitness groups, nutritional education), smoking cessation, and caregiver recommendations to support a safe transition.

CASE STUDY

Patient Information

Paul is a 58-year-old white male with a past medical history of HTN, CAD, hypercholesterolemia, obesity, and COPD with a history of tobacco use who developed chest pain due to angina while at work. He was treated on site with nitroglycerin and oxygen before being transported by emergency medical technicians (EMTs) to the emergency room. Upon admission, his blood pressure was 162/102 with a heart rate of 96 at rest, a respiration rate of 22, and an O₂ saturation of 90%. He underwent an EKG and cardiac catheterization to identify arterial blockages and subsequently underwent surgery for a CABG × 4. The left lower extremity great (long) saphenous vein (GSV) was harvested for grafting during the procedure. Paul initially tolerated the surgery well, but experienced lower extremity edema and pain that impacted his early mobilization and recovery. Once medically stable, Paul's interdisciplinary team determined that he would benefit from additional medical management and rehabilitation prior to discharge home.

Reason for Occupational Therapy Referral

In addition to decreased strength, endurance, and reduced functional mobility, Paul has ongoing discomfort at both sternal and graft sites, and he is functioning below his baseline for ADLs. He lives alone and must be independent with ADLs and many IADLs before returning home. His ultimate goal is to return to work.

Assessment Process and Results

The evaluation was conducted in Paul's room via informal interview, observation, and the FIM.⁵⁸ He reports fatigue and 4/10 pain at his graft site, but agrees to participate as tolerated. His sternum is covered with a protective dressing, whereas his lower extremity incision is open to the air with staples visible.

Paul states that he is in the process of a divorce, which has added to his recent stress. He works approximately 60 hours a week in the retail industry, which he

reports is also highly stressful. He lives in a second floor single-level condo with one flight of stairs to enter and bilateral rails. His bathroom includes a tub/shower combo, but no equipment. Prior to surgery, he was independent with all mobility, ADLs, and IADLs. Paul admits to eating a large portion of fast food and leading a generally sedentary lifestyle, even though he knows he should be making healthier decisions because of his heart condition. He has not taken a vacation in 6 years and reports watching televised sports as his only leisure interest.

Throughout the assessment, Paul appeared fatigued with moderate increase in activity demand, although his vitals were stable and he only reported a mild increase in pain at his graft site with movement. He was able to perform mobility with a rolling walker (RW) and supervision, but benefited from verbal cues to refrain from pushing with his UEs to protect his sternum. He ambulated 15 feet to the bathroom and sponge-bathed sitting sink-side, but was able to stand for up to 1 minute at a time as needed. He required moderate assistance (Mod A) for both bathing and dressing tasks because of the sternal precautions impacting his ability to reach his lower extremities, and to bend and twist his torso. He reported significant fatigue with increased cardiopulmonary workload. A basic cognitive screen indicated that Paul was alert and oriented to person, place, and date; able to follow multistep directions; and demonstrated intact short- and long-term memory. At the end of the evaluation, Paul expressed his concerns regarding returning to work and how he would manage the lifestyle changes recommended by his cardiologist.

Occupational Therapy Problem List

- Limited activity tolerance impacting mobility and participation in ADLs/IADLs
- Limited knowledge of available adaptive equipment to assist with ADLs
- Limited knowledge of energy conservation education and effective pacing strategies
- Inconsistent application of sternal precautions with ADLs and mobility
- Limited knowledge of lifestyle modifications consistent with cardiologist's heart-healthy recommendations, including smoking cessation
- Increased signs of stress associated with life events and decline in function with limited knowledge of stress management strategies
- Limited knowledge of community-based resources

Occupational Therapy Goal List

Anticipated length of stay: 7 to 10 days

Duration and frequency of OT sessions: Approximately 45 to 60 minutes per day, 5 to 6x per week

- Complete ADL routine with modified independence (Mod I) sitting/standing as tolerated with appropriate use of adaptive equipment and application of energy conservation strategies and sternal precautions.
- Complete simple meal prep or laundry task with Mod I and appropriate energy conservation and work simplification strategies, and application of sternal precautions.
- Purchase adaptive equipment to maximize functional independence with ADLs upon discharge home.
- Explore stress management strategies, including healthy leisure pursuits, and plan to implement them in daily routine.
- Participate in disease management and lifestyle modification strategies.
- Explore community resources regarding smoking cessation.

Intervention

Paul's treatment plan consisted of increasing functional mobility and activity tolerance through ADLs and IADLs in order to maximize functional independence. It was of primary importance to include disease/stress management education, energy conservation skills, and adaptive equipment use via all tasks to better manage his condition and prepare for safe discharge. He was encouraged to pace himself throughout the day while gradually increasing tolerance for more demanding tasks in order to manage all necessary activities upon discharge. He was instructed in energy conservation strategies to perform tasks more efficiently and with less fatigue while continuing to build endurance. Discussion about the benefits of adaptive equipment was embedded into ADLs, and he was encouraged to trial recommendations during bathing and dressing tasks while maintaining sternal precautions. Once he had mastered his ADL routine, he more confidently participated in meaningful IADL. Energy conservation, work simplification strategies, and application of sternal precautions were included in kitchen activities, as well as light housekeeping, allowing Paul to perform tasks more efficiently and confidently.

Addressing disease management education to help implement lifestyle changes was an important step in empowering Paul to take responsibility for his health and minimize the risk of future cardiac events. Paul committed to smoking cessation and agreed to review the literature provided as well as follow up with community resources. He also agreed to explore stress management strategies and healthier leisure options. He completed both the Stress Management Questionnaire (SMQ)⁵⁹ and Interest Checklist⁶⁰ to understand his stressors and potential areas of interest. Paul identified the warning signs associated with burnout and anger, and was educated about the physical effects of high level and prolonged stress on his heart. He identified several healthier leisure tasks to explore and expressed an interest in relaxation strategies. He was introduced to progressive muscle relaxation strategies and guided imagery as an additional means of reducing stress.

Paul met all long-term goals by the anticipated date and was discharged home at an independent level for mobility, and at a Mod I level of function for ADLs and simple IADLs. He agreed to receive OT upon discharge to ensure a safe transition home, apply his new strategies in his own environment, and continue to build activity tolerance via higher level IADLs so that he could perform these meaningful tasks to a satisfactory level and ultimately return to work. As a short-term measure and although he was still unable to drive, he also agreed to a home delivery service for his groceries and a home health aide to assist with heavier household tasks.

Evidence Table of Intervention Studies for Cardiac and Pulmonary Disorders

Intervention	Description	Participants	Dosage	Research	Benefit	Statistical Significance
--------------	-------------	--------------	--------	----------	---------	--------------------------

Intervention	Description	Participants	Dosage	Research	Benefit	Statistical Significance
Early mobilization in mechanically ventilated patients vs. control group ³⁹	Sedated adults receiving mechanical ventilation in the ICU provided with mobilization to minimize long-term immobilization complications	One hundred and four participants randomly assigned to intervention or control group; 49 received mobilization during daily interruption of sedation; 55 received daily interruption of sedation only	Daily; duration of intervention varied	Randomized, double-blind, controlled trial Level II	Higher number of intervention group participants returned to independent level compared to control group.	Return to independence occurred in 59% of intervention group vs. 35% of control group ($p < 0.2$; odds ratio = 2.7 [95% confidence interval or CI 1.2–6.1]). Intervention group had shorter delirium duration (median 2 days, interquartile range [IQR] 0.0–6.0 vs. 4.0 days, 2.0–8.0; $p < 0.2$) and more ventilator-free days (23.5 days, 7.4–25.6 vs. 21.1 days, 0.0–23.8; $p < 0.05$).
Supervised or unsupervised structured exercise program vs. control group ²⁸	Inpatient, outpatient, or community-based setting exercise program	Six thousand one hundred and eleven participants	Varied from study to study. Minimum 2 weeks with minimum follow-up of 12 weeks	Systematic review and meta-analysis of 34 randomized controlled trials Level I	Participants in exercise-based cardiac rehab programs had a lower rate of re-infarction, cardiac, and all-cause mortality.	Reduction in all-cause mortality (odds ratio = 0.74; 95% CI 0.58–0.95). Reduction in cardiac mortality (odds ratio = 0.64); lower risk of re-infarction (odds ratio = 0.53); 95% CI 0.38–0.76.
Short-term pulmonary rehabilitation compared to brief advice ²⁹	Rehabilitation group included exercise and education. Brief advice group given instruction and advice on exercise with handout.	One hundred and three participants with severe COPD randomly assigned to pulmonary rehab or advice group. Fifty-four assigned to pulmonary group; 48 to the advice group.	Participants in rehabilitation group seen twice per week for 6 weeks. Advice participants received 1 hour individual advice and education.	Randomized controlled trial Level I Trial did not have blinded therapists or participants. Intervention time varied.	Rehabilitation group increased shuttle walking distance compared to advice group.	Statistically significant differences between group rehabilitation program and brief advice groups at 3 months in terms of shuttle walking distance (34.1 m; 3.0–65.3, $p < 0.05$)

Chapter 41

Orthopedic Conditions

Colleen Maher and Rochelle J. Mendonca

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Identify the role of the occupational therapist in assessing and planning treatment for persons with occupational dysfunction secondary to injuries, disease, or conditions affecting the musculoskeletal system.
2. Select appropriate assessments and plan treatment according to the stages of recovery following a musculoskeletal injury or conditions of the upper extremity.
3. Describe how to accomplish daily life tasks without causing adverse sequelae following fracture or surgery to the back, hip, and upper extremity.
4. Describe the phases of fracture management of the upper extremity and how to optimize occupational functioning at each stage.
5. State the principles of body mechanics and describe how to apply them to activities and tasks of daily life.

CHAPTER OUTLINE

Introduction
Purpose and Role of Occupational Therapy in Orthopedics
Occupational Therapy Evaluation in Orthopedics
Occupational Therapy Treatment in Orthopedics
Upper Extremity Fractures
Rotator Cuff Pathologies
Hip Fractures
Degenerative Hip Disease
Case Study

TERMINOLOGY

Abduction pillow brace: a sling or brace that positions the shoulder in 30° to 45° of abduction to protect the repaired supraspinatus.

Codman's pendulum exercises: shoulder exercises in which the client stands or sits, bends over at the hips so that the trunk is parallel to the floor, and swings the arm passively or actively in various linear and circular motions.¹

Controlled range of motion: active or passive movement within a predetermined safe arc.

Scapular plane: the midpoint between shoulder flexion and abduction. The majority of functional activities occur in this plane.

Shoulder immobilizer: adjustable elastic band that fits around the waist with two straps that position and secure the arm in a slightly abducted and internally rotated position.

Trendelenburg gait: ambulation pattern that results from a weakened gluteus medius muscle; the client lurches toward the injured side to place the center of gravity over the hip; it is characterized by dropping of the pelvis on the unaffected side at heel strike of the affected foot.

Volkman's ischemia: increased compartment pressure in one anatomic area of the extremity as a result of a fracture or crush injury.

Introduction

Orthopedic conditions include injuries, diseases, and deformities of bones, joints, and their related soft tissue structures: muscles, tendons, ligaments, and nerves. In the United States, one out of two people aged 18 and older suffer from orthopedic conditions.² These conditions can be

caused by traumatic events, such as motor vehicle, sports, recreational, or work-related accidents; by cumulative trauma; by obesity; or by congenital anomaly. This chapter provides an overview of the occupational therapy assessments and treatment interventions used with adult clients who have orthopedic conditions. Specifically, it reviews upper extremity and hip fractures and their sequelae, hip surgery for trauma and disease, and shoulder injuries and their effects on function.

Purpose and Role of Occupational Therapy in Orthopedics

The aim of occupational therapy in orthopedic rehabilitation is to help clients achieve maximal musculoskeletal functioning in order to perform their everyday activities. In the acute stage of recovery, the occupational therapist's role is to help relieve pain, decrease swelling and inflammation, assist in wound care, maintain joint or limb alignment, and restore function at the injury site. The therapist teaches the client to safely perform tasks and activities while protecting the injury site for healing. As healing progresses, the occupational therapist works with the client to restore activities of daily living (ADLs) and other occupational tasks.

For individuals who have a chronic joint disease, such as osteoarthritis, the occupational therapist's role depends on the stage of recovery and the directives of the treatment team. The occupational therapist may directly help relieve pain, realign structures, or reduce the stress on soft tissue, or work closely with the physical therapist to relate the functional program to the treatment offered in physical therapy. As the acute episode of pain decreases, the occupational therapist focuses on an individually tailored education program to help the client physically and psychologically make the required lifestyle changes to reach and sustain optimal occupational functioning.

Occupational Therapy Evaluation in Orthopedics

Evaluation is an ongoing process that is carefully coordinated with the stage of recovery. The occupational therapist selects assessments that will provide sufficient information to plan and to direct treatment but will not threaten the injured or inflamed structure during healing. The occupational therapist chooses assessments based on several factors that may include the postsurgical precautions provided by the surgeon, the level of bone healing, the chosen method of reduction and stabilization, and the plan for movement during soft tissue healing or the acute inflammatory episode. The therapist assesses participation in life roles, including areas of occupations, performance skills and performance patterns, as well as impairments of capacities and abilities.

Participation in Life Roles

Although resumption of life roles may not be possible at the start of the rehabilitation program, life roles regulate the choices made during treatment planning and serve as the end point for treatment planning. The therapist notes activities and tasks that can and cannot be accomplished.

Impairments of Abilities and Capacities

Physical impairments are directly measured by various assessment instruments. The surgeon's protocol may stipulate no movement or no force at or near the fracture or surgical site, or it may require **controlled range of motion** beginning immediately or within the first 2 to 6 weeks after stabilization. If the surgeon's protocol requires complete rest of the injured tendon, bone, or joint, range of motion (ROM) measurements are deferred until movement is permissible. If the client is on a specific program, such as controlled ROM, the therapist measures the joint, adhering to the precautionary boundaries, and does not allow the client to exceed the limits of the surgeon's prescription. The adjacent joints are measured, and a treatment program is designed for any adjacent joint that demonstrates less than normal function. Detailed strength testing with applied resistance is deferred until there is bony consolidation and tissue healing, or the acute inflammation has calmed. Because of the force required, grip and pinch testing are usually deferred for 2 to 4 weeks following cast removal in forearm fractures. The occupational therapist not only focuses on direct measurement of the injured and adjacent anatomical regions but also closely observes the client's total body response in terms of postural changes, pain responses, and psychological reactions. Assessing strength after a fracture or surgery should only be performed when ordered by the orthopedist.

Occupational Therapy Treatment in Orthopedics

The most important treatment goal is the restoration of occupational functioning. To achieve this, the client needs to be directed from the start of recovery to move and to use all joints that are not affected by the injury or the disease. For clients who have an upper limb fracture, rotator cuff repair, or a short-term inflammation, the therapist may recommend temporary use of the uninjured hand alone to perform some ADLs, assisted by adaptations such as pump bottles for toothpaste and shampoo, a button hook, or a rocker knife. Other ADLs may require the temporary assistance of another person so as not to disturb the healing region. When the client is medically ready, the occupational therapist, through careful activity analysis, ascertains how the client can safely resume tasks that correspond with the achieved recovery status to reintegrate the injured, postsurgical or inflamed limb into activity safely. Attention is directed toward redeveloping the function of the injured limb to resume its capacity in mobility, stability, weight bearing, and ultimately skilled activity. When a condition is chronic or has postsurgical precautions, such as a total hip replacement, the therapist recommends alternative methods, adaptive equipment, or environmental modification for safe task completion.

Upper Extremity Fractures

As long as orthopedic surgeons have been treating fractures, there has been a controversy between those who recommend movement and those who recommend rest. The surgeons prescribing rest as a fracture treatment keep their clients immobilized in traction, plaster, or fiberglass for long periods after stabilization. For many surgeons, however, the goal in fracture treatment is to mobilize the injured structures as quickly as is compatible with healing and return the client to work and leisure activities.¹

The goal of fracture treatment is to achieve a precise and effective stabilization for optimal recovery and return to function. Closed fractures that are relatively undisplaced and stable may be managed by protection alone, without reduction or immobilization. Fractures that are undisplaced, but unstable, do not need reduction but do require positioning and immobilization by external fixation methods such as a sling, cast, or a fracture brace. Open reduction internal fixation (ORIF) surgically reduces open fractures, closed fractures that are unstable, and where the bone fragments cannot be approximated accurately by closed manual reduction alone. The bone fragments are brought into closer anatomical alignment during surgical reduction and are stabilized by insertion of an internal fixation device, such as a nail, pin, screw, rod, or compression plate or by an external fixator.³ Surgical repair can also include prosthetic devices that are implanted to restore joint motion.

Fracture healing has a general timetable that is confirmed routinely by physical examination and x-rays to reveal the healing status before advancing the rehabilitation program. The estimated healing time for uncomplicated upper extremity fractures in adults is as follows: callus formation 2 to 3 weeks, union 4 to 6 weeks, and consolidation 6 to 8 weeks. For uncomplicated lower extremity fractures, the estimated healing time is as follows: callus formation 2 to 3 weeks, union 8 to 12 weeks, and consolidation 12 to 16 weeks.⁴

There are three phases of fracture healing: the inflammation phase, the reparative phase, and the remodeling phase.⁵ The timing, amount, and kind of therapy depend on the location and kind of fracture, the method of fracture reduction selected by the orthopedic surgeon, and, in some instances, the age of the client. Early movement prevents the unwanted side effects of immobilization: stiff joints, disuse atrophy, and muscle weakness.

Shoulder Fractures

The shoulder complex comprises the glenohumeral joint, scapulothoracic joint, sternoclavicular joint, and acromioclavicular joint. The shoulder complex not only provides a wide range of movements for hand placement but also provides the important functions of stabilization for hand use, lifting, pushing, reaching, and weight bearing.⁶ The shoulder is considered the most challenging portion of the body to rehabilitate. After a shoulder fracture, the therapy goals are delicately balanced to relieve pain, to restore movement and muscle strength, to allow for callus formation and the approximation of the bony fragments in the injured region, and to return to a maximal level of functioning. The progression of the exercise program and return to functional tasks is directed by the orthopedist based on radiographic imaging of the fracture site.

Immobilization of the shoulder results in stiffness and pain; therefore, nonoperative and postoperative therapy programs call for a specific regimen of passive range of motion (PROM),

active-assisted range of motion (AAROM), or active range of motion (AROM) within a controlled, guarded range. The therapist must remember that PROM differs from passive stretching. PROM is movement of the limb by an external force to its available end range or prescribed end range. Passive stretching is movement of the limb by an external force to its available end range and then applying overpressure.

Passive stretching is contraindicated in the early stages of fracture healing. Emphasis is on the client resuming nonresistive functional activities and using the injured limb as soon as movement is allowed.

Conservative or Nonoperative Management

Because immobilization quickly results in stiffness, shoulder motion begins as soon as the acute pain diminishes in stable or minimally displaced shoulder fractures. Therapy begins with sling immobilization. Controlled exercise programs can begin as early as 1 to 2 weeks postinjury and include **Codman's pendulum exercises** and gentle PROM. PROM is performed in supine with shoulder forward flexion, abduction in the **scapular plane**, and internal rotation and external rotation (initially may be restricted). AROM of the uninvolved joints should begin at this time. ADLs are performed using one-handed techniques. Gentle submaximal isometrics may begin at 4 weeks for flexion, abduction, and internal rotation. At 6 weeks, the client can begin AROM.⁷⁻⁹ AROM should begin in gravity-lessened positions and progress to against gravity, with the therapist making certain that there are no unwanted compensatory movements such as shoulder hiking. Light self-care activities can begin at this time. Self-care activities should be nonresistive and include only those in a gravity-lessened position (such as reaching for a salt shaker in the middle of a table while standing). The client can be weaned off the sling when AROM begins. At 8 to 12 weeks, the sling is usually discarded, and the client can begin isotonic strengthening. After 12 weeks, sports, leisure, and work activities are initiated.⁷⁻⁹

Postoperative Management

Unstable shoulder fractures usually require surgical intervention for fixation. The protocols are based on the classification of fracture, the type of surgical procedure, and the age and activity level of the client, and they often follow the guidelines as originally described by Neer.¹⁰ Some postoperative protocols start with early mobilization programs, whereas others have a period of immobilization. A study found no difference in function between those who received early mobilization immediately versus those who started mobilization 3-weeks postsurgical fixation.¹¹ When approved by the surgeon, the sequence of exercise begins with Codman's pendulum exercises (see Fig. 41-1). Codman's pendulum exercises are performed with the client bending over so that the injured upper limb is perpendicular to the floor. In this gravity-assisted plane, the client does clockwise and counterclockwise circular movements and flexion, extension, abduction, and adduction. Codman's pendulum exercises may be contraindicated if the upper extremity is edematous.

Figure 41-1 Codman's pendulum exercise.

Also, during the first 6 to 8 weeks, PROM of shoulder flexion and external rotation to 40° are started in supine, as are isometric exercises, a stimulant for fracture healing and callus formation. By 6 weeks, AROM, nonresistive therapeutic activities, and light ADLs begin. Strengthening starts at 12 weeks.^{8,12}

Humeral head fractures that are unstable and significantly displaced are often surgically treated with humeral head replacement, known as hemiarthroplasty (see Fig. 41-2). A total shoulder arthroplasty is considered for clients with severe arthritis in combination with a proximal humerus fracture.¹³ Another surgical approach is the reverse total shoulder replacement. This approach is used when there is significant damage to the rotator cuff or severe arthritis of the glenohumeral joint. The major limitation of this surgery is impaired shoulder rotation.^{14,15}

Figure 41-2 Hemiarthroplasty.

Therapy for total shoulder arthroplasty varies with the design of the prosthesis and the surgical procedure. The rehabilitation program begins within the first 1 to 2 days after surgery. The exercises should not cause any pain. The key to a satisfactory functional result is early achievement of shoulder elevation and external rotation in the plane of the scapula. Passive shoulder elevation done lying supine with the opposite hand assisting the affected limb, and use of an exercise wand to perform passive external rotation, which may be restricted to 30° , are

introduced during the first 3 to 5 days after surgery.^{16,17} Codman's pendulum exercises are added at 1 week post-op.⁸ The client is instructed to perform the exercises four to six times daily. Because the subscapularis tendon may be incised during surgery and the integrity of the rotator cuff may be disrupted, some surgeons introduce external rotation slowly in the first 4 weeks; others incorporate passive external rotation on the second postoperative day. The preferred position for passive external rotation exercise is with the humerus in slight scaption. During this phase, the client is instructed to begin nonresistive everyday activities, such as brushing teeth and self-feeding, while keeping the shoulder adducted to the side. At 3 weeks, submaximal isometrics are added. AROM is added at 6 weeks. Progress AROM from supine to sitting, avoiding compensatory movements such as shoulder hiking.¹⁶ At 8 to 12 weeks, Thera-band exercises, free weights, and purposeful activities that emphasize shoulder elevation and rotational movements are initiated. At 12 weeks, the client is instructed in sports and work activities. Weight bearing on the injured arm is not allowed for at least 6 months.^{10,17} The goal is to achieve 135° of shoulder elevation (scaption), which is considered functional AROM, and 50° of internal and external rotation.

Following the initial treatment of closed reduction of fractures in the shaft of long bones, such as humeral shaft fractures, the surgeon may prescribe a functional fracture brace as popularized by Sarmiento,^{18,19} as shown in Figure 41-3. The lightweight thermoplastic fracture brace allows for motion above and below the fracture site and minimizes the detrimental effects of prolonged immobilization. The client is closely monitored for biomechanical alignment and desired, controlled movement. The therapist adjusts the fracture brace to facilitate comfort, to respond to changes such as a reduction of limb volume, and to adjust the amount of movement the splint permits. Management of humeral shaft includes Codman's pendulum exercises and PROM exercises that are performed several times a day to prevent stiffness. The therapist must be careful to flare and roll the edges of the shell to prevent compromise to circulation and nerve impingement while allowing available movement.

Figure 41-3 Thermoplastic humeral fracture brace to support the length of the humerus during healing.

In the case of humeral shaft fracture, there is a risk of radial nerve damage because of the location of the injury relative to the course of the radial nerve. Radial nerve injury is characterized by the inability to extend the elbow, wrist, and digits. Other complications that are common with humeral shaft fractures are delayed union and nonunion.

For phase II, the therapist encourages AAROM, progressing to AROM and lightly resistive exercises. The surgeon will guide the therapist on the timing to begin each of these exercises. These exercises often begin with the client supine and progress to seated, in which the weight of the extremity is first supported by the therapist. Phase III addresses both stretching and strengthening. As healing permits, the client can combine shoulder forward flexion with abduction with or without external rotation.¹²

Elbow Fractures

Elbow motion gives the individual the capacity to position the hand in space close to or far from the body for fine motor activities and to function as a stabilizer for strength activities.²⁰ These movements are accomplished by two degrees of freedom: flexion and extension at the ulnohumeral and radiohumeral joints, and pronation and supination at the proximal radioulnar joint. Intercondylar and supracondylar fractures (the extension type) are the most common of the distal humerus fractures that impact elbow function. These fractures are associated with complications that include malunion and peripheral nerve injury and have a risk of **Volkman's ischemia**, a compartment syndrome of the forearm. Ischemia, considered an urgent medical matter, can be caused by an increase in pressure within a fascia-surrounded compartment. Signs of ischemia include severe pain with passive stretching; pale, bluish skin color; absence of forearm radial pulse; and decreased hand sensation and paralysis.²¹ Report these signs immediately.

Immediate medical action is important if Volkman's ischemia is suspected. The common surgical approach includes a decompressive fasciotomy. One unfortunate complication is Volkman's ischemic contracture, which can be mild to severe and often requires additional surgeries. Under the close supervision of the surgeon, the occupational therapist will focus on restoring functional ROM, managing scar tissue, and regaining function.²¹

The nondisplaced or minimally displaced supracondylar fracture may be treated with closed reduction and immobilization in a removable cast or thermoplastic splint. After 1 to 2 weeks, the splint is removed daily for gentle AROM in a hinge splint.²² The splint is discharged after 6 weeks and client is encouraged to use his or her extremity for light ADLs.

Complex elbow fractures, which include displaced supracondylar fractures and intercondylar fractures, are most often treated with open reduction and well-secured fixation.²³ Active motion begins 2 to 3 days after surgery. The elbow fracture is splinted in 90° of flexion rather than extension because flexion has greater functional importance. The splint is removed by the therapist to begin gentle AAROM. ROM of elbow flexion and extension is best performed in a supine or seated position with the distal humerus supported by a pillow or towel roll (see Fig. 41-4). Gravity will assist with flexion and extension. Adhere strictly to any ROM restrictions. If the client also injured the collateral ligaments, restrictions on forearm rotation during elbow flexion and extension may be prescribed by the orthopedic surgeon. Forearm ROM is performed in a seated position with the elbow flexed at 90°.²⁰ Gentle PROM and light isotonic exercises are usually initiated between 6 and 8 weeks. The client is encouraged to use his or her extremity for light self-care activities. At 8 weeks, there is an increased emphasis on restoring full ROM and increasing strength. In the elderly, elbow fractures are often treated with a sling alone, and active movement begins early to prevent stiffness and pain. A functional arc of motion for daily activities can be regained, but full ROM is not always achieved.

Figure 41-4 Range of motion of the elbow.

Radial head fractures can be treated with closed reduction or, depending on the severity, may require radial head excision. Radial head fractures seldom require more than a sling for immobilization. Active pronation and supination exercises are encouraged early. Emphasis should be placed on regaining active supination. Full supination is more difficult and painful than pronation.²⁰ Supination and pronation exercises should be performed seated or standing, with the shoulder adducted to the side and elbow flexed to 90° (see Fig. 41-5). Exercises should be performed several times daily, with a minimum of two sets of 10 repetitions. Exercises should be pain-free. Continuous passive motion (CPM), dynamic supination splint, and static progressive splinting can be used to further encourage forearm rotation.

Figure 41-5 Forearm supination pronation.

Rotator Cuff Pathologies

The shoulder complex is the foundation of all upper extremity movements. The rotator cuff musculature plays an integral part in the function and control of the shoulder complex. The supraspinatus performs humeral elevation, the infraspinatus and teres minor perform external rotation, and the subscapularis performs internal rotation. Besides the actions they produce, the rotator cuff musculature functions as a force couple to control the head of the humerus on the glenoid fossa. Its anatomical location at the subacromial space, between the coracoacromial arch and the head of the humerus, makes the rotator cuff extremely vulnerable to compression (see Fig. 41-6). Charles Neer¹⁰ described a hooked acromion (type 3) as a possible cause of impingement syndrome that could progress to a tear. The supraspinatus also has an area of hypovascularity known as the critical zone. This zone is where the supraspinatus tendon inserts on the greater tuberosity of the humerus. Because of its anatomical location and area of hypovascularity, the tendon of the supraspinatus is the most commonly impinged rotator cuff tendon. Clients with rotator cuff pathology are often faced with the inability to perform the most personal self-care tasks. Activities such as toileting, hair care, and hooking a bra are all dependent on a normally functioning rotator cuff.

Figure 41-6 Subacromial space.

Shoulder Impingement Syndrome

Shoulder impingement syndrome is a compression of the structures found in the subacromial space. Structures found in the subacromial space (superior to inferior) include the subacromial bursa, supraspinatus, joint capsule, and long head of the biceps. Shoulder impingement syndrome is most commonly caused by a hooked acromion and or repetitive or sustained elevation of the shoulder above 90°. If shoulder impingement syndrome goes untreated, it can result in a rotator cuff tear. Neer¹⁰ developed a classification system to better understand the progression of shoulder impingement syndrome. Stage I is described as edema, inflammation, and hemorrhage. In this stage, the bursa and/or the tendons become irritated and inflamed. The symptoms can be reversed with occupational therapy intervention. The focus should be on activity modification. In stage II, the bursa and tendons become thick and fibrotic. At this stage, a person can be treated conservatively; however, recovery may take longer. In stage III, a person may present with bone spurs and partial- or full-thickness tears. A small tear is less than 1 cm, a medium tear is 1 to 3 cm, a large tear is 3 to 5 cm, and a massive tear is greater than 5 cm.²⁴

Rotator Cuff Tendonitis and Bicipital Tendonitis

A person may have rotator cuff tendonitis and or bicipital tendonitis, but not shoulder impingement syndrome. The chief complaint of tendonitis is pain during humeral movement above 90°. In most cases, the client is independent with ADLs; however, the client will

experience pain while performing these tasks. Common causes are repetitive overhead use, curved or hooked acromion, weakness of shoulder or scapula musculature, and capsular tightness. Tendonitis can be treated conservatively with pain modalities, activity modification, strengthening exercises, and occupation-based activities.

Bursitis

Shoulder bursitis is inflammation of the subacromial bursa. Subacromial bursitis can be differentiated from rotator cuff tendonitis if the client has pain during passive shoulder elevation and is pain-free during AROM and muscle testing of the rotator cuff. It is rarely a major source of pain and usually coexists with shoulder impingement syndrome.²⁵ See the section on shoulder impingement for causes.

Rotator Cuff Tear

Tears of the rotator cuff can be of partial or full thickness. Causes include trauma, progression of impingement syndrome, and degenerative changes of the tendon and aging. Clients with rotator cuff tears will present with difficulty performing activities above shoulder level and will often compensate by hiking the shoulder using the upper trapezius muscle. Rotational movements, such as reaching the small of the back to tuck a shirt in or remove a wallet from a back pocket, can also be limited. Rotator cuff tears can significantly limit a person's occupational functioning. Rotator cuff tears are diagnosed using magnetic resonance imaging (MRI) and magnetic resonance arthrography (MRA).²⁶ Some partial tears can be treated conservatively with activity modification and strengthening of scapula and rotator cuff muscles. Surgical options for those clients who do not benefit from conservative treatment include arthroscopic, mini-open, and open repairs. Postoperative therapy focuses on regaining full ROM, scapula and rotator cuff strengthening, practicing ADLs, and other meaningful tasks.

Evaluation of the Nonsurgical Client

The evaluation should begin with an occupational profile and a thorough history. Discuss the mechanism of injury. Was it a sudden onset or gradual onset? If it was a gradual onset, try to determine what activity or sustained posture led to the rotator cuff problem. Also discuss the client's level of pain (scale of 0–10). Is the pain localized or referred? What activities or occupations cause pain? Can the client sleep on the involved side? The therapist should also observe the client's posture and symmetry of the scapula at rest and during upward rotation. The physical assessments can then begin with asking the client to perform various functional movements such as reaching the small of the back, reaching the opposite axilla, and touching the top of the head. Active cervical ROM and sensory testing the C4 to T1 dermatomes should be performed to eliminate the possibility of cervical involvement. Palpation of the rotator cuff tendons will assess tenderness and swelling. Special tests should be administered to determine all the involved structures. Special tests for rotator cuff pathology include:

- **Neer impingement sign:** Forced forward flexion with the shoulder internally rotated. If the patient expresses pain, the sign is positive, indicating compression and/or inflammation of the supraspinatus and/or long head of the biceps (Fig. 41-7).

Figure 41-7 Neer impingement sign.

- **Hawkins test:** Shoulder and elbow are flexed to 90° followed by forced internal rotation. If the patient expresses pain (Fig. 41-8), the test is positive, indicating compression and/or inflammation of the supraspinatus and long head of the biceps.

Figure 41-8 Hawkins test.

- **Jobe's test (empty can test):** Shoulder elevation to 45° and internal rotation (thumb facing down). Therapist applies resistance to abduction (downward force) (Fig. 41-9). Positive sign is weakness or pain. This test indicates a tear of the supraspinatus tendon. Repeat the same test at 90°. If pain is only experienced at 90° position, suspect bursitis.

Figure 41-9 Jobe's/Empty can test.

- **Drop arm test:** Patient's arm is positioned in 90° of abduction. The patient slowly lowers his or her arm to the side. The test is positive if the patient drops the arm to the side, indicating a supraspinatus tear (Fig. 41-10A and B).

Figure 41-10 A, B. Drop arm test.

- **Biceps Speed's test:** Shoulder flexed to 90°, forearm supinated, and elbow extended. Resistance is applied to flexion (downward force using a long lever arm). Positive sign is pain over bicipital groove (Fig. 41-11).²⁷⁻³¹

Figure 41-11 Biceps Speed's test.

ADLs should be assessed by observing the client using the involved extremity during activities that are within low range (waist level), mid-range (shoulder level), and high range (above shoulder level). The therapist should note any compensating or expressions of pain while performing the activities. There are also numerous standardized functional assessments specific to the shoulder, some of which should be included in the evaluation. Examples of standardized functional assessments that address World Health Organization International Classification of Functioning, Disability and Health (ICF) components: impairments, activity limitation, and participation restriction include the Disabilities of Arm, Shoulder and Hand (DASH), American Shoulder and Elbow Surgeons Self Report, Shoulder Disability Questionnaire, Shoulder Pain and Disability Index, and the Penn Shoulder Score.³²⁻³⁶

Treatment of the Nonsurgical Client

Conservative treatment should begin with educating the client on activity modification. The client should be instructed to avoid above shoulder level activities until pain subsides. Sleeping postures should also be addressed. The client should avoid sleeping with the arm above shoulder level or in an adducted and internally rotated position. Combined adduction and internal rotation for a long period of time can further compromise the blood supply of the supraspinatus tendon. Exercise should focus on pain-free ROM. Begin with PROM. As pain decreases, progress to AROM. Strengthening should include isometric and isotonic exercises for the rotator cuff and scapula musculature. Also improve ROM and strength through functional activities such as dressing (Fig. 41-12A to C). Investigate what occupations are most important to the client and have him or her bring in the necessary equipment such as a golf club or tennis racquet. The long-term goal is to return the client to unrestricted, pain-free occupational functioning.

Figure 41-12 Progression of strengthening program. **A.** Isometric resistance to external rotation. **B.** Isotonic resistance to external rotation. **C.** Functional activity that incorporates external rotation.

Evaluation of the Postsurgical Client

The evaluation for the postsurgical client will be guided by the surgeon. Request for occupational therapy services can begin as early as 24 hours after surgery, but may be delayed up to 6 weeks after surgery. The decision to begin therapy and how to progress the client is based on many factors that include size and location of the tear, tissue quality, surgical approach, and the surgeon's protocol.³⁷

Treatment of the Postsurgical Client

Early mobilization and delayed mobilization programs have been shown to have similar results in regard to improvement of tissue healing and functional return.¹³ Initiation of treatment following a rotator cuff repair will be based on the size of the tear, type of surgical repair, tissue quality, and surgeon's protocol. After surgery, the client is placed in an **abduction pillow brace** or sling. The sling is to be worn at all times except for exercise. Clarify with the surgeon to see if the sling can be removed for bathing. Following repair of a small or medium tear, the client will begin with PROM/AAROM. The movements emphasized should include pain-free Codman's pendulum exercises, passive shoulder elevation, and internal/external rotation in the slightly abducted position in the scapular plane. An ice pack should be used before, during, and after exercise to decrease pain and swelling. The client should be instructed to perform these exercises at home using the uninvolved arm to supply the power. Internal and external rotation is performed with the client supine and the shoulder slightly abducted to 30° (in the scapular plane) and elbow flexed to 90°. A cane or stick is held in both hands, whereas the uninvolved arm supplies the power to move the involved extremity toward the stomach (internal rotation) and away from the stomach (external rotation) (see Fig. 41-13). Depending on the tension of the repair, the surgeon may set ROM limits. The client is also instructed to begin AROM of the elbow, forearm wrist, and hand. Overhead pulleys are only used if requested by the surgeon because repetitive shoulder elevation may irritate the repair.

Figure 41-13 Cane exercise for internal and external rotation.

During this time, the client should be instructed in one-handed techniques to perform ADLs. The involved shoulder should not be used for any activity at this time, unless indicated by the surgeon. At 6 weeks or later if following the delayed protocol, the client progresses to AROM. Begin in gravity-lessened positions and progress to against-gravity movements. Shoulder extension and internal rotation to the small of the back are added when approved by the surgeon. Encourage the client to achieve functional ROM. Engage the client in light nonresistive ADL. Avoid compensatory movements such as hiking the scapula or lateral bending of the trunk. Strengthening can be initiated 10 to 12 weeks postsurgery to prepare the client for functional activities. Initially, the strengthening program begins with isometric exercises for the rotator cuff and scapula stabilization exercises. The client then progresses to isotonic exercises using Thera-band and free weights.¹⁶ All strengthening should be performed below 90° and be pain-free.

Initially, exercises using free weights should begin supine to lessen gravity and prevent compensating. Then eventually increase to against-gravity strengthening remaining below 90°. ³⁷⁻³⁹ Later, light ADLs above shoulder level can be emphasized (if there is no hiking of the scapula), including cooking and folding laundry. At 12 weeks, the client can begin light-resistive occupation-based tasks. No lifting over 5 lb. Again, the long-term goal is to return the client to normal pain-free occupational functioning.

Following repairs of large and massive tears of the rotator cuff, the client is immobilized in an abduction brace. ⁴⁰ ROM begins with pendulum exercises only. ROM restrictions vary depending on the surgeon's protocol. Some clients begin PROM within the first week, and others begin 6 weeks following surgery. AROM does not occur until 8 to 12 weeks post-op. ¹⁶ The preparatory interventions (exercise and ice) and purposeful activities are the same as for a small and medium tear, but the time frame of when they start are delayed. Time frames are determined by the surgeon. The treatment protocols given here are only guidelines; communication with the surgeon should be ongoing throughout the client's rehabilitation.

Hip Fractures

It is estimated that by the year 2030, there will be 289,000 individuals diagnosed with a hip fracture. ⁴¹ There are three types of hip fractures: femoral neck fracture, intertrochanteric fracture, and subtrochanteric fracture. Intertrochanteric hip fractures and femoral neck fractures are the most common fractures in adults older than 50 years of age. ^{42,43} Intertrochanteric fractures are more common in individuals with osteoporosis. Many of these clients have comorbidities that affect the duration and potential of the rehabilitation program. ⁴⁴

Hip fractures can be treated with closed reduction, which includes bed rest, traction, or early mobilization. The large majority of hip fractures are treated with open reduction internal fixation (ORIF) using pins, screws, plate, or rods ^{13,43} (see Fig. 41-14). Hemiarthroplasty is the treatment for some fractures of the neck and head of the femur. Hemiarthroplasty is a partial joint replacement in which the femoral head and neck are replaced by a prosthesis. After excision of the femoral head, the stem of the prosthesis is inserted distally into the medullary canal of the femur so that its head articulates with the normal acetabulum. ⁴³ If destructive changes have taken place in both the femur and the acetabulum, a total hip arthroplasty (THA) is necessary. ¹³

Figure 41-14 Intertrochanteric hip fractures and femoral neck fractures.

Occupational Therapy Following a Hip Fracture and Surgery

Occupational therapy should begin with an evaluation that includes an occupational profile to identify occupations that were meaningful to the client prior to the hip fracture. Incorporation of these meaningful activities in the acute care phase of the treatment is an important step in preparing the client for discharge.⁴⁵ The restrictions for weight bearing and hip movement on the operated leg are directly related to the severity and location of the fracture, the surgical approach, the ability of the fixation device or prosthesis to withstand stress, the integrity of the bone, the weight of the client, and the client's cognitive status.⁴⁶ The physical therapist teaches the client to use a walker or crutches, depending on percentage of body weight allowed on the operated limb, which ranges from non-weight bearing (0% weight), to touchdown weight bearing (10%–15% weight), to partial weight bearing (30% weight), to 50% weight bearing (50% weight), to full weight bearing (75%–100% weight).⁴⁶ The occupational therapist teaches the client to complete ADLs safely, corresponding to the medical orders that may or may not include ROM and weight bearing restrictions. For some clients, preexisting factors or the risk of dislodging the new hip joint may necessitate the assistance of another person for lower extremity dressing and for bathing.

Close communication among the members of the rehabilitation team is imperative to provide the client with the best quality of care and consistency in learning how to function after surgery. Essential to the planned discharge following a hospital stay of less than a week, is the therapist's evaluation of the client's ability to perform basic and instrumental ADLs safely and independently and the need for adapted equipment and/or assistance of others.^{47,48}

It is best to teach the client who is restricted to non-weight bearing or toe-touch weight bearing to sit to perform ADLs to conserve energy and increase safety. Once the client can do partial weight bearing or weight bearing as tolerated (WBAT), he or she can safely stand while grooming. For at least 6 weeks, and for some clients longer, movement may be restricted. The therapist must be reminded to thoroughly review the chart for weight bearing status and possible ROM restrictions. Movement restrictions after hip surgery may include:

- No hip flexion beyond 90°, including movement of the trunk over the thighs
- No hip rotation (avoid internal rotation for posterolateral approach and external rotation for anterolateral approach)
- No crossing the operated leg over the unoperated leg
- No adduction of the operated leg

Because these restrictions preclude bending over or bringing the foot closer to the hands, adaptations are required to resolve performance challenges in bathing, dressing, functional mobility, and home management. Long-handled dressing and grooming devices are provided, and the therapist teaches the client to bathe and dress the operated side using these devices to avoid bending over (flexion) or crossing the operated leg (adduction). Some examples of adaptive devices include:

- Reacher or dressing stick to don and doff pants
- Sock aide to don and doff socks
- Extended-handled shoehorn (medial side for posterior surgical approach and lateral for the anterior approach) or elastic laces can be adaptations to don and doff shoes

For bathing, if permitted, some clients shower standing. Instructions for transferring in and out of the tub from a standing position include:

To Get Into the Bathtub

- Stand with feet parallel to the tub with the operated leg next to the bathtub.
- Shift body weight to unoperated leg.
- Hold onto a grab assist rail for support.
- Position the operated leg into hip extension and knee flexion; then abduct the hip to allow the leg to go over the edge of the bathtub.
- Extend the knee on the operated side once the leg is over the tub edge.
- Place the foot on the nonskid bath mat inside the tub.

- When balance is secure, transfer the body weight to the operated leg. Lift the unoperated leg over the edge of the tub and place the foot on the bath mat.

To Get Out of the Bathtub

- Position oneself so feet are parallel to the side of the tub and the operated leg leads (goes out of the tub first).
- Use the same procedure as for getting into the tub.

Others prefer to sit to conserve energy or feel secure, and they require a bath bench. The bath bench must be high enough so the hip does not flex more than 90°. To reduce hip flexion during sitting and rising, the client is instructed to use a raised toilet seat, bed, and chair. The client is encouraged to sit in a reclined position enhanced by a wedge cushion or a small rolled pillow or towel at the junction of the chair's seat and back, as originally described by McKee.⁴⁹

The client who must sit in a regular-height chair is taught to stand up without overflexing the operated hip. In a chair with armrests, the client scoots to the front edge of the seat, keeping the operated hip extended, uses the armrests to push straight up without bending the trunk forward, and then stands upright holding onto a walker (Fig. 41-15A to C). In a chair without armrests, the client moves to the side of the chair so that the operated thigh is over the edge with the foot placed at the midline of the chair. This places the operated hip in extension, puts the foot close to the center of gravity, and enables the person to gain momentum to stand without excessive hip flexion. With this technique, the unoperated hip, knee, and ankle are in position for weight bearing. A cushion or folded blanket will increase the height of the chair.

Figure 41-15 Sit-to-stand transfer for a client with partial weight bearing status after total hip arthroplasty. **A.** Extends knee and pushes off arms of chair. **B.** Avoids flexing hip past 90° while pushing off. **C.** Maintains partial weight bearing status when standing.

By 6 weeks, almost all clients walk with a cane, and some walk unassisted; most can return to driving a car, swimming, and work.⁴⁶ Physical restrictions against bending to put on shoes or socks, sleeping on the operated side, and using a regular-height toilet seat are often lifted 8 to 12 weeks after surgery; however, the surgeon will determine this.

Degenerative Hip Disease

Some orthopedic conditions are chronic. One is progressive hip pain from degenerative disease. When that pain interferes with activities and tasks of daily life despite medication, rest, reduction in lower extremity loading by the use of a cane, walker, or crutches, and physical therapy, hip surgery is indicated.¹ After hip replacement surgery, therapists teach the clients to move the operated leg within the ordered weight bearing and movement restrictions.

Occupational Therapy after Elective Hip Surgery

A number of surgical procedures are used for the reduction of hip pain. They include osteotomy, arthrodesis or hip fusion, hip resurfacing, and partial or total hip arthroplasty. To select the procedure, the orthopedic surgeon considers not only the client's age and physical status but also his or her occupational requirements and lifestyle. The most common are partial or total hip arthroplasty (THA).

A THA surgically replaces the entire hip joint destroyed by disease or trauma. The main benefit of hip replacement is to resolve arthritic pain. Joint replacement surgery can also restore

the length of the limb and its alignment, which has the potential to improve ROM and function.⁵⁰ This surgery replaces the arthritic acetabular cup with a titanium cup and polyethylene plastic liner. The femoral head is replaced with a femoral head implant made of ceramic and a titanium stem component (see Fig. 41-16).

Figure 41-16 Total hip arthroplasty.

The surgical approach to perform the THA varies among surgeons. The most common is the posterolateral approach.⁵¹ With this approach, there is no disruption to the gluteus medius and minimus muscles, and therefore, hip abduction is not compromised. The risk of the posterolateral approach is posterior dislocation. To avoid dislocation, immediately following surgery, the client is placed in an abduction pillow. Some surgeons also opt to place the ipsilateral knee in a knee immobilizer to further decrease the risk of dislocation. The client is instructed to avoid hip flexion beyond 90°, adduction, and internal rotation.^{51,52} Another common approach is the anterolateral approach. With this approach there is a limited risk for dislocation. Some surgeons follow a no-restriction protocol,⁵³ whereas other surgeons have specific restrictions that may include avoiding flexion beyond 90°, avoid hip extension, adduction, and external rotation.^{52,54}

Another decision the surgeon must make when performing a THA is what type of implant fixation he or she will use. The choices are cemented, cementless, or hybrid prostheses.⁵⁵ The cemented total replacement usually requires 4 to 6 weeks of WBAT using a standard or rolling walker, and then the client progresses to a straight cane. The cementless prosthesis, which depends on ingrowth of porous bone for stability, requires 6 to 12 weeks of partial weight

bearing before a cane is used. Some surgeons may initially order non-weight bearing. In the case of the hybrid prosthesis, in which the femoral portion is cemented and the acetabulum is uncemented, 4 to 6 weeks of partial weight bearing precedes introduction of a cane.⁵¹

Early mobility and rapid recovery protocols start the client in therapy as early as postoperative days 0 to 1.⁵⁶ Preoperative education should be the first phase of occupational therapy for the client receiving a THA. Hip precautions, demonstration of long-handled equipment, and medically necessary durable medical equipment should be presented. Preoperative education has been linked to reducing anxiety.⁵⁷ The first 2 months after THA is critical for protection and function of the new hip joint. The postsurgical program is designed to allow for healing of the trochanter and soft tissues and for development of a capsule around the joint for future stability.

The client learns to transfer from supine to sitting to standing without flexing the operated hip beyond 90° by keeping the knees apart (hips abducted) and sliding out of a bed to take weight on the unoperated leg. Some clients use an overhead trapeze bar to assist this transfer. The client also needs to practice transferring from a variety of surfaces such as a high chair, tub bench, raised toilet seat, and a car seat using a walker. To protect the prosthesis, the occupational therapist instructs the client in adaptive procedures and in methods to modify the environment to allow for safe performance of ADLs and homemaking tasks.

The client with a cemented or hybrid total hip prosthesis usually begins partial weight bearing with a rolling walker or crutches immediately after surgery. In some instances, these clients can withstand full weight bearing within the first 3 days; however, many orthopedic surgeons wait 3 weeks before ordering full weight bearing.⁴⁶ The ADL program, which can be taught with the client standing, uses the bathing and lower extremity dressing techniques described for fractures. The client with a cementless THA is usually toe-touch weight bearing for the initial recovery phase and is conservatively progressed to partial weight bearing.⁴⁶ This necessitates learning ADLs from the seated position. Once 50% weight bearing is ordered, the ADL program is upgraded to allow for standing with a cane. The cane is used until the **Trendelenburg gait** disappears.

Usually, after a THA, clients do not receive outpatient therapy following inpatient rehabilitation, although many may receive home care occupational and physical therapy for safety assessment and/or treatment. Between the second and third month after surgery, clients usually resume all routine daily activities, with hip precautions still applicable.

CASE STUDY

Client Information

Lucy is a 68-year-old female who has been discharged to home following a 2-week length of stay in an acute care rehabilitation hospital secondary to a car accident and resultant low back strain and right rotator cuff injury. Lucy's medical care included arthroscopic repair of the supraspinatus with a **shoulder immobilizer** and pain management for low back pain. The focus of her occupational therapy while in the rehabilitation hospital included ADL training, functional mobility, and pain management.

Reason for Occupational Therapy Referral

Lucy has been referred for outpatient occupational therapy services to increase independence in ADLs and instrumental activities of daily living (IADLs). Additional orders include remove shoulder immobilizer to begin gentle PROM to the right shoulder and AROM of the uninvolved joints. Prior to her accident she was independent (I) with all ADLs and IADLs.

Assessment Process and Results

The outpatient occupational therapy evaluation reveals that Lucy lives alone in a one-story condominium with two steps to enter. She has one bathroom that has a tub and shower unit with no grab bars. Lucy has a small kitchen and prior to her accident she cooked all her own meals. Lucy identified gardening and cooking as meaningful occupations.

Assessment of Lucy's range of motion revealed that she has full AROM of her left uninvolved upper extremity and of the uninvolved joints of the right upper extremity. PROM of the right shoulder included the following: shoulder elevation (scaption) 0° to 85°, internal

rotation to stomach, and external rotation 0° to 10°. Right shoulder pain was rated as a 7/10 and is reported to be worse at night.

Lucy requires minimal assistance for upper body dressing. She is unable to place her right upper extremity through the sleeve of her shirt and instead wears loose T-shirt that she pulls overhead and over her arm while wearing her sling. She is unable to don her socks, however is modified independent for donning her pants. Lucy uses a tub bench that was given to her during her inpatient stay to transfer to-and-from the tub. She reports having difficulty washing her hair with one hand.

Lucy has identified cooking as an activity she is having difficulty with due to surgical precautions. She is unable to open containers, cut food, or lift pots and pans. She is presently unable to drive and is concerned about grocery shopping.

Occupational Therapy Problem List

- Decreased ROM secondary to right rotator cuff repair
- Decreased independence in basic ADLs
- Shoulder pain that interferes with sleep
- Decreased independence with IADLs

Occupational Therapy Goal List

- Increase PROM of right shoulder elevation (scaption) to 130° in preparation for participation in hair care in 2 weeks.
- Decrease pain to a 5/10 by proper positioning of the right UE in 1 week.
- Client will be modified (I) for cutting food using a rocker knife in 1 week.
- Client will be modified (I) for dressing upper body in 1 week.
- Client will be modified (I) for simple meal preparation using a one-handed technique in 1 week.

Intervention

Treatment began with a preparatory method using a hot pack × 15 minutes (skin checked and OK). This was followed by passive pendulum exercises and PROM (supine) for shoulder elevation (scapular plane), internal rotation, and external rotation. Lucy was instructed by the occupational therapist on how to correctly perform the pendulum exercises as a home program three times daily: 10 repetitions clockwise and 10 repetitions counter clockwise. The exercises were followed by proper positioning of Lucy's right upper extremity (supine) using a pillow in slight shoulder elevation and external rotation for comfort while sleeping. Lucy reported the change in position when sleeping has decreased her shoulder pain at night.

The therapist worked with Lucy on performing her ADLs using one-handed techniques. The therapist instructed Lucy to don a button down shirt by releasing her right arm from the sling and relaxing her arm in a pendulum position. Using her left uninvolved extremity, pull the sleeve gently onto the involved extremity and up to the shoulder, Lucy is then instructed to reach behind her neck with her left hand and grasp the collar to move the shirt around her back and place her uninvolved arm in the sleeve. To button her shirt one-handed, she is instructed to begin with the bottom button to help align the buttons and button holes correctly. Lucy is taught additional one-handed techniques to perform other ADLs such as one-handed cutting and opening containers needed for cooking. These one-handed techniques now enabled Lucy to only require modified independence to perform her ADLs.

At 6-weeks her PROM included shoulder elevation (scaption) 0° to 150°, internal rotation to stomach, and external rotation 0° to 50°. Right shoulder pain was rated as a 4/10. Lucy was able to perform all her ADLs with modified independence using one-handed techniques. The referring physician upgraded orders to begin AROM and progress to strengthening at 8 weeks. The occupational therapist started Lucy with AROM in supine to lessen gravity and prevent any substitutions. Other preparatory tasks included cane exercises and wall walking to prepare her to perform purposeful activities such as reaching into cabinets and the refrigerator for cooking items. At 8 weeks, the therapist instructed Lucy in isometrics and slowly progressed to isotonic exercises. Prior to discharge, the therapist progressed Lucy to perform an

occupation-based activity of cooking a full meal, which she identified as meaningful. Lucy was able to perform the cooking activity independently using her involved extremity without any compensatory movements.

Best Evidence for Occupational Therapy Practice in Orthopedics

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Comparison of a standard care group (SC) to a combined care group (CT) in patients hospitalized for hip fracture ⁵⁸	The SC group received standard medical, nursing and physical therapy treatment and the CT group received the standard care as well as individual occupational therapy.	Totally, 122 patients with hip fracture were allocated to two groups (CT = 61, SC = 61). After losses at follow-up, 116 were analyzed (CT = 57, SC = 59).	The SC group received physical therapy 5 days/week starting the day after surgery for 30 minutes daily. Patients in the CG group received the physical therapy treatment that the SC group received, in addition they received 20 minutes of occupational therapy 5 days/week starting the day after surgery.	Randomized controlled trial, level I	Integrating occupational therapy as a key component of hip fracture rehabilitation shows short- and long-term improvements in emotional distress, fatigue, and function.	CT group reported lower fatigue at 6 months ($p < 0.044$), whereas SC group had a greater increase in emotional distress at 1, 3, and 6 months ($p < 0.001$). At 6 months, the CT group showed better results in ADLs ($p < 0.048$). Both groups showed an increase in hip function throughout the intervention ($p < 0.001$).
Total shoulder arthroplasty (TSA) for degenerative osteoarthritis of the humeral head and glenoid ⁵⁹	TSA followed by a standardized postoperative rehabilitation protocol including range of motion exercises and gradual progression in active resistive movements.	Totally, 13 patients who received a TSA for degenerative osteoarthritis of the humeral head and glenoid and 10 matched controls (controls) with no shoulder problems.	TSA followed by a standard rehabilitation protocol with passive ROM, external rotation limited to 0° and abduction to 90° for 4 weeks. Progressive active resistive motion was allowed for 4–6 weeks and no limitations after 10–12 weeks.	Case-control study, level III	TSA with standard rehabilitation improves range of motion and performance in activities of daily living for individuals who have degenerative shoulder osteoarthritis.	No significant differences in ROMs between groups except in abduction/adduction while combing hair ($p = 0.001$) and reaching a high shelf ($p = 0.008$). Preoperatively to 6-months postoperatively, use of the arm in ADLs increased (31.5%–90.8%). Active flexion increased on average from 85.0 to 140.40, and abduction from 67.50 to 122.70.

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Comparison of occupational therapy (OT) to home-based exercise program (EP) as a conservative treatment in patients with full-thickness isolated rotator cuff tears ⁶⁰	OT group received supervised exercises determined by the supervising therapist. EP group received an exercise booklet with detailed instructions and demonstrations for exercises to restore neuromuscular control at the shoulder as well as strength and ROM including type of exercises, repetitions, intensity, training, rest phases, and dairy for weekly planning.	Totally, 37 patients with unilateral, symptomatic, atraumatic rotator cuff tears (OT = 22, EP = 16)	The OT group received supervised exercises three times per week for 8 weeks. The EP group were required to participate in two training unites to be performed for 30 minutes, each once in the morning and once in the evening.	Randomized controlled trial, level I	Standardized home exercise programs have the same benefits as occupational therapy interventions in improving pain, strength, quality of life, and range of motion at the shoulder.	Both groups improved in pain, strength, impingement signs, and quality of life. EP group had higher subjective health status compared with OT group ($p < 0.049$). Shoulder ROM improved in both groups, with the highest gains in abduction. EP group showed more improvement in abduction peak torque compared with the OT group.
Early postoperative individualized occupational therapy ⁶¹	Occupational therapy group (OTG): individual ADL and IADL training, including the use of technical aids plus one home visit Control group: conventional care	One hundred patients aged ≥ 65 years having undergone surgery for hip fracture. All lived independently, and none used walking or technical aids prior to hospitalization (randomized to group). Ninety completed the study (10% attrition).	After the third to fourth postoperative day, the OTG received 45–60 minutes of individualized training (including technical aids) each weekday morning for 3–33 days. The control group received conventional care from the nursing staff for 3–23 days. All patients received instruction in walking with mobility aids.	Randomized controlled trial, level IB1b	OT sped up the ability of patients to perform ADLs. At discharge, the OTG had significantly better ability to dress, complete personal hygiene, toilet, and bathe independently compared with the control group. No other factors explained the outcome. After 2 months, all patients had regained independence.	Klein–Bell ADL Scale subtests: Dressing: $F_{(2,91)} = 79.0, p = 0.0001, r = 0.79$. ^a Toileting: $F_{(2,90)} = 5.97, p = 0.02, r = 0.34$. Bathing/hygiene: $F_{(2,91)} = 17, p = 0.0001, r = 0.52$. Mobility: $F_{(2,91)} = 2.20, p = 0.1, r = 0.21$. 52% of the OTG needed technical aids and adaptation of their homes.

^a r value was calculated from data reported, using a formula for F with $df_{\text{numerator}} > 1$. Effect size (r) is considered large if ≥ 0.50 , medium if ≥ 0.30 , and small if ≥ 0.10 .

Rheumatoid Arthritis and Osteoarthritis

Anne Crites and Preethy S. Samuel

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe key features of rheumatoid arthritis and osteoarthritis.
2. Identify clinical sequelae that interfere with meeting occupational performance goals.
3. Select assessments to optimize occupational performance for clients with rheumatoid arthritis and osteoarthritis.
4. Describe interventions to enable clients with rheumatoid arthritis and osteoarthritis to continue, resume, and/or adopt new occupational performance goals.
5. Describe methods of helping clients with rheumatoid arthritis and osteoarthritis to understand and adopt self-management methods during occupational performance.

CHAPTER OUTLINE

Rheumatoid Arthritis: Definition, Prevalence, and Background
Rheumatoid Arthritis–Related Functional Impairments in Daily Occupation
Osteoarthritis: Definition, Prevalence, and Background
Osteoarthritis-Related Functional Impairments in Daily Occupation
Evaluation of Functional Skill Deficits Secondary to Rheumatoid Arthritis and Osteoarthritis
Interventions for Functional Skill Deficits Secondary to Rheumatoid Arthritis and Osteoarthritis
Case Study

TERMINOLOGY

- Bouchard nodes:** hard, bony outgrowths at the proximal interphalangeal (PIP) joints due to osteoarthritis (OA).
- Boutonnière deformity:** joint deformity characterized by flexion of the PIP joint and hyperextension at the distal interphalangeal (DIP) joint.
- Cachexia:** loss of muscle mass as the inflammatory processes affects muscles and the metabolism in rheumatoid arthritis (RA).
- Chondropenia:** loss of cartilage faster than the rate of repair in the osteoarthritic joint.
- Crepitus:** feeling or sound of crunching, creaking, or grating coming from the articular surface during range of motion.
- Disease-modifying antirheumatic drugs (DMARDs):** drugs that affect the immune response or suppress the disease process (e.g., methotrexate).
- Fibrillation:** the initial degenerative changes in OA, marked by softening of the articular cartilage and development of vertical clefts between groups of cartilage cells.

Heberden nodes: hard, bony outgrowths at the DIP joints caused by OA.

Joint protection techniques: the application of ergonomic principles in daily activities, work, and leisure to reduce internal and external stress on the joints and soft tissues.

Mallet finger deformity: deformity resulting from damage to the extensor tendon at the DIP joint.

Swan-neck deformity: hyperextension of the PIP joint and flexion at the DIP joint.

Synovitis: inflammation of the synovial membrane (which lines synovial joint capsules, the function of which is to produce synovial fluid, which lubricates joints).

Volumetry: a water displacement measure of hand volume, conducted by inserting the hand to a specified depth in a measuring cylinder containing a specified amount of water.

Z deformity of OA thumb: carpometacarpal (CMC) joint adduction, metacarpophalangeal (MCP) joint hyperextension, and interphalangeal (IP) joint flexion.

Z deformity of RA thumb: excessive hyperextension of the IP joint and flexion of the MCP joint of the thumb.

Rheumatoid Arthritis: Definition, Prevalence, and Background

Rheumatoid arthritis (RA) is an autoimmune, chronic, systemic inflammatory disease affecting the joints. It is the most commonly diagnosed type of inflammatory arthritis. In the United States, about 1.5 million adults are estimated to live with RA. Women are two to three times more likely than men to develop RA in their lifetime. The most common age of onset of RA is between 30 and 60 years, with younger age of onset for women.¹

Rheumatoid Arthritis Etiology and Pathophysiology

The cause of RA is unknown. The disease process is initiated by an interaction between genetic, hormonal, environmental, and lifestyle factors. Joints can be damaged within months of symptom onset.² The pathological changes observed in the joints include the following:

- **Synovitis:** Thickening of the synovial membrane with increased synovial fluid causes edema around the joint. Edema-related pressure stretches nociceptors in surrounding tissues, causing pain.
- **Pannus:** Protein-degrading enzymes released from inflammatory cells lead to hypervascularization and thickening of synovial membrane to form pannus (inflammatory tissue) that invades the bone and cartilage at the joint margins, leading to chondral and subchondral erosions.
- **Cachexia:** Loss of muscle mass as the inflammatory processes affects muscles and metabolism.
- **Joint instability:** Prolonged joint swelling stretches and weakens joint ligaments and capsules, thereby disrupting the stability of the joint.
- **Joint deformity:** Abnormal movement in the joints with weak ligaments and disrupted structures leads to deformities.
- **Fatigue:** Inflammatory proteins (e.g., tumor necrosis factor alpha) that are released lead to marked fatigue.

Rheumatoid Arthritis Course and Prognosis

The progression of RA varies considerably among individuals. Except in rare cases of spontaneous remission within the first 6 months of symptoms, most people diagnosed with RA have periods of exacerbations and remissions. The three distinct disease courses of RA are as follows:

1. **Monocyclic:** About 20% have one episode ending within 2 to 5 years of initial diagnosis without any recurrence. Early diagnosis and/or aggressive treatment with **disease-modifying antirheumatic drugs (DMARDs)** can arrest disease progression.
2. **Polycyclic:** About 75% experience fluctuating disease activity over the course of the condition, which can last for many years.
3. **Progressive:** About 5% RA continues to rapidly increase in severity and is unremitting.

Rheumatoid Arthritis Signs and Symptoms

Signs and symptoms of RA include symmetrical presentation of polyarticular pain, edema, early morning stiffness, malaise, and fatigue. The four stages of the inflammatory process in RA are *acute* characterized by red, hot swollen joints with pain, tenderness, and stiffness; *subacute* associated with morning stiffness but less pain and tenderness; *chronic active* and *chronic inactive* with reduced pain and increased tolerance but low endurance. RA can also affect the eyes, skin, lungs, heart, gastrointestinal system, kidneys, nervous system, and blood. RA typically has a gradual onset, with symptoms appearing first in the hands and feet. However, in about 20%, the onset is rapid, and clients wake one morning with multiple painful, stiff, and swollen joints, requiring emergency care. The upper limb joints that are usually affected are the wrists (85% of people with RA), metacarpophalangeal (MCP) joints (80%), elbows (70%), proximal interphalangeal (PIP) joints (65%), and shoulders (60%). In the lower limb, knees (80%), ankles (70%), metatarsophalangeal (MTP) joints (70%), and hips (30%) are affected. Additionally, the cervical spine (35%) and temporomandibular joint (25%) can also be affected.³ Although there is no cure, early diagnosis and intervention can slow disease progression.

Rheumatoid Arthritis Hand

In women with early RA (<2 years), average losses are 20° of wrist extension, 30° wrist flexion, 15° MCP flexion, and 60% of normal power and pinch grip strength. A third develop hand deformities.⁴ Early aggressive DMARD therapy, however, may be lowering such losses that have not been documented because of the absence of recent research on RA hand deformities. Deformities develop because of persistent synovitis, disrupted joint structures that alter joint mechanics, and both normal and abnormal forces over joints during daily use of hands.⁵ For example, power grip to hold a hammer requires MCP ulnar deviation, especially in the fourth and fifth fingers, promoting ulnar deviation at weakened MCP joints. During lifting, external pressures in a volar or longitudinal direction increase strain on weakened wrist ligaments. Strong pinch grips increase intrinsic muscle pull, promoting imbalance at the IP joints (Fig. 42-1).

Figure 42-1 Rheumatoid arthritis: right-hand post-op metacarpophalangeal (MCP) arthroplasty, left-hand MCP subluxation and ulnar drifting.

Rheumatoid Arthritis Wrist Joint Changes

The ulnar side of the wrist is an early site of inflammation. The triangular fibrocartilage is disrupted, allowing the proximal carpal row to rotate ulnarward. The distal row compensates by sliding radially, resulting in a gradually radially deviating wrist. Persistent synovitis promotes laxity of the wrist ligaments. Radioulnar ligament laxity allows rotation of the radius and ulna, with the ulnar styloid becoming more prominent. Extensor carpi ulnaris then displaces volarly, passing beneath the wrist joint axis, exerting a flexor pull. This, combined with wrist ligament laxity, and the natural volar incline of the distal radius, increases risk of wrist volar subluxation. Radial deviation at the wrist disrupts biomechanics of the extensor and flexor tendons, causing these to exert an ulnar pull at the MCP joints.

Rheumatoid Arthritis Metacarpophalangeal Joint Changes

Persistent synovitis weakens MCP collateral ligaments, volar plates, and dorsal hoods, leading to joint instability. The finger extensors can slip volarly and ulnarly, increasingly acting as weak flexors. Normal MCP joint features further contribute to ulnar deviation once joint structure is disrupted. These include (1) the flexor tendons normally approach the index and middle fingers from an ulnar direction exerting a significant ulnar torque, (2) the metacarpal head anatomically predisposes to tendons slipping ulnarward, and (3) the ulnar interossei exert a stronger pull than the radial ones. See Box 42-1 to observe this phenomenon in the middle finger.

Rheumatoid Arthritis Interphalangeal Joint Changes

Persistent synovitis can also disrupt positioning of the extensor tendon central slip and lateral bands at the PIP joints, allowing a **Boutonnière deformity** to develop. Similar changes can result in **Z deformity of the RA thumb**. MCP joint inflammation can also cause protective spasms in the interossei, causing MCP flexion during finger extension (the intrinsic plus position), which further contributes to Boutonnière and **swan-neck deformity** development. View the video listed in Box 42-1 representing the mechanics of a swan-neck deformity in active fisting. Appreciate the lateral bands as they have become overstretched and drop below the axis of the PIP joint and thus function to hyperextend the PIP in conjunction with the terminal tendon flexing the distal interphalangeal (DIP) joint.

View video of splinting for swan neck and appreciate the control of the hyperextension provided by the three-point pressure splint.

Rheumatoid Arthritis Medical Management

The goal of pharmacotherapy is to rapidly reduce inflammation to prevent or limit joint damage. The earlier the patient starts DMARDs such as methotrexate, the better the outcome. Combination of medicines (e.g., methotrexate, and/or leflunomide, sulfasalazine, or hydroxychloroquine) is recommended in moderate-to-severe disease and has better outcomes than monotherapy, with no difference in drug tolerability or toxicity.⁶ Biologic drugs such as etanercept, infliximab, or adalimumab are used if DMARDs are ineffective, or if there are poor prognostic indicators.⁷ Early aggressive use of combined DMARD therapy and biologics has improved outcomes of those newly diagnosed with RA. These medications decrease proliferation of synovial tissue, thereby reducing the incidence of severe wrist and hand deformities as seen in the past. Common surgical procedures of the wrist and hand joints include synovectomy, tenosynovectomy, tendon repair and transfers, joint arthroplasty, and arthrodesis.⁸

Rheumatoid Arthritis–Related Functional Impairments in Daily Occupation

The loss of productivity due to RA is substantial because many are diagnosed in their working years of adulthood. About 60% of those diagnosed with RA from the early stages have difficulty with hand function and challenges completing activities of daily living (ADL).⁹ About 20% to 70% of working adults stop working within 7 to 10 years of initial diagnosis.¹ Once unemployed, they are unlikely to return to work. This suggests that two-thirds could benefit from occupational therapy (OT) for hand and ADL difficulties, and at least one-third could benefit from work rehabilitation. Although physical activity is known to decrease pain, improve physical function, and reduce 40% of health care costs, one in three adults with arthritis are inactive.¹⁰

Osteoarthritis: Definition, Prevalence, and Background

Osteoarthritis (OA) is a clinical syndrome of joint pain linked with degenerative joint changes. OA is the most common form of arthritis and the leading causes of pain and disability worldwide. OA affects 30.8 million adults in the United States.¹ OA is a metabolically active, dynamic process involving all joint tissues (cartilage, bone, synovium, capsule, ligaments, and muscle). It primarily affects the cartilage in the hands (thumb carpometacarpal [CMC], PIP, and DIP joints) and weight-bearing joints specifically, cervical and lumbar spine, hips and knees. The lifetime risk of developing symptomatic OA of the hip joint is 25%,¹ the knee joint 46%,¹ and the

hand 40%.¹¹ OA is more prevalent among woman aged 50 years or older,¹² whereas among people aged 45 years or younger, OA is more prevalent among men.¹

Osteoarthritis Etiology and Pathophysiology

OA is caused by the damage of joint cartilage attributed to multiple risk factors: genetic (heritability accounts for 40% to 60% of hand, knee, and hip OA), constitutional factors (more common in women, with age, and with higher body weight), and biomechanical factors (e.g., joint injury, greater occupational or leisure use of a joint, reduced muscle strength, joint laxity, or misalignment). Any synovial joint can develop OA, but structural changes do not always cause symptoms. Pathophysiological changes include **fibrillation**, loss of articular cartilage, and remodeling of adjacent bone with new bone formation (osteophytes). Focal synovial membrane inflammation can occur because of irritation from osteophytes and other joint changes. These changes suggest that OA is a repair process, which is initially effective, resulting in a structurally altered but symptom-free joint. However, continued damage or ineffective repair or **chondropenia** means symptomatic OA results.¹³

Osteoarthritis Course and Prognosis

OA may affect one joint or be multifocal. Onset is typically gradual, although the progression of OA can vary widely based on whether it was a result of an injury or insult to the joint such as a fracture or an insidious onset. Although OA is often viewed as a part of the aging process, types of OA have different prognoses. More than half of all individuals diagnosed with knee OA progress significantly to qualify for a knee replacement.¹ People with IP joint OA become asymptomatic after a few years, although structural joint changes such as nodes persist that can affect function. Thumb base OA frequently continues, causing pain and disability. Hip OA has the poorest outcome, with a significant number needing hip replacements after 1 to 5 years.¹⁴

Osteoarthritis Signs and Symptoms

Signs and symptoms of OA include joint pain, initially on activity that reduces with rest. Over time, pain is persistent and can disturb sleep. Pain is caused by the stretching of nociceptors in the joint capsule due to focal synovitis, increased vascular pressure in subchondral bone, and from spasm of muscles surrounding the involved joints. Joint stiffness occurs after sleep or prolonged inactivity known as the gel phenomenon, which typically lasts 5 to 30 minutes and reduces with movement. Postactivity flare-ups of edema and pain are common symptoms. Joint guarding and decreased willingness to move the painful joint contributes to muscle weakness and limitations in range of motion (ROM). **Crepitus** can occur in advanced cases during ROM with a feeling or sound of crunching, creaking, or grating coming from the articular surface. Hip OA often presents as groin pain.

In hand OA, the repair process can lead to osteophyte formation at joint margins and focal synovitis in affected joints. Hand OA most commonly affects the DIP and CMC joints.¹² Bony enlargement and persistent synovitis can cause joint ligament laxity. Combined with forces exerted on the hands during daily use, deformities can result. At the PIP joints, bony enlargements are known as **Bouchard nodes**, and at the DIP joints, they are known as **Heberden nodes** (Fig. 42-2). **Mallet finger deformity** results at the DIP joint if the distal extensor digitorum communis tendon attachment is disrupted by bony enlargement. The classic thumb deformity in OA consists of squaring at the CMC joint, with **Z deformity of the OA thumb**, which results from CMC joint adduction, MCP joint hyperextension, and IP joint flexion.

Muscle wasting is noticeable in the thenar eminence, and finger, thumb, and wrist movement reduces.

Figure 42-2 Osteoarthritis: the hand and osteoarthritis showing wrist, carpometacarpal, Bouchard nodes (proximal interphalangeal joint), and Heberden nodes (distal interphalangeal joint).

Osteoarthritis Medical Management

The goal of pharmacotherapy is to decrease pain and stiffness and to improve joint mobility and physical activity. Acetaminophen and topical nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen gel) are recommended for pain relief. If necessary, oral NSAIDs may be prescribed. Capsaicin cream or intra-articular steroid injections may be used if problems continue.¹⁴ Early medications were found to have gastrointestinal complications. Newer medications target only the COX-2 enzymes while protecting the prostaglandins in the gastrointestinal tract. These COX-inhibiting nitric oxide donators (CINODs) have been demonstrated to control pain and reduce inflammation while maintaining gastrointestinal safety.¹⁵ If conservative management fails to resolve pain and the degenerative nature of the disease causes further loss of mobility and function in ADLs, surgery may be recommended. Common surgical interventions include joint replacements, such as total hip arthroplasty (THA) and partial and total knee arthroplasty (TKA). The most common procedure of the CMC joint of the thumb is arthroplasty with ligament reconstruction with tendon interposition (LRTI). Arthrodesis, or joint fusion, is reserved for only the most painful joints that have not responded to all other interventions.¹⁶

Osteoarthritis-Related Functional Impairments in Daily Occupation

People with combined finger and CMC OA have the poorest function. In women with hand OA, grip strength is only 57% of normal.¹⁷ Estimates indicate that 80% of those with OA experience some degree of movement limitation and 25% cannot perform major ADLs.^{18,19} One in five with OA have to give up work or retire early because of their condition, and four in five are in constant pain. About 5% of working-age adults with OA report arthritis-attributable work limitations with three lost workdays per year per person.¹

Evaluation of Functional Skill Deficits Secondary to Rheumatoid Arthritis and Osteoarthritis

Assessment identifies client factors, performance skills, and impairments to participation in meaningful life activities. Treatment effectiveness can be evaluated if standardized, reliable, valid measures are used.

Initial Interview

A chart review of patients' medical history, comorbidities, and current medications will help with the history taking component of the interview. For RA, it is helpful to know how long the patient has been taking DMARD or biologic drugs because, if started recently, functional gains may be expected. The interview should also gather information about the social history, which should include whether patients live alone or with others; care of pets, children, and elderly parents; and type of home. It should include a summary of their prior level of function to the present episode of care. The initial interview should also focus on occupational performance: ADL (personal and instrumental); rest and sleep; work (paid or volunteer); education (formal or informal); and leisure, social, and community activities. For example, the Canadian Occupational Performance Measure (COPM) is a semi-structured interview requiring about 20 to 40 minutes to administer that focuses on activity limitations and participation.²⁰ COPM administration ends with identification of the five problems related to self-care, work, or leisure with ratings for each of them by importance, performance, and satisfaction with performance.

As problems are reported, it is essential to explore why they occur: Is it due to pain? Fatigue? Stiffness? Physical limitations (e.g., in movement, strength, endurance)? Environmental factors (e.g., barriers, lack of equipment)? Psychological factors such as poor concentration, low mood, or lack of confidence or knowledge about their condition (self-efficacy)? Performing specific activities because of fears of pain and/or fatigue, or a lack of information about alternatives?

Ask how patients spend a typical weekday and weekend. How much time is spent in activity and in rest or leisure activities? Do patients take regular rest breaks or keep pushing themselves even though fatigued? How are they coping with competing demands of work and home life? How much do they understand about their condition, and what they could do themselves to make a difference? Objective and subjective assessments are selected according to client priorities.

Body Functions and Activity Limitations

ADL observation is more appropriate for those unable to self-report limitations because of comorbid cognitive problems and postsurgery, because changing circumstances can reduce self-awareness of limitations. Interview is more appropriate for those with low mood, which is prevalent among those living with RA and OA.²¹ Using self-reported questionnaires saves time and indicates the need for comprehensive evaluations when required.

- **The Health Assessment Questionnaire (HAQ) and HAQ-DI (disability index)**²² is a 20-item instrument that can be self-administered in approximately 5 minutes and is widely used in rheumatology clinics for quick screening of eight categories of functioning (dressing, rising, eating, walking, hygiene, reach, grip, and usual activities). Scores, however, worsen if assistive devices are used, and hence, the instrument is unsuitable as an OT outcome measure.
- **The Short-Form Valued Life Activities Scale (S-VLA)**²³ is a 14-item instrument that can be self-administered in 2 to 4 minutes and is reliable and valid for clients with RA. The S-VLA assesses a broad range of life activities (self-care, leisure, and social activities such as work, travel, caring, household tasks, and gardening) and use of behavioral accommodations to monitor disability.

- ***Measure of Activity Performance of the Hand (MAP-Hand)***²⁴ is an 18-item instrument that can be self-administered in 3 minutes and has established reliability and validity for clients with RA. The MAP-Hand screens hand function deficits by evaluating performance in eight activities using a four-point rating scale. Total scores range from 0 to 54.
- ***Patient Rated Wrist and Hand Evaluation (PRWE and PRWHE)***²⁵ is a 15-item instrument that can be self-administered in 5 to 10 minutes. The instrument was originally developed for distal radius fractures, but was later modified to include other hand conditions, and possesses validity and reliability data for clients with arthritis. The instrument evaluates pain and function to determine degree of disability; develop treatment goals; predict prognosis of injury from baseline scores; measure clinically important changes; and communicate limitations meaningfully to clients, other health care professionals, and insurance companies.
- ***Michigan Hand Outcomes Questionnaire***²⁶ is a 37-item instrument that can be self-administered in 15 minutes and has established reliability and validity for clients with RA and OA. The instrument evaluates hand aesthetics, pain, ADL, work, function, and satisfaction with hand function. There is also a brief 12-item version²⁷ that is available and has validity for clients with OA and RA.
- ***The Evaluation of Daily Activity Questionnaire (EDAQ)***²⁸ involves a comprehensive evaluation of common effects of arthritis on body functions (e.g., mood, pain, stiffness) using a 10-point rating scale and has the ability to perform 138 daily activities with and without ergonomic methods/assistive devices using a four-point rating scale. The EDAQ is available in multiple languages, can be self-administered in 30 to 60 minutes, and has established reliability and validity for clients with RA and OA.
- ***The Arthritis Impact Measurement Scale-2 (AIMS2)***²⁹ is a 101-item instrument that can be self-administered in 20 to 30 minutes and assesses the negative impact of arthritis in the past 4 weeks with regard to arm function, mobility, physical activity (walking, bending, lifting), dexterity, household activity (managing money and medications, housekeeping), work, social activities, ADL, pain, depression, and anxiety. Total scores using the Guttman response scale range from 0 to 60, where lower scores represent better health status. The AIMS2 was psychometrically tested with clinical sensitivity to measure treatment effect in clients with RA and OA. AIMS2 is available in multiple languages and in different versions (short-form has 26 items that can be completed in 10 minutes; pediatric and geriatric versions).

Activity Diaries

A diary of how the client spends a typical weekday and weekend day, with each day divided into half-hour periods, helps identify occupational balance. Several designs exist. For example, the patient can write the main activity completed in each half hour, indicate level of pain and fatigue experienced using a 10-point rating scale, and note whether rest was taken.

Mobility and Upper Limb Function

Overall movement can be assessed, if necessary, using the Gait Arms Legs Spine (GALS), a reliable, valid musculoskeletal screening examination³⁰ that takes 5 to 10 minutes to administer. See Box 42-1 for the link to a video that shows the examination being conducted.

Hand and Upper Limb Assessment

In RA, a tender and swollen joint count can be conducted for hand splint assessment or to monitor progress over time. See Box 42-1 for a link to a video that shows this assessment performed as part of the Disease Activity Score-28.³¹ **Volumetry** that measures hand girth can be used to measure hand edema. Although reliability of circumferential measurements has not been shown, they can be helpful for documenting the swelling of an isolated joint, especially when volumetry will not capture hand girth. Circumferential measurement of involved joints can be compared to the contralateral side, if uninvolved, or to adjacent joints in the case of the digits. In RA and OA, recording hand appearance (e.g., the presence of joint swelling, pain, and deformity) on a hand chart is particularly useful, as is digital photography. ROM should be measured using standard goniometric methods.

Grip strength can be assessed using the Jamar dynamometer, although this is less accurate for weak grip. Pinch strength can be measured with a B&L pinch gauge, which is also reliable. Normative data are published for grip and pinch measured using the Jamar and B&L gauges.³² Other reliable and valid hand assessments include (1) the *Grip Ability Test*, which takes 5 minutes to administer and consists of pouring water from a jug, placing a paper clip on an envelope, and pulling Tubigrip over the hand and forearm³³; (2) the *Sequential Occupational Dexterity Assessment (SODA)*,³⁴ a more detailed assessment requiring about 15 to 20 minutes to measure bimanual dexterity activity in RA; and (3) the *Nine-Hole Peg Test (NHPT)*, which measures unilateral fine manual dexterity, is compact, simple, and easy and takes 5 minutes to administer.³⁵

Work Assessments

Evaluation of work is important in the rehabilitation of persons with arthritis. Interviews, screening tools, and self-assessments, such as the Work Environment Survey-Rheumatic Conditions,³⁶ Worker Role Interview,³⁷ and Manual Work Instability Scale,³⁸ are all effective tools for identifying employment-related problems and the client's perceptions of abilities, limitations, and expectations related to work.

- ***Ergonomic Assessment Tool for Arthritis (EATA)***³⁹ documents task description, equipment used, typical activities at work during 1 day, work postures, work demands, and work station layout. The EATA helps guide observation and recording during a work site visit and job analysis, or can be conducted as an interview and/or client self-report.
- ***Functional Capacity Evaluation (FCE)***⁴⁰ is an observational and functional assessment of work ability that describes a person's ability to perform work activities. FCE is an umbrella term that includes evaluation systems such as the WorkHab, WorkWell Systems, and Matheson systems.

Interventions for Functional Skill Deficits Secondary to Rheumatoid Arthritis and Osteoarthritis

The overarching goal of occupational interventions is to enable patients to improve their occupational performance and participation in daily-life roles and routines, despite the functional impairments due to arthritis. In the *acute stage* of inflammation, the focus of treatment should be on gentle passive and active ROM to the point of pain (without stretch). In the *subacute stage*, treatment can include both active and passive ROM, gentle passive stretch, and isotonic and graded isometric exercises with minimal stress to joints. In the *chronic active* and *inactive stages*, treatment focuses on stretch at end range, and resistive isotonic and isometric exercises that do not stress the joints. The key factors to consider when developing treatment plans are to

respect pain, avoid fatigue, manage stress, prevent deformities when possible through avoidance of stress to inflamed tissues and joints or excessive activity/exercise during a flare-up or exacerbation, use thermal modalities with caution and limit the application of heat to 20 minutes, use resistive exercise with caution, and be aware of sensory impairments. Therapeutic programs should promote weight-bearing activities, and ROM as tolerated with affected joints and as much as possible with unaffected joints, and aerobic exercise. Interventions to reduce functional impairments associated with RA and OA in all stages can be broadly classified into five categories: client education, physical agent modalities, edema management, orthotic devices, and therapeutic activities and exercises. The focus of intervention varies by the stage of the inflammatory process. Interventions are summarized in Box 42-2.

Box 42-2

Comprehensive List of Occupational Therapy Interventions in Rheumatology

Activities of Daily Living (ADL) Rehabilitation

- Work rehabilitation: including on-site work assessments, ergonomics; work assistive devices; employer liaison; work environment adaptation; functional capacity evaluation; work hardening
- Avocational rehabilitation: voluntary work, adult education, and leisure opportunities; modifying leisure activities
- Stress and pain management
- Relaxation training
- Communication and assertiveness training

Counseling

- (may also include cognitive-behavioral therapy if the therapist has postgraduate training)
- Family/caregiver liaison and support
- Advice on social security benefits and community resources
- Exercise for health and well-being (e.g., Tai Chi, yoga, swimming, walking, low impact dance programs)
- Self-management education (individual and group work) using cognitive-behavioral approaches
- Activity/role planning, goal clarification, and setting
- Ergonomic education (joint protection), fatigue management

Assistive Technology and Adaptive Equipment

- Orthoses (e.g., resting and working hand splints, elbow and neck orthoses)
- Hand and upper extremity therapy and exercises (active range of motion [ROM], passive ROM, resistive and dexterity exercise)

Therapeutic Activities

- Home assessment, recommendations for environmental and housing adaptations

- Mobility aids prescription (including wheelchair/powering aids), driving/transport advice
- Total joint replacement postoperative management (ADL retraining, assistive technology)
- Foot care advice and simple orthoses (e.g., metatarsal pads, arch supports, insoles)

Physical Agent Modalities

Nonpharmacological interventions that include physical agent modalities can be beneficial in reducing pain and stiffness, although extant research on their effectiveness is inconclusive.¹² Heat applications such as superficial hot-packs, infrared radiation, paraffin wax bath, fluidotherapy, and hydrotherapy have the potential to reduce pain, muscle spasms, and increase elasticity of periarticular structures.¹² Therefore, these applications are best used for 10 to 20 minutes before engaging in therapeutic exercises or activities.¹⁵

Cold applications such as ice-packs and cryotherapy are preferred over thermotherapy in active joints where intra-articular heat increase is contraindicated, such as during an exacerbation of RA symptoms. Care should be used in selection of heat and cold modalities with attention to the stage of the disease process and monitoring of vascular reactions, and skin and tissue responses. Heat is generally preferred for the effects on pain and periarticular structures. Warm water soaks and baths/showers can alleviate pain and stiffness for people with arthritis.

Ultrasound uses high-frequency sound waves to provide mechanical and thermal effects that can improve healing of soft tissue, decrease the inflammatory response, increase blood flow, increase metabolic activity, and decrease pain based on emerging evidence.^{41,42} Electrostimulation such as transcutaneous electrical nerve stimulation (TENS) that involves noninvasive delivery of electrical signals via superficially placed skin electrodes can reduce pain for people with arthritis and improve hand grip strength.¹² Low-level laser therapy uses a single wavelength of light to produce not a thermal effect but photochemical reactions in the cells to promote soft-tissue healing, reduce inflammation, and reduce acute and chronic pain seen in OA and RA.⁴³

Edema Management

Interventions to reduce edema focus on improving circulation to the affected limb. Increased use of the affected limb within pain limits must be strongly encouraged as well as elevation of the involved limb above the heart when at rest. Avoidance of the dependent position will reduce fluid retention within the extremity. Gentle hand pumping (fisting) combined with elevation should be encouraged to improve circulation. Contrast baths that involve immersing the swollen arm or leg alternatively in hot and cold water can also reduce edema.⁴⁴ Compression gloves can decrease edema, reduce nocturnal pain, and reduce pain and stiffness during daytime activities, because they are easily worn in activity, although the evidence is still inconclusive.¹² Kinesiotaping that involves the use of an elastic therapeutic tape can reduce edema and pain without restricting use of the affected limb in daily activities for those with RA⁴⁵ or OA.⁴⁶ Caution should be used with fragile skin.

Orthotics

Splints are used to reduce local inflammation, reduce soft-tissue and joint pain, correctly position joints, improve joint stability, and improve hand function. During the *acute stage* in the inflammatory process of RA, splints can be used to support the joints in their open-packed position, allowing the most space in the joint and reducing

pain associated with swelling. Joint effusion can cause damage to the soft-tissue structures surrounding the joint. Therefore, joints should be placed as close to a functional position as possible. Splint wear regimen should include intermittent removal, gentle ROM, and use of the hand in daily activities.

Static Resting Splints

Resting splints can reduce localized pain and inflammation by providing support in an anatomically correct position at rest. They can be worn at night and/or during daytime rest periods. Although the research evidence can be mixed, there is clinical consensus on the value of using resting splints for those living with RA⁵ and OA¹⁵ (Fig. 42-3).

Figure 42-3 Resting pan splint.

Wrist Orthoses

Wrist orthoses are widely used with many available designs. A close fit, not impeding MCP and thumb movement, is needed. They can be worn for nighttime pain relief if the person has wrist, but not MCP or IP pain. Their main aim is to reduce torque during heavy tasks involving the wrist and to stabilize the wrist in a functionally effective position (i.e., 10°–15° of extension). Wrist orthoses are more effective in reducing hand pain than improving grip strength or hand function.¹⁵ Supportive wrist splints can be beneficial when worn during heavy activities, such as ironing, gardening, housework, and at work.

Metacarpophalangeal Splints

Small palm-based splints can have a wrist and forearm component to reduce medial force on the MCPs and maintain fingers in correct alignment. These splints reduce ulnar deviation of the fingers and improve hand function in people with RA with established MCP deformities.⁴⁷

Finger Splints

Swan-neck splints apply three-point pressure around the PIP joint to prevent PIP joint hyperextension and subsequent DIP flexion. They can be made or bought in thermoplastics or made in silver. Both types can improve dexterity and hand function, and many clients prefer prefabricated splints.¹² In the case of significant swelling at the PIP joint, custom thermoplastic three-point pressure splints can be fabricated. See Box 42-1 for a link to a video of three-point products' thermoplastic “ring” splint preventing swan-neck deformity in active fisting.

Thumb Splints

Short, hand-based splints are designed to immobilize the CMC joint only, the CMC and MP, or a longer hand/ forearm splint if pain extends to the wrist. Evidence suggests that CMC joint splints can reduce pain, improve function, and avoid or delay surgery in OA.⁴⁸ Many prefer a short flexible splint to longer more rigid versions (Fig. 42-4). See Box 42-1 for a link to a video of an occupational therapist making a pattern and fabricating a custom short opponens splint.

Figure 42-4 Short opponens splint.

Therapeutic Activities and Exercises

Physical activity for people with RA also has favorable effects on bone by slowing joint destruction and increasing bone mineral density as evidenced by radiographs.⁴⁹ Short-term aerobic exercise programs comprising activities such as cycling or running for 1 hour each day four to five times a week for about 5 days a week are effective in RA.⁵⁰ Resistance training not only increases muscle strength but reduces systemic inflammation. However, in the acute phase of inflammation or flare-up, resistive exercises are contraindicated. Aquatic aerobic programs are considered more effective for people with OA.⁵¹ Engaging in physical activity for people with arthritis is associated with improved self-esteem, quality of sleep, reduction of pain, and depressive symptoms.⁴⁹ People with arthritis are often not physically active owing to low energy, fear of aggravating pain, and also because of low awareness of these benefits.

Occupational therapists should develop home programs that integrate physical activity into daily routines and teach home maintenance programs for ROM, strength, and aerobic exercises. People often need advice tailoring exercise and activity to suit their changing ability and to progress gradually, rather than overdoing it. Efficacy of home exercise programs is contingent on educating patients about the benefits of physical activity—how it reduces pain, improves fitness, and increases energy levels as muscle strength and aerobic capacity increase, and in RA and OA, how it helps

protect joints as stronger muscles compensate for weakened ligaments. Working together with other specialists, such as physical therapists and recreational therapists, can maximize the outcomes of home programs.

Hand Exercises

Exercise is effective in improving hand strength (grip and pinch) and function and to reduce pain in RA⁵² and OA.¹⁵ The addition of an individually tailored resistive hand exercise program to the usual care of people with RA on a stable drug regimen led to improved hand function without any adverse effects.⁵² In hand OA, exercises can improve grip by up to 25% and reduce pain.⁵³ However, exercise must be sustained, otherwise the benefits are lost. Exercise diaries and goal setting help people sustain exercising. Opportunities to remind people to restart, if they lapse, are essential. A simple home program is described in Box 42-3.

Box 42-3

A Home Hand Exercise Program

<p>Find a comfortable position: support the arm to avoid shoulder aching.</p> <ul style="list-style-type: none"> • Warm up by moving the joints a little first and/or soaking in warm water for a few minutes. • Exercise 3 days the first week, increasing repetitions and number of days over 2 to 4 weeks, to 10 repetitions most daily.
<p>Range of Motion</p> <ul style="list-style-type: none"> • Wrist extension/flexion • Forearm pronation/supination • Tendon gliding exercise • Radial finger walk
<p>Muscle Strength and Dexterity Exercise</p> <p>Use a good handful of therapeutic putty. Five minutes initially, gradually increasing to 10 to 15 minutes. (Caution: Do not use during acute phase of inflammation or with unstable joints.)</p> <ul style="list-style-type: none"> • Gently knead and squeeze. • Push fingers into dough and push out straight. • Pinch off dough with each finger/thumb in turn. • Roll into a sausage (two hands). • Form a “ring doughnut” from the sausage. Put the fingers/thumbs in the hole; stretch out.
<p>Grip a 0.5-L (16.9-fl oz) water bottle (with a “waist” filled with water or sand). Support the forearm.</p> <ul style="list-style-type: none"> • Lift bottle up and down slowly, first with palm facing down 10 times, and then with the palm facing up 10 times. • Isometrically (statically) squeeze the bottle with a 10-second hold, repeat 5–10 times.

Ergonomics in Arthritis

The term *ergonomics* is most literally translated to mean “the laws of work.” It is the science of addressing human performance in relation to occupational tasks and applying the most efficient use of equipment, tools, and the environment to promote health and safety. Related approaches are *joint protection*, *energy conservation*, and *body mechanics*. **Joint protection** aims to reduce loads on joints and reduce deforming forces, thus minimizing risks of injury. Patients with rheumatic conditions causing joint or soft-tissue pain and swelling, loss of motion, and deformities often have decreased energy and may require more energy for even basic activities. Energy conservation techniques function to conserve energy resources, so an individual can perform tasks at a higher level of function without expending more energy. Body mechanics focuses on minimizing strain on body structures by preserving a balance of musculature. The emphasis is on maintaining a neutral position through muscle co-contraction, thereby supporting the soft-tissue structures (joints, ligaments, muscles, and tendons) during daily activities. Ergonomic and joint protection principles are

summarized in Box 42-4. For more information, consult the following resources: www.osha.gov/SLTC/ergonomics/ or <http://ergo.human.cornell.edu/>.

Box 42-4

Ergonomic (Joint Protection) Principles

- Respect pain.
- Distribute load over several joints.
- Reduce the force and effort required in activities.
- Use correct patterns of movement.
- Use good body positioning, posture, and moving and handling techniques.
- Use the strongest, largest joint available for the job.
- Avoid staying in one position for too long.
- Use ergonomic equipment, assistive devices, and labor-saving gadgets.
- Pace activities: balance rest and activity, alternate heavy and light tasks, and take microbreaks.
- Use work simplification: plan, prioritize, and problem solve.
- Modify the environment and equipment location to be ergonomically efficient.
- Maintain muscle strength and range of motion.
- Use adequate lighting.

Goals of Ergonomics

The goals of the ergonomic approach in RA and OA are to:

1. **Reduce pain** during activity, and at rest, resulting from pressure on nociceptive endings in joint capsules, caused by inflammation and/or mechanical forces on joints
2. **Reduce forces on joints:** Internal (i.e., from muscular compressive forces, e.g., during strong grip) or external (i.e., forces applied to joints while carrying or pulling/pushing objects)
3. **Reduce secondary inflammation** and subsequent strain on soft tissues resulting from excess (i.e., beyond tolerability) force on already inflamed and/or disrupted joints
4. **Reduce loading** on articular cartilage and subchondral bone, thus preserving joint integrity and reducing risk of development and/or progression of deformities
5. **Reduce pain resulting from overuse** (i.e., beyond tolerability) of deconditioned muscles
6. **Reduce fatigue**, by reducing effort required for activity performance, thus improving function

Ergonomic Methods

Hand ergonomics in RA include changing movement patterns to limit strong grips, twisting movements, and sustained grips to reduce MCP forces; to limit lifting heavy objects and sustained wrist radial positioning to reduce wrist volar and radial forces; and to limit tight, prolonged key, tripod, and pinch grips to reduce volar and ulnar forces on the MCP, IP, and CMC joints. Approaches are similar in OA, although there is no need to emphasize reducing ulnar forces on the second through fifth MCPs, because these are not affected. The rapid decline of hand function often seen in early RA and hand OA suggests that effective ergonomic education should be provided early to improve and maintain function or prevent problems.

Ergonomics and Assistive Technology

According to the Assistive Technology Act of 1998 (amended in 2004), *assistive technology* is defined as “any item, piece of equipment or product system whether acquired commercially, modified, or customized that is used to increase, maintain or improve functional capabilities of individuals with disabilities.” In RA and OA, the focus is to reduce the effort required using ergonomic equipment or products with *universal design*, that is, devices that are designed for an array of abilities and to be easy for all to use such as levered-handled faucets and doorknobs. Avoid lifting using wheels; put shopping in a folding hand cart, easily kept in the trunk of the car when not in use. Avoid bending and kneeling; sit on a garden kneeler/stool when weeding. Wear cushioned, shock-absorbing insoles in shoes to reduce pressure on foot and knee joints when walking and standing. At work, use voice-activated software to reduce keyboarding. Communicate using hands-free phones (headsets, speaker, or voice-to-text). There are many kitchen and household products available in stores and via the Internet, such as jar openers and electric can openers. Encourage people to consider features of good design when creating or selecting assistive technology and universal design products. Ergonomic products should be

- Lightweight, durable, compact
- Nonslip with larger handles
- Comfortable to hold and easy to maneuver
- Attractive and acceptable to the user
- Simple to operate, multipurpose (if appropriate)
- Reduce stress to all joints needed to operate the device
- Affordable

Altering Movement Patterns and Use of Proper Joint and Body Mechanics

In hand activities, two hands can be used, and the load can be spread over the palmar surface (Fig. 42-5). Movement patterns can be changed by, for example, turning a jar lid using the thumb, index, ring fingers, and thumb web space. The fingers are kept in correct anatomic alignment, and ulnar forces are avoided. Placing Dycem (nonslip matting) under items reduces effort to stabilize objects with the nondominant hand (Fig. 42-6). Using offset knife with built-up handle promotes a neutral wrist position with less effort for grip. Using an adapted cutting board with prongs to hold the food in place reduces effort to stabilize the food item (Fig. 42-7).

Figure 42-5 Distribute the load using two hands to carry laundry soap.

Figure 42-6 Altering movement patterns avoiding ulnar forces opening container, using Dycem to secure the object requiring decreased force to stabilize the object.

Figure 42-7 Assistive technology: offset knife w/ built-up handle, adapted cutting board stabilizes food.

Objects should be kept closer to the body when lifting and carrying, and/or a stronger larger joint can be used. For example, avoid carrying a shopping bag using a hook grip in the hand (Fig. 42-8). Alternatively, use a bag with longer handles pulled over the shoulder or backpacks to distribute weight on both the shoulders. Avoid prolonged sitting and standing. Change position frequently. Smartphones and smartwatches have apps that offer intermittent reminders for such postural adjustments and movement breaks. For people with knee and foot pain, a counter-height chair or an adjustable perch stool reduces standing when preparing food or ironing. For postoperative hip and knee replacements or patients with limited ROM in hips, knees, or spine, assistive devices such as long-handled shoe horns and sock aids can assist with donning lower extremity clothing (Fig. 42-9). Work surfaces and items should be within the reach of the arms. Maintain efficient postures when working (e.g., avoid sitting with a forward head posture when working at a desk or reading). Book stands, writing slopes, and document holders help. Keep the back straight using supportive seating, such as ergonomic office chairs and higher back supportive sofas. Poor posture and positioning increase muscle fatigue and pain because greater energy is used to maintain biomechanically inefficient postures.

Figure 42-8 Using stronger, larger joints and holding closer to the body: carrying a grocery bag.

Figure 42-9 Sock aid to don socks caused by loss of motion in spine, hip, or knee, or post-op range of motion precautions.

Restructuring Activities, Work Simplification, and Altering the Environment

Can an activity be done differently? For example, rather than taking a sauce pan to the sink, holding it while it fills, and carrying it back across the kitchen, fill it with a lightweight measuring cup instead (Fig. 42-10). Use a pot/pan stabilizer to assist with the effort required to hold the pan in place. Could shopping be done via the Internet to save driving, walking, and carrying bags? Reorder the sequence of tasks within activities to increase efficiency. Eliminate unnecessary tasks: Do all items need to be ironed? Keep frequently used equipment easily accessible and within reach. Unclutter

and reorganize work areas to streamline work processes. Locate equipment to promote correct joint positioning (e.g., keyboards). Raise or lower work surfaces to maintain good posture. Ensure storage is efficient (e.g., use stepped shelves in cupboards and sliding racks so that jars, cans, and boxes are easily reached).

Figure 42-10 Restructuring activity: fill pan with measuring cup/use of pan holder to assist stabilizing pan.

Fatigue Management

Fatigue can be caused by physical and psychosocial factors. Physical factors include pain, increased physical demands because of altered joint biomechanics, deconditioning because of insufficient physical activity, and/or overdoing activities (the boom–bust cycle). In RA, the inflammatory process contributes to fatigue and also causes anemia and muscle cachexia. Psychosocial factors (e.g., depression, anxiety, helplessness, stress, poor self-efficacy), poor social support (e.g., lack of understanding from family and friends), and work pressures contribute to fatigue. A variety of strategies help reduce fatigue, including ergonomic approaches at home and work, activity pacing, increasing physical activity/exercise, and stress management. Encourage clients to manage stress using mindfulness therapy, relaxation, meditation, and cognitive–behavioral therapy.

Activity Pacing

Many find taking a rest break difficult because it can be seen as “giving in.” Rest “recharges the batteries,” allowing people to keep going for longer. Rest recommendations include taking microbreaks for 30 seconds every 5 to 10 minutes or so, stretching and relaxing joints and muscles being most used, or taking a rest break for up to 5 minutes every 30 to 60 minutes. Frequency depends on fatigue severity. Rest breaks allow muscle recovery time. Help develop habits by using computer screen prompts, a kitchen timer, or a mobile phone alarm (or set to vibrate) to remind the person to take the rest break.

Activity Planning

Balance activities to alternate between light, medium, and heavy tasks during the day and week. A “boom–bust” cycle is common, with people doing too much on good days and suffering the consequences for the next few. Breaking this habit requires attitudinal change. Many fear the consequences of failing to meet responsibilities. Activity diaries help people see boom–bust patterns. Use a diary with a line for each day of the week, each divided into 24 hours, showing 7 days on one page. The person completes this over a week, coloring the hours of high activity in red, medium in amber, and low in green, with rest colored blue. This graphical shows how clients are overdoing activity and why they are fatigued.

Sleep Hygiene

A sleep diary that could include apps on smartwatches or smartphones can help identify why sleep is problematic. Solutions can include change of mattress and pillow (e.g., memory foam); establishing a regular bedtime and relaxing evening routine (e.g., listening to a relaxation recording, warm bath, or hot milky drink); avoiding stimulants (coffee, tea, alcohol, nicotine, and caffeinated soft drinks) before bedtime; reducing stimuli in the bedroom (e.g., no TV or computer use) and black-out curtains; and muted colors. Improving sleep can help in fatigue management.

Vocational Rehabilitation

Vocational rehabilitation includes (1) job modifications or “accommodations” such as ergonomic changes (restructuring work tasks, assistive technology and adaptations, work station/place redesign, and splints); (2) psychosocial and informational strategies (increasing confidence to ask for job modifications, work rights, statutory [imposed by law] VR service availability, and coping strategies); and (3) liaising with employers (about job and hours flexibility and better understanding of the condition), occupational health, and statutory services. Evidence indicates that vocational rehabilitation when combined with comprehensive OT improved self-perceived ability to manage self-care, work and leisure, work instability, work satisfaction, and pain reduction.⁵⁴

Postoperative Management

The postoperative management of surgical interventions of the wrist and hand due to RA and OA are most often managed by the occupational therapist who specializes in hand therapy. Treatment typically consists of custom thermoplastic splint fabrication to provide support to the surgical area protecting percutaneous pins and surgical scars in a position that is most conducive to recovery of motion without disruption of the procedure. There are specific postoperative protocols related to the various surgical procedures, which vary from surgeon to surgeon. Most often, the patient is initially immobilized followed by active and passive ROM to restore joint mobility and progressive strengthening, coordination retraining, and hand use to tolerance. Some procedures such as MCP joint arthroplasty with tendon repositioning include dynamic splinting to allow for controlled early mobilization of the joints and excursion of the tendons during the healing phase of recovery.

Postoperative management of hip and knee replacements include education of the various precautions for motion to prevent disruption of the joint prosthesis and training in lower body dressing and hygiene with adherence to motion restrictions. Assistive technology such as long-handled reachers, sponges, shoe horns, and sock aids are provided when necessary for independence in ADLs (see Fig. 42-9). Adaptations to typical movement patterns such as transferring in and out of bed, and up and down from the toilet or chairs are reviewed with the client and caregivers.

Theoretical Frameworks and Clinical Outcomes

All of the abovementioned interventions assist clients in adapting their lifestyle to improve self-management and occupational balance. However, changing habits and routines is not easy. On average, adherence rates are about 50% for many interventions. Theoretical frameworks such as the transtheoretical model, social cognitive theory, and cognitive-behavioral therapy can be invaluable in fostering long lasting change via the process of OT interventions.⁵⁵ According to the transtheoretical model, people cycle through five stages (precontemplation, contemplation, preparation, action, and maintenance) when modifying health behaviors with lapses possible at any of these stages. If the person is not yet ready to make changes, *motivational interviewing* can help to foster attitudinal changes. The following are examples of motivational interviewing questions that can be self-rated on a scale ranging from 0 to 10:

- How important is it for you to reduce these symptoms and continue these activities?
- How confident do you feel about making changes?
- How ready are you to make changes?

Let the client discuss his or her concerns, which are commonly about negative self-image, embarrassment, not wanting to use assistive devices, wanting to remain as he or she is, not wanting to take the time to change, or concerns that using ergonomics makes tasks slower and more difficult.

Enhance principles of social cognitive theory by encouraging clients to participate in self-help groups. Group interventions enable modeling, problem-solving, peer support, and idea exchange. Watching others like themselves successfully perform actions enhances their beliefs that they can also succeed, therefore encourage participating in support groups (virtual or in-person). Group members must be encouraged to reinterpret physiological signals; clients should be assisted to perceive differences in disease symptoms and increased symptoms (e.g., aches, fatigue, joint swelling) from overdoing activities.

Incorporate the cognitive-behavioral approach by helping clients set short (weekly action plan) and long-term goals such as remaining at work. Explain how assistive technology and ergonomics can propel them toward their goal. Encourage clients to apply principles of ergonomics in work and leisure activities. Between sessions, ask them to self-monitor: watch movements during common activities (e.g., making a meal, at work) as they normally do them. What forces occur? Is there aching, pain, or fatigue? Ask them to reflect and compare with the ergonomic approaches they are learning. Often, “the penny drops”; clients begin to see the connection between ergonomic approaches and a reduction in pain and fatigue.

CASE STUDY

Patient Information

Aanya is 45-year-old Indian woman with a 3-year history of RA. She is stable on DMARDs. At her last 6 monthly rheumatology appointment, she complained of increasing pain in her right wrist, hand, shoulder, and feet. She is a full-time fourth-grade schoolteacher, the quality of her work is affected greatly because she is right handed, and she is unable to take time off work. She lives in a first floor, one-bedroom apartment.

Reason for Occupational Therapy Referral

Aanya was referred by her rheumatologist for assessment of hand function, help with work problems, and self-management education. She wants to keep working full time.

Assessment Process and Results

Because Aanya's priority is work, she was assessed using the Work Environment Survey-Rheumatic Conditions (WES-RC) and an activity diary. Every day, in the classroom, Aanya regularly uses an interactive whiteboard, desktop computer, tablet, and cell phone. She has to move round the classroom and bend frequently to help students with activities in small groups. She drives to work and has a full briefcase to carry to the car. She buys lunch at the school cafe. Work consumes all her time and energy, and she is unable to manage her housework. Aanya buys ready meals and seeks help from her friends and family. She spends weekends recovering, and the pain reduces, but she is often still tired. Her sleep is disturbed by hand pain at night. Her pain and fatigue decrease during school vacations. She enjoys her work very much despite the daily pain and fatigue, but has no energy left for leisure and community engagements.

Physical examination of Aanya's hands, wrist, shoulder and feet (using the Gait Arms Legs Spine [GALS]), and tender and swollen joint count showed a mild inflammatory process and no deformity. Bilateral grip strength was 30 lb (norm is about 60 lb). On a Visual Analog Scale (VAS) for pain and fatigue, Aanya scored 7 of 10 for both after workday. Self-administration of the EDAQ indicated that she had problems in cooking, meal preparation (such as opening jars, peeling vegetables, and lifting pots/pans), cleaning using the vacuum cleaner and mop, sewing, knitting, and social outings such as bowling.

Occupational Therapy Problem List

- Right wrist, MCP, shoulder, and foot pain worsen during the workday, especially when she is using the interactive whiteboard at work that requires prolonged standing.
- Difficulty with home maintenance
- Difficulty preparing meals
- Limited leisure activities
- Poor sleep because of nocturnal hand pain

Occupational Therapy Goal List

- Use ergonomic approaches to reduce wrist, MCP, shoulder, and foot pain during work, home, and meal preparation activities.
- Use fatigue management (activity pacing) to reduce fatigue.
- Wear right wrist orthosis to protect her hands during heavier activities and compression glove at night to reduce pain and morning stiffness.
- Perform hand exercises daily to improve grip strength and endurance.
- Identify leisure and community engagements that demand less energy consumption.

Intervention

- Identify activities that are most important to Aanya to accomplish each day at work, home, and in the community.
- Identify long-term goals and set priorities together; teach how to action plan short-term goals.

- Provide ergonomic education emphasizing self-analysis of activity, problem-solving, and practicing alternative methods to reduce joint stress. Practice each session.
- Explore alternative equipment to operate the interactive whiteboard to reduce shoulder movement (e.g., light pens); alternative mouse and keyboard designs; use voice-activated software to reduce keyboarding time.
- Explore adapted equipment for carrying heavy briefcase (e.g., wheeled briefcase, folding hand cart). Discuss use of online assessment with kids to reduce marking and getting books home.
- Explore using a stool with wheels around classroom to scoot between tables and reduce standing/bending.
- Discuss fatigue management, such as pacing activities and microbreaks. Discuss goals to practice and how to fit into routines.
- Review meal preparation activities, teach ergonomic methods, and review equipment available in shops to reduce wrist and MCP stress (e.g., easy jar, can openers, adapted cutlery with built-up handles such as Good Grip knives).
- Review driving such as padded steering wheel, and hand and arm positioning.
- Identify and fit appropriate right wrist splint, fit right compression glove. Explain wearing time of orthoses and purpose. Train in appropriate donning, doffing, and general care.
- Teach hand exercise program (ROM and strength): Practice and grade-up weekly.
- Review adaptive equipment/techniques to help with knitting and sewing.
- Recommend socialization by joining a book club (virtual or in-person).

Evidence Table of Intervention Studies for Arthritis

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Ergonomics (i.e., joint protection [JP]) for adults with RA ⁵⁶	Standard arthritis education program versus a JP program using educational, behavioral, motor learning, and self-efficacy-enhancing strategies	$n = 65$ (JP); $n = 62$ (standard) programs; RA: Mean age: 50 years; 30 men, 97 women	Both study and control groups received 8 hours of intervention (4 × 2-hour weekly meetings). Study group received JP training in addition to the information that control group received on RA, exercise, pain, and foot care.	Randomized controlled trial (RCT) Level I	Four years post-treatment, JP group continued to have better ADL scores and JP adherence than control group.	Study group significantly improved in ADL ($p = 0.04$, effect size, $r = 0.15$), early morning stiffness ($p = 0.01$), and behavioral assessment ($p = 0.001$, $r = 0.27$) and fewer hand deformities: MCP ($p = 0.02$) and wrist joints ($p = 0.04$) in study group.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Wrist splints to support the wrist to permit functional use of the hand in adults with RA during daily activities ⁵⁷	Review of the effect of wrist splints on reducing pain, increase strength and dexterity, and in functional activities for adults with RA	Twenty-three studies from 1981 to 2009 were reviewed: with total sample 1,492 participants.	Wide variety of splints and variable disease duration lead to diverse splint wearing regimen. Use of splint was task specific, for example, greater use of splints in heavy tasks such as vacuuming.	Mixed-methods systematic review Level I	Working wrist splints reduced pain and improved grip in RA, but effect on function was unclear.	Strong quantitative evidence (including nine RCTs) supported by conclusions from two qualitative studies indicates that working wrist splints reduce pain ($d = 0.7-0.8$), moderately improve grip strength ($d = 0.3-0.4$), and decrease dexterity.
Assess the benefits and harms of exercise for people with hand OA to reduce pain, increase grip and pinch strength, increase dexterity, maintain joint stability and ROM ⁵⁸	Comparison of RCTs with and without exercise. Intervention content varied widely in content (i.e., type of exercises, adding lower and upper arm exercises), mode (i.e., group-based or home-based or both).	Pooled analyses of data from five trials ($n = 381$). Majority of participants are females: 66%–100% Mean age most frequently 60–65 years.	Dosage varied from three times daily to three times a week, and supervision ranged from full supervision of all sessions to all home based.	Meta-analysis Level I	Low-quality evidence that exercise improves hand pain, function, joint stiffness, and grip strength. Uncertain on changes in pinch strength, quality of life, adverse events between groups	Hand pain: Standardized mean difference (SMD): -0.27 (95% confidence interval [CI]: $0.47-0.07$) Hand function: SMD: -0.28 (95% CI: $0.58-0.02$) Stiffness: SMD: -0.36 (CI: -0.58 to -0.15) Grip strength: SMD: 0.34 (CI -0.01 to 0.69) Pinch strength: SMD: 0.20 (CI: -0.10 to 0.49)

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Effect of assistive technology (AT) in people with hand OA ⁵⁹	Study group received informational materials and AT (splints and assistive devices). Control group received informational materials on hand OA, hand exercises, ergonomic suggestions.	Seventy participants: (n = 35) group, n = 4 (didn't complete all assessments). Mean age = -60.5 years 97% females	Total number of splints were 39 (8 right hand, 5 left hand, and 13 bilateral) and total devices of 347 (median = 11, range 1-17) were given.	Observer-blinded, RCT Level I	AT was well tolerated and used (92%) and significantly improved activity performance and satisfaction with performance.	<i>COPM Performance</i> Mean difference (MD) = 1.8 (95% CI: 1.1-2.6) <i>COPM satisfaction</i> MD = 1.7 (CI: 0.7-2.6), moderate-to-large treatment effect (effect size of 0.9)

Chapter 43

Hand Impairments

Debbie Amini

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe clinical features of common hand diagnoses.
2. Describe impact of hand impairments on occupational participation.
3. Identify elements of a client-centered and occupation-based evaluation of the hand.
4. Identify outcome measures used to identify goals of occupational therapy intervention.
5. Discuss assessment tools used to determine the status of client factors and performance skills impacting occupational performance.
6. Identify intervention approaches and techniques to enhance occupational participation of persons with hand impairment.
7. Recognize the impact of various interventions on client factors and performance skills affected by hand conditions.
8. Identify orthotics that can be applied to the wrist and digits to minimize, prevent, or correct hand deformity.
9. Explain the importance of occupation-centered intervention goals.
10. Discuss the evidence for occupational therapy interventions for hand impairments.

CHAPTER OUTLINE

Description of Common Hand Diagnoses
Functional Impairment in Daily Occupation Resulting from Hand Impairments
Evaluation and Intervention of Functional Skill Deficits Secondary to Hand Impairments
Basic Interventions
Conclusion
Case Study

TERMINOLOGY

- Claw deformity:** finger position of MP hyperextension and proximal interphalangeal (PIP) flexion associated with muscle imbalance in ulnar-innervated structures; also called *clawing*.
- Contracture:** lack of passive motion caused by tissue shortening.
- Counterforce strap:** support used over flexor or extensor muscle wads to support muscles and prevent maximum muscle contraction, decreasing load on the tendon; often used to reduce symptoms of lateral or medial epicondylitis.
- End feel:** quality of joint motion at end range when moved passively; can be hard, firm, or soft.
- Extensor lag:** inability to extend a joint actively when passive movement is available.
- Froment sign:** a symptom of ulnar nerve impairment in which a forceful lateral pinch elicits thumb IP flexion because of weakness of the adductor pollicis.
- Intrinsic tightness:** decreased IP flexion with MP extension as a result of imbalance in the extensor systems of the digits because of shortening of the lumbricals and interosseous muscles.
- Joint traction:** a treatment technique in which the ends of the bones that create the joint are gently pulled apart from each other to allow the bone ends within the joint to glide over each other.
- Neuroma:** disorganized mass of nerve fibers that can occur following nerve injury and may create significant nerve pain with associated hypersensitivity.

Wartenberg sign: a symptom of ulnar nerve impairment in which a client is unable to adduct the small finger with hand palm down on the table.

Description of Common Hand Diagnoses

Human hands function elegantly; they gesture and express, touch and care, and dress and feed. Conditions of the hand, which may be cosmetic or functional or both, can greatly affect the ability of clients to successfully participate in desired occupations. The purpose of this chapter is to introduce readers to the elements of hand rehabilitation, including knowledge of common diagnoses and basic techniques used in the clinical setting.

Tissue Healing

Scar tissue, a natural consequence of the tissue healing process, is a common focus of all hand rehabilitation intervention. Owing to the close proximity of the anatomical structures within the hand as well as their highly mobile nature, the impact of scar can be catastrophic when it creates blockages to movement in the form of adhesions, changes in density, alignment, and shape of surrounding soft tissue that change or block movement patterns and shift angles and lines of pull.

Tissue heals in the following phases: inflammation, fibroplasia, and maturation or remodeling. The inflammation phase lasts several days. It includes vasoconstriction followed by vasodilation, with white blood cell migration to promote phagocytic removal of foreign bodies and dead tissue. Depending on the diagnosis, rest is often recommended during the inflammation phase.

The fibroplasia phase starts at approximately day 4 and continues for 2 to 6 weeks. In this phase, fibroblasts synthesize scar tissue. The wound's tensile strength increases gradually with the increase in collagen fibers. At this time, active range of motion (AROM) and orthotics may be appropriate to protect healing tissues and promote balance in the hand.¹

The maturation, or remodeling, phase may last for years, but tissue is usually more responsive early rather than late in this period. The remodeling phase reflects the changing architecture and improved organization of collagen fibers and the associated increased tensile strength. Although gentle resistive activity may be appropriate during maturation, its use should be monitored because it may also generate an inflammatory response leading to increased scar formation; gentle application of corrective dynamic or static orthoses may also be appropriate.²

Tolerance of tissues to controlled stress requires monitoring throughout all phases of intervention. As tissue continues to heal, the wound contracts, and the scar shrinks. Collagen continues to remodel because it is constantly doing in uninjured tissue.

Any upper extremity injury can result in the serious and sometimes irreversible problem of a function-limiting hand stiffness. Edema, the body's natural response to trauma, is the main culprit in the series of events, leading to a stiff hand. Crushing injuries that create diffuse edema and a significant inflammatory response are one example of a precipitating injury for a still hand. However, even an injury in the proximal upper extremity can cause serious stiffening of the digits when edema persists, scar is present, and the extremity is not mobile. The challenge for occupational therapy is to strike a balance between rest and movement. Too much rest may increase or maintain edema and allow for adhesion formation and the development of joint **contractures**. Too much movement may increase the inflammation and lead to more scar formation. The right amount of rest in an appropriate position reduces inflammation and promotes healing. Proximal motion plus well-tolerated functional use, particularly while elevated, help to reduce edema and restore motion. Various surgical interventions may be indicated to reduce stiffness of the hand and may include open or closed joint capsule or ligament release, scar removal, and tendon lengthening or release.³

Tendinopathy

Tendons are extensions of muscles made up of poorly vascularized connective tissues that primarily connect to bone to create changes in joint angle for function. Tendinopathy is a general term for conditions of tendons known as tendonitis or tendinosis. These conditions can occur anywhere along the length of the tendon and have varied pathophysiology ranging from overuse to inflammatory pathology due to systemic disorders such as rheumatoid arthritis (RA) or diabetes mellitus (DM) among others, which result in tendon adhesions or thickening. Histological findings in the sheath associated with these underlying conditions include collagen

breakdown, over vascularization, and fibrocartilage metaplasia, resulting from compression and shear during tendon gliding.⁴

Tendinosis refers to chronic degenerative changes in the tendon in which there is an absence of inflammatory cells. Prolonged repetitive stress of conditions such as stenosing tenosynovitis put mechanical strain on the tendon, causing micro ruptures. Because of a lack of a robust intrinsic blood supply and uneven strain, the healing and remodeling responses are altered.⁴ Because the pathology is not primarily inflammatory, treatment approaches for this type of tendinopathy emphasize interventions that restore nourishment to collagen.⁵

The pain associated with tendinitis/tendinosis can be severe and can seriously impact performance in all areas of occupation. Biomechanical deficits include muscular weakness, inflexibility, and scar tissue; symptoms include pain with AROM, with resistance, and with passive stretch of the involved structures. Several specific tendon conditions are described in the subsequent sections.

Lateral Epicondylitis (Tennis Elbow)

Lateral epicondylitis involves the extrinsic extensors of the hand at their origin. The extensor carpi radialis brevis is most commonly involved. Pain is at the lateral epicondyle and extensor wad (the proximal portion of the extensor muscles) and can be at a level that significantly limits daily activity of the client (see Fig. 43-1). Pain is most pronounced with activities involving resisted wrist extension, but may be continuous and interfere with sleep. This diagnosis is differentiated clinically from radial tunnel syndrome, a painful nerve compression, in which tenderness occurs more distally over the radial tuberosity. Test for radial tunnel syndrome with the middle finger test (positive if there is pain secondary to resisting the middle finger proximal phalanx while the client maintains elbow extension, neutral wrist, and metacarpophalangeal [MP] extension) or by percussing distally to proximally over the superficial radial nerve. This percussion test is positive if it elicits paresthesia.⁶

Figure 43-1 Lateral epicondylitis. (Shutterstock/Aksanaku.)

Initial medical intervention may include a corticosteroid injection into the area surrounding the extensor muscle origins with surgical intervention reserved for unrelenting cases that have not responded to conservative approaches, including therapy, for 9 to 12 months.

Medial Epicondylitis (Golfer Elbow)

Medial epicondylitis involves the extrinsic flexors at their origin on the volar aspect of the medial elbow. The flexor carpi radialis (FCR) is most commonly involved. Pain is at the medial epicondyle and flexor wad (the proximal portion of the flexor muscles) and worsens with resisted flexion and pronation (see Fig. 43-2). Although not as common as lateral epicondylitis, medial

epicondylitis can impede the ability of the client to engage in daily activities, particularly those involving resisted wrist flexion.

Figure 43-2 Medial epicondylitis. (Shutterstock/Aksanaku.)

Medical intervention is same as for lateral epicondyle with corticosteroid injection and possible surgery for nonresponsive cases.

De Quervain Tenosynovitis

De Quervain tenosynovitis is tendinitis involving the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) tendons at the first dorsal compartment of the wrist. It is the most common upper extremity tenosynovitis. Finkelstein test is positive if there is exquisite pain with passive wrist ulnar deviation while flexing the thumb (see Fig. 43-3). This diagnosis occurs frequently among golfers, knitters, new mothers, and racquet sports players. Thumb posture in sustained hyperabduction at the computer space bar or on a cellular phone may also cause or worsen de Quervain. Differential diagnosis is for carpometacarpal (CMC) arthritis, scaphoid fracture, intersection syndrome, and FCR tendinitis.⁷

Medical intervention typically involves the use of nonsteroidal anti-inflammatory drugs (NSAIDs) with possible corticosteroid injection into the first dorsal compartment. Cases that are nonresponsive to conservative methods, that also include immobilization and therapy, may require surgical release of the first dorsal compartment to relieve pressure and friction on the APL and EPB tendons.

Trigger Finger

Trigger finger or stenosing tenosynovitis of the digital flexor(s). The usual cause is the development of a nodule on the flexor tendon sheath and stenosis at the A-1 pulley, which is part of the fibro-osseous tunnel that prevents bowstringing of the digital flexors.⁸ Pain is present over the A-1 pulley of the digital flexor (see Fig. 43-4) with resisted grip and during catching or locking of the finger in composite flexion when the nodule on the flexor sheath is caught on the proximal edge of the A-1 pulley.⁹ The snapping of the locked finger into extension is the “triggering,” referred as trigger finger.

Figure 43-3 Finkelstein test for de Quervain disease. (Shutterstock/ellepigrafica.)

Figure 43-4 Flexor tendon pulley system—there are five annular (A1, A2, A3, A4, and A5) and three cruciate (C1, C2, and C3) pulleys. Note that A2 and A4 are the most important pulleys to preserve. The odd-numbered annular pulleys overlie joints: A1 (first annular pulley) overlies the MCP joint, A3 (third annular pulley) overlies the PIP joint, and A5 (fifth annular pulley) overlies the DIP joint (not shown). The even-numbered annular pulleys and the cruciate pulleys overlie the phalanges, A2 (second annular pulley) overlies the proximal phalanx, A4 (fourth annular pulley) overlies the middle phalanx, C1 (first cruciate pulley) is distal to A2 on the proximal phalanx, and C2 and C3 (second and third cruciate pulleys) are proximal (C2) and distal (C3) to the A4 pulley on the middle phalanx. DIP, distal interphalangeal; MP, metacarpophalangeal; PIP, proximal interphalangeal.

The origin of this impairment can be overuse or not overuse. It has been strongly associated with diabetes and RA.

Medical management often consists of a mixture of steroid and local anesthetic injected into the flexor sheath. If symptoms persist beyond conservative interventions, the surgeon may surgically release the A-1 pulley to stop the repeated inflammation caused by the triggering and reduce chance of recurrence. The nodule itself may or may not be removed and will eventually be reabsorbed once friction from the A-1 pulley is removed.

Nerve Injury

The terminal branches of the peripheral nervous system that innervate the upper extremity arise from the brachial plexus that originates from spinal segments C5 to T1. Several terminal nerves innervate the soft-tissue structures of the arm, but the major nerves responsible for movement and sensation of the forearm and hand are the median, ulnar, and radial nerves. The various mechanisms of nerve injury include acute or chronic compression, stretch ischemia, electrical shock, radiation, injection, and laceration.¹⁰ When injury or disease occurs to a neural structure in the upper extremity, there is a high likelihood of the phenomenon known as double or multiple crush syndrome where damage to the physiology of one nerve impacts another.¹¹ All forms of nerve pathology can result in significant changes in sensory awareness, pain, and movement of the hand and arm, leading to significant impairments to functional performance.

Nerve Compression

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is the most common upper extremity nerve entrapment. It results from compression of the median nerve within the carpal tunnel at the wrist. The carpal tunnel is formed by the carpal bones dorsally and the transverse carpal ligament (flexor retinaculum) volarly. The tunnel acts as a pulley for the nine long finger flexor tendons during gripping^{12,13} (see Fig. 43-5). Because the space within the carpal tunnel is very small, swelling such as that seen in pregnancy or wrist fractures, or thickening of the tendons as seen in tendinopathy, can lead to circulation, compromising pressure on the nerve. The resulting ischemia results in sensory and, ultimately, motor dysfunction in the distribution of the median nerve.¹⁴

Figure 43-5 Carpal tunnel cross section.

Typical complaints include hand numbness, particularly at night or when driving a car, along with pain and paresthesia in the distribution of the median nerve (thumb through radial ring finger pads), and clumsiness or weakness.¹⁴ Medical intervention for CTS can include cortisone injection to reduce inflammation, provision of over-the-counter wrist orthosis, and surgery that includes cutting the transverse carpal ligament in two, thus reducing pressure on the nerve and tendons.¹⁴

Cubital Tunnel Syndrome

Cubital tunnel syndrome is the second most common upper extremity nerve entrapment and is the most commonly compressed site of the ulnar nerve, at its location between the medial epicondyle and the olecranon.¹⁵ Typical complaints include proximal and medial forearm pain that is aching or sharp; decreased sensation of the dorsal and palmar surfaces of the small finger and the ulnar half of the ring finger; and weakness of interossei, adductor pollicis (AP), flexor carpi ulnaris (FCU), and flexor digitorum profundus (FDP) of the ring and small fingers. A **claw deformity** (*clawing*) may be more evident if the FDP is not involved because the long flexors are unopposed; **Wartenberg sign** and **Froment sign** may be seen. Grip and pinch strength are decreased, and clients complain of dropping things. Symptoms are worse when the elbow is flexed repeatedly or is held in flexion because this position dramatically reduces the volume of the cubital tunnel.¹⁶ Understandably, symptoms may increase at night if the person sleeps with the elbow flexed.

Cubital tunnel syndrome may result from trauma, such as a blow to the elbow or fracture or dislocation of the supracondylar or medial epicondylar area, or it may be due to chronic mild pressure on the elbow. Associated diagnoses include osteoarthritis (OA), RA, diabetes, and Hansen disease. Medical intervention depends on the cause of the condition and typically involves cortisone injection to reduce swelling within the cubital tunnel or surrounding structures, surgical decompression of the cubital tunnel, and/or anterior relocation of the ulnar nerve superficially or under muscle tissue.¹⁷

Posterior Interosseous Nerve Syndrome

Posterior interosseous nerve syndrome (PINS) is purely motor. It presents two clinical pictures. In one, paralysis affects all muscles innervated by the posterior interosseous nerve, with inability to extend the MP joints of the thumb, index, long, ring, or small fingers. Wrist extension occurs only radially because of paralysis of extensor digitorum and extensor carpi ulnaris (ECU). In the

other presentation of this syndrome, the person cannot extend the MP joint of one or more digits. Paralysis may spread to other digits if it is not treated on a timely basis.¹⁸

A common site of entrapment of the posterior interosseous nerve is at the supinator muscle, where it pierces the two heads of this muscle. Other causes include soft-tissue tumors, RA with synovial proliferation, and radial head fractures or dislocations. Therapy focuses on maintaining passive range of motion (PROM) and orthotic selection to prevent deformity and promote function. Medical intervention for PINS that is not managed with conservative techniques involves surgical decompression of the nerve.

Compression of the radial nerve more proximally can lead to “Saturday night palsy,” which is an ischemic event caused with sustained reduction of the blood supply to the nerve at the level of the humerus and is seen when a person sleeps on his or her arm without movement or uses axillary crutches incorrectly.

Nerve Laceration

Peripheral nerves, unlike tendons, are vascular, have an internal metabolism, and must regenerate after significant injury or laceration. A tendon is more similar to a rope, in that if cut in two, it can be repaired and return to its primary function of moving joints within several weeks. However, when a nerve is cut, the portion distal to the laceration will die and eventually be reabsorbed by the body; the tunnel that houses it will atrophy and limit any potential for spontaneous reinnervation. To offer any potential for reinnervation, the distal portion of a severed nerve must be reattached to the proximal portion that contains the nucleus in as close to perfect alignment as possible. The desired outcome is for the axons to regrow into the existing nerve tunnels in hopes that they will reach the terminal end plates that are sensory or motor in nature.¹⁹

Nerve lacerations are categorized as complete or partial. Stretching and contusion injuries can occur along with the laceration. Nerve reconstruction is termed primary if within 48 hours, early secondary if within 6 weeks, and late secondary after 3 months. Nerve repairs have a better prognosis for recovery if they are repaired sooner and are located more distally. Axonal regeneration for a more proximal laceration places a great deal of stress on the nerve cell that may not be able to nourish full regrowth. After an initial period of proximal axonal degeneration from the trauma of the laceration, axons can regenerate at the rate of up to 3 mm per month.¹⁹

On occasion, a **neuroma** can develop along the nerve or at that anastomosis that causes significant pain when touched. Impaired functional use of the hand caused by the hypersensitivity of this nerve scar can be reduced with padding to protect the painful area or through surgical removal. Occupation dysfunction of varying degrees will occur as a result of nerve lacerations because of motor impairment and/or sensory impairment.

Median Nerve Lesions

Median nerve laceration at the wrist results in low median nerve palsy, with denervation of the opponens pollicis and abductor pollicis brevis of the thumb and of the lumbricals to the index and long fingers. Clawing of the index and long fingers does not usually occur because the interossei remain ulnarly innervated. Loss of sensation of the radial side of the hand is present. With the absence of thumb abduction and opposition, the thumb rests in adduction, where it may become contracted (see Fig. 43-6). Median nerve laceration creates serious functional loss of manipulation and sensibility of the thumb, index, and long fingers and leads to an “ape hand” deformity. Motor recovery usually occurs before sensory recovery.

Figure 43-6 Thenar wasting (atrophy of thumb muscles) due to median nerve injury.

Injury near or at the elbow is called a high median nerve injury. Along with the motor loss identified earlier, there is denervation of FDP to the index and long fingers, flexor digitorum superficialis (FDS) to all digits, pronator teres, and pronator quadratus. The median nerve is considered the most important sensory nerve, and its loss severely compromises hand function. In therapy, prepare clients for probable tendon transfers by preventing deformity with orthotics and by maintaining PROM of pronation, digital MPs in flexion, digital IPs in extension, and thumb CMC abduction. Visual cues, adaptive devices, and modified handles may help compensate for the functional loss.

Ulnar Nerve Lesions

Laceration of the ulnar nerve at the wrist, a low ulnar lesion, results in loss of most of the hand intrinsics. Denervation of the abductor digiti minimi, flexor digiti minimi, and opponens digiti minimi results in flattening of the hand with loss of the ulnar transverse metacarpal arch. Denervation of thumb AP and deep head of flexor pollicis brevis results in loss of thumb adduction and MP support; denervation of dorsal and volar interossei results in loss of digital abduction or adduction; and denervation of lumbricals to the ring and small fingers results in extrinsic imbalance. The ring and small fingers present a “claw hand” deformity, a position of MP hyperextension and PIP flexion associated with muscle imbalance in ulnar-innervated structures (see Fig. 43-7). Fine manipulation skills are compromised. Sensory loss involves small, ring, and sometimes part of the long finger, known as the ulnar digits.

Figure 43-7 Clawing of digits due to ulnar nerve injury.

A high ulnar nerve lesion is often identified with trauma at or proximal to the elbow. There is involvement of the muscles listed earlier and denervation of FDP of the ring and small fingers

and of FCU. Ring and small finger clawing is less apparent with the high lesion but becomes noticeable as the FDP are reinnervated and are unopposed by the still-absent intrinsics.

Radial Nerve Lesions

Low radial nerve injury of the deep motor branch is called posterior interosseous palsy. Presentations vary, but brachioradialis and extensor carpi radialis longus function are usually present. Efforts to actively extend the wrist yield strong radial deviation; MP extension is affected. Sensation on the dorsal radial hand is affected, although this may not significantly impact function as a result of the overlapping sensory input of the median nerve.

A high radial nerve injury commonly occurs with humeral fractures because this nerve spirals around the humerus. Damage to the radial nerve in this area leads to absent wrist and digital extensors and a “wrist drop” deformity (see Fig. 43-8). Sensory loss occurs on the dorsal–radial hand, which interferes less with function than does sensory loss on the palmar hand. Triceps function remains, but the supinator and all wrist and finger extensors lose function. Tenodesis, or the passive mechanical flexion of the MCPs and IP joints with active wrist extension, is lost as is the ability to stabilize the wrist in extension while using the digits for function.¹⁹ **Intrinsic tightness** can occur, leading to difficulty with MP extension and IP flexion if length of interosseous and lumbrical muscles are not maintained during the period of lost extrinsic extension.

Figure 43-8 Wrist drop due to radial nerve injury.

Fractures

Distal Radius Fracture

Distal radius fractures (distal radioulnar joint [DRUJ] fractures or wrist fractures) are among the most common upper extremity fractures.^{20,21} DRUJ fractures are often caused by a fall on an outstretched or extended hand and are known as Colles fracture if the fracture has dorsal displacement leading to a dinner-fork deformity (see Figs. 43-9 and 43-10), or Smith fracture if the wrist was flexed at the time of injury and has a volar displacement leading to a garden-spade deformity (see Fig. 43-11). Medical management will depend on the severity and type of the fracture. Considerations include fragmentation, angulation, open fracture, concurrent ulnar fracture, and compression of the distal fragment into the proximal bone. Plaster splints followed by circumferential casting with closed reduction (setting) of the bone, surgical open reduction, and internal fixation and closed reduction with percutaneous pinning are options for fixing and immobilizing DRUJ fractures. The main complication associated with distal radius fracture is traumatic arthritis caused by malunion or poor alignment of the distal portion of the bone when healing. Decreased wrist ROM, decreased grip strength, alteration of the carpal alignment, and instability may ensue. Other complications include extrinsic tightness, tendon rupture, compression of the median or ulnar nerve, and complex regional pain syndrome (CRPS).²²

Figure 43-10 Dinner-fork deformity.

Figure 43-11 Smith fracture; garden-spade deformity.

Ligament Injury

Ligament injuries are also known as strains and sprains. Their severity, which may be underappreciated, is described as grade I through grade III. In grade I, the ligament remains intact, but there is diffuse individual fiber disruption. In grade II, there is complete disruption of one of the joint capsule's major retaining ligaments. In grade III, there is complete disruption of one collateral ligament in addition to injury to dorsal and/or volar capsular structures. Pain, decreased ROM, and risk of flexion contracture are the most common problems associated with grades I and II injuries. Joint instability may occur with grade III injuries.²³

Skier's Thumb

Disruption of the ulnar collateral ligament of the thumb MP joint occurs with acute radial deviation. This diagnosis, which may entail avulsion of bone fragment at the ligamentous insertion, is often seen among people who fall while skiing. Injury to the radial collateral ligament of the thumb MP occurs only one-tenth as often.²⁴ Grade III ulnar collateral ligament

injuries require surgical repair with interosseous wire because an avulsed ligament will retract and not return to the original insertion on the bone, leaving joint instability (see Fig. 43-12).

Figure 43-12 Hand-based thumb MP orthosis to immobilize grade I or II skier thumb injury. MP, metacarpophalangeal.

Tendon Injury

The flexors and extensors of the fingers are relatively superficial and susceptible to lacerations, avulsions, and rupture. The finger tendons most at risk for damage are the extrinsic—so named because their muscle bellies are located outside the hand. The lack of large bulky muscle in the hand itself allows the fingers to complete precision movements and fine motor tasks. However, to accomplish fine movements so far from their origin, the tendons must glide over several joints through a tendon sheath and work in balance with each other and the small intrinsic muscle group within the hand. Injuries to the tendon are some of the most complex hand injuries resulting from their limited vascularity and the significant impact that scar tissue will have on their mobility.²⁵

Flexor Tendon Injury

Surgical repair of flexor tendon injury is a complex undertaking performed by specialists in the field. Multiple structures are potentially involved including more than one tendon (FDP and FDS), the pulley system, digital arteries, and, possibly, digital nerves that can affect prognosis and functional outcome.²⁶ Many precautions and contraindications vary according to the details of the client's surgery and the surgeon's specifications and preferences. Five anatomical zones describe flexor tendon injury to the index, long, ring, and small digits (see Fig. 43-13). Zone I is from the insertion of the FDS to the insertion of the FDP. Zone II is the area where the FDS and FDP both lie within the flexor sheath, from the A-1 pulley to the FDS insertion. This region has memorably been dubbed “no man's land” to reflect the technical challenge and historically poor prognosis for repair in this area.^{9,25} Zone III describes the area from the distal edge of the carpal tunnel to the A-1 pulley of the flexor sheath, including the lumbrical muscles. Zone IV is where the flexor tendons lie under the transverse carpal ligament in the carpal tunnel. Injuries in this zone may include the median and ulnar nerves. Zone V is the area from the forearm flexor musculotendinous junction to the border of the transverse carpal ligament.^{9,25}

Figure 43-13 The five zones of the hand based on flexor tendon anatomy.

Physicians usually indicate specific postoperative positioning guidelines to protect repaired structures following flexor tendon repair that serve to allow preservation of gliding but limit forces that can cause rupture of the repair.

Extensor Tendon Injury

Seven zones describe the digital extensors for the index, long, ring, and small fingers, and five zones describe the thumb extensors (see Fig. 43-14). Injury in zones I and II leads to a mallet deformity, which follows disruption of the terminal extensor tendon and manifests itself as distal interphalangeal (DIP) **extensor lag**. Depending on the nature of the problem, an injury to zone I or II may not require surgical intervention and will be referred to therapy or the surgeon will simply immobilize the DIP continuously in extension for 6 to 8 weeks.²⁶ Extensor injuries in zones III and IV lead to a boutonnière deformity and can be treated conservatively or through surgery depending on the extent of the tendon damage. Without intervention, the deformity becomes “fixed” or permanent because of volar displacement of the lateral bands secondary loss of the central slip and eventual volar plate contracture. Injury in zones V, VI, and VII will require surgical repair followed by either immobilization or controlled early motion protocols.

Figure 43-14 The seven zones of the hand based on extensor tendon anatomy.

Functional Impairment in Daily Occupation Resulting from Hand Impairments

Regardless of the specific diagnosis, hand impairments have the potential to impact client factors in the areas of sensory functions and neuromusculoskeletal and movement-related functions that include tactile sensation, pain, joint mobility and stability and muscle strength, and endurance.¹ Impairments of these client factors will affect the ability of the hand and upper extremity to engage in activities involving motor skills and, ultimately, impact the ability of the client to engage in desired occupations the extent of which can be impacted by pain levels, the context and environment, and the adaptability of the client.¹

For example, a flexor tendon laceration and repair of the dominant hand of an auto mechanic may impact his ability to complete work-related tasks for up to 12 weeks. Working on car engines requires force and precision and the environment where the work takes place does not allow for open wounds and may limit use of protective orthotics. This same individual may not have any difficulties with activities of daily living (ADLs) or instrumental activities of daily living (IADLs) because of some assistance received from his supportive spouse and ability to adapt to using his nondominant hand functionally. Conversely, a client with de Quervain stenosing tenosynovitis may find the condition so painful that she is unable to complete dressing activities that require small fastenings, cook dinners from scratch, or complete laundry tasks due to resisted grasping, but is able to work as an accountant-cum-computer data entry while using a customized orthotic device (see Fig. 43-15).

Figure 43-15 Forearm-based thumb spica orthosis for de Quervain tenosynovitis. Used to provide pain relief and promote functional pinch.

Evaluation and Intervention of Functional Skill Deficits Secondary to Hand Impairments

All occupational therapy evaluations must assess deficits in the various aspects of the domain, including occupations, through administration of outcome measures or use of an interview process. The occupational profile,²⁷ a required component of the 2017 CPT evaluation codes for occupational therapy, organizes information and documents what the client cannot do and what he or she wants to do, needs to do, or is expected to do, in addition to identifying additional supports and barriers to participation, such as the context and environment.²⁸ Outcome measures, such as the Canadian Occupational Performance Measure (COPM), assist the therapist in creating the occupational profile and identifying areas of occupation that will be targeted during the course of intervention.²⁹ Outcome measures also provide a way to document the amount of improvement and report that improvement to payers and other stakeholders such as physicians.

Once the profile is complete, the occupational therapist looks more specifically at the client factors, skills, and performance patterns that are barriers to the identified areas of occupation. This section of the evaluation is known as the analysis of occupational performance according to the Occupational Therapy Practice Framework (OTPF). Table 43-1 lists common assessment tools used in occupational therapy for the hand and their purpose.

Table 43-1. Common Assessment Tools for the Hand

ASSESSMENT TOOL	PURPOSE	TECHNIQUE	ASPECT OF THE DOMAIN
Visual Analog Scale (VAS)	Client report of pain level	Client chooses level on 1–10 scale.	Sensory function of pain
Observation of wound	To determine stage of healing and assess change	Determine size (length, width, depth), exudate color, odor, and tissue color (red, yellow, black) through observation and measurement	Skin integrity
Scar assessment	To determine the status and type of scar (hypertrophic, keloid) and possible impact on hand usage	Observe scar location, length, width, and height and suppleness. Determine whether banding is present, whether joint motion is limited, and hypersensitivity is present.	Skin integrity
Vascular assessment	Determine whether circulation is compromised	Cyanosis, erythema, pallor, gangrene, or grayish color indicates vascular compromise. To test digital capillary refill, apply pressure to the fingernail or distal pad of the involved digit. Color should return within 2 seconds of release of pressure. Compare the refill time to that of uninvolved digits.	Circulatory system
Circumferential measurements	Determine changes in size of the hand and fingers to note changes in edema	Wrap small tape measure around desired part of hand. Note placement and provide consistent force reading result. Document finding to the mm (e.g., 2.5 cm or 25 mm)	Circulatory system, skin integrity

ASSESSMENT TOOL	PURPOSE	TECHNIQUE	ASPECT OF THE DOMAIN
Volumeter	Determine changes in hand volume to note changes in edema	Using a commercially available volumeter, immerse client hand as instructed and measure water displaced in milliliters	Circulatory system, skin integrity
Goniometers (varying sizes and style)	Determine AROM and PROM of each joint to determine whether motion is compromised, indicating joint, tendon, muscle, or skin impairment. Comparison of active (muscle contacting active) vs. passive (outside force) motion are the same or different provide additional information on the status of tendon mobility and muscle strength	Use goniometer sized according to joint being measured. Use technique described in Chapter 13	Neuromusculoskeletal status
Grip and pinch strength	Determine grip and pinch strength to obtain baseline and determine level of strength compared to noninvolved hand. Norm tables can be used for general comparison, although functional strengths can vary client to client. There may be approximately 10%–15% difference in strength between dominant and nondominant hands, with dominant hands usually being stronger. It is routine to measure three pinch patterns: lateral, three-jaw chuck, and tip. As with grip, compare pinch scores with those of the contralateral extremity.	Jamar dynamometer and pinch meter or comparable reliable devices are used following recommended technique. When properly calibrated, the Jamar dynamometer is one of the best instruments to assess grip strength because of its reliability, face validity, and accuracy.	Muscle strength
Manual muscle testing	Manual muscle testing is particularly useful for monitoring progress following peripheral nerve lesions. Facilities usually have their preferred method of grading, which may be numerical or descriptive.	Follow standard testing methods described in the literature. Strength is graded on a scale of 1–5 (trace-poor-fair-good-normal) with specific criteria for determining each grade.	Muscle strength
Semmes monofilaments and observation	To determine tactile sensation of the hand to determine areas of degeneration or regeneration, determine specific nerve involvement, and ensure that client is aware of loss of protective sensation for safety with temperature and sharp objects	Inspect the client's hand for dryness, moistness, shiny skin, calluses, and possible reduced wrinkles and tissue bulk (see Chapter 12). The Semmes-Weinstein Monofilament Test assesses pressure threshold and provides a valid and reliable means of determining levels of protective sensation.	Tactile sensation
Moberg Pickup Test	Determine functional ability of hand with median nerve lesion	The Moberg Pickup Test is a structured assessment that measures the speed of picking up and placing small household items with vision and vision occluded. A difference in time and behavior of hand picking up items indicates possible median nerve sensory impairment.	Sensation
Box and Block Test	Measures gross manual dexterity	Client transfers 1-inch blocks from one side of box to the other. The score is the number of blocks transferred in 1 minute for each hand. Test-retest reliability and inter-rater reliability of the Box and Block Test is high, norms are available for persons aged 20–75 years and older.	Motor skills

ASSESSMENT TOOL	PURPOSE	TECHNIQUE	ASPECT OF THE DOMAIN
The Purdue Pegboard Test of finger dexterity	Tests finger or fine motor dexterity	This standardized tool assesses picking up, manipulating, and placing little pegs into holes with speed and accuracy using a wooden board with two rows of tiny holes plus reservoirs for holding pins, collars, and washers. Four subtests are performed with the subject seated. The subtests for preferred, nonpreferred, and both hands require the client to place the pins in the holes as quickly as possible, with the score being the number of pins placed in 30 seconds. The subtest for assembly requires the client to insert a pin and then put a washer, collar, and another washer on the pin, with the score being the number of pieces assembled in 1 minute. The tool has normative data and is valid and reliable. ³⁰	Motor and finger manipulation skills
Nine-Hole Peg Test	Measures finger dexterity among clients of all ages	Test administration is brief—only involving the time it takes to place nine pegs in holes in a 5-inch square board and then remove them. Found to have high test-retest reliability coefficients (0.95 for right hands and 0.92 for left hands). High inter-rater reliability has been reported. ^{47,48}	Motor skills
Upper Extremity Performance Test for the Elderly (TEMPA)	Assesses hand dexterity using nine tasks: (1) pick up and move a jar, (2) open a jar and take a spoonful of coffee, (3) pour water from a pitcher into a glass, (4) unlock a lock, (5) take the top off a pillbox, (6) write on an envelope and affix a postage stamp, (7) put a scarf around one's neck, (8) shuffle and deal cards, and (9) use coins, and pick up and move small objects.	Instructions are in the manual. The test takes about 15–20 minutes for an unimpaired elderly subject and about 30–40 minutes for an impaired elderly subject. Normative data for young adults have been determined. TEMPA norms were established on adults aged 60 years or older ($n = 360$) by 10-year age groups and by gender. Inter-rater reliability of the TEMPA ranged from 0.96 to 1.00. Test-retest reliability was excellent. ⁴⁹	Motor skills
Manual Ability Measure (MAM-20) ⁵⁰	Offer clients the opportunity to discuss their injuries in the context of their daily lives and lend insight into the needs that must be addressed	A 20-item self-report questionnaire. Tool consists of two parts: (1) a client demographic sheet and (2) a self-report task list consisting of items that the client rate on a 4-point scale based on his or her perceived ability to complete tasks. It also includes a VAS for pain and column for indicating if skill can be completed with the noninvolved hand.	Motor skills to complete functional activities
Canadian Occupational Performance Measure (COPM)	Client-centered approach to assessment of perceived functional abilities, interest, and satisfaction with occupations	Interview-based valid and reliable tool is scored and can be used to measure outcomes of treatment.	Participation in occupations
Disabilities of the Arm, Shoulder, and Hand (DASH) assessment	Assists with the development of the occupational profile through its valid and reliable measure of clients' functional abilities	Consists of 30 predetermined questions addressing function within performance areas. Clients are asked to rate their recent ability to complete skills on a scale of 1 (no difficulty) to 5 (unable).	Performance in predetermined activities Visit the DASH/QuickDASH website at http://www.dash.iwh.on.ca

Psychosocial Factors Affecting Therapeutic Outcomes

Occupational therapists should be aware of the specific mental functions that underlie the ability of the client to cope and adapt to an injury or condition of the hand. If these client factors appear to contribute to occupational dysfunction, they must be assessed and addressed to ensure a positive treatment outcome that provides the client with the expected result. Adaptive responses to hand impairment are influenced by body image as well as individual functional needs and contextual elements. The personal or symbolic meaning of the hand, self-esteem, family and friend support systems, and coping strategies all influence outcome. Whenever possible, encourage clients to participate in their care and to return to their typical habits, roles, and routines as soon as possible. Empower clients by ensuring health literacy, listen well, use

nonmedical terminology and instructional diagrams, and encourage some amiable conversation as appropriate.³⁰

Motivation is the most important variable favorably influencing recovery. Realistic expectations and appropriate communication that emphasizes participatory decision-making and education are also important. Psychological symptoms related to hand trauma resolve best when intervention occurs early.

Goal Setting

Identified occupational therapy outcomes and goals must reflect the desired occupational performance of the client. The number of degrees of motion achieved is less important than whether the client can open a door, get dressed, or return to work. To this end, all goals should have occupation as the focus. In hand rehabilitation, there is often a desire to follow a bottom-up approach to treatment—in other words, to measure factor and skill-level abilities and to write goals addressing these areas. One way to address these areas while keeping the documented goals as occupations is to create a list of behavioral objectives that represent the underlying factors needed to participate in the occupation addressed in long- and short-term goals. This third level of goal writing does not become part of the medical record, but can assist with clinical decision-making.³¹ For example, for a long-term goal addressing self-care, with a short-term goal specifically addressing face washing, a behavioral objective may describe the expected outcome of forearm supination and hand strength.

Although some hand specialists do incorporate purposeful activity into intervention, more support is needed for an approach to hand therapy that leads with concepts of occupations as both the means and the ends of intervention.³² One way to achieve this is to integrate client-directed goals and typical daily activities and occupations into specialized hand therapy intervention planning and implementation. Occupation elicits adaptive responses that do not occur with exercise alone. Compared to isolated exercise, activities and occupations promote more coordination and better movement quality.³³ An example of isolated hand therapy exercise to increase grip strength is gross grasp with therapy putty or exercise grippers. An example of activity to increase strength would be putting away groceries, starting with light items, and progressing to heavier objects.

Occupation-as-means instills occupational therapy's heritage in what might otherwise be a less function-oriented context.³² The examples cited earlier become therapeutic occupation with the use of activity that is meaningful to the particular person to accomplish the therapeutic goal. If the client enjoys baking, then rolling dough with a rolling pin would be a therapeutic occupation to promote grip function (see Fig. 43-16).

Figure 43-16 Using rolling pin as therapeutic activity to encourage flexion of digits. (Shutterstock/Africa Studio.)

Basic Interventions

Edema Control

Elevation, active exercise and movement of the extremity, and compression have been the mainstays of edema control. Treatment of upper extremity edema has also historically included retrograde massage, string wrapping, compression garments, and modalities such as an intermittent pressure pump and therapeutic cold (see Fig. 43-17).

Figure 43-17 Ice pack for reduction of edema. (Shutterstock/Andrey_Popov.)

Prior to initiating an edema reduction plan, the therapist should determine the type of edema present in the limb. Peripheral edema of the hand can often be caused by the increase in blood supply with capillary leaking surrounding the inflammatory response of the healing mechanism. Lymphedema is a more chronic, pitting edema may be caused by impaired lymphatic function requiring a specialized approach to reduction include stimulating the lymphatic system to remove large plasma proteins.³⁴

Scar Management

Compression (e.g., Isotoner gloves, Tubigrip, or Coban wrap) and mechanical forces of vibration are traditionally used to promote scar softening and maturation (see Fig. 43-18). Silicone gel applied over the scar and topical creams such as Mederma are effective in reducing the appearance of scar.^{35,36} Other materials inserted in gloves and orthotic devices, such as padding, or elastomer can also be used to provide a more even custom distribution of compressive forces over the scar. Application of micropore tape over incision scars is gaining popularity. It has been shown to be very effective and is much more affordable than the other options.³⁴

Figure 43-18 Elastic wrap providing compression to reduce scar on dorsal thumb IP. IP, interphalangeal. (Shutterstock/Melodia plus photos.)

Differential Digital Tendon Gliding Exercises

Tendon gliding exercises maximize total gliding and differential gliding of digital flexor tendons at the wrist to reduce the risk of scar adhesions between the tendons and surrounding tissue that can occur following tendon injury and repair, crushing injury, and fractures, particularly of bones in the fingers (see Fig. 43-19). Because scar is one of the primary culprits leading to long-term hand dysfunction, tendon gliding exercises are a mainstay of most home exercise programs. Occupations that involve use of the hand in both hook and gross grasp positions can also encourage differential gliding of the tendons and lead to improved motion of digits through participation. Examples can include kneading bread dough, carrying grocery bags in the affected hand, and transferring clothing items from the washer to the dryer. It should be noted that

activities requiring resistance must be avoided until the tensile strength of the repair allows (see Fig. 43-20).

Figure 43-19 Tendon gliding for flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP). **A.** Start. **B.** Glides FDS and FDP; **C.** Biases FDS. **D.** Biases FDP. **E.** Maximal FDS and FDP.

Figure 43-20 Using meaningful activity of kneading dough to improve hand strength and mobility. (Shutterstock/Vladimir Volodin.)

Blocking Exercises

Blocking is a technique that also improved tendon gliding/excursion and that can assist with capsular stretch. The technique involves blocking finger joints from either flexing or extending in order to increase the tendon force at the impacted joint. The therapists' hand, the client's nonaffected hand, or a device such as a splint or scrap of splinting material or wood can block the desired joints. For example, when blocking to increase PIP extension, the MP joint is held in flexion while the client attempts to extend the PIP and DIP joints through activation of the extensor mechanism and intrinsic muscles responsible (see Fig. 43-21). Another example of blocking to increase DIP flexion would involve maintaining the MP and PIP joints in full

extension with an external device or opposite hand while pulling the DIP into flexion (see Fig. 43-22).

Figure 43-21 Blocking splints. MP splint blocks MP in flexion, promoting PIP and DIP extension. (A) Palmer view of a blocking splint, (B) Radial view of a blocking splint. DIP, distal interphalangeal; MP, metacarpophalangeal; PIP, proximal interphalangeal.

Figure 43-22 Actively flexing the DIP while blocking the PIP and MP joints. DIP, distal interphalangeal; MP, metacarpophalangeal; PIP, proximal interphalangeal.

Instruct clients who do blocking exercises to exercise comfortably into the end range to remodel the tissue. Teach him or her to do the exercises frequently and slowly, holding at the comfortable end range for 3 to 5 seconds. Occupations and activities that naturally block sets of joints and allow for force application to a specified tendon include holding onto a steering wheel (block MCPs and flex IPs), playing guitar (affected hand changing chords), sweeping, or raking leaves (see Fig. 43-23).

Figure 43-23 MP flexion blocked, while IPs flex to hold chords on guitar. MP, metacarpophalangeal; IP, interphalangeal. (Shutterstock/Have a nice day photo.)

Diagnosis-Specific Interventions

If not contraindicated by medical diagnosis, encourage the client to achieve gentle full arcs of available motion with functional use or exercise instead of performing quick or incomplete arcs of motion that are less effective. Use occupations or meaningful activities that target the structures requiring motion. If needed for preparation, preparatory tasks such as grasping and releasing various items can be used. If the client's hand is painful or more swollen after use or exercise, the amount of activity being performed should be decreased temporarily.³⁷

Avoid aggressive PROM. It is okay to coax tissues to lengthen within their available comfortable range, but always respect the feeling of tissue resistance, and do not exceed it. Gentle passive motion, if indicated, should be accompanied by **joint traction** (a gentle pressure applied to pull the end of the bones apart) to promote gliding of the joint surfaces. Sustained holding of a position is much more effective than fast jerky stretches, which frequently add to the inflammation.

During the acute inflammatory stage, static splinting is usually most appropriate. After the inflammation has subsided and while the joint displays a soft **end feel**, dynamic splinting is productive. Inflamed tissue is not as flexible as uninflamed tissue.³⁷ Watch closely for signs of inflammation and return to static splinting as indicated. Later, if there is a hard **end feel**, serial static or static progressive splinting will most likely be needed.³⁷ Many clients with hand impairments complain of morning stiffness. Night splinting, which can be very helpful for this problem, also corrects tissue tightness that limits daytime use of the hand. Always ensure that no contraindications for dynamic splinting are present.

Tendinopathy

Treat the acute phase with ice, compression, elevation of the involved structures, and rest, if needed, to manage pain. Anti-inflammatory physical agent modalities, considered preparatory methods in the OTPF may be useful at this time, but remember that tendinitis/tendinosis may not be primarily inflammatory. Orthotic use is individualized to the client's and physician's preferences. Orthotic intervention may be most beneficial and least problematic at night. There are also clinical compromises associated with disuse from immobilization.

After the inflammation subsides, upgrade intervention to restore normal function through gradual use of hand balanced with rest; avoid pain. Instruct in tendon gliding exercises in a pain-free range and progress from isometric exercises with gentle contractions of involved structures to isotonic exercises. Gradually introduce low-load, high-repetition strengthening in short arcs of motion. Then increase the arc of motion and modify proximal positions to be more challenging if appropriate for work simulation. Instruct in gentle flexibility exercises in a pain-free range. It is often difficult for clients to learn to perform slow and pain-free passive stretch. Aerobic exercises and proximal conditioning are essential.

Prevent reinjury by teaching the client to avoid repetitive motions using muscles involved in the specific diagnosis (e.g., trigger finger caused by repetitive grasp and release). In addition, specific combination of motions that may not be highly repetitive but that put significant stress on

a tendon should be avoided (e.g., de Quervain tenosynovitis exacerbated by pinching while wrist is flexed and ulnarly deviated).

Easily recognizable issues, such as poor posture or trunk twisting with reaching and lifting, should be solved by working with the client to understand the goals of the activity and changes to position or technique that will allow the goal to be reached more efficiently. Instruct in pacing to avoid fatigue that leads to inflammation. Use of the upper extremities without support together or alone, in an asymmetrical manner, and lateral to trunk can be very taxing. People with distal symptoms recover well by focusing intervention on posture, conditioning, and proximal strengthening. Using handheld tools with ergonomic design can be helpful. Even a small ergonomic adjustment, such as learning to lift bilaterally with proper body mechanics or making use of a telephone headset instead of laterally flexing the neck and elevating the shoulder to hold the receiver, can often lead to dramatic improvement.

Lateral Epicondylitis (Tennis Elbow)

Exercises should include proximal conditioning and scapular stabilizing as well as eccentric loading of the wrist extensors to strengthen without exacerbating inflammation of the muscle origin. Eccentric loading consists of grasping a small dumbbell (1–2 lbs), supination of the forearm, dropping the wrist into extension with gravity assist, holding the wrist in extension, pronating the forearm, and slowly lowering the wrist into flexion—work up to 3 sets of 10 repetitions and repeat several times per day.³⁸ An orthosis to support the wrist in extension can be used at night and during arm-intensive activities during the day to rest the muscle origins at the lateral epicondyle; wrist position recommendations range from neutral to about 30°. A **counterforce strap**, which is a strap placed over the extensor wad to prevent full muscle contraction to reduce the load on the tendon during the day with activity, and KinesioTape (KT) can also be utilized as conservative approaches to reduce pain and inflammation³⁹ (see Fig. 43-24).

Figure 43-24 KinesioTape applied to the forearm to reduce symptoms of lateral epicondylitis and promote healing. (Shutterstock/staras.)

Medial Epicondylitis (Golfer Elbow)

Exercise should promote proximal conditioning. Avoid activity that requires force at end ranges. Provide built-up handles to reduce forces on flexor muscles. As with lateral epicondylitis, eccentric loading in reverse can assist in strengthening wrist flexors without adding stress to the muscle origins. An orthosis maintaining the wrist in neutral or a counterforce strap over the flexor wad will assist in reducing forces on the muscle origin.

Modifications and alternatives to activities that are responsible for or exacerbate the diagnosis are made to reduce repetitive and/or forceful wrist flexion and grasping, especially when coupled with forearm pronation.

De Quervain Tenosynovitis

Teach clients to avoid wrist deviation, especially in conjunction with pinching. Provide built-up handles and a forearm-based thumb spica orthosis, leaving the IP free. Watch for irritation from the radial orthosis edge along the first dorsal compartment. Modify or suggest alternatives to

activities that bring on or exacerbate condition. Physical agent modalities including ice and iontophoresis with dexamethasone can be applied to reduce inflammation.

Trigger Finger

Therapy for stenosing tenosynovitis consists of splinting the MP in neutral to prevent composite digital flexion (preventing triggering) while promoting tendon gliding and place-and-hold fisting to maintain motion and strength while preventing triggering. Built-up handles, padded gloves, and pacing strategies are helpful. The client must be instructed to avoid the triggering of the digit as much as possible, as abrupt tendon force re-inflames the tissue. Physical agent modalities such as ice to reduce inflammation and ultrasound to enhance circulation and reduce scar may be effective.

If surgery is required, postsurgical intervention will include early gently mobilization of digit with grading of activity to minimize inflammation and scar formation, tendon gliding, and activity modification if needed for discomfort and decreased finger flexion caused by tendon bowstringing.

Nerve Injury

Following nerve injury, therapy promotes functional performance in the areas of occupation with ADL training and adaptive equipment and assists in prevention of deformity with orthotics and appropriate PROM. Occupational therapy provides valuable education to clients about their diagnosis and general recovery sequence and teaches protective guidelines to compensate for sensory loss. Therapists monitor changes in sensory and motor function and help prevent joint contractures and imbalance by reevaluating ROM, sensation, and muscle status. Orthotic modifications are based on clinical changes over time.

Compression Injuries

All nerve compression injuries can potentially lead to pain, sensory impairment, muscular weakness, and eventual loss of function. All share additional commonalities with regard to etiology that can include the narrowing of a fibrous space due to inflammation, edema, tissue hypertrophy, tumor, or another pathological condition (e.g., synovial changes due to RA). Once the etiology is understood, both conservative and medical interventions can be determined. If conservative methods are an option, they may include immobilization with an orthotic to either provide positioning for optimal circulation to the nerve (e.g., CTS) or to rest the area surrounding the nerve to reduce inflammation (e.g., cubital tunnel syndrome). Myofascial-type massage to improve mobility of tissue within the fascial planes and nerve gliding exercises can also be trialed to improve circulation and free nerves from adhesions.

CARPAL TUNNEL SYNDROME

Conservative therapy for CTS includes night splinting with the wrist in neutral because this position minimizes pressure in the carpal tunnel, exercises for median nerve gliding at the wrist, differential flexor tendon gliding exercises, ergonomic modification, and postural training. Teach clients to avoid extremes of forearm rotation or of wrist motions and to avoid sustained pinch or forceful grip. For example, thick padded automobile steering wheel covers are helpful as are ergonomic computer keyboards that are split and angled to maintain forearms in slight supination. In the case of pregnancy-induced CTS, consider techniques to reduce edema, such as isotoner gloves, retrograde massage, and ice packs.

Postoperative therapy, when necessary, consists of edema control, scar management, desensitization as needed, nerve and tendon gliding exercises, and eventual strengthening. Many therapists postpone strengthening exercises until at least 6 weeks following carpal tunnel release to avoid inflammation. Pillar pain, or pain on the lateral aspects of the palm, may be present and can be minimized with deep pressure massage and padded gloves, if needed, during hand-intensive activities.

RADIAL TUNNEL SYNDROME.

Conservative treatment of the radial nerve compression in the forearm includes wrist extension splinting to reduce pressure of extensor muscle mass and to limit contractions of the muscles that can cause exacerbation. Because radial nerve compression can be caused by resisted wrist extension with grasping, as is seen in forearm strengthening exercises, the client may be instructed to reduce the force or frequency of activities contributing to the condition. Radial nerve

compression can also be caused by use of a tennis elbow strap that is applied incorrectly or used for extended periods of time. If the client is using a tennis elbow strap device, check to ensure that is not causing or contributing to the radial nerve compression. Radial nerve gliding and myofascial-type massage can also be trialed to reduce discomfort. A nonresponsive compression may require surgical decompression.

CUBITAL TUNNEL SYNDROME.

Conservative therapy for cubital tunnel syndrome includes edema control, orthosis or padding the elbow, and positioning guidelines to avoid leaning on the elbow, elbow-flexed postures, and elbow-intensive activity. An elbow orthosis positioned at approximately 30° of flexion helps ensure circulation to the ulnar nerve while sleeping and, at other times, during the day. Types of orthotics include elbow pads or soft splints, pillows, and anterior or posterior thermoplastic orthoses. Additional therapy includes proximal conditioning, postural and ergonomic training, and ulnar nerve gliding exercises. Retrograde massage and gentle ice treatments can also be trialed to reduce any inflammation that may be contributing to the nerve compression.

Nerve Laceration

Repaired nerves require a period of protection to reduce stress on the delicate anastomosis that can be pulled apart or encounter traction forces that will create a gap, leading to a high likelihood of neuroma formation. Postoperative therapy for all hand nerve repairs includes fabrication of an orthosis that limits movement of the joint(s) crossed by the nerve in close proximity to the repair. For example, a digital nerve repaired at the level of the middle phalanx will require the MP and IP joints be secured in a flexed position. Although protected from extension forces, the client is instructed to remove straps from the orthotic to actively and passively flex the finger to maintain joint and tendon integrity. The dorsally based orthotic is not removed from the digit for added protection during the exercises. If the orthotic is removed for cleaning, the client is instructed not to straighten the finger. This same principle can be applied to other joints in the hand and arm depending on the nerve repair.

As the anastomosis heals, the angle of the orthosis will be increased to allow the nerve to gently lengthen. Once completely healed (approximately 6–8 weeks), the device will be discontinued and may be replaced by an antideformity orthosis, as described later in this section.

However, although the repair may have healed, the regrowth of the axons and reinnervation of motor and sensory end plates must still occur. The nerve will regrow at the rate of 1 inch per month; a radial nerve injury at the humeral level may take up to 18 months for regrowth.

The occupational therapist ensures that the client is aware of the location and degree of sensory loss and how to protect the area from temperature, pressure, and sharp objects. Clients are instructed not to use the unaffected hand to gauge the impact of even minimal temperature or pressure changes (e.g., an ill-fitting orthosis) on the insensate hand; because of damaged autonomic fibers, the insensate hand may not respond the same as a noninjured hand. The therapist should avoid the use of thermal modalities or forceful massage to the scar tissue. Silicone gel sheets provide scar reduction without mechanical pressure or friction to the skin.

As the nerve regrows, the therapist assists the client with grading of daily activities to ensure that strength is gradually increased, that function returns—with adaptations if needed—and that delicate healing tissues are not overstressed.

Injuries to the three major nerves of the hand may require long-term orthotic use to prevent permanent deformities. For the ulnar nerve, a dorsal hand-based device that maintains the MPs in flexion will direct the force of the intrinsic muscles to extend the IPs that are otherwise held in a clawed position from the loss of the balancing forces of the ulnar nerve innervated long finger flexors. In the case of a median nerve injury, an orthosis that secures the thumb in a position of abduction and opposition will maintain function of the hand and prevent an adduction contracture of the thumb. A radial nerve injury will benefit from a device that holds the wrist and MP joints in extension and includes the thumb. An orthosis that suspends the digits with soft-finger loops and dental floss and has a thermoplastic base that does not cross the wrist will utilize and preserve a tenodesis motion for grasp and release. A more simplistic and easy-to-manage prefabricated wrist extension splint can also work well to prevent the functional limitations of the drop-wrist deformity.

Distal Radius Fracture

Immobilization Phase

Appropriate early therapy intervention can make a huge difference in the client's overall functional recovery. If the digits are allowed to become swollen and stiff, the long-term functional results can be devastating. These fractures are common among older people with osteoporosis and balance problems. Temporary loss of independence following fracture can trigger an irreversible downward spiral in the client occupational functioning.

Typical medical management of Colles fracture is cast immobilization, usually above elbow with the elbow in 90° of flexion to prevent forearm rotation during the first 3 weeks. When the client is put in a short arm cast and the elbow is freed, begin elbow AROM for flexion and extension, but avoid resisted elbow motion so as not to stress the fracture healing. Do not perform elbow PROM without medical clearance, and be very gentle. Biceps tightness commonly follows elbow immobilization.

Certain fractures require some form of fixation. Some physicians delay the referral of clients to therapy, but postponing the initiation of therapy can result in significant problems with edema and decreased ROM. It is a good idea to communicate with referring physicians and encourage routine early therapy referral for this diagnosis.

While the client has percutaneous pins, provide pin site care as the physician prescribes using sterile technique and standard precautions. Teach the client digital ROM and tendon gliding exercises, and instruct in precautions related to cast wearing. It is critical to monitor for cast tightness because a tight cast can cause CRPS. Call the physician if the cast is too tight. Discourage the use of slings because they promote unnecessary proximal stiffness, guarded posture, and disuse.

The onset of shoulder restrictions, which can be attributed to additional trauma occurring at the time of the wrist fracture, is problematic and should be immediately ruled out or treated. Physicians most assuredly appreciate therapists' input regarding early signs of this problem. To prevent a frozen shoulder, proximal ROM is a high treatment priority. Instruct in shoulder flexion, abduction, internal rotation, and external rotation. Perform as thorough a physical assessment as tolerated and as cast constraints permit. This may have to be done in phases. Early identification of guarding, excessive pain, or autonomic signs can alert the team to the possibility of CRPS.

Following distal radius fracture, the recovery of function depends on restoration of motion and strength and on maximizing the length-tension relationship of the digital flexors and extensors.³⁴ Edema can contribute to decreased ROM at uncasted areas. Clients are often surprised that uninjured and uncasted areas can stiffen.

The goals of early therapy during immobilization are to normalize edema and achieve as nearly normal AROM of uncasted areas as possible. During this period, intrinsic tightness, extrinsic tightness, and digital joint tightness may occur. The chance of tendon adherence is increased following open reduction and its accompanying incisional scar. Various blocking splints may be used with functional activity and exercise to resolve joint or musculotendinous tightness. Differential tendon gliding exercises are extremely important. Frequent exercise throughout the day is better than a few long sessions. It is generally advised to perform exercises every hour or 2, perhaps 5 to 10 repetitions each, maintaining the end position comfortably for 3 to 5 seconds. Incorporate exercises into occupations, including ADL, as much as possible.³⁷

If extrinsic musculotendinous tightness persists, it may be appropriate to add night static progressive splinting or low-load, long-duration dynamic splinting in conjunction with exercise to normalize extrinsic length. Consult the physician before making this determination.

Mobilization Phase

When fracture immobilization is discontinued, physicians often recommend a custom-fabricated volar wrist orthosis. This is protective and can be corrective to help restore functional wrist motion (usually extension). This temporary support is particularly helpful if the client maintains habitual wrist flexion because this "doggy-paw" posture leads to development of the undesirable deformity position of MP extension, PIP flexion, and thumb adduction and extension discussed earlier. At this stage of therapy, there is usually measurable limitation in ROM, with clients reporting awkwardness and decreased function. Consult the physician for medical clearance and

guidelines for forearm and wrist ROM. Teach the client to wean off the protective orthosis according to the physician's guidelines, which are individualized. Edema control continues to be the highest priority until it is resolved. AROM and ADL can help correct the edema. Guided motor imagery has also been shown to be effective with wrist fractures.⁴⁰

At any time, but especially in this early stage, overzealous therapy is harmful. Clients and families who think they should be aggressive in their home programs need education and reinforcement to avoid overdoing it. Use written material and illustrations to teach them how to observe tissue responses and monitor inflammation. Temperature elevation or redness over the joints of digits may indicate that intervention is eliciting an inflammatory reaction and should be adjusted accordingly.⁴¹

It is extremely important to retrain the wrist extensors to function independently of the extensor digitorum. Have the client practice wrist extension with available composite digital flexion, being especially sure the MPs are flexed. Then have the client flex the wrist with the digits relaxed but extended to isolate the wrist flexors. It is also important to retrain the extensor digitorum to function independently of the intrinsics. Have the client extend the MPs with the IPs slightly flexed to isolate the extensor digitorum.

Gradually upgrade therapy with increasingly challenging motions, combined motions, and activities aiming to restore joint suppleness and musculotendinous lengths. Client selected dexterity activities, such as cat's cradle, and games, such as pick-up sticks, promote spontaneous functional movements. Sorting drawers and folding small items of clothing are good home activities (see Fig. 43-25). Initiate graded functional strengthening with medical clearance, usually after good motion has been achieved. Upgrade carefully, monitor client and tissue responses, and adjust the intervention accordingly.

Figure 43-25 Sorting clothes as therapeutic activity to improve hand function. (Shutterstock/Sandra van der Steen.)

Ligament Injury

Grade I ligament injuries, also considered sprains, may produce enough discomfort during functional activities that they require rest, thermal modalities, and temporary modifications to work, ADL, and leisure activities. Rest may require the use of a customized orthotic device depending on the location of the injury and the painful dysfunction experienced. Therapeutic heat or cold can be recommended to the client depending on the acuity of the injury; cold will reduce pain and inflammation, and heat will reduce chronic pain and increase extensibility of a stiff joint. In addition to pain control and adaptations, grade II injuries will require longer immobilization until ligament fibers are healed enough to ensure stability of the joint. During immobilization, gentle protected active movement should be encouraged within anatomical lines of motion to maintain joint flexibility but prevent reinjury. As mobilization is discontinued, client should return to normal levels of activity within pain tolerance. Grade III injuries will require surgical intervention to reattach the ligament to bone with occupational therapy to improve functional use of hand following full healing.

Skier's Thumb

Skier's thumb (grade 3 ligament injury of the ulnar collateral ligament of the thumb MP) may require surgical intervention for ligament reattachment. During the post-op immobilization period, the occupational therapist can provide a protective hand- or forearm-based thumb spica orthosis and edema control techniques. ROM exercises for noninvolved joints and recommendations for use of the hand for light ADLs are initiated. After approximately 1 to 2 weeks, the client is instructed to complete gentle ROM exercises for the MP joint that will progress over time. Strength and motion of the IP joint are also addressed because full MP flexion may not be achieved, especially among older clients. Resistive exercise will be started at approximately 6 weeks; then lateral pinch and tip pinch (which may not be for 12 weeks owing to the strenuous nature of the tip pinch). The hand-based spica orthosis may be used beyond 12 weeks if needed for additional joint protection during strenuous activity. Scar hypersensitivity caused by the underlying radial sensory nerve is common.

Flexor Tendon Repair

Various protocols exist for controlled mobilization, using a dorsal orthosis with the wrist in 10° to 30° of flexion, MP joints in 40° to 60° of flexion, and IP joints ideally in full extension (unless there has also been a digital nerve repair). The involved IP joints may have to be in some flexion if a digital nerve has been repaired. The Duran protocol entails passive digital flexion and extension within the protective orthosis to achieve 3 to 5 mm of differential digital tendon excursion.^{42,43} With this protocol, gentle active motion begins with medical clearance about 4 weeks after surgery.

Another popular protocol is known as the Kleinert protocol and involves passive flexion–active extension with rubber band attachments to the fingernails within the protective dorsal orthosis.⁴⁴ The client performs gentle active digital extension, and the rubber band provides passive digital flexion within the confines of the protective orthosis. Exercises are gradually increased to 10 repetitions comfortably every waking hour. At night, the digits may be strapped carefully and comfortably to the dorsal hood of the orthosis to counteract the tendency to develop PIP or DIP flexion contractures.

The Chow protocol uses a combination of the Duran and Kleinert techniques. With advances in suture techniques, flexor tendons protocols are incorporating early active motion in clients who are good candidates (see Fig. 43-26).⁴⁴

Figure 43-26 Early active motion protocol dorsal protective orthosis with elastic traction and hinged wrist.

With all three protocols, active flexion of the digits begins at approximately 4 to 6 weeks from initial repair and increases in frequency and intensity until the client can return to full function, usually 12 weeks or after repair. When the physician gives medical clearance to discontinue the dorsal protective orthosis, begin a graded program to promote functional movement. Edema control and scar management remain high clinical priorities. Assess closely and determine tissue-specific limitations that guide the therapy program. Tendon gliding exercises and place-and-hold exercises are typical early techniques. Corrective splinting is useful, along with ADL, graded activity, and upgraded exercise as appropriate.

Extensor Tendon Repair

Zone I or II extensor tendon injuries, also called mallet finger deformities, not requiring surgical intervention will be immobilized in slight hyperextension for a minimum of 8 weeks, leaving the PIP joint free. The occupational therapist may create a custom orthosis or fit a premade device. The physician may also provide this device. Once provided to the client, it is essential to instruct the client in use of the device, including cleaning of the digit and changing soiled tape or self-adhesive wrap applied to hold it in place. The therapist will also instruct the client in AROM and gentle PROM to noninvolved joints of the hand, especially the PIP joint of the digit.

Once the tendon has healed, the client will begin gentle active flexion activities to regain motion lost through immobilization. Flexion activities must be balanced with active extension to ensure that there is no recurrence of DIP extensor lag. Use of the extension orthosis should continue between exercise sessions and eventually reduced to times of sleep only. However, if a lag is noticed during the day or is getting more pronounced over time, the client should be instructed to resume splinting as needed to recover DIP extension.

Extensor injuries in zones III and IV lead to a boutonnière deformity, an imbalanced digital position of PIP flexion and DIP hyperextension. The deformity is caused by volar displacement of the lateral bands secondary to involvement of the central slip. In nonoperative cases, splint the PIP in full extension for 6 weeks, and promote DIP active and passive flexion to prevent stiffness of the oblique retinacular ligament. In operative cases, follow the physician's guidelines, which may vary in timing and technique of mobilization and splinting. When the client is medically cleared to begin PIP active exercises, watch closely for PIP extensor lag, and modify therapy and splinting accordingly.

Injury in zones V and VI may be treated by immobilization or controlled early motion.⁴⁵ Specific positioning and motion guidelines vary from surgeon to surgeon and are modified according to each client's tissue responses. Multiple complex orthotics may be needed to achieve a program that balances rest and motion appropriately.

Injury in zone VII is likely to result in restrictions because of the development of adhesions. Communicate closely with the surgeon for specific positioning and motion guidelines.

Conclusion

Occupational therapists who work with individuals with hand injuries and conditions must have comprehensive knowledge of body functions and structures, including the musculoskeletal and nervous systems. In addition, they understand and appreciate the relationships of client factors to performance skills, performance patterns, occupations, and the context/environment of the client. Advanced levels of knowledge of diseases and conditions affecting the hand and upper extremity and their potential impact on occupational participation are also integral to this practice area. Therapists are also well versed in a variety of assessment tools, outcome measures, and specialized treatment techniques that support occupational performance. The role of occupational therapy within hand rehabilitation as with all other specialized areas of practice is to ensure that the client can participate in the desired areas of occupation, regardless of the impact of conditions, disease, or the environment.

CASE STUDY

Patient Information

Sage is a 31-year-old who is married and recently adopted an infant. Sage began to experience pain in the radial side of the right dominant wrist that has caused significant difficulties with caring for the infant child. Activities such as diapering, connecting and disconnecting the car seat straps, opening and closing fastenings on all clothing, and preparing food are becoming impossible to complete because of significant pain and limited motion of the thumb into flexion and wrist into flexion and ulnar deviation. Sage was seen by a physician at the local hospital orthopedic clinic who diagnosed the condition as de Quervain tenosynovitis and provided a corticosteroid injection into the first dorsal compartment.

Reason for Occupational Therapy Referral

Owing to the difficulties in childcare and other basic ADLs, the physician ordered occupational therapy assessment and treatment following the injection. In addition, the therapy order

included the provision of a thumb spica orthosis.

Assessment Process and Results

The occupational therapy evaluation took place the day of the doctor visit and began with the completion of the Occupational Profile.²⁷ The results of the profile indicated that Sage has significant concerns with the ability to care for the new baby and complete self and home care activities due to significant pain and stiffness. Although the cortisone injection made the wrist and thumb somewhat less painful immediately following, the doctor indicated that it may take several days for the de Quervain to be resolved. With regard to environmental supports, Sage indicated that her partner shares the childcare responsibilities, but that her partner works outside the home during the day and returns home later in the evenings. Sage does not have any knowledge of modifications to task completion and is not clear on the cause of the pain; no orthosis has been provided.

The analysis of occupational performance was conducted next and included assessments targeting active motion of the wrist and thumb and pain level. Results are as follows:

Assessment	Criteria	Results
Visual Analog Scale (VAS) for pain	At rest	4/10
	With activity	9/10
Goniometric assessment of AROM	Wrist flexion/extension (normal = 70°/75°)	10°/30°
	Radial deviation/ulnar deviation (normal = 20/35)	15°/10°
	Thumb MP composite flexion with wrist neutral (opposite hand 55°)	12°
	Isolated thumb MP flexion with neutral wrist (opposite hand 56°)	20°

Visual inspection indicates swelling and fullness at the radial wrist in the area of the first dorsal compartment; bruising is apparent due to the injection several hours ago. Findings of the client factors of pain and motion limitations due to tenosynovitis of the first dorsal compartment are consistent with functional limitations being reported.

Occupational Therapy Problem List

- Difficulty caring for new infant
- Difficulty with clothing fasteners on self and infant
- Difficulty with cooking activities

Occupational Therapy Goal List

- Client will report pain-free abilities to bath, dress, and secure infant in car seat within 2 weeks.
- Client will report the ability to dress self fully including securing all fasteners within 2 weeks.
- Client will report the ability to prepare food for the family without pain within 2 weeks.

Intervention

Sage was provided with a prefabricated thumb spica orthosis for intermittent use during the immediate postinjection phase. Instructed to use splint whenever engaged in resistive child care and ADLs. Instructed to decrease orthosis usage as pain subsides and motion improves. Sage was also instructed in gentle AROM activities, including wrist flexion and extension, supination, pronation, and radial and ulnar deviation (with thumb flexion and without thumb flexion). Instruction in use of therapeutic ice to decrease pain as needed and gentle retrograde massage was also provided.

Sage was seen for a follow-up visit 2 weeks later, where ergonomics with regard to hand usage and childcare activities were reviewed. Sage was instructed to avoid resisted ulnar deviation and pinching with thumb whenever possible through attention to position of hand and wrist and to use built-up handles on cooking devices if needed. If pain appears to be returning, instruction to return to full-time splint usage and to use therapeutic cold to reduce

inflammation was provided. At time of second visit, ROM had returned to normal, and pain was reduced to 2/10 with activity and 0 per the VAS at rest.

Evidence Table for Occupational Therapy Interventions for Hand Impairments

Intervention	Description	Participants	Dosage	Research Design and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome
Effect of immobilization of metacarpophalangeal joint in thumb carpometacarpal osteoarthritis on pain and function ⁴⁶	Comparison of the effectiveness of two different static orthoses on pain and functional abilities on CMC OA.	Eighty-four patients, 91.7% females (mean standard deviation [SD] age, 60.1 ± 9.6 years), with thumb CMC OA were randomized into one of two groups. For group A, a Ballena orthotic was constructed, and for group B, a Colditz orthotic was constructed.	Both orthoses were worn for 3 months.	A quasi-experimental trial Level II	Both orthoses improved pain level and functional abilities (F[1.0] ¼ 413.327 and F[1.0] ¼ 211.742; both <i>p</i> < 0.001). There was no statistically significant difference between two groups regarding pain recovery and functional improvement (F[1.0] ¼ 0.075 and F[1.0] ¼ 7.248; both <i>P</i> > 0.05)	Sample size and power calculations indicated the number of participants needed in each group to be 40. Calculations were based on a difference on a 100-mm VAS, assuming an SD of 20 mm, a two-tailed test, an alpha level of 0.05, and a desired power of 80%. In all analyses, <i>p</i> < 0.05 were considered statistically significant.
The effects of KinesioTape on the treatment of lateral epicondylitis ³⁸	Application of KT with and without tension on pain intensity, pain pressure threshold, grip strength, and disability in individuals with lateral epicondylitis (LE), and myofascial trigger points (MTPs) in forearm muscles.	Thirty women with LE and MTP in the forearm muscles were randomly assigned to KT with tension and placebo (KT without tension).	The treatment was provided three times in 1 week, and outcome measures were assess pre–post treatment.	Randomized clinical trial Level I	The application of KT produces a reduction in pain intensity and upper extremity disability in subjects with LE and MTP in the forearm muscles, and KT with tension was more effective than placebo group.	Study showed no significant difference between groups in variables either immediately or after 1 week. However, Disabilities of the Arm, Shoulder, and Hand (DASH) questionnaire and VAS during activity were statistically significant between the two groups.

Intervention	Description	Participants	Dosage	Research Design and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome
Effectiveness of the graded motor imagery to improve hand function in patients with distal radius fracture: a randomized controlled trial ⁴⁰	To investigate the effectiveness of graded motor imagery (GMI) in hand function in patients with distal radius fracture	Thirty-six participants were randomly allocated to either GMI (n ¼ 17; 52.59 [9.8] years) or control (n ¼ 19; 47.16 [10.5] years) groups.	The GMI group received imagery treatment in addition to traditional rehabilitation, and the control group received traditional rehabilitation for 8 weeks.	Single-blinded, randomized controlled trial Level I	GMI appears to provide beneficial effects to control pain, improve grip strength, and increase upper extremity function in patients with DRFx.	Statistical power analyses were used to determine the optimum sample size using DASH score. The minimum necessary sample size was 15 subjects for each group, with a 20% absence rate. The alpha level used in determining the sample size was 0.05, and the ideal power was considered to be 80%.
Effectiveness of edema management techniques for subacute hand edema: a systematic review ³⁴	This systematic review examined the evidence of effectiveness of a range of hand edema treatments on hand volume.	Ten studies met the inclusion criteria. Study quality ranged from 23 to 41 of 48 points on the Structured Effectiveness Quality Evaluation Scale (SEQES). A total of 16 edema interventions were evaluated across the studies.	The following inclusion criteria were used for study selection: randomized controlled or controlled trials in adults who have subacute swelling after a recent upper limb musculoskeletal trauma or cerebral vascular attack or after surgery. Two independent assessors rated study quality and risk of bias using the 24-point MacDermid SEQES.	Systematic review Level IIb	Manual edema mobilization (MEM) techniques should be considered in conjunction with conventional therapies, in cases of excessive edema, or when the edema has not responded to conventional treatment. MEM is not advocated as a routine intervention.	Owing to heterogeneity of the patient characteristics, interventions, and outcomes assessed, it was not possible to pool the results from all studies. Therefore, a narrative best evidence synthesis was undertaken. There is low-to-moderate quality evidence with limited confidence in the effect estimate to support the use of MEM methods in conjunction with standard therapy to reduce problematic hand edema.

Intervention	Description	Participants	Dosage	Research Design and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome
Comparison of effects of eccentric training, eccentric-concentric training, and eccentric-concentric training combined with isometric contraction in the treatment of lateral elbow tendinopathy ³⁸	The effectiveness of eccentric training, eccentric-concentric training, and eccentric-concentric training combined with isometric contraction in the treatment of lateral elbow tendinopathy.	A group of 34 patients with later elbow tendinopathy was randomly allocated to group A ($n = 11$) who underwent eccentric training, group B had eccentric-concentric, and group C who had eccentric-concentric and isometric training.	All patients received five treatments per week for 4 weeks.	A randomized clinical trial Level III	The eccentric-concentric training combined with isometric contractions was the most effective treatment.	The eccentric-concentric training combined with isometric contractions produced the largest effect in the reduction of pain and improvement of function at the end of the treatment ($p < 0.05$) and at any of the follow-up time points ($p < 0.05$).

Amputations and Prosthetics

Lisa Smurr Walters

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Design treatment programs for preprosthetic and prosthetic management of upper limb amputations.
2. Discuss upper limb amputation levels and respective prosthetic options.
3. Describe the psychological implications of amputation and the therapeutic management.
4. Discuss treatment program considerations for persons with lower limb amputations.
5. Discuss challenges of treating individuals with multiple limb loss.

CHAPTER OUTLINE

Amputation Epidemiology
Amputation Medical Management
Functional Impairment in Daily Occupation after Amputation
Evaluation after Amputation
Intervention for Pain, Neuromusculoskeletal, and Sensory Impairment after Amputation
Intervention for Independence in ADLs after Amputation
Intervention with the Upper Limb Prosthesis
Rehabilitation after Lower Limb Amputation
Conclusion
Case Study

TERMINOLOGY

Body-powered (BP) prosthesis: an upper limb device that operates from an individual's proximal motions (typically the muscles of the shoulders, neck, and back).

Externally powered (EP) prosthesis: an upper limb device that operates through external power.

Functional envelope: the area of space in which the patient can effectively operate an upper extremity prosthesis.

Heterotrophic ossification: bone that abnormally grows in soft tissue where it should not exist and it commonly occurs after trauma to the musculoskeletal system, brain, or spinal cord.

Hybrid prosthesis: an upper limb device that combines two prosthetic options into one; the most common combination is with a transhumeral prosthesis with a BP elbow and EP terminal device.

Musculoskeletal pain: discomfort that occurs in other areas of the body, such as the back, neck, shoulder, or contralateral limb, as a result of overuse or poor body mechanics.

Myodesis: surgical technique that involves directly suturing muscle or tendon to amputated bone in order to provide optimal distal muscle stabilization.

Myoplasty: surgical technique that involves suturing muscle to muscle and then placing it over the end of the amputated bone before closing the wound; more commonly used in patients with poor vascular health.

Neuroma: an injured nerve in which severed nerve fibers form a disorganized mass of nerve cells (neuroma) that is painful with direct pressure.

Terminal device (TD): an upper limb prosthetic component that is inserted at the distal end of an upper limb prosthesis and is used to grasp and release objects; may be a hook or hand.

Amputation Epidemiology

There are nearly two million people living with upper or lower limb loss in the United States, and this is expected to increase to 3.6 million by 2050.¹ Annually, more than 185,000 persons in the United States have amputations.² Amputations are classified as major and minor amputations. Major limb amputation(s) are proximal to the wrist or ankle, whereas minor limb amputation(s) are distal to the wrist (hand and fingers) or ankle (foot and toes). The ratio of lower limb to upper limb amputation varies depending on the source cited. The estimated ratio of general lower limb amputations to upper limb amputation is 52:1.¹ Major lower to upper limb amputation ratio is estimated to be 40:1.³ In all, 92% of all upper limb amputations occur below the wrist, whereas 65% of all lower limb amputations occur at or above the ankle.¹

Levels of upper and lower extremity amputation are illustrated in Figures 44-1 and 44-2, respectively. The term interscapulothoracic is an amputation of the arm, scapula, and clavicle, resulting in the loss of hand, arm, and scapular function. The term transhumeral is an amputation through the humerus, resulting in a loss of hand, wrist, forearm, and elbow function⁴ and decrease in shoulder internal and external rotation. Transradial is an amputation through the radius and ulna, resulting in reduced forearm motion and loss of wrist and hand function.⁴ Partial hand is an amputation through all or a portion of the metacarpals, and partial or complete amputations of the digits are referred to as digit or partial finger amputations. Partial hand and digit amputations result in complete loss or partial loss of grip function⁴ and may impact dexterity and coordination. The term transfemoral is an amputation through the femur above the knee, whereas a transtibial amputation is one below the knee through the tibia and fibula.

Figure 44-1 Levels of upper extremity amputations.

Figure 44-2 Levels of lower extremity amputations.

The main causes of amputation are dysvascular disease (54%), trauma (45%), and cancer (less than 2%).¹ Other causes include infection and congenital limb deficiency in which a complete limb is absent or a portion of the limb is shortened at birth. The most common cause of lower limb amputation is dysvascular complications from diabetes, arteriosclerosis, smoking, or a combination of these.⁵ Nearly 70% of all upper limb amputations are the result of trauma⁶ and injury occurred primarily to males aged 15 to 45 years in work-related accidents.⁷

Sequelae

Course and prognosis after amputation varies based on the cause of limb loss as well as other present comorbidities (e.g., soft-tissue or musculoskeletal damage, neurovascular

impairments, **heterotrophic ossification**). With acquired amputations, the surgeon's aim is to preserve as much limb length as possible. This aim, however, must be balanced against wound healing capability and residual limb coverage, patient preference, rehabilitation potential, and local prosthetic expertise and availability.⁸ Fitting of a prosthesis does not begin until sutures are out and residual limb wounds are healed.

Signs and symptoms related to dysvascular disease that may lead to amputation may include nonexistent or failed medical or revascularization options of the extremity, significant loss of soft tissue as a result of the dysvascular condition, or complications from infections that can only be managed by surgical interventions.⁹ Because trauma is the leading cause of upper limb amputations, there are often no signs or symptoms that lead up to the amputation.

There are a number of secondary health effects that may occur after amputation, which may include poor nutritional intake, reduced exercise, obesity, tobacco use, hypertension, hypercholesterolemia, skin issues, diabetes, and cardiac disease.¹⁰ Patients who present with amputations related to dysvascular disease are at high risk for further complications about the residual limb and/or amputation of the contralateral limb because of the systemic nature of the disease process. They are also at higher risk for other health problems, such as cardiovascular disease, cerebrovascular accident, renal disease, and peripheral neuropathy.⁵ Patient education should focus on the importance of engaging in a healthy lifestyle, including proper diet, regular exercise, avoidance of nicotine, and benefits of routine follow-up with medical providers for annual wellness examinations.

Individuals with major limb loss are at higher risk for the development of various medical and musculoskeletal complications.¹¹ Individuals with lower limb amputation are at higher risk for upper limb nerve entrapment.¹² According to research, individuals with unilateral upper limb amputation experience **musculoskeletal pain** in the neck, upper back, shoulders, and remaining limb,¹³ but specific factors that lead to these conditions are not clear.¹⁴ Preservation of the residual and contralateral limb, the individual's general health, and wellness are integral parts of ongoing care for these patients.¹⁵

Use of Prosthetic Devices

The level of amputation may affect the use of a prosthesis. The more proximal the amputation, the more difficult a prosthesis is to use. There are fewer joints and muscles available, so more complex suspension strategies are needed for control, device weight is greater, and more energy is required to use a device. The percentage increase in energy costs of prosthetic ambulation is 9% to 28% for unilateral transtibial, 40% to 60% for a unilateral transfemoral, 41% to 100% bilateral transtibial, and 280% for bilateral transfemoral amputations.¹⁶

Various reasons are cited in the literature why a patient decides to use or not use a prosthesis.¹⁷ Comfort and function have long been accepted as important factors. Studies have attempted to reveal additional predictor variables of prosthetic use. In one study of 107 upper limb amputees, 56% wore a prosthesis for approximately 11 hours per day for an average of 24 days per month; this study identified longer length of the residual limb, the absence of phantom limb pain, and married status as variables associated with the use of a prosthesis.¹⁸ Military service members from recent conflicts have higher than previously recorded acceptance and use rates that may be a result of improved comfort and function of prostheses.^{19,20} Literature suggests that upper limb prosthetic rejection rates may decline if patients with upper limb amputation receive sufficient training by a highly specialized, interdisciplinary clinical

team that provides focused patient education and empowerment throughout the individual's rehabilitation process.²¹

Amputation Medical Management

Patients living with limb loss are best cared for by a physician-led, multidisciplinary team with the patient at the center of the team.^{5,6} The multidisciplinary care team is identified as the "team" here forth. The team may include the patient's support system; surgeon; a physician, preferably a physiatrist with experience in amputation rehabilitation; a case manager, case worker, or social worker; prosthetist; occupational therapist; physical therapist; behavioral health provider; trained peer support visitors or peer mentors;^{5,6} and assistive technology specialist, if necessary.²² Patients are active, equal members of the team and should be involved in a shared decision-making process in order to maximize their rehabilitation outcome with or without a prosthesis.^{5,6,23} Ongoing, frequent, and routine open communication among the team members and the patient is imperative to ensure progress toward goals and for the patient to obtain higher levels of independence in both activities of daily living (ADLs) and instrumental activities of daily living (IADLs).⁶

Table 44-1. Phases of Rehabilitation

PHASE	BEGINNING EVENT MARKER	ENDING EVENT MARKER	INTERVENTION FOCUS
Perioperative ^{5,6} (<i>upper and lower limb amputations</i>)	Decision to amputate or after traumatic amputation	All wounds are healed, sutures are removed, the patient the patient has been medical cleared and has maximized independence in self-care ADL using adaptive strategies, assistive technology, or durable medical equipment.	<ul style="list-style-type: none"> • Wound care and healing • Edema control • Scar management • Pain control • Joint mobility and progressive physical conditioning • Psychological and emotional support • Connect with peer visitor or mentor.
Preprosthetic Training ⁶ (<i>upper limb amputations, only</i>)	Postsurgical period ends	Patient receives a preparatory (temporary) or definitive (permanent) prosthesis.	<ul style="list-style-type: none"> • Provide emotional support. • Stabilize limb volume, desensitize sensitive areas of residual limb, and optimize residual limb shape. • Progressive resistance exercises • Facilitate independence in ADL, change of dominance, and activities to strengthen motor patterns in preparation to operate the prescribed device. • Determine optimal type of prosthesis to meet patient's goals.
Prosthetic Training ⁶ (<i>upper limb amputations, only</i>)	Delivery of temporary or definitive prosthesis	Patient demonstrates a successful functional outcome with proper prosthetic use during desired functional activities.	<ul style="list-style-type: none"> • Control training • Repetitive drills • Functional training to learn to integrate the prosthesis as an assistive tool in daily activities that align with patient goals

ADL, activity of daily living.

Individuals with multiple limb loss present a unique set of challenges. Frequent team meetings regarding the initial focus of rehabilitation, achievable goals, and progression of prosthetic training for both upper and lower extremity amputations is highly recommended.^{5,6} General considerations that will influence rehabilitation for this subset include (1) increased body temperature secondary to reduced body surface area; (2) increased risk of joint contractures, weight gain, deconditioning, and bone resorption as a result of immobility; (3) unique pain management needs, given architectural changes to the musculoskeletal system; (4) psychosocial issues, such as the importance of body image acceptance and return to work; and (5) likely ongoing medical risks, such as cardiovascular disease, metabolic dysfunction, musculoskeletal pain, and arthritis.²⁴⁻²⁶

Phases of Rehabilitation

In general, experts consider three phases of rehabilitation after amputation (see Table 44-1): perioperative, preprosthetic, and prosthetic training.^{5,6} The beginning and end of each phase does not represent fixed points in time; they often overlap and, depending on the patient's recovery process, may be sequential. Additionally, throughout the patient's life as he or she learns to define a new normal, as well as receive different devices, he or she will move throughout these phases.^{5,6} The focus of this chapter is primarily on management of individuals with upper limb amputation with general discussion on management of patients with lower limb loss. Therapists are encouraged to consult the appropriate Veteran's Administration/Department of Defense (VA/DoD) Clinical Practice Guidelines on upper⁶ or lower extremity amputation⁵ for more detailed information as well as other references when working with patients with multiple limb amputation.^{27,52,58,63,66}

Patient Education

The team is charged with educating the patient and family throughout all phases of rehabilitation.^{5,6} To facilitate informed decisions, clinicians should provide clear and appropriate education that, at a minimum, includes surgical interventions when possible, amputation level, wound healing, residual limb management, pain management, rehabilitation programs and sequence of care, patient safety, potential psychological consequences and psychosocial adjustment issues, procedural and recovery issues, peer support groups, prosthetic types and options, and expected functional outcomes.^{5,6} Patients with upper limb amputation should also be educated about overuse syndromes in the neck/upper back, the shoulders, and the remaining limb.^{12,13}

Managing Expectations of an Upper Limb Prosthesis

The human hand executes numerous postures, prehension patterns, grip and pinch forces to engage in activity or with an object. Restoring functional capabilities of the hand through a prosthesis is an exceptional challenge because natural sensory feedback cannot be restored through any commercially available prosthesis. Many patients with upper limb loss have initial prosthetic expectations that are not realistic; no one device can restore human hand function, sensation, or appearance. Furthermore, a frequent goal of returning function and aesthetic appearance are often incompatible with each other in currently available prosthetic options.²³ It is critical that the team provide patient and family education to better manage device expectation.

An upper limb prosthesis is considered a tool to assist in the performance of a task or tasks and should not be considered a prime mover during any activity. Task performance can be achieved through activity modification, work simplification, compensatory strategies, commercially available adaptive aids, customized adaptive equipment design, and with the assistance of a prosthetic device. Success is unique to

each individual patient,²⁸ and patients often benefit from the use of more than one type of prosthesis to regain independent function and restore quality of life.^{6,23}

Upper Limb Prosthetic Options

The most common upper extremity prosthetic options currently available include passive, **body-powered (BP)**, **externally powered (EP)**, **hybrid**, and activity-specific prostheses. Passive prostheses do not have an active grasp but do provide functional benefits and can enhance individual recovery by restoring a sense of normalcy.²⁹ Depending on the level of amputation and prosthetic design, ratcheting passive joints may be used for heavy-duty activity (see Fig. 44-3) after a partial hand amputation. Passive prostheses are available to replace any part of a limb, from a single digit to a whole arm. A BP system operates through a cable and harness system that captures body motions proximal to the amputation to create tension through the cable and open or close the **terminal device (TD)**. There are BP options for major and minor amputations. With major amputations, BP TDs operate through one of two systems, voluntary-opening or voluntary-closing. In a voluntary-opening design, the TD remains in the closed position until force is exerted through the cable to open the TD. Terminal device often closes through force of rubber bands placed at the base of the TD. A voluntary-closing design remains open until force captured through the cable closes the TD; therefore, grip strength in this design is dependent on the strength of the prosthetic user. An EP system uses power external to the body for operation. A common type of EP prosthesis is known as myoelectric that requires electrical signals produced from muscle contractions to operate powered components. A hybrid system is a combination of two types of devices. Most commonly, this includes BP and electric components and is an option for patients with amputation at or above the elbow. An activity-specific prosthesis is designed for a specific function or activity, such as weight lifting or swimming.

Figure 44-3 Heavy-duty positional locking index finger prosthesis by Point Designs, LLC (Louisville, CO) for a partial hand amputation.

A prosthesis is comprised of a socket, frame, and components. The socket encapsulates the residual limb and often has a very intimate fit to the skin. The frame encases the socket to provide stability and rigidity and serves to restore the length of the missing extremity. It may also house internal components, such as the wrist mechanism, batteries (if necessary), or electronics (if applicable). Components include prosthetic joints and TDs. Some prostheses require harnessing to suspend the device from the residual limb. Some devices require use of socks or silicon sleeves that are placed over the residual limb before donning the device to enhance comfort or suspension. Some devices may include a cover such as a glove or sleeve that is external

to the frame and some components. Often, these covers provide a more natural appearance of the missing limb.

Each prosthetic option has specific socket designs for various levels of amputation, as well as harnessing and suspension options, and available TDs. These topics are beyond the scope of this chapter; however when working with patients with upper limb amputation, the occupational therapist should meet with the fitting prosthetist to learn about device operation, appropriate device use, component information, and, if EP, control setup because all will impact prosthetic training.

Individuals with bilateral upper extremity amputations and amputation of three or more limbs present unique challenges when selecting the prosthetic systems. Early fitting with a temporary prosthesis on at least one upper limb is strongly recommended³⁰ to reduce dependency for self-care activities. One study identified that those with congenital amputation fit within 2 years of birth or those with acquired amputation fit within 6 months of amputation were 16 times more likely to continue prosthesis use.¹⁷ Additional studies suggest that early fitting and prosthetic training may foster acceptance and use of the prosthesis.^{21,31} If an early postoperative prosthesis is prescribed, daily communication between the patient, occupational therapist, and prosthetist is imperative to maintain proper fit and function.⁶

Functional Impairment in Daily Occupation after Amputation

Regardless of the level of limb loss or if the amputation is of the lower or upper extremity, every facet of an individual's life, as well as the family's, is impacted to some degree. Therefore, renegotiation is required. Consider how you would get up to go to the restroom at night if you did not have a leg. How would you dance at a wedding if you were missing an upper and lower limb, or cut food with a knife and fork if you were missing the radial portion of the hand?

Degree of impairment is influenced by the level of amputation, whether the patient has an upper or lower extremity amputation, the number of limbs amputated, and the presence of comorbidities. Additionally, level of functional impairment after an amputation or amputation(s), particularly of the upper extremity, is very individualized, because presentations uniquely vary. In general terms, those with more proximal amputations and multiple limb involvement tend to experience greater functional impairment in daily occupations than those who have unilateral distal amputations. Individuals with higher level of upper limb amputation (above the elbow) tend to experience greater challenges with accepting and using prostheses,⁸ whereas those with partial hand amputation report greater perceived levels of disability than those with major upper limb amputation.³² Patients with unilateral upper extremity limb loss experience difficulties with bimanual ADL and IADL. Limited evidence identifies that individuals with dominant hand injury have greater functional impairment,³³ and it has been the clinical experience of this author that individuals who sustain an amputation of the dominant hand demonstrate greater levels of impairment because the nondominant hand is forced to become the primary limb and executor of most activity.

Emotional Impact

Limb loss affects not only physical function but also the patient's competence and satisfaction in life roles: self-maintenance, family, and home; self-enhancement, such as engaging in leisure and community activities; and self-advancement as a worker or student.³⁴ Reactions to amputation are as complex as the unique nature of each human, and an individual's personality and belief system may influence how he or she responds to limb loss. Emotional reactions to the loss of a limb have been likened to grieving the loss of a loved one, and it impacts body integrity and sense of self.²² Often, an initial response is shock and disbelief. Depression rates in those with lower limb

amputations are higher than general population rates for up to two years after amputation.³⁵ Individual beliefs related to appearance and self-consciousness in public after lower limb amputation were associated with both distress and psychosocial adjustment difficulties.^{35,36}

Patients with upper limb amputation are more likely than the general population to screen positive for depressive symptoms and post-traumatic stress disorder (PTSD).^{37,38} Individuals with partial hand amputation are even more likely to screen positive for these psychological changes. Pain affects PTSD and depressive symptoms in this population because it impacts positive emotions and postinjury activity.³⁹ Furthermore, individuals who are less resilient tend to engage in avoidant coping behavior which is prospectively predictive of higher PTSD and depression.⁴⁰

The patient may project negative feelings onto others so it's beneficial to encourage open discussion, develop a relationship based on trust and respect, and collaborate with the other team members to facilitate the patient's psychological adjustment and reintegration into previous roles. The therapist should communicate with and, when necessary, refer the patient to a behavioral health provider throughout the psychosocial adjustment periods of survival, recovery, and reintegration after limb loss.

The therapist should also provide the patient and caregiver(s) information about the therapy process and establish realistic goals and outcomes to help clarify expectations and reduce fear and anxiety, and reference materials on topics to include information on coping and adjusting to the amputation, information on prosthetic options, tips on how to manage ADLs independently, and a list of organizations as resources. Actively listening to the patient and understanding life roles and future goals foster a sense of trust and control for the patient.

The therapist may introduce the patient to a peer visitor who has a similar amputation to facilitate discussion of stages of recovery, the rehabilitation process, and problem-solving strategies. Peer visits are most successful when the patient meets someone of the same sex, age, and with the same type of amputation.⁶ Attendance to local or virtual amputation support groups may also be helpful for the patient to enhance his or her support structure.

Evaluation after Amputation

Evaluation of the patient with upper limb loss consists of a formal interview, physical evaluation, and observation of ADL and IADL performance, when possible. The evaluation is often ongoing and directed by the patient's recovery after amputation. The therapist notes the mechanism of injury and any comorbidities that occurred if the amputation is a result of trauma. If the surgical report is available, it is helpful to know if the residual limb muscles were surgically managed by **myodesis** or **myoplasty**.

The intent of the patient interview is to develop the patient's occupational profile to understand the personal, social, and cultural contexts and how he or she influences the individual response to injury. Key areas to discuss include vocational responsibilities, avocational interests, cultural factors, coping strategies, level of family or caregiver support, spiritual support, roles and responsibilities at home and in the community, accessibility to resources and services, as well as financial limitations or constraints. It is also helpful to learn if the patient has had previous exposure to individuals with amputation to assess his or her familiarity and to identify any language barriers, the patient's educational level, and the preferred learning style to effectively communicate and train the patient.⁶

Evaluation of Pain Associated with Amputation

The therapist should assess the presence, quality, intensity and duration of residual limb pain (RLP), associated musculoskeletal pain, phantom limb sensation (PLS), and phantom limb pain (PLP). The most often used pain assessment is the Visual Analog Scale (VAS) (0–100 mm), followed by the numeric rating scale (0–10) and verbal rating scale (0–3 = nil/mild/moderate/severe).⁴¹ Both RLP and PLP occur more frequently and are more intense for those who have an upper limb amputation versus those with a lower limb amputation.⁴² Postoperative RLP is expected and typically subsides as edema resolves and wound healing progresses. Recurrence or chronic RLP may be a result of several different causes and should be evaluated by the team to determine proper treatment.

Associated musculoskeletal pain occurs in other areas of the body, such as the back, neck, shoulder, or contralateral limb. This pain is often a result of compensatory motor patterns of the trunk and extremities from overuse and/or poor body mechanics because of fit and use of a prosthesis or no prosthesis use.⁶ Other comorbidities may also be a source of this type of pain.

Nonpainful sensation experienced in the missing limb is PLS. PLS may be described as a sense of the phantom limb still being present, temperature changes, itching, pressure, and tingling. PLS is a universal phenomenon that is remarkably real to the patient and may last long term. The cause of PLS is still not clearly understood and is most common in adults with traumatic amputations, although it has been known to occur with congenital limb loss.⁴³

PLP is any pain that is perceived in the amputated limb that is often described as an intense burning, stabbing, crushing, or shooting pain and is most common in traumatic amputations. PLP is exceptionally common after limb loss and is not clearly understood. Current theories suggest that the causes are related to central nervous system changes and peripheral nervous system damage.⁴⁴ Recent evidence specifically suggests that a substantial reorganization of the primary sensory and motor cortices occurs after hand amputation that is correlated with PLP.⁴⁵

Evaluation of Neuromusculoskeletal and Sensory Impairments after Amputation

The therapist should measure residual limb length to the nearest bony landmark, measure edema through circumferential or figure-of-eight measurement, describe limb shape (i.e., cylindrical, conical, bulbous, or irregular), assess integrity of distal soft tissue, and assess any open or healing wounds (if present), as well as scar characteristics. Adherent scars can be problematic in the socket, resulting in a blister or skin breakdown.⁴⁶ The therapist should assess functional range of motion of the upper and lower extremities, proximal residual limb muscle strength, muscle strength in the contralateral limb, and observe unilateral and bilateral hand function. In the literature, the Modified Box and Blocks and the Jebsen-Taylor Test of Hand Function (JTHF) light- and heavy-can tests have been used to assess hand function with and without a prosthesis.^{47–49} The therapist should assess proprioceptive, touch functions as well as residual limb sensitivity to pressure and temperature, as well as identify any areas of significant sensitivity about the residual limb that may be exceptionally tender to the touch, causing the patient to withdraw the limb. These may be signs of a **neuroma** or heterotrophic ossification, which may impact wear of prosthesis or use of the residual limb in ADLs. If the patient has lost a portion or all of the dominant hand and will be working on change of dominance training, assess dexterity of the nondominant hand.

Evaluation of ADL and IADL after Amputation

In an acute care setting, the Functional Independence Measure (FIM) may be used to determine ADL status after amputation. In outpatient settings, generic outcome

measures are used, such as the Disabilities of the Arm Shoulder and Hand (DASH) or Canadian Occupational Performance Measure (COPM), although neither is validated with upper limb amputation. The QuickDASH was recently validated for use in this population,⁵⁰ and the Patient Specific Functional Scale (PSFS) has also been used,⁴⁷ but the measure is validated for individuals with upper limb musculoskeletal issues.⁵¹ Regardless of setting, it's important to determine the individual's current level of functioning in bathing/showering, toileting and toilet hygiene, dressing, feeding, functional mobility, personal device care, personal hygiene and grooming, sexual activity, and rest and sleep.

The therapist should also assess the patient's abilities to navigate a healthy return to desired IADLs, areas of education, work, play, leisure, and social participation as the patient progresses through recovery. Return to IADL may be influenced by the patient learning his or her "new normal," so this may involve exploration of new occupations or return to prior occupations using different strategies or approaches. Returning to or integrating into new IADL is very individualized and may occur years after amputation, particularly if it is determined that the patient is not safe to return to his or her prior occupation and would benefit from vocational rehabilitation services.

Evaluation of the Prosthesis after Amputation

Initially, after device delivery, the occupational therapist evaluates the patient's ability to care and use prosthesis, specifically the ability to safely operate all components; ability to properly clean, maintain, wear, and use the device; and comfort and fit of the prosthesis. If the patient is fit with an EP prosthesis, the therapist must have a good understanding of the prosthetic control setup in order to assess and direct prosthetic controls training. Control setup refers to how the patient switches between components (i.e., elbow control, wrist control, and hand) as well as grip patterns, if available with the TD. The therapist should contact the prosthetist if there are any questions about the prosthesis setup.

Therapists may evaluate patient satisfaction with the prosthesis using standardized measurement tools as well as measuring performance while using a prosthesis; however, there is no gold standard for measurement. Adult patient satisfaction has been measured using the Trinity Amputation and Prosthetic Experience Scales (TAPES).⁴⁷ Unfortunately, there are few optimal functional clinical tests that assess upper limb prosthetic skill or performance in daily activity.³¹ Generic time-based tests that reflect skill of device operation use⁵² include the Southampton Hand Assessment Procedure (SHAP)⁵³ and the JTHF.⁵⁴ Others that demonstrate capacity of use⁵² include the Assessment of Capacity for Myoelectric Control (ACMC)⁵⁵ and the Activities Measure for Upper Limb Amputees (AM-ULA).⁵⁶

Intervention for Pain, Neuromusculoskeletal, and Sensory Impairment after Amputation

Occupational therapy treatment to address the abovementioned impairments will typically begin in the perioperative phase. Interventions involve residual limb management, range of motion and strengthening, and change of dominance training.

Residual Limb Management

Postoperatively, residual limb management includes wound healing, limb protection, edema control, residual limb shaping, pain management, and decreasing any areas of hypersensitivity.⁶ In the upper limb, the residual limb is postoperatively wrapped in a figure-of-eight pattern with gauze and a compressive wrap. In the lower limb, postoperative dressings vary, depending on the level of amputation, surgical technique, healing requirements, patient compliance, and surgeon preference.⁵⁷ Dressings may

include soft dressings similar to those used on the upper limb, nonremovable rigid dressings, immediate postoperative prostheses (IPOPs), removable rigid dressings, and prefabricated postoperative devices.⁵⁷ Soft dressings are typically used on patients with dysvascular disease.⁵⁷ Wound drains may be in place in either the upper or lower limb to help with edema.

Healing after an uncomplicated amputation follows a standard wound healing progression. If a skin or sheet graft is present, the therapist should follow wound care guidance provided by the surgeon or wound care team. Typically, sutures or staples are in place for 3 to 4 weeks, and the patient may be cleared to get the limb wet during this period. The limb may be cleaned with antibacterial soap and clean water and then gently dried. An appropriate dressing is applied, which may include use of a sterile nonadherent impregnated gauze, followed by gauze squares and gauze wrap applied in a figure-of-eight pattern. Once all sutures or staples are out, wounds are healed and maturing, the patient is instructed to wash the limb daily with water, mild soap, and dry thoroughly.

To facilitate wound healing, protect, shape, and reduce pain in the residual limb, the patient and caregiver are instructed about the importance of figure-of-eight wrapping. The wrap must be applied in a figure-of-eight diagonal configuration, with the most pressure applied at the end of the limb to shape the residual limb into a conical shape if possible (Fig. 44-4). The bandage must conform firmly to the limb, be worn continuously, and reapplied immediately if it loosens. The patient or caregiver is advised to remove the wrap two to three times daily to examine the wound and assess skin for any redness or excessive pressure. The wrap is worn for 23 hours a day, and a clean bandage should be applied at least every 2 days.

Figure 44-4 Wrapping technique for transhumeral amputation. Repeat diagonal turns as necessary to cover the limb with no constriction.

Once wound drainage stops, use of an elastic compression shrinker or sock may be considered to replace the compression wrap if the residual limb skin can tolerate the shear forces from a shrinker application. Patients with diabetes often do not use a shrinker until 21 days postoperation.⁵⁷ The shrinker will be worn for the same duration as the compressive wrap and is worn after each prosthetic wear session and at night. It is recommended to continue to use the shrinker for up to 18 months until residual limb scars mature, shape, and size stabilize.⁵⁸

Management of a patient's pain after amputation is complex and requires a team-based, patient-centric approach that blends pharmacological and nonpharmacological treatment strategies throughout all phases of rehabilitation. Nonpharmacological

treatment strategies include transcutaneous electrical nerve stimulation (TENS), desensitization, graded motor imagery or mirror therapy⁵⁹ (Fig. 44-5), scar mobilization, relaxation, and biofeedback.⁶ No single approach has proven to be clearly successful.⁶

Figure 44-5 A patient with a transhumeral amputation performing mirror box therapy. Position the mirror at the patient's midline with the residual limb behind the mirror. Instruct him to continuously look at the reflection of the intact limb while performing mirror box therapy.

Desensitization of the residual limb is necessary to prepare for fitting the socket or using the residual limbs in daily activities. Desensitization of the residual limb can be accomplished through percussion (tapping, rubbing, and vibration) with and without desensitization media and progressive loading against various surfaces. Loading begins with very resilient media, such as soft foam, to variously resistant and textured, such as layers of felt, a bucket of rice, and a mound of clay. Once sutures are out, the patient and family receive instruction about scar massage to prevent or release adhesions and soften scar tissue, which can also help with pain.

Maintain or Increase Range of Motion and Strength

A physical conditioning program to increase or maintain the range of motion of all joints proximal to the amputation is initiated, which also increases circulation and reduces edema. Chronic limitation in shoulder external rotation on the side of limb deficiency is not uncommon,⁶⁰ so a structured shoulder stretching program in all planes of movement is initiated. The patient's anatomical sense of the phantom limb can be used to achieve motion in all planes. Bilateral horizontal adduction is beneficial for patients with bilateral limb loss to promote the use of the residual limbs at midline for self-care task performance.⁵⁸ In general, all patients with upper limb loss at any level are encouraged to incorporate the residual limb or digits into bilateral tasks during ADLs as much as possible.

A strengthening program focused on periscapular stabilization, rotator cuff strengthening, and strengthening of all major muscle groups proximal to the amputation is initiated bilaterally to increase endurance and prepare the limb for use or the weight of a prosthesis. Use of TheraBand CLX bands (Performance Health, Boiling Brook, IL) or lined weight-lifting cuffs such as Medicordz wrist cuffs (NZ Manufacturing, Tallmadge, OH) are recommended for residual limb resistance training. The contralateral side should be included if limitations are noted. A core strengthening program is initiated to promote postural control, balance, and endurance and to reduce asymmetry of the trunk and spine, which commonly occurs with upper limb loss.⁶⁰ Core stabilization during residual and upper limb strengthening promotes postural

control in preparation for wearing and using a prosthesis, which may be perceived as heavy to the user.⁵⁸

Change of Dominance

Change of dominance activities after dominant upper limb amputation must receive special attention.⁶¹ The behavioral and neurological effects from long-term forced use of the nondominant hand are largely unknown.⁶² *Handwriting for Heroes* (Loving Healing Press, Ann Arbor, MI; <http://www.handwritingforheroes.com/>) provides a structured 6-week program to change handwriting dominance. Education regarding one-handed techniques as well as recommend adaptive equipment³³ can greatly help the patient.

Intervention for Independence in ADLs after Amputation

A patient receiving a prosthesis must develop skills to be proficient with and without a prosthesis in his or her ADL because there will be times when the prosthesis will be in for repair. There are numerous adaptive strategies as well as adaptive equipment options available to assist patients with daily activities, such as:

- Nonslip grip materials
- Universal cuffs, Eazyhold universal cuff grip assist (EazyHold, Simi Valley, CA; www.eazyhold.com), or modified quadriplegic palmar clip with palmar pocket
- Built-up foam or Elastack (Sutton Scientifics, Inc., Star, NC) for handles or utensils
- Customized handles or tools with Allfit thermoplastic pellets (Orifit industries, Belgium)
- Modified long-handled sponges or wall-mounted back scrubbers
- Soap pockets or bath ropes
- Rocker knives (consider handle shape to maximize independence)
- Elastic shoelaces or Lock Laces (Positive Distribution, LLC, Durham, NC; www.locklaces.com)
- One-handed nail clippers and nail brushes
- Multipurpose bottle openers, electric can, and jar openers
- Pocket dresser (Performance Health Holdings, Inc., Warrenville, IL) or button hook
- Zipper pulls or key rings placed on zippers
- Pumps for bottles

Additionally, there are resources that discuss strategies to increase ADL independence after multiple limb loss, which are of great benefit to the occupational therapist.^{6,63,66} Task analysis, creativity, and collaborative problem-solving between the occupational therapist and patient are paramount.

Intervention to Prepare for Prosthetic Fitting

Patients receiving a prosthesis will progress to the preprosthetic training phase while continuing necessary interventions initiated in the perioperative phase. Preprosthetic training focuses on acquiring necessary knowledge to operate the prescribed device and strengthening motor patterns so the patient is prepared to operate the prosthesis upon delivery. A collaborative relationship between the occupational therapist and prosthetist is critical during this and subsequent phases to properly prepare the patient for and train the patient on device use as well as problem solve prosthetic issue that may evolve during training.⁶³

A patient fit with a BP device will use different body motions to operate the device depending on the level of amputation (see Table 44-2). Wrist-driven or hand-based prostheses use wrist flexion and extension or residual digit flexion and extension, respectively, to operate the prosthesis. Operation of transradial BP prosthesis is

achieved through humeral flexion and scapular abduction. Function of a transhumeral BP prosthesis requires not only the same motion as a transradial prosthesis to operate the TD (Fig. 44-6) but also scapular depression and humeral extension and abduction to operate the elbow lock (Fig. 44-7). Strengthening of the serratus anterior, pectoralis major, and pectoralis minor on the side of the amputation is beneficial for a patient receiving a BP prosthesis.⁵⁸

Table 44-2. Motions to Operate Body-Powered Components Based on Level of Amputation

LEVEL	TERMINAL DEVICE OR DIGIT OPERATION	ELBOW COMPONENT OPERATION
Partial finger	PIP or MP flexion and extension	NA
Partial hand	Wrist flexion and extension	NA
Wrist disarticulation and transradial amputation	Humeral flexion and scapular protraction	NA
Elbow disarticulation and transhumeral	Humeral flexion and unilateral or bicipital protraction (see Fig. 44-6) Incorporating chest expansion may be used if necessary.	Combination of scapular depression, and humeral extension and abduction (see Fig. 44-7) to lock/unlock elbow

MP, metacarpophalangeal; NA, not applicable; PIP, proximal interphalangeal.

Figure 44-6 Teaching activation of voluntary-opening (VO) terminal device (TD). With elbow locked, the therapist guides the patient's upper arm forward to open TD. (Illustration by Gregory Celikyol.)

Figure 44-7 Motions (arrows) necessary to lock or unlock the elbow of a transhumeral prosthesis. **A.** Abduction with depression. **B.** Extension. **C.** Combined movement pattern of extension, depression, and abduction. (Illustration by Gregory Celikyol.)

Muscle site testing and training is typically necessary for patients receiving an EP prosthesis. Testing is done by the prosthetist or therapist using a special myotester, such as Myolab II (Motion Control, Inc., Salt Lake City, UT) or Myoboy (Ottobock, Austin, TX), or a biofeedback computer program. With traditional direct control setup, prosthetic electrodes are applied to the residual limb typically over the agonist and antagonist muscles bellies. Figure 44-8 depicts a two-state direct control transradial system whereby two separate muscle groups are used to operate the TD. The intent is to choose muscle sites, or myosites, that are physiologically similar to the outcome motion and also produce strong electrical signals when contracted. Ideally, the two contractions can be isolated from one another. The preferred myosite is one in which the patient can maintain a steady contraction for at least 2 to 3 seconds and relax for the same amount of time. Wrist extensors and flexors are commonly chosen to achieve open and close of the TD or electric digits. For transhumeral amputations, the common choices are the biceps and triceps. For higher level amputations, as in shoulder disarticulation or interscapulothoracic amputations, the choices for control may be pectoralis or infraspinatus. To switch between prosthetic joint components, a co-contraction may be necessary or a strong versus light contraction may be used depending on the control set by the prosthetist. Once the optimal myosites are determined, the patient practices with the feedback device to hone strength and isolate the skill of each myosite contraction. A single-case study is presented in the literature that describes utilization of a virtual reality environment to enhance motor learning for a patient training to use an advanced upper limb prosthesis in the preprosthetic phase of rehabilitation.⁶⁴

Figure 44-8 Myoelectric prosthesis, a direct control two-state system in which two separate muscle groups operate the terminal device. **A.** 1, The muscle contracts and creates an electrical signal that can be measured in microvolts (1 millionth of a volt). 2, The electromyography (EMG) signal is detected by the surface electrode. 3, The EMG signal is processed by the electronics and transmitted to the electronic relay in the hand. **B.** 1, When the electronic relay receives an EMG signal from the wrist flexors, the circuit is complete, and the electricity from the battery runs the motor to close the hand. 2, When the relay receives an EMG signal from the wrist extensors, the motor runs in the opposite direction to open the hand. Intervention with the Upper Limb Prosthesis

Use of a prosthesis is an important assistive tool, particularly because individuals with upper limb amputation tend to be younger, otherwise healthy individuals who have years of productivity remaining in life.³¹ As previously discussed, some literature indicates a high abandonment rate in upper limb prosthetics. Proper training, however, may be helpful to improve compliance and use. Upper limb prosthetic training tends to be clinic dependent and is not grounded in evidence-based practice but rather expert opinion.⁶ Recent literature has suggested the consideration of neurorehabilitation principles in the provision of prosthetic training because motor learning is a fundamental principle that must be considered when learning to integrate a prosthesis.⁶⁵

Patients who are candidates for a prosthesis are fit with a device and then begin prosthetic training. The initial stage of treatment can generally be covered in one or two therapy sessions and should include the following:

- Evaluation to determine roles, tasks, and activity needs and preferences
- Evaluation of the prosthesis
- Explanation of the program goals to the patient
- Teaching the patient to don and doff the prosthesis
- Discussing the wearing schedule with the patient
- Teaching limb hygiene care
- Teaching care of the prosthesis

The therapy program for the prosthesis is addressed in two phases: (1) prosthetic controls training and (2) prosthetic functional use training.

Don and Doff the Prosthesis

The patient should be able to don and doff the full prosthetic system as independently as possible. The full prosthetic system may include a residual limb sock(s) or prosthetic liner, prosthetic socket, and harnessing as appropriate.⁶⁶ To don a prosthesis with a harness, the patient can either put it on like a coat or over the head like a pullover. Doffing involves reversal of the steps taken to don. When donning an EP or activity-specific prosthesis, the patient may use alcohol-based lubricant gels, powder, or a pull sleeve on the residual limb. The pull sleeve helps to guide the residual limb into the socket and provides the best skin and socket fit (Fig. 44-9, A–C). If a valve is used to maintain socket suspension, the valve is applied last when donning. Doffing requires release of the suction needed for socket suspension by removing the valve and either applying lubricant gel along the socket trim lines or working the residual limb soft tissue out of the socket. To promote the highest level of independence, the patient, therapist, and prosthetist may need to collaborate to determine the simplest or most ideal method for donning and doffing.

Figure 44-9 Transradial myoelectric prosthetic donning method with pull sock. This method can also be used to don transhumeral-level myoelectric prosthesis. A. Don the pull sock over the residual limb. B. Pull the lanyard of the pull sock through the socket opening. C. Pull the pull sock completely through to ensure good skin contact.

Donning of a passive device often involves use of an alcohol-based lubricant gel or use of special lotion. A thin layer of lubricant or lotion is applied to the inside of the device and to the residual limb. The patient pushes the limb into the socket and works all the air out to create a suction fit. Doffing also requires release of the suction by pinching the proximal edge of the prosthesis to create an air pocket in the socket. The patient should never pull the device off solely from the distal aspect because this may damage the prosthesis.

Residual Limb Inspection and Device Care

The patient or caregiver is educated about the importance of frequent residual limb inspection and signs and symptoms associated with poor residual limb tolerance, which include skin redness, irritation, or skin breakdown.⁶ Any areas of redness on the residual limb that do not resolve within 20 minutes after device removal should be reported to the prosthetist, and the device should not be reapplied until after the patient has a prosthetic follow-up. Inspection of the residual limb after device removal is an essential part of the patient's daily routine.

Regardless of the type of prosthesis, the patient is expected to become proficient in basic prosthetic maintenance procedures for the device, as appropriate. These include (1) maintaining the socket daily (i.e., daily cleaning and socket inspection); (2) powering the device on and off and battery charging procedures, as applicable; (3) maintaining components (i.e., routine cleaning and lubrication); (4) adjusting the harness; and (5) replacing the rubber band and changing the cable system for BP prosthesis.⁶⁶ The prosthetist is responsible for appropriate patient education and

training of the abovementioned procedures, and the therapist ensures the patient can complete each task proficiently and with maximal independence within his or her everyday environment.

Prosthesis Wear Schedule

The patient and family are educated on the device wear schedule. Wear time is a gradual process to develop tolerance to the socket and device suspension. The importance of gradually increasing the wearing time cannot be overemphasized, particularly for patients with decreased sensation and scar tissue.⁶⁶ Initial wear time is for 30 minutes three times per day, followed by a residual limb skin inspection. If there are no signs of poor fit, wear time may be increased by 15 minutes each session and should be continued until the patient tolerates device wear all day or for the necessary amount of time to complete selected activities of the patient.

Prosthetic Controls Training

Controls training is necessary for patients fit with BP, EP, and passive positional devices. The prosthetist educates the patient how to control the device, and the therapist works with the patient to develop skill with control progressively grading the environment. Refer to Figures 44-10 and 44-11 for schematic overview of controls training for BP and EP prostheses by level of amputation, respectively. The intent of controls training is for the patient to correctly and consistently operate each device component(s), learn to preposition component(s) to reduce awkward body mechanics as appropriate during use, and hone skills in proportional control. Prepositioning refers to positioning components either passively (BP or passive) or actively (BP or EP) prior to task execution to reduce proximal compensatory movements during device operation. The therapist instructs the patient to determine the most natural and efficient device position before grasping an item. Proportional control involves the user learning to elicit ample force with the TD or prosthetic digits to grasp objects without dropping or crushing. Limited studies of able-bodied users learning to operate myoelectric⁶⁷ and BP⁶⁸ simulators found that initiating grasp training indirectly (e.g., picking up an object with the intact hand and transferring it to the TD) resulted in improved gripping performance time. It is very beneficial for BP users to spend time performing direct grasping activities to learn TD orientation in relation to the object being grasped, or properly prepositioning the device.⁶⁸ In addition to the use of intermanual transfer skills, the transfer of motor skills from the trained hand to the untrained hand is very beneficial for learning proportional control.⁶⁹ Control training is often very repetitive in nature, which is necessary to establish new motor patterns with device use. Further information about controls training can be found in the references.^{52,58,63,66}

Figure 44-10 Controls training for body-powered prosthesis by level of amputation. *TD*, terminal device.

Figure 44-11 Controls training for externally powered prosthesis by level of amputation. *TD* terminal device.

The therapist should consult with the prosthetist for guidance with any concerns about system setup and operation that are identified during control training. The length of control training varies, depending on the type of device, the patient's gadget tolerance, cognition, and motivation. It is not uncommon for those with higher level amputations to require more control training as well as those with more advanced EP prosthesis.²¹

Functional Training with the Upper Limb Prosthesis

Spontaneous, automatic, skillful use of the prosthesis as an assistive tool during bimanual tasks is the hallmark sign of a skilled prosthetic user. The goal of functional training is to teach the patient how to use the device as a tool to maximize independence and reduce caregiver burden, safely integrate the device into daily bimanual activities appropriately, reduce learned compensatory motions from one-handed use during bimanual tasks, maintain proper body mechanics during device use, and instill patient confidence in the ability to operate and rely on the device for function.

A person with a unilateral amputation can be expected to use the prosthesis primarily for sustained holding or for stabilization. Table 44-3 suggests how some activities can be accomplished. A key component to successful training is deliberate practice using the prosthesis for realistic, functional tasks. Much of functional training involves repetition to help the patient develop new motor pathways in the brain to execute daily tasks with skill and efficiency using the prosthesis. A small case study used modified constraint-induced movement therapy as part of a 3-week home prosthetic training program and results showed a meaningful change based on objective performance measure scores whereas self-report outcome measures demonstrated mixed results.⁷⁰

Table 44-3. Suggested Approaches for Functional Activities: Unilateral Upper Limb Amputation

TASK	PROSTHESIS	INTACT LIMB
Eating		
Cut food	Hold fork	Cut with knife
Butter bread	Stabilize bread	Spread toward body
Fill glass from faucet	Hold glass	Turn knob or lever
Carry tray	TD in midposition to hold	Hold in midposition
Peel fruit	Stabilize with TD	Peel
Dressing		
Don and doff shirt or blouse	Don: prosthesis in sleeve first; doff: remove intact arm first	Don: intact arm last; doff: remove prosthesis last
Put clothing on hanger	Hold hanger	Place clothing on hanger
Buckle belt	Stabilize belt	Push belt through buckle
Tie bow	Stabilize lace	Manipulate and make loops
Button cuff on intact side	Use buttonhook (or sew on button using elastic thread)	Hold cuff in place with fingertips while using buttonhook
Use zipper	Hold fabric with TD	Pull zipper
Desk skills		
Write	Stabilize paper	Write
Insert letter in envelope	Hold, stabilize envelope at end	Insert letter and seal
Use phone, dial, take notes	Hold receiver: TD or with chin and shoulder	Dial and write

TASK	PROSTHESIS	INTACT LIMB
Draw line with ruler; use paper clip	Stabilize ruler; hold paper	Draw line; apply clip
General skills		
Take bill from wallet	Hold wallet or stabilize on table	Manipulate wallet and remove bill
Wrap and unwrap package	Stabilize box and paper	Manipulate box, paper, tie
Thread needle	Hold needle	Thread needle

TD, terminal device.

It is also important that the user complete activities within a reasonable length of time while using minimal extraneous movement and energy expenditure. The therapist encourages patients to analyze and see similarities among situations and reminds them of relevant principles. This prepares the patient to respond with a sense of control in unpredictable situations.

In the final stage, prosthetic functional use skills are further developed, and ADLs that are more demanding are introduced. Exploration of use of a prosthesis during IADL performance should also be considered and encouraged if use of a prosthesis is appropriate and not contraindicated for the type of device used. Advanced functional training centers on the patient's goals and is very individualized, so therapy should take place in the clinic as well as in relevant environments and contexts in which the patient engages in occupations. Visits to the community, home, school, and work are strongly advised. This brings the patient and therapist into the actual environment, away from simulated, static settings of a clinic. Figures 44-12 to 44-15 show sample functional ADL and IADL tasks.

Figure 44-12 The practice of holding a bottle of water with a myoelectric prosthesis and electric hand is an excellent functional activity to learn proportional control and build individual confidence in the prosthesis.

Figure 44-13 Practicing bimanual tasks with a myoelectric prosthesis and electric hand. This individual changing a diaper and dressing a doll using his prosthesis as an assist.

Figure 44-14 Tying military boots with a body-powered prosthesis. The individual is using the hook as an assist to hold the lacing during this task.

Figure 44-15 Using a hybrid prosthesis and electric hook for a bimanual home maintenance task. The individual has prepositioned the elbow and wrist to stabilize hardware with the electric hook and securing it with a drill using intact hand.

Driving and Community Mobility

Driving is usually of considerable importance. Many patients are eager to return to driving following either an upper and/or lower limb amputation. Safe and independent driving involves a complex interaction of multiple systems to include one's physical, visual, cognitive, and behavioral abilities. When appropriate, the patient should be referred for a comprehensive driving assessment. The driving rehabilitation specialist will complete an assessment and make recommendations for any needed adaptive equipment or vehicle modifications. For example, a spinner knob or driving ring may be recommended for patients with a unilateral upper extremity amputation. Installation of a left-foot accelerator bar and pedal may be necessary for a person with a right lower extremity amputation. Hand controls can be installed for patients with bilateral leg amputations. Patients are encouraged to contact their state licensing agency or department of motor vehicles to determine whether there are any limitations or driving restrictions for those individuals with amputations.

Rehabilitation after Lower Limb Amputation

The therapeutic program for patients with lower limb amputations requires collaboration between the physical therapist and the occupational therapist. This may occur in the acute care setting immediately following amputation, in an outpatient clinic, or in the patient's home. Both therapists will perform an evaluation of the patient. The physical therapist is typically responsible for limb wrapping, core and lower limb strengthening exercises, range of motion, preprosthetic, prosthetic, and gait training.

Initial patient treatment sessions by both professionals may focus on ADLs to include patient and family education on wound care, limb wrapping, bed mobility, transfers, and basic wheelchair propulsion and management skills. After lower limb amputation, the therapist must consider general health condition, strength, and endurance and how these influence patient safety when performing ADL or IADL. Safety is a major concern with lower limb amputations, particularly for patients with

other comorbidities. Patient and family are educated on safety precautions with specific activities such as transfers. Treatment sessions may include safe transfers from the wheelchair to the bed, toilet, furniture, and car. Early patient education on desensitization of the residual limb is also addressed.

The occupational therapist may also include other self-maintenance skills, such as kitchen tasks, housecleaning, and bed-making during the treatment sessions. Home and community visits with the patient may be indicated. During standing activities and ambulation, special attention is paid to balance, posture, and equal weight bearing through both lower extremities. Visual or verbal cues should be used to correct these impairments, if necessary. The physical therapist or the occupational therapist will teach fall recovery to the patient and the family because safety after amputations is always important.

The occupational therapist may recommend home modifications and equipment. Equipment often includes a transfer tub bench or shower chair for use while showering and bathing and grab bars in the shower/tub and around the toilet. These rails provide a means of arm support that assists with lowering to the toilet and coming to the standing position safely.

The primary surgical or medical team will clear the patient to start wearing a shrinker on his or her lower residual limb prior to receiving the first prosthesis. The patient needs to be educated on the proper shrinker donning techniques and care of the shrinkers and liners. The shrinkers should have no wrinkles, and seams should not be over bony areas or the scar. The patient must inspect the skin on the residual limb daily to check for any changes in skin integrity before and after shrinker, liner, or prosthetic wear. If the patient has difficulty inspecting the residual limb, a long-handled mirror may be used to assist.

The physical therapist will assess and recommend the lower extremity prosthetic wearing schedule, the amount of assistance required, and assistive devices needed, as well as readiness for any standing or ambulation activities. A patient needs to be able to don and doff the lower extremity prosthesis independently. If unable, a family member needs to be educated and able to demonstrate the proper technique in donning and doffing the prosthesis. The occupational therapist continues to address ADLs with the patient both with and without the prosthesis. The occupational therapist works with the patient to identify how to incorporate the prosthesis into daily activities while assessing energy, effort, balance, transfer, and mobility skills. Energy conservation methods should be included in the program. Further information pertaining to rehabilitation strategies for individuals with lower limb amputations can be found in the reference.⁴⁶

Conclusion

Rehabilitation of an individual with an amputation is best managed through a holistic, multidisciplinary approach with a team of clinicians highly specialized in amputation rehabilitation.⁶ Rehabilitation after amputation is a process that takes time in order for the patient to accommodate the phases of adjustment, acceptance, healing, recovery, and ultimate mastery of skills needed to achieve higher levels of function and independence after such a life-changing event. The field of prosthetics is rapidly developing and necessitates expertise to remain abreast of new technologies; however, keystone principles of occupation-based, patient-centered rehabilitation remain the foundation for a successful rehabilitation experience.

CASE STUDY

Patient Information

Alex is a 25-year-old, right-hand–dominant, married male injured in a work-related accident. He sustained a right partial hand amputation of digits 1 to 3 after a 1200-pound metal object crushed his hand. He works as a machinist, making heavy equipment engine parts. He has a GED and has worked for the company for 3 years. Attempts were made to salvage his fingers, and he was treated with multiple irrigation and debridement, but ultimately his fingers could not be saved. His right thumb, and index and middle fingers are amputated at the middle metacarpal level, and he had no impairments to the ring and small fingers.

Reason for Occupational Therapy Referral

Alex is referred to outpatient occupational therapy for evaluation and treatment of his right hand after amputation 4 weeks ago.

Assessment Process and Results

During his initial outpatient appointment, the goals and expectations of the patient and his family were determined. Alex's pain, neuromusculoskeletal, and sensory status, as well as his ability to participate in his roles and occupations were determined. The extent of education he and his family had received about rehabilitation after amputation and prosthetic options was identified. During the evaluation, he reported that he has burning electric-type pain in his phantom fingers that worsens at night. He has little tolerance for light touch or deep pressure to his residual hand. His incisions are well healed, and the sutures have been removed, but there is a layer of thick dead dermis over the incision. His motion in his remaining digits and proximal joints on the right arm and on the left are within functional limits. His strength in the right shoulder, elbow, and left arm are normal, but his right wrist and hand strength are limited by pain. He is not using his right hand in any activity. He gets help from his spouse to wash his back, left underarm, and dry off. He has difficulty applying deodorant to his left underarm, holding his razor and toothbrush with either hand, and managing buttons and zippers on clothing. He cannot floss his teeth, cut his nails, and needs his wife to cut his food because he cannot hold a knife and fork. He also has a difficult time stabilizing plates when he eats. He has difficulty holding his cell phone, texting or dialing phone numbers, and typing on his computer keyboard. He likes to work in his shop at home fixing up old cars, but he has not touched his shop since the accident. He and his wife enjoy going to dance halls on weekends, but he has not wanted to go out; he is afraid of what people will think of him, and he does not like to be asked about his hand. He is not sure that he can return to work and do his previous job. He is not sleeping well, identifying that his mind races about his future and the many unknowns. He has met with the local upper limb prosthetic specialist, looked at device options, and is going to get a passive positional finger prosthesis so that he can get back into his home shop.

Occupational Therapy Problem List

- Dependence in some ADL and IADL

- Residual limb sensitivity
- Phantom limb pain
- Decreased strength in right wrist and hand
- Loss of prehension of the dominant hand
- Disuse of right dominant hand in activity, resulting in performance of most tasks one handed
- Sleep problems
- Avoidant coping behaviors

Occupational Therapy Goal List

Long-term goal: Alex will be independent in ADL and actively participate in home management, meal preparation, and shopping in 3 months.

Initial short-term goals:

- Alex will be able to perform ADLs with modified independence using adaptive equipment and adaptive strategies with his left hand and residual right hand.
- Alex will demonstrate compliance with a prescribed home exercise program to manage his right residual hand sensitivity to optimize use and prepare for fitting of a prosthesis.
- Alex will increase his right wrist strength to 5/5 and increase his right-hand strength to 40% of the mean for his age to prepare his right hand for use in activity.
- Alex will demonstrate compliance with change of dominance training by completing the *Handwriting for Heroes* program within 6 weeks.
- Alex will self-select and use relaxation strategies to calm his mind in preparation for sleep five nights of the week.
- Alex will self-identify two positive coping strategies that he will use when participating in structured therapeutic community reintegration activities.

Intervention

Alex is seen two to three times per week for 4 weeks in the clinic. Treatment focuses on identifying adaptive equipment items that will help reduce pain and fatigue when using his right residual hand (e.g., built-up foam on handles) and increase his independence with ADL. A residual limb management program will be initiated to address hypersensitivity, adherent scar, and weakened musculature in the right wrist and hand. Strengthening exercises will involve isometric and kinetic exercise with use of a wrist cuff or TheraBand CLX (Performance Health Holdings, Inc., Warrenville, IL) resistance bands, despite not being able to comfortably hold weight in his right hand. Strengthening of the extrinsic and intrinsic muscles of the right hand will be addressed as well with resistive putty. Dexterity training of the left hand as well as change of dominance activities will be incorporated into treatment. Exploration of various relaxation strategies as well as active coping strategies will be explored with the patient. He will be expected to self-select one of each strategy during future treatment. He will also explore graded motor imagery to help self-manage his PLP. Once fit with his prosthesis, he will be trained on device care, wear, and safe use as an assistive tool in daily activities. Attention will be given to repositioning the prosthesis to optimize secure grip of light objects and motor learning because his left hand will have to become the prime executor of tasks with the right hand providing support.

Next steps:

- Continue to assess and improve ADL and IADL status with and without prosthesis.
- Meet with a peer visitor who has a similar level amputation.
- Explore local support groups and support patient through psychological recovery process.
- Facilitate community reintegration.
- Educate patient and family in risks of developing overuse injuries, use of proper body mechanics during activity performance with and without the prosthesis, and training in work simplification and energy conservation strategies.
- Collaborate with multidisciplinary care team about vocational rehabilitation and support patient through exploration.
- Provide patient and family education about additional prosthetic options that may be useful tools in his future (e.g., passive silicone restoration or EP devices).
- Communicate results of discussion to multidisciplinary team and prosthetist.

Evidence Table of Intervention Studies for Amputation Rehabilitation

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Mirror therapy to reduce PLP in unilateral males with upper limb amputations ⁵⁹	Experimental group ($n = 9$) completed mirror therapy. Control group ($n = 6$) completed covered mirror or mental visualization therapy.	Active duty service members, beneficiaries, or retirees between the age of 18 and 70 years with unilateral upper extremity amputation. Subjects were randomly assigned to either the mirror therapy group (MTG) ($n = 9$) or the control group (CG) ($n = 6$).	Both groups completed 15 minutes daily of structured movement of the intact and residual limbs using the assigned therapy (MTG vs. CG), 5 days/week for 4 weeks. Subjects in the CG were given option to switch to mirror therapy after 4 weeks (20 sessions).	Randomized controlled trial Level I	Eight (89%) subjects in MTG experienced a decrease in PLP and a decrease in the time spent experiencing PLP. Seven subjects in the MTG initially reported constant pain and five no longer reported this at the end of the intervention. Five in the CG who crossed over to the MTG all had a decrease in pain severity and time experiencing pain.	In the MTG, the group pain score decreased from a mean of 41.4 to 27.5 mm on a 100-mm VAS ($p = 0.001$), therapy had a large effect on pain reduction (Cohen's $d = 0.971$), and therapy had a large effect on time experiencing pain (Cohen's $d = 0.924$).

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Comparison of (1) learning direct grasp tasks (DG); (2) learning indirect grasp (IG) tasks; (3) learning fixation (FIX) tasks (i.e., stabilize object with device and execute task with intact hand); (4) learning a combination (COM) of all three tasks; and (5) no practice to learn to grasp with myoelectric prosthetic simulator and an Ottobock VariPlus Speed hand ⁶⁷	The experimental group (EG) (1) practiced learning assigned tasks with a myoelectric simulator (2) to assess performance improvement, SHAP test administered at pretest, posttest, and two retention tests. The CG performed the SHAP two weeks apart with no training.	Able-bodied, right-handed participants with normal or corrected to normal vision, and no earlier experience with a prosthetic simulator were randomly assigned to the EG (DG, IG, FIX, COM) ($n = 31$). CG was 31 gender-matched participants.	EG learned each assigned task with simulator for five sessions over a 2-week period. The DG, IG, and FIX groups performed 15 trials with four objects in a random order. The COM group performed five trials per object per task (DG, IG, FIX), resulting in 20 trials per task.	Randomized controlled trial Level I	Training is necessary to improve skill in prosthetic use. Fine motor control of the myoelectric hand (e.g., adjusting opening and closing to different object characteristics) takes longer to learn than gross motor control (i.e., positioning the prosthesis in space). Begin myoelectric training with IG tasks in order to promote success with device use. Use a blocked, repeated order structure in training to improve overall function faster. Learning grip force takes a long time and requires special attention and use of deformable objects.	Significantly larger improvement on SHAP in EG as compared to CG ($F = 21.61, p = 0.00$). DG and COM regulated grip force better over sessions, whereas IG showed no improvement in object compression ($F = 3.22, p = 0.01$); however, IG had fastest performance. Shorter reach times were observed with hard resistance objects ($F = 11.66, p = 0.00$).

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Comparison of (1) learning direct grasp tasks (DG), (2) learning indirect grasp (IG) tasks, (3) learning fixation (FIX) (i.e., passive object stabilization with the device and tasks), (4) learning a combination (COM) of all three tasks, and (5) no practice to learn to grasp with body-powered prosthetic simulator with TRS voluntary-closing Hook, Grip 3, and figure 9 harness ⁶⁹	The EG practiced learning the tasks they were assigned with a BP prosthetic simulator. The SHAP was administered at pretest, posttest, and two retention tests (2 weeks and 3 months) to assess performance improvement. The CG performed the SHAP with no training.	Training group of 30 right-handed able-bodied participants were randomly assigned to one of four training groups: DG $n = 7$, IG $n = 8$, FIX $n = 7$, and COM $n = 8$. CG of 17 right-handed able-bodied participants.	The EG learned each assigned task with simulator for five sessions over a 2-week period. The DG, IG, and FIX groups performed 15 trials with four objects in a random order. The COM group performed five trials per object per task (DG, IG, FIX), resulting in 20 trials per task.	Randomized controlled trial Level I	EG and CG improved on the SHAP at posttest and both retention tests. DG showed biggest improvement in functionality after training. IG used less force than the COM group while picking up objects, suggesting that IG benefits force control with BP device. DG training helps the user learn how to orientate the hook to the object to be grasped. Start BP training with IG tasks.	Shorter reach times in IG group ($p < 0.03$) Grip force control takes time to learn ($F = 4.21$; $p < 0.03$). Largest SHAP improvement in DG group (exact value not presented)

Diabetes

Brigette Vachon Catherine Donnelly and Setareh Ghahari

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Differentiate type 1 and type 2 diabetes and population-based risk factors.
2. Identify risk factors for diabetes and impact on population health.
3. Know the long-term medical complications of diabetes.
4. Understand how diabetes and other chronic conditions can influence occupational performance in youth and adults/elderly with type 1 and type 2 diabetes.
5. Understand diabetes self-management principles, behavioral change models, and evidence-based interventions.
6. Explain the importance of an interprofessional team care approach to support diabetes self-management.
7. Use occupational therapy interventions to help people with diabetes adapt to their chronic condition and adopt a healthy occupational lifestyle.

CHAPTER OUTLINE

Diabetes Epidemiology
Impact of Diabetes on Daily Occupations across the Life Span
Self-Management of Diabetes
Behavioral Change Models
Self-Management Education and Self-Management Support Programs
Occupational Therapy for People Living with Diabetes
Conclusion
Case Study

TERMINOLOGY

Diabetes distress: emotional burdens and worries that are part of the person's experience when he or she needs to manage a severe and demanding chronic disease like diabetes.

Diabetes mellitus: a disease in which the body's ability to produce or respond to the hormone insulin is impaired, resulting in abnormal metabolism of carbohydrates and elevated levels of glucose in the blood and urine. There are two main types of diabetes: type 1 and type 2. People with type 1 diabetes don't produce insulin. People with type 2 diabetes don't respond to insulin as well as they should and later in the disease often don't make enough insulin.

Glycated hemoglobin (HbA1c): any derivative of hemoglobin in which a glucose molecule is attached to the hemoglobin molecule. The most abundant form of glycated hemoglobin is hemoglobin A1c (HbA1c), levels of which are significantly increased in diabetes.

Hyperglycemia: high level of blood glucose caused by the body's inability to properly use or make the hormone insulin that leads to symptoms such as increased urination, extreme thirst, and unexplained weight loss.

Insulin: a protein hormone, produced in the pancreas, that is crucial in regulating the amount of sugar (glucose) in the blood. Lack of this hormone results to diabetes mellitus.

Nephropathy: a kidney disease that affects the ability of the kidney to excrete any waste products and to regulate the water and acid–base balance of the body.

Neuropathy: a disease of the peripheral nerves, usually causing weakness and numbness. When blood glucose levels stay high for an extended period of time, it can damage the nerves, particularly the nerves in the lower limbs.

Retinopathy: disease of the retina resulting in impairment or loss of vision. In the most serious cases, retinopathy can lead to blindness.

Self-management: a person's ability to manage the symptoms, treatment, physical and psychosocial consequences, and lifestyle changes inherent in living with a long-term disorder.

Diabetes Epidemiology

Diabetes: Prevalence and Importance of the Problem

The prevalence of diabetes has been steadily increasing in recent years, with up to a fourfold increase in the past 40 years.¹ The highest prevalence rates are found in the North American and Caribbean Regions, with an estimated 10.8% of the population. In

low- and mid-income countries, there is a greater predominance of individuals with diabetes who are under 65 years old as compared to high-income countries where the greatest proportion of individuals with diabetes are over the age of 65 years.¹ It is anticipated that the prevalence of diabetes will continue to rise, most notably in those countries transitioning from low income to middle income.¹

This growing epidemic of diabetes is related to multiple factors, including obesity, urbanization, aging populations, and sedentary lifestyles.² The impact of diabetes is tremendous. From an economic perspective, the global economic burden is 1.4 trillion dollars, and this number will rise substantially by 2030. Diabetes is estimated to result in 3.96 million deaths, accounting for 6.8% of the global mortality.¹

Definition of Type 1 and Type 2 Diabetes

Diabetes is a chronic disease. It causes blood sugar levels to rise higher than normal because the body cannot produce **insulin** or cannot properly use the insulin it produces.^{3,4} Insulin is a hormone produced by the pancreas that helps to regulate blood glucose levels and transport glucose from the bloodstream into the cells. In type 1 diabetes, the body does not produce insulin. Type 1 diabetes occurs most often in children, adolescents, or young adults and represents only 10% of people with diabetes.³ The exact causes of type 1 diabetes are still unknown, but the body's immune system destroys the beta cells in the pancreas that produces insulin. Hypothesis is that it would be related to a genetic predisposition or certain environmental factors.^{2,3} The risk of a child to develop type 1 diabetes is approximately of 5% if one parent is affected or 15% if they both have the disease. The risk is higher if the father is affected. There is also a small higher prevalence of type 1 diabetes in men, but reasons for the sex difference are still unknown.²

Type 2 diabetes is the most common form of diabetes, accounting for 90% of cases.³ In type 2 diabetes, the body either does not produce enough insulin or does not use it properly, leading to a **hyperglycemia**. This phenomenon is called insulin resistance: the pancreas produces extra insulin to compensate, but over time is not able to produce sufficient insulin to keep blood glucose levels normal.³ The body, then, cannot effectively use glucose as an energy source. The chronic hyperglycemia of diabetes is associated with relatively specific long-term microvascular complications affecting the eyes, kidneys, and nerves, as well as an increased risk for cardiovascular disease.⁴

Diabetes Diagnostic Criteria

The American Diabetes Association (ADA) recommends that individuals are diagnosed with diabetes when their fasting levels of glucose in the blood reaches 7.0 mmol/L or higher, and/or the level of **glycated hemoglobin** (HbA1c) in the blood is 6.5% or higher.³ The term prediabetes is used for people whose HbA1c levels are between 6.0% and 6.4%.³ These individuals are at high risk of developing diabetes and the diabetes-related complications. However, not all individuals with prediabetes will necessarily progress and develop diabetes. Prediabetes and type 2 diabetes are often manifestations of a broader underlying disorder called metabolic syndrome.^{3,4} Metabolic syndrome is a highly prevalent, multifaceted condition characterized by a combination of medical conditions that increases the risk of heart disease. People with this syndrome present some or all of the following abnormalities: high blood glucose, abdominal obesity, hypertension, dyslipidemia, high triglycerides, and insulin resistance.⁴

Diabetes Risk Factors

There is a matrix of both genetic and lifestyle risk factors that interact within the broader physical and sociocultural environment.^{2,5} Although there is noted to be a clear genetic predisposition to type 2 diabetes, there is also strong evidence to suggest that type 2 diabetes could be prevented and that lifestyle plays a substantial role. The single strongest risk factor for type 2 diabetes is a high body mass index (BMI), with up to 61% of cases attributed to BMI >25.² Physical activity level can also predict the development of type 2 diabetes. Activity and exercise can help prevent obesity and increase insulin sensitivity. Individuals who exercise most frequently were found to have 25% to 60% less risk of developing type 2 diabetes,² regardless of the presence of other risk factors. Diet and lifestyle factors play a significant role, and it has been clearly demonstrated that the incidence of **diabetes mellitus** can be reduced by up to 58% through lifestyle interventions.^{2,6} Other known risk factors are dietary habits, high blood pressure, heredity, ethnicity (Aboriginals, Africans, Asians, Latin-Americans), and level of education.²

Complications

Individuals may experience several complications associated with both type I and type 2 diabetes that impact daily occupations (see Table 45-1). These complications can be categorized in two types: microvascular (small blood vessels) and macrovascular (large blood vessels).⁷ Microvascular complications include **retinopathy** (eye

damage), **nephropathy** (kidney damage), and **neuropathy** (nerve damage). Macrovascular complications include stroke, heart attack, and circulatory disease. Individuals with diabetes also have a high level of psychosocial stress with higher rates of anxiety and depression.

Table 45-1. Diabetes Complications, Prevention, and Treatment

COMPLICATION	SCREENING	PREVENTION	TREATMENT
Microvascular complications			
Retinopathy	Dilated fundus examination	Yearly eye screening examination Glycemic control Blood pressure control	Laser surgery Low-vision rehabilitation
Neuropathy	Clinical examination Monofilament test	Glycemic control Preventive foot care Appropriate footwear	Pain management Sensory rehabilitation Foot ulcer care
Nephropathy	Urine microalbumin test (proteins in urine)	Glycemic control Blood pressure control	Dialysis
Macrovascular complications			
Stroke	Risk factors screening	Diet and exercise Healthy daily routines and habits Smoking cessation	Medication to control blood pressure and lipids Stroke and/or cardiac rehabilitation Lifestyle redesign
Heart attack			
Circulatory disease			
Psychosocial complications			
Anxiety and depression	Symptoms screening	Social and health professional support Healthy daily routines and habits	Medication Psychotherapy Self-management support Physical activity

Impact of Diabetes on Daily Occupations across the Life Span

Because of the extent and nature of complications, people living with diabetes can experience a wide range of difficulties in their daily occupations, such as difficulty performing activities of daily living (ADLs), limited community mobility, decreased energy, social isolation, poor time usage, poor daily planning, lack of meaningful leisure activities, and diminished healthy habits.⁸ The management of diabetes is complex and requires both medical monitoring and

lifestyle management, including, but not limited to, monitoring blood glucose levels, injecting insulin, taking medications, healthy eating, and engaging in regular physical activity. **Self-management** of diabetes impacts occupations across the life span.^{8,9}

Type 1 Diabetes

Type 1 diabetes is often diagnosed in childhood and can have a significant impact on daily routines and activities.¹⁰ In young children, the impact is felt across the families as parents and caregivers support the medical management of diabetes. Childhood diabetes may be difficult to control, leading to multiple medical appointments and ultimately resulting in lost-school days and challenges participating in after-school activities. Research has found that children with diabetes have poorer school outcomes compared to those without diabetes.¹¹ As children move to adolescents and take responsibility for their own management, there can be challenges with adherence to medical and lifestyle management.¹⁰ Adolescents are faced with unique developmental challenges that can influence the ways in which they successfully manage the daily self-care activities of diabetes. Furthermore, hormonal changes during puberty may reduce adolescents' insulin and can require more attention and planning to maintain metabolic control.¹² This is a crucial time to develop self-management skills, particularly related to developing health habits and routines that will lay the foundation for management in adulthood.¹³ Diabetes self-management activities can create feelings of being different from their peers and may lead to feelings of exclusion and isolation. Type 2 diabetes in children and youth is a more recent phenomenon, and there is a higher mean age at diagnosis and greater complications compared to children and youth with type 1 diabetes.¹⁴ Less is written about this populations, but the impact on occupations will be similar.

Type 2 Diabetes

Type 2 diabetes is most often diagnosed in adulthood: a time that involves juggling multiple roles where finding the time for self-management and for implementing healthy eating and exercise can be a significant challenge. It is also a time within the life span where the worker role is dominant. Burda and colleagues¹⁵ identified 10 broad areas of diabetes management behaviors to support people with diabetes applying for work and functioning in the workplace. These behaviors considered both the technical and medical management of diabetes at work, highlighting that some jobs will be

more challenging to incorporate self-management activities than others, particularly those that have rigid schedules and long shifts. The authors also considered communication of health-related needs to coworkers, both related to incidents that may occur at work or potential health-related work absences.¹⁵

Other areas of occupation are also impacted. Marinho and colleagues¹⁶ administered the Canadian Occupational Performance Measure (COPM)¹⁷ to 475 individuals with type 2 diabetes. They found that the top three areas of difficulties related to mobility, self-care, and management of household activities. The authors also found that lack of physical activity, presence of diabetic neuropathy, depression, and pain were associated with these occupational performance challenges.¹⁶

In a survey conducted among 52 older adults with diabetes, work and leisure participation were identified as the top areas of occupation for which they experienced the most difficulties. Older adults with diabetes have a higher rate of functional decline, both related to the disease process itself and increasing diabetes complication with aging, as compared to those without diabetes.^{18,19} Impaired cognitive and physical functions and low education level among the elderly can require more support to make lifestyle changes.²⁰ Also, as seen in the adult population, diabetes impacts mobility, and in older adults, this results in a higher risk of falls.¹⁸

There are a number of issues related to diabetes that impact occupation across the life span. Social stigma related to diabetes has been found to have social, occupational, and emotional consequences. For example, fear of social embarrassment, rejection, being treated differently, or damaging relationships with significant others are common concerns associated with injecting insulin.²¹ In childhood and adolescents, there is stigma related to time away from school and school-related activities.¹¹ Adults with type 2 diabetes also report feeling embarrassed when they need to refuse unhealthy food options at social events.²²

The use of technology in monitoring and managing diabetes integration of technology has evolved significantly, and the impact on the use and integration of technology across the life span needs to be considered.²³ In youth and children for whom technology is part of their everyday routines, technology is seen as something that can readily be incorporated into diabetes management.²⁴ In older adults, a recent qualitative study that examined the use of technology to provide real-time continuous glucose monitoring found that the

technology provided a sense of safety and enabled them to engage in their daily routines with the knowledge that their sugars were under control.²⁵

Fatigue was also found to be related to psychological factors, such as depression or emotional distress, and can be a barrier to self-management, such as engaging in healthy eating or participating in a regular exercise plan.^{26,27}

Finally, it is critical to consider the sociocultural contexts because diabetes will have a unique impact on occupation depending on cultural beliefs, values, and practices.²⁸

Psychosocial Adaptation

Because diabetes is a chronic condition, people with this disease will need to adapt to this new life situation. People with chronic diseases generally go through a transformation process that “seeks to make sense of their new self, their new illness, and their new life by participating in a process of interpretation and transformation of personal meaning perspectives.”²⁹ Thus, people living with diabetes will need to gain new knowledge and skills and learn new ways of being to deconstruct their current ways and reconstruct new meaning perspective.²⁹ The Process of Transformation Model: Rehabilitation of Chronic Illness and Disability was developed by Dubouloz et al.²⁹ (see Fig. 45-1). It describes the various stages, steps, or phases that an individual can go through to adapt to a chronic condition. It is composed of three phases: the trigger phase, the process of changing phase, and the outcomes phase.

Figure 45-1 The Process of Transformation Model: Rehabilitation of Chronic Illness and Disability. (Reprinted with permission from Dubouloz CJ, King J, Paterson B, Ashe B, Chevrier J, Moldoveanu M. A model of the process of transformation in primary care for people living with chronic illnesses. *Chronic Illn.* 2010;6(4):282–293.)

In the trigger phase, the person is suddenly faced with the limits and losses of disease. For diabetics, the symptoms are often described as silent in its early stages. Nevertheless, the onset of the diagnosis requires people to make important changes to their life habits to prevent important complications. The pressure felt to suddenly change these habits may cause some distress, resistance, or even denial of the disease.³⁰ This can last a few months to a few years before people describe being ready to engage in the change process. The trigger phase is a state of disorientation where clients try to make sense of what is happening to them. They rely on external sources of information, such as advices from professionals, to maintain hope for the future.

The process of changing phase comes with the development of readiness for change. People with chronic diseases usually find it difficult to explain why and how they became ready to change. Nevertheless, they report that it was prompted by the constant reminders and encouragements they received from health care professionals, family, and friends, but also by an inner reconciliation or confrontation with their reality.

Finally, in the outcomes phase, the individual has adopted new meaning perspectives, new feelings, new behaviors, or even a new identity. They learn to live with their conditions and are able to adopt a future-oriented perspective to life. People in this phase show behavioral and emotional stability. However, there is no final outcome, and people living with diabetes need to constantly develop and cope with change in their condition and, therefore, may require them to cycle through the model multiple times.

Self-Management of Diabetes

Self-management is a widely used term and is defined by the active participation and engagement of clients in the management of their health and treatment to live well with their long-term condition.^{31,32} Thus, self-management is an active process and involves individuals taking necessary actions to meet their health, psychological, social, and emotional needs associated with living with one or more chronic disease.^{31,32} Self-management places the responsibility with the individual, but requires managing his or her condition within his or her environment. In a concept analysis, Udli³³ described that antecedents or prerequisite conditions for clients to engage in self-management are information regarding chronic disease, self-efficacy or the confidence in one's ability to engage in health behaviors, social, family and emotional support, intention, goal setting and

planning, and partnering with health care professionals. She also described dimensions of self-management as the use of information and resources necessary to equip clients with the knowledge and tools to be successful in self-management behaviors; adherence to a plan of care, active participation, and responsibility for one’s own care; and informed decision-making to provide clients the capacity to make individual best choices and used adapted self-management strategies on a day-to-day basis.

As defined by Miller et al.,³² “chronic disease self-management is a fluid, iterative process during which clients incorporate multidimensional strategies that meet their self-identified needs to cope with chronic disease within the context of their daily living. Strategies are multidimensional because they require the individual to incorporate intrapersonal, interpersonal, and environmental systems to maximize wellness.” For people with diabetes, self-management includes adopting multiple self-care behaviors in different areas, such as healthy eating, being active, monitoring blood sugar, taking medication, problem-solving related to diabetes control, reducing risks related to complications, and healthy coping with a chronic condition^{34,35} (see Table 45-2). Expected outcomes of self-management are improvement or maintenance of disease severity, number of exacerbations or complications, treatment adherence, health care resources utilization, functional status, and quality of life.³⁵

Table 45-2. Diabetes Basic Self-Management Recommendations

RECOMMENDATION	GOAL	ACTIONS
Adopting healthy eating habits	Keep blood sugar level at target Reduce risk of diabetes complications	Eat three meals a day Count carbohydrates (approximately 45–60 g per meal) Limit sugar and sweets Limit high-fat food Drink water Limit alcohol consumption
Monitoring blood glucose level	Assess how lifestyle and medication affect blood glucose levels	Use a blood glucose meter to check blood sugar level at home as often as recommended by the health care team

RECOMMENDATION	GOAL	ACTIONS
Doing regular physical activity	Improve blood pressure control, level of energy, and body's sensitivity to insulin to help manage blood sugar levels Maintain or get to a healthy weight	Do both aerobic and resistance exercise Do moderate-to-vigorous aerobic exercise for approximately 150 minutes/week Start slowly, progressively increase time and intensity of exercise Check effect of exercise on blood sugar level
Taking medication daily	Lower blood sugar level Reduce risk of heart disease	Understand the purpose of medication Stick to a schedule Use a pill box Use an alarm or reminders
Taking care of feet	Avoid foot ulcers and amputation	Check feet every day for cuts, cracks, blisters, or sores Trim nails straight across Apply good skin lotion See footcare specialist when needed Appropriate footwear, with room to prevent skin irritation
Accessing psychosocial resources and support	Prevent diabetes distress, anxiety, and depression	Inform family and friends on ways to support diabetes management Engage in peer support groups Build a health care team Maintain healthy daily routines and habits Mindfulness and relaxation practice

Diabetes Self-Management as an Occupation

Engaging in self-management is difficult for people because it requires them not only to change their habits but also to develop new knowledge and skills.⁹ These individuals need to adopt a new routine that provides temporal organization and structure to daily life. In a study conducted by Fritz,⁹ in low-income women, changing routines to support diabetes self-management required not only that they become aware of their routines but also that they change underlying habits and situations that shape these patterns. For example, this meant understanding how other habits, such as sleeping habits or working long hours, can support or help healthy eating or exercising.

Social and spatial coordination of routines were also found to be important for self-management time and resources.⁹ For example,

coordinating family or caregiver responsibilities was important to secure time for self-management tasks or getting support from friends and relatives for transportation. Geographical distribution of daily routines also impacted self-management habits. For example, a convenient and easy access to low-costs meal at fast-food restaurants on the way to work was found to negatively affect diabetes self-management. Furthermore, participants reported the importance of time to develop diabetes self-management. This meant integrating in closed time routines, such as morning routine or working hours, components of self-management performed every day (e.g., medication management, blood glucose monitoring), and integrating activities such as practicing new recipes or trying a new physical activity in weekly open time. Thus, a key finding of this study is that modifying existing routines is a real challenge. Diabetes self-management needs to be included in daily occupations to meet the demands of daily life, but this also requires having the support to become aware of these routines to understand the ways in which they positively or negatively influence engagement in self-management.

Behavioral Change Models

There are several models that can be used to support occupational therapy interventions aimed at changing behaviors to promote self-management of diabetes symptoms.

Self-Regulation Theory

Self-regulation describes the ability to monitor the results of one's actions and then choose a subsequent behavior.³⁶ Three ingredients are required for self-regulation: (1) a set of standards, goals, or ideals with meaning and relevance to the person's specific life situation; (2) the person's ability to self-monitor and determine whether anything needs to be changed to meet the his or her needs and standards; and (3) in case maintaining the desired standards is not possible, adjustments are required. A person with higher self-regulatory skills is more able to manage an impulse. However, where there are several competing demands, the person's ability to regulate might be diminished.

Goal Setting and Goal Striving Theory

One example of a self-regulation model is Goal Setting and Goal Striving.³⁷ A "goal" is mental image of a desired state or outcome that a person considers as the ultimate result of his or her actions. It is by setting goals that a sense of urgency and motivation to achieve

these commitments is attained. If the goals are set at the level that they seem unattainable, the individual will be reluctant or less motivated to pursue his or her goals. The characteristics of the goals include how motivational orientation they are, their level of difficulty, the type of the goal, how specific the goal is (concrete or abstract), and the proximity of the end state. People tend to be involved with goal-oriented behaviors if the goals are intrinsically motivated, feasible, and harmonious with their other personal goals.³⁷ Achievable goals with moderate level of challenge are more likely to be approached and pursued by people.

Self-Efficacy Theory

Self-efficacy is defined as the confidence or belief that an individual has in his or her ability to execute a particular cognition or behavior.³⁸ Self-efficacy is a part of self-regulatory processes through which individuals shape environmental and interpersonal resources and behavior toward a desired end.³⁸ The concept of self-efficacy is the central tenet of Bandura's Social Learning Theory.³⁸ This theory emphasizes the underpinning role of personal mastery in the psychological and behavioral processes, leading to behavioral change.³⁹ Based on Bandura's theory, efficacy beliefs have a potent influence in self-knowledge and beliefs of self-determination, and they direct human behavior on a fundamental level.^{38,40} Based on this theory, in order for individuals to make important changes in their lives to increase health outcomes, they must believe in their capability of making such changes.⁴⁰ Even if they have skills to make changes, it is possible that their poor belief in their capability result in not taking any actions.

The key concepts of Bandura's Social Cognitive Theory are listed as follows:

- **Competence mastery:** When a person practices a task and repeatedly achieves successful experiences, his or her self-confidence would improve, which will result in repeating the task over time.
- **Vicarious learning:** Observing other people's success in similar behavioral change results in the belief that the person has the ability to make a change in his or her own behavior.
- **Social persuasion:** The use of positive verbal persuasion can help influence an individual to take actions. Positive messages from others such as "great work" and "you are improving well" help the person build confidence.

- **Self-appraisal:** This involves becoming self-aware of feelings when a person is in a stressful situation. There is a need to be self-aware in order to understand feelings of anxiety or stress that may prevent us from performing the task or achieving the goal.

As self-efficacy beliefs and expectations strongly influence individual's choices, decisions, behaviors, and persistence,⁴¹ many argue that a good self-management program should rest on a theoretical basis of changing self-efficacy.⁴²

Transtheoretical Model

The Transtheoretical Model is focused on behavioral change and is articulated through the stages of change.⁴³ Based on this model, people generally go through several stages of changes before they can maintain the new behavior. People at *precontemplation* stage have no intention of taking any action to change their behavior. It can be because of lack of motivation, lack of information, or lack of awareness of how the changes can help them. When people are at a *contemplation* stage, they might have better awareness of importance of changes but feel ambivalent about making the necessary changes. At *preparation* stage, there is intention to take action and an action plan is in place. People at an *action* stage have modified behaviors and taken actions to make changes to their lifestyle. The *maintenance* stage is when people are maintaining their behavioral changes and become increasingly confident that they can maintain their lifestyle changes.⁴³

Chronic Care Model

Wagner⁴⁴ created the Chronic Care Model (CCM), a primary care-based framework for individuals with chronic conditions. The CCM includes four essential and independent components: self-management support, delivery system design, decision support, and information technology.⁴⁵ These components function in the broader context of community and health care system. The CCM highlights the importance of productive interaction between informed, activated clients, and prepared proactive health care providers. The CCM encourages the health care providers to work collaboratively with their clients and support the management of their conditions.

Management of a chronic condition has two active parties: one is the person who needs to have knowledge and skills to manage the condition and can apply those skills to his or her life; and the other one is the health care provider who helps the person manage his or her condition by providing him or her information, encouragement,

and support. This is in opposed to prescribing to the client what to do, and when and where make changes. The health care provider invites the client to have input in defining the problem, set goals, and plan to manage a certain problem. Sustained follow-up is also known as essential to self-management support.

Self-Management Education and Self-Management Support Programs

The diabetes self-management education and support (DSMES) is well known as a critical component of care for all people with diabetes. The National Standards for Diabetes Self-Management Education and Support⁴⁶ emphasizes that people with diabetes should be engaged in management and intervention plans in every stage of their condition.

Self-Management Education and Support

Self-management education is defined as the ongoing process of facilitating learning of knowledge and skills necessary for people with a chronic disease to actively engage in self-management delivered by specialized health care professionals.³⁵ Self-management support is an activity provided by health care professionals to assist people with chronic diseases to manage their condition on an ongoing basis.³⁵

Self-management support can be peer led or provided in collaboration with social and health care professionals working in the community. Thus, self-management education comprises any educational processes that provide individuals with the knowledge and skills to inform decisions and increase their capacity and confidence to apply these skills in daily-life situations. Diabetes self-management programs should include both education and support and contain multiple strategies to help ongoing adaptation to one's condition, progressive learning, and adapted and personalized behavioral change facilitation. The expertise of professionals, but also of individuals who live with diabetes, is important because they can share with others their experiential knowledge and provide genuine and comprehensive support to others going through the same or similar adaptation process.

Chronic Disease Self-Management Program

Self-management programs are well known for improving quality of life, self-efficacy, and decreasing health care utilization in people with chronic conditions. One of the most studied evidence-based self-management programs is the Chronic Disease Self-Management

Program (CDSMP) developed by Lorig et al. in 1978.⁴⁷ The generic program⁴⁸ includes 6-week sessions that are 2.5 hours each. The program is delivered by two trained and licensed facilitators. The facilitators are lay leaders, that is, a person with a chronic condition who had training for facilitating the program. During the program, the participants gain confidence and acquire skills to better manage their condition. The program is found to be effective in improving general health and lowering health care utilization.⁴⁸ The program has been used worldwide, translated to many other languages, and used for several conditions such as arthritis, diabetes, health disease, multiple sclerosis, and stroke. The program is usually presented as a group face-to-face program, but there is evidence that the online version of the program is also effective.

Team Care Approach for Diabetes Management

Client living with diabetes need the support from an interdisciplinary team who will work collaboratively to improve diabetes self-management and prevent complications. Evidence suggests that a team approach can lower the risk for diabetes complications.⁴⁹ Working with family physicians, nurses, pharmacists, nutritionists, social workers, and other health care professionals is essential to answer the multiple and constantly changing needs of clients.⁵⁰ Tricco and colleagues⁵¹ showed, in a meta-analysis, that strategies targeting diabetes care teams led to significant improvements in clients' blood glucose, cholesterol, and blood pressure levels. However, barriers to interprofessional collaboration in primary care are frequent and are related to lack of knowledge of other professionals' role and lack of communication.⁵² It is thus important to learn what everyone on the team can bring in terms of expertise (see Table 45-3), how they can help in answering clients' needs, and using good communication tools, such as the electronic medical record, to share information between team members.

Table 45-3. Other Professionals' Role in Diabetes Management

PROFESSIONAL	MAIN ROLE	RELATED PATIENTS' NEEDS
--------------	-----------	-------------------------

PROFESSIONAL	MAIN ROLE	RELATED PATIENTS' NEEDS
Family physician	Monitoring risk factors and complications, coordinating care, and referring to specialist medical care as required	Maintaining and monitoring blood glucose levels Controlling hypertension and lipids Being aware a medical test results Knowing personal blood glucose level target Helping with smoking cessation
Kinesiologist	Supporting engagement in physical activity and healthy life habits	Doing regular physical activity Understanding effect of physical activity on blood sugar level
Nurse	Providing diabetes self-management education and foot care	Understanding diabetes and signs of hypoglycemia and hyperglycemia Knowing how to take medication and blood glucose monitoring device Knowing general diabetes self-management skills Caring for feet
Nutritionist	Supporting engagement in healthy eating and development of personalized eating plan and goals	Knowing what to eat Reading food labels Calculating carbohydrates Managing body weight
Optometrist	Vision care, conducting eye examination	Preventing eye complications
Pharmacist	Adjusting medication, preventing drug interactions, providing support for adherence to medication	Knowing how to take medication Understanding possible medication interactions
Physiotherapist	Providing rehabilitation to manage any complications (e.g., stroke, cardiac), supporting physical activity	Managing pain Doing regular physical activity
Podiatrist or foot care specialist	Supporting foot care, including nail and skin care, ensuring proper footwear and orthotics	Caring for feet Wearing appropriate footwear

PROFESSIONAL	MAIN ROLE	RELATED PATIENTS' NEEDS
Psychologist	Providing psychological support, monitoring symptoms of anxiety and depression	Improving and maintaining self-management motivation Receiving psychological support for self and family and friends
Social worker	Providing psychological support, connecting to community resources, supporting families	Managing costs associated with diabetes care Participating to social and group activities to support self-management Receiving psychological support for self and family and friends

Occupational Therapy for People Living with Diabetes

The focus on occupational therapy interventions in this chapter is on supporting individuals in managing diabetes. Although occupational therapists can provide interventions for complications that arise from diabetes including amputations, visual impairment, and neuropathy, the specific interventions for these health conditions are found in other chapters.

The primary role for occupational therapists working with individuals with diabetes is to support the individuals in the engagement in healthy lifestyles to manage diabetes.⁵³ Occupational therapists working with individuals with diabetes will be primarily situated in community and primary care settings, working in an interprofessional team, or a patient-centered medical homes.⁵⁴ Patient-centered medical homes provide more comprehensive and coordinated care than physician only care and thought to provide more efficient delivery of services. Within interprofessional primary care teams in Canada, one study found that the proportion of individuals with diabetes who were seen by an occupational therapist had fewer emergency department visits compared to those who were seen by a physician only.⁵⁵ With the increasing prevalence of diabetes and other chronic diseases, it is anticipated that there will be a greater emphasis on team-based primary care models.⁵⁶ Primary care continues to be an emerging area of practice for occupational

therapists, and supporting individuals to live with diabetes in this setting is an important role.

Occupational Therapy Evaluation

People with diabetes often do not have the opportunity to receive occupational therapy services. However, the occupational therapist can help them recognize and act on the difficulties they encounter by taking into account all their lifestyle habits and occupations in order to better integrate self-management activities into their occupational routine and better manage the psychological and social impacts that diabetes can cause.

The occupational therapists intervention process will begin with an assessment of the client's difficulties in performing personal, leisure, and work activities, including diabetes self-management activities. The physical and emotional dimensions of the person are relevant to assess, such as pain, mobility, and the presence of **diabetes distress** or depressive symptoms. Social support is also very important to help clients engage in self-management, and occupational therapists should assess the availability and amount of social support to which the person has access. Another important aspect of the environment is resources available in the community for people living with diabetes and the person's economic situation that may influence different life habits choices. Nevertheless, the most important aspect of the occupational therapist assessment process is documenting occupational issues experienced by client that may be related to diabetes self-management activities; adaptation to the diseases and its physical, psychological, or social consequences; diabetes complications such as low vision or neuropathy; or occupational balance between self-care, work, leisure, and self-management activities.

Based on the conceptual model used by the occupational therapist, different tools can be used to conduct the assessment process and to assess the effects of the intervention. If the COPM is selected to guide the process, it can be used to help the client identify and prioritize his or her occupational issues.⁵⁷ The COPM is an individualized, client-centered outcome measure.¹⁷ A semi-structured interview enables the client to identify areas of difficulty in the areas of self-care, productivity, and leisure. The client rates the importance of each identified issue on a scale ranging from 1 to 10 (1 = *with great difficulty or not satisfied*, 10 = *with no difficulties or completely satisfied*). Clients subsequently rate as many as five identified problems on their perceived level of performance and

satisfaction with their performance on each of the five identified issues. On reassessment, clients rate their performance and satisfaction on the issues identified in the initial assessment. A change score is obtained by subtracting the post-treatment score from the initial score. The COPM has been found to be both a reliable and a valid measure across diagnostic categories and treatment settings.⁵⁸ Because many diabetes interventions are goal oriented, the COPM was felt to offer an individualized assessment that then enabled planning for targeted intervention strategies.¹⁶ Additionally, the individual nature of the COPM was felt to support individuals in prioritizing their self-management strategies to specific functional challenges.

Occupational therapists can also complete their assessment using diabetes-specific questionnaires that can allow them to document their clients' perceptions of diabetes self-management and impacts on their quality of life. The Summary of Diabetes Self-Care Activities Measure⁵⁹ and the Diabetes Self-Management Questionnaire⁶⁰ are two questionnaires documenting five self-management domains: general diet, specific diet, exercise, blood glucose testing, and foot care. The Audit of Diabetes-Dependent Quality of Life (ADDQoL)⁶¹ is a 19-item questionnaire assessing the impact of diabetes on 19 life domains, including physical functioning, symptoms, psychological well-being, social well-being, role activities, and personal constructs. Clients can evaluate life domains that are relevant to themselves and indicate the importance of those domains to their quality of life as well as the direct impact of diabetes on those domains.

Occupational Therapy Intervention

As described by Youngson,⁶² occupational therapists can bring their unique occupation-focused perspective to support clients with diabetes and the health care team. The additional contribution of occupational therapists within the team was seen as supporting the integration of diabetes self-management into everyday activities and routines, intervening at the environmental level, empowering individuals in self-management, addressing work/life, and supporting occupational balance.⁶³ It is important for occupational therapists not to duplicate services already offered and rather focus of our interventions on the “how to do” instead of the “what to do.” Overall, the focus of occupational therapy interventions is to understand the challenges of self-management, support engagement in the process of change, and consider multiple occupational choices. Many people living with diabetes can benefit from

occupational therapy when they experience difficulties with their self-management, work, and daily activities. Client with complications such as vision loss, neuropathic pain, or amputation can even more benefit from occupational therapists' expertise in assessing, improving, and adapting for impairment or incapacities and reducing disability.⁶⁴ For example, occupational therapy can help in using safe cooking methods, provide techniques to help adherence to medication regimen, use low-vision devices to measure insulin; teach protective techniques, and compensate for peripheral sensory loss.⁶⁴ Occupational therapists can also use cognitive-behavioral and problem-solving approaches to support clients with diabetes distress or depression to improve their occupational performance.

Resilient, Empowered, Active Living with Diabetes

The Resilient, Empowered, Active Living with Diabetes (REAL) intervention⁶⁵ is an evidence-based occupational therapy-led diabetes intervention and is an adaptation of Lifestyle Redesign intervention.⁶⁶ The REAL intervention includes seven modules that support individuals in incorporating diabetes self-management tasks into everyday routines. Topics include goal setting, living with diabetes, activity, and health (see Fig. 45-2).

Figure 45-2 Resilient, Empowered, Active Living with Diabetes (REAL) intervention. (Reprinted with permission from Pyatak EA, Carandang K, Davis S. Developing a manualized occupational therapy diabetes management intervention: Resilient, Empowered, Active Living with Diabetes. *Occup Ther J Res*. 2015;35(3):187–194.)

The intervention is goal based, and the modules are designed to be delivered in a way to meet each individual's diabetes management goals and needs. The intervention can be delivered over a 6-month period. The REAL intervention consists of four core principles

informed by multiple theoretical perspectives. The first principle recognizes that occupations take place in multiple contexts and that the interrelationships between body structures and functions and the environments influence occupation. The second principle is the importance of using narrative to understand the impact of diabetes on everyday activities. The third principal considers goal-directed and habitual actions. The fourth principal considers the individual as a complex system and, in doing so, understands previous life experiences and evolving behavioral patterns over time. Originally developed for adults, research has demonstrated that this is also a feasible intervention for young adults.⁶⁷ Although there have been no published outcome studies on the REAL intervention, REAL offers a manualized occupation-focused diabetes education program that would fit well in a primary health care or community setting.

Do-Live-Well Program

The Do-Live-Well is an occupation-focused health promotion framework that “depicts the relationship between what people do every day and their health and well-being.”^{68(p2)} The Do-Live-Well framework includes four sections: (a) dimensions of experience, (b) activity patterns, (c) health and well-being outcomes, and (d) forces that influence activity engagement⁶⁸ (see Fig. 45-3).

Figure 45-3 Do-Live-Well program. (Reprinted with permission from Moll SE, Gewurtz RE, Krupa TM, Law MC, Lariviere N, Levasseur M. “Do-Live-Well”: a Canadian framework for promoting occupation, health, and well-being. *Can J Occup Ther.* 2015;82(1):9–23.)

The activity patterns component of the Do-Live-Well considers not only the activities people engage in but also how they engage in them. Five elements are considered: engagement, meaning, balance, control/choice, and routine. For individuals with diabetes, these elements could be explored when examining healthy activities and how to implement these into daily life. The framework has not

directly been applied to individuals with diabetes, but rather offers a broad perspective that can bring an understanding of activity patterns to support the application of diabetes self-care into daily routines. Because the Do-Live-Well is grounded in health promotion, it offers an ideal framework for occupational therapists working with individuals with diabetes to develop targeted interventions.

Conclusion

In conclusion, the occupational therapist has an important role to play in helping people with diabetes and all those with different chronic conditions. Occupational therapists can support their adaptation to this major life change and help them improve their self-management skills. Although occupational therapists are not yet considered as full members of the diabetes interdisciplinary team, their role in supporting the development of occupational balance and integration of self-management activities into daily routine work and leisure activities must be promoted.

CASE STUDY

Client Information

Francisca is a 54-year-old woman who was diagnosed with type 2 diabetes 1 year ago. She has a BMI of 32 (>30 is considered obese) and also a history of hypertension. She lives with her husband and her two grandchildren in a two-bedroom apartment. Francisca is a personal support worker who works full time at a nursing home and alternates between day and afternoon shifts. She also picks up some additional shifts on the weekends to make ends meet. Her husband is not working, and she is the primary wage earner. Together, they are raising their granddaughters ages 3 and 5. Francisca attended a diabetes education class just after she was diagnosed last year and has been struggling to get her HbA1c levels below 8. With so little time, she has been unable to implement the self-management strategies.

Her goal is to find ways to manage her diabetes as she doesn't like to take medications. She is hoping to learn more about strategies to manage her diabetes and how she can fit these into her busy daily routine.

Reason for Referral to Occupational Therapy

Francisca receives her primary care services at the community health center down the street. She was referred to the primary care occupational therapist to assist in managing her daily routines and activities to improve her overall diabetes management and support a healthy lifestyle. Because of the demands of both work and caregiving for her grandchildren, Francisca has been having difficulty finding the right balance in her life.

Assessment Process and Results

Francisca's assessment was completed at the community health center in the occupational therapists office. The COPM was used to identify the problems Francisca is having in her daily activities. She identified a number of programs, and her five most important issues were shopping for healthy groceries, playing in the park with her granddaughters, walking at work, swimming at the recreation center, visiting her sister.

Canadian Occupational Performance Measure Results

	Performance	Satisfaction
Shopping for healthy groceries	5	5
Playing in the park	3	4
Walking at work	6	3
Swimming at the recreation center	2	2
Visiting her sister	4	4

In addition to the COPM, she completed a diabetes questionnaire exploring her self-management strategies. It was noted that she is currently using very few of the strategies she had been introduced to a year ago. She also had a hard time articulating her goals and was generally overwhelmed during the assessment. At one point, she became teary when describing how she is trying to cope with her diabetes and also look after both her husband and her grandchildren. Francisca was noted to become short of breath when walking the length of the center's hallway. Francisca did not report any sensory changes in her hands or feet; however, her footwear was noted to in poor condition and poorly fitting.

Occupational Therapy Problem List

- Difficulties with instrumental activities of daily living (IADLs), specifically shopping
- Decreased social engagement
- Decreased endurance impacting on walking and swimming
- Difficulties looking after and playing with her granddaughter
- Difficulties coping with diabetes management

Occupational Therapy Goal List

Long-term goal: Francisca will be able to engage in health-promoting activities, including swimming, walking, healthy eating, and playing with her grandchildren in 3 months.

Initial short-term goals:

- Francisca will be able to identify complications that are related to diabetes and describe diabetes self-management strategies.
- Francisca will be able to identify and create a daily routine that will enable her to implement self-management strategies.
- Francisca will attend aquafit at the recreation center two times per week.
- Francisca will shop for and prepare healthy meals on a daily basis.
- Francisca will play at the park with her grandchildren on the weekends.
- Francisca will be able to walk for 20 minutes with no shortness of breath.

Intervention

Francisca attended the REAL diabetes education program at the community health center. She completed each of the seven modules over 6 months and was able to schedule her appointments to fit with her work schedule. In the first module, Francisca developed two goals using the Goal Attainment Scale. These goals were used to tailor the intervention to support her in implementing strategies into her busy routine. Francisca learned more about diabetes and began to have a better understanding of the importance of managing her diabetes. She was able to describe the complications related to diabetes and established a daily routine of monitoring her blood sugars. She was also able to come up with a plan to better communicate her desire to use self-management as opposed to medications to her physician. She made arrangements to attend the diabetes clinic offered at the center on a more regular basis. A great deal of time was spent

reviewing her daily routines and finding how she can better implement the self-management strategies. She worked with her employer to reduce her evening shifts so she could see her grandchildren and regularly attend aquafit. Francisca also began to plan her weekly meals and, together with her grandchildren, planned weekly shopping trips to the grocery store and farmers markets. Francisco recognized how difficult the diagnosis of diabetes was emotionally and recognized that eating junk food was something she did to manage her emotions. She attended a Choices for Change workshop given by the dietitian and was able to lose 25 lb over 6 months.

On completion of the REAL program, Francisco attends twice yearly follow-up occupational therapy appointments to ensure her strategies are fitting into her daily routines.

Chapter 46

Alzheimer Disease and Other Dementias

Rosanne DiZazzo-Miller

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Classify and define the various types of dementias.
2. Identify and select appropriate assessments for patients with dementia.
3. List relevant interventions for clients with dementia.
4. Describe areas of need for caregiver assessments and interventions that empower both persons with dementia and caregivers.
5. Analyze a case study and develop an intervention plan inclusive of client-centered care and occupation-based goals.

CHAPTER OUTLINE

Description of Alzheimer Disease and Other Dementias
Functional Impairment in Daily Occupation
Evaluation and Intervention of Functional Skill Deficits Secondary to Alzheimer Disease and Other Dementias
Case Study

TERMINOLOGY

Alzheimer dementia: a label that refers to the underlying disease or the entire continuum of the disease.

Alzheimer disease: the most common form of dementia, comprising approximately 60% to 80% of dementias, and involves neurological plaques and tangles responsible for cognitive deficits.

Creutzfeldt–Jakob disease: type of dementia that is rare, progressively fatal, and specifically causes memory, coordination, and behavioral impairments.

Dementia with Lewy bodies: type of dementia that results from abnormal clumps of the protein alpha-synuclein with onset typically resulting in motor and cognitive impairments.

Frontotemporal lobar degeneration: formerly called frontotemporal dementia; is a type of dementia that includes primary progressive aphasia, Pick’s disease, corticobasal degeneration, and progressive supranuclear palsy.

Mild cognitive impairment (MCI): believed to be a precursor to Alzheimer dementia that affects mild thinking impairments, although activities of daily living (ADLs) remain intact.

Mixed dementia: type of dementia that exists when there is evidence of two or more causes of dementia.

Neurocognitive disorder (NCD): the newly replaced *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* term for dementia, although diagnostic information remains the same.

Parkinson disease: a neurodegenerative disease that presents with movement challenges (e.g., rigidity and tremors) and often results in dementia from accrued Lewy bodies in the cortex, along with clumps and tangles.

Preclinical dementia: occurs when brain changes are noted (e.g., cerebrospinal fluid or biomarkers) that show disease onset; however, no visible symptoms are observed or reported.

Vascular dementia: form of dementia that accounts for approximately 40% of dementias (10% present with vascular dementia alone) and occurs most commonly from blood vessel blockage.

Description of Alzheimer Disease and Other Dementias

Epidemiology

Epidemiology refers to new cases within a given time period and population. Approximately 484,000 people in the United States aged 65 years or older developed **Alzheimer dementia** in 2018.¹ As the population ages, risk increases. Approximately 66,000 new cases of Alzheimer dementia occur among people aged 65 to 74 years. This figure increases to 245,000 new cases among people aged 85 years and older (i.e., defined as the oldest old).¹⁻³ A person develops Alzheimer dementia in the United States every 65 seconds—a figure that will increase to every 33 seconds by 2050.¹ The estimated lifetime risk for Alzheimer dementia based on gender for women at age 65 was approximately 1 in 10, compared to approximately 1 in 20 for men.¹ As the baby-boomer generation reaches age 65, the number of people aged 65 years and older is expected to reach 7.1 million by 2025; therefore, the number of people in this age group diagnosed with Alzheimer dementia is projected to increase from 5.5 million to 13.8 million.¹ The duration of Alzheimer dementia for people aged 65 years and older is between the ages of 4 and 20 years. Alzheimer disease–related death rates have also dramatically increased for people aged 65 to 74 years.¹

Definition

Although dementia and **Alzheimer disease** are often used interchangeably, it is important to understand each term and how both contribute to this area of clinical study. Dementia is a group of symptoms, or syndrome, that manifests from a variety of causes and in multiple ways. Several types of dementia exist, and it is common for patients to have more than one type—referred to as **mixed dementia**.¹ There are also individuals who have dementia-like symptoms without evidence of Alzheimer-related brain changes, resulting from disorders such as depression, alcohol abuse, and vitamin deficiencies.^{1,4} Regardless of type or cause, common symptoms of dementia include challenges related to memory, communication, and problem-solving. Often at the root of these challenges lies neurons that have been damaged or destroyed. Alzheimer disease is a condition in which neurons have been damaged or destroyed, affecting mobility and bodily functions, and is ultimately fatal.¹

The National Institute on Aging (NIA) and the Alzheimer’s Association set forth revised guidelines in 2011 for the diagnosis of Alzheimer disease.⁵ Originally, and as seen in the 1984 diagnostic criteria, diagnosis was heavily based on physician clinical judgment with feedback from family and friends. The updated guidelines continue to include physician judgment and family input, but now also include biomarker tests to measure the actual presence or absence of the disease.^{1,6} Biomarker tests typically include the amount of beta-amyloid in the brain as shown on positron emission tomography (PET) scans, proteins in fluid such as tau and beta-amyloid in the cerebrospinal fluid, and glucose metabolism in the brain.^{1,7} In addition to these changes, three stages of Alzheimer disease have been identified in the revised guidelines: (1) one stage with dementia (i.e., dementia due to Alzheimer disease), (2) one stage in which symptoms are present (e.g., **mild cognitive impairment [MCI]** secondary to Alzheimer disease and dementia secondary to Alzheimer disease), and (3) one stage without symptoms (e.g., **preclinical dementia**, preclinical Alzheimer disease).^{1,8} Table 46-1 provides information on the three main areas included in the revised guidelines for diagnosing Alzheimer disease.

Table 46-1. Terminology in 2011 Revised Guidelines for Diagnosing Alzheimer Disease

STAGE	DESCRIPTION
Dementia due to Alzheimer disease	Evidence of an Alzheimer-related biomarker in addition to challenges with behavior, memory, and thinking that impact occupational functioning
Mild cognitive impairment due to Alzheimer disease	Evidence of an Alzheimer-related biomarker in addition to challenges with cognition that is more than what is considered normal given his or her age
Preclinical Alzheimer disease	Evidence of brain changes (e.g., cerebrospinal fluid and blood), yet no noted challenges with memory. Can occur up to 20 year prior to symptom onset

Data from Alzheimer’s Association¹ and Sperling et al.⁸

Prevalence and Background

Every 3 seconds, someone in the world develops dementia.⁹ An estimated 50 million people worldwide have dementia, and this number is projected to double every 20 years.⁹ With the fastest growth of older individuals in China, India, and southern Asia, the greatest number of estimated

cases of people with dementia is in Asia with 22.9 million, followed by Europe at 10.5 million, the Americas at 9.4 million, and Africa with 4 million.⁹ In the United States, Midwestern states on average have the lowest occurrence of Alzheimer dementia (e.g., 13.6%–20.2%) compared to western states, which range from 26.9% to 40%.¹ States with over 40% occurrence rates include Nevada, Arizona, Virginia, South Carolina, and Georgia.¹ The estimated cost of dementia in 2015 was calculated as \$818 billion in the United States alone; this figure is anticipated to increase to \$2 trillion worldwide by 2030.⁹ There is an estimated 5.7 million cases of people with Alzheimer dementia in the United States, with about 200,000 individuals under the age of 65.¹ This number increases with age; for example, 3% of people in the 65 to 74 year age group have Alzheimer dementia—a figure that steadily increases to 80% in people aged 75 years or older.¹ Although age does not appear to have a bearing on gender, women comprise the majority of Alzheimer or other dementias at 3.4 million in the United States compared to 2 million men.¹

Given these statistics, it is important to understand the existence of a treatment gap between high- and low-income countries, suggesting that three-quarters of people with dementia are undiagnosed and do not have access to treatment or other supports available to people with formal diagnoses.⁹ This treatment gap presents many opportunities for occupational therapists since often, proper screening secondary to common occurrences such as falls and other accidents can lead to formal diagnosis and proper intervention and support.

Etiology

Researchers believe that various factors contribute to or influence the onset and progression of dementia, leaving the etiology unknown.¹⁰ The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* replaced the term dementia with **neurocognitive disorder (NCD)** in an attempt to reduce stigma related to the definition of dementia—which originated from the late 18th-century *demens*, meaning “out of one’s mind.”^{11,12} This change has no bearing on disease description. Complex attention, executive function, learning and memory, language, perceptual-motor function, and social cognition continue to be the six cognitive domains affected in both mild and major NCD.¹¹ In addition, subtypes of minor and major NCD are now outlined in the *DSM-5*, including those due to Alzheimer disease, **frontotemporal dementia**, **dementia with Lewy bodies**, traumatic brain injury, substance/medication-induced dementia, Prion disease, **Parkinson disease**, Huntington disease, other medical conditions, multiple etiologies, and unspecified NCD.^{11,12} Given the various causes of dementia, increasing age is the most important risk factor because the number of people with dementia doubles every 5 years.⁵

Lifestyle and Genetics

Age, family history (i.e., a parent, brother, sister, or child with dementia), and genetics increase risk.¹³ The most probable cause of late-onset Alzheimer dementia is likely due to a combination of environmental and lifestyle factors and genetics.⁵ Heart disease, stroke, and high blood pressure are believed to contribute to the development of Alzheimer disease, and therefore, proper diet, physical activity, smoking cessation, and moderating alcohol consumption may improve health and decrease disease risk.^{1,5,13} Various types of infections and brain trauma, such as concussions, are also believed to play a role in the development of dementia.

One primary concern expressed by patients with dementia relates to whether they have passed on a genetic heritage to their children. Genes can have variant forms or mutations. Variant genes mixed with others account for qualities such as height. Mutations can be more harmful and may ultimately lead to a faulty gene that is inherited through generations, such as the gene responsible for Huntington disease.¹³ Dementia is more likely to be caused by a mutated gene rather than a variant gene, although multigene variants have been linked to dementia in some families. Genetics play different roles in the four most common dementia types: Alzheimer disease, vascular dementia, dementia with Lewy bodies, and frontotemporal dementia.¹³

Owing to familial clustering (i.e., many close family members are affected by Alzheimer disease), researchers suggest that genetic mutations may be responsible for dementia.¹³ Although no one specific gene has been found responsible for Alzheimer disease, studies have found that a mutation of one of three genes may be responsible, including amyloid precursor protein (*APP*), presenilin gene 1 (*PSEN-1*), and presenilin gene 2 (*PSEN-2*).¹³ People who have one form of the apolipoprotein (E APOE) on chromosome 19 have been shown to possess increased risk.⁵ Other genes that have been identified as having a role in Alzheimer disease include *CLU*, *CRI*, *PICALM*, *BINI*, *ABCA7*, *MS4A*, *CD33*, *EPHA1*, and *CD2AP*.¹³ Early-onset Alzheimer disease—defined as people aged 30 through mid-60s—is believed to be highly linked to genetics, although not all cases

are. If a mother or father carries the genetic mutation seen on chromosomes 21, 14, and 1, their offspring have a 50/50 chance of inheriting the mutation and a high risk of developing early onset.⁵ To put this into perspective, more than 450 families carry the *PSEN-1* gene mutation on chromosome 14, which causes 80% of early-onset familial Alzheimer disease.^{5,13} The *APP* gene mutation on chromosome 21 is present in more than 100 families worldwide.^{5,13} This is important because *APP* affects the production of the protein beta-amyloid, and a buildup of beta-amyloid in the brain is hypothesized to be a major contributing factor to Alzheimer disease. The mutation of *PSEN-2* on chromosome 1 is present in more than 30 families, which is thought to be responsible for late-onset Alzheimer disease.^{5,13} Although these genes have been identified, only 1 in 10 have a strong family pattern of inheritance. Rather than inheriting these genes from one generation to the next, more than 20 gene variants have been identified as at-risk genes and do not show much support related to inheritance.

The second most common type of dementia after Alzheimer disease is **vascular dementia**.¹ Although no known single-gene mutations have been found for vascular dementia, mutations in *NOTCH3* and *CADASIL* appear to play a role in some rare forms of vascular dementia.¹³ Additionally, *APOE* may be linked to vascular dementia, although research has not found definitive evidence. Here again, high cholesterol, high blood pressure, type 2 diabetes, and family history of stroke or heart disease can increase risk and have been shown to heighten the likelihood of developing vascular dementia in later life.¹³

Frontotemporal dementia is the main type of dementia for which genes may play the largest role because there is a strong family history in 10% to 15% of people with this dementia type and up to 30% of cases are linked to a single gene.¹³ Mutations in three genes, *C9ORF72*, genes for the proteins tau (*MAPT*), and progranulin (*GRN*), can be linked to most familial frontotemporal dementia cases.¹³ In fact, if someone carries *MAPT* or *GRN*, offspring have a 50/50 chance of inheriting the mutation, and nearly all who have this mutation will develop frontotemporal dementia.¹³ In addition, a new gene variant, *THEM106B*, has been found to increase the risk for developing frontotemporal dementia.¹³

Unlike frontotemporal dementia, genetics regarding dementia with Lewy bodies is not well understood, and there is little research supporting any familial link toward the development of this dementia type. Therefore, no genetic mutations have been identified, although some gene variants, such as *APOE*, which plays a key role in Alzheimer disease, and glucocerebrosidase (*GBA*) and alpha-synuclein (*SNCA*), which play a role in Parkinson disease, have been shown to increase the risk for dementia with Lewy bodies.¹³

Genetic testing can be performed as a diagnostic measure for people who have already been diagnosed with dementia or as a predictive measure for relatives who are concerned that they may carry dementia-related genes based on family history. Genetic testing is available for the Huntington disease gene (*HTT*), Alzheimer-related genes (*APP*, *PSEN-1*, *PSEN-2*), and frontotemporal-related genes (*MAPT*, *GRN*, *C9ORF72*); however, testing may be offered only under specific conditions and with appropriate counseling.¹³

Dementia Course, Prognosis, Signs, and Symptoms

As can be seen, each type of dementia has differing features. Table 46-2 provides an outline of the course and prognosis, signs and symptoms, and medical management for each dementia type discussed in this chapter.

Table 46-2. Dementia Type, Course and Prognosis, and Signs and Symptoms

DEMENTIA TYPE	COURSE AND PROGNOSIS	SIGNS AND SYMPTOMS
Alzheimer disease	Alzheimer disease is the most common type of dementia and can begin years before signs or symptoms develop. As a slowly progressive brain disease, the most common pathologies include accumulation of plaques and tangles inside neurons and ultimately neuron damage and death, thereby affecting their ability to transmit impulses. May live 20+ years after diagnosis.	The most common signs and symptoms of Alzheimer disease center on challenges with memory, such as recent conversations and events. Apathy and depression may develop followed later by challenges with communication, judgment, behavior, and confusion. The end stages of Alzheimer disease progress to the point of expressive aphasia, dysphagia, and mobility problems.

DEMENTIA TYPE	COURSE AND PROGNOSIS	SIGNS AND SYMPTOMS
Vascular dementia	Vascular dementia is the second most common type of dementia and is also commonly found with people who have another type of dementia. Typically, clients with vascular dementia have evidence of some type of infarct or bleeding in the brain caused by blockage or damage of blood vessels. People typically live 5 years after symptoms are present.	Rather than challenges with memory, the most common signs and symptoms of vascular dementia include executive functions such as impaired judgment, decision-making, and organization. With progression, additional cognitive and motor challenges typically occur.
Dementia with Lewy bodies	In dementia with Lewy bodies, there are clumps present in the cortex, resulting in cognitive impairment. Dementia with Lewy bodies is often a comorbidity with Alzheimer disease, thereby leading to a mixed dementia diagnosis. People typically live 6–12 years after symptoms are present.	Most often, clients will report difficulty with sleeping early on. This is typically followed by visual hallucinations and mobility impairments, including Parkinsonian-type motions.
Frontotemporal lobar degeneration	Frontotemporal lobar degeneration previously referred to as frontotemporal dementia is often affected by nerve cells in the frontal and temporal lobe regions of the brain, resulting in atrophy of these brain structures. Layers of the cortex have abnormal proteins. Frontotemporal lobar degeneration includes a behavioral-variant form, primary progressive aphasia, Pick disease, corticobasal degeneration, and progressive supranuclear palsy.	Typically, symptoms develop with a younger onset of 45–60 years. Signs and symptoms are seen most predominantly through changes in behavior and personality as well as expressive and receptive aphasia with memory challenges present later in disease progression.
Parkinson disease	Parkinson disease begins with degeneration of nerve cells that produce dopamine. Much like dementia with Lewy bodies, Parkinson disease presents with clumps in the cortex as well as clumps and tangles in the substantia nigra.	Motor control is mostly affected including movement that is slow, rigid, with tremors present that affect mobility.
Creutzfeldt–Jakob disease	Prion, which is a misfolded protein, causes other proteins in the brain to malfunction. Etiology is unknown, although there is a possibility of a link to heredity and/or prion infection. A variant form of Creutzfeldt–Jakob disease is thought to have been caused by mad cow disease.	Rare and rapidly fatal impairment of memory and coordination with noted behavioral changes
Normal pressure hydrocephalus	Normal pressure hydrocephalus is caused by cerebrospinal fluid that is not reabsorbed and, therefore, causes a buildup of fluid and pressure in the brain. History of brain hemorrhage and meningitis may present an increased risk. Occasionally, shunts may be effective in draining the additional fluid.	Signs and symptoms include challenges with mobility and memory, and incontinence.

Data from Alzheimer's Association¹ and Dening and Sandilyan¹⁴

Medical Management

The medical management of Alzheimer dementia includes both pharmacological and nonpharmacological interventions to treat the spectrum of symptoms present in the various disease stages. As mentioned earlier, some diagnoses require biomarkers, although the majority of diagnoses rely heavily on the report and documentation of mental decline. Some biomarkers such as beta-amyloid and tau levels in cerebrospinal fluid, and brain changes noted through imaging via magnetic resonance imaging (MRI) or computed tomography (CT), can rule out other conditions that may cause symptoms similar to Alzheimer dementia, such as stroke, tumors, or head trauma.^{13,15} PET scans of the brain can reveal the presence of amyloid plaques.¹⁵ In fact, an imaging tracer (i.e., Pittsburgh compound B, flutemetamol F18, and florbetaben F18) can reveal amyloid plaques during PET scans.^{13,16,17} Cerebrospinal fluid proteins can also be used to analyze the presence of Alzheimer-related cerebrospinal fluid proteins, as well as measurable changes in urine or blood levels with biomarkers such as tau and beta-amyloid.^{15–17}

There is currently no cure for Alzheimer disease. The main purpose of intervention is to maximize activities of daily living (ADLs), memory, cognition, mood, behavior, quality of life, and social participation, as well as to ensure a safe living environment. Five Food and Drug Administration (FDA)-approved Alzheimer drugs (Aricept, Razadyne, Exelon, Namenda, and Namzaric) can slow the progression of symptoms by supporting communication of the neurons, synapses, and neurotransmitters in the brain.¹⁸ Managing behavioral and psychological symptoms—which typically include agitation, aggression, depression, mood, and psychosis—are typically first addressed through nonpharmacological means such as minimizing challenges, and maximizing safety and comfort for the person with dementia.¹⁸ No drugs have been FDA approved to address behavioral and psychiatric symptoms from dementia, although various psychological drugs such as antipsychotics, antidepressants, anticonvulsants, and mood stabilizers have been found helpful.^{18,19}

Functional Impairment in Daily Occupation

As shown in Table 46-2, the course and symptoms of dementia vary depending on type. Cognition, behavioral and psychological changes, ADLs, and motor control are the main areas of functional impairment and are noted throughout the various stages of dementia progression. Generally, dementia is broken into three stages: early, middle or moderate, and late or severe. However, the seven-stage model based on the Global Deterioration Scale²⁰ uses the following criteria:

- **Stage 1:** No noted impairments.
- **Stage 2:** Very mild cognitive decline, although nothing more beyond normal aging.
- **Stage 3:** Mild cognitive decline is present and noticeable by family and friends.
- **Stage 4:** Moderate cognitive decline to the point that neurologists can make a diagnosis. Challenges are present in short-term memory and basic arithmetic.
- **Stage 5:** Moderately severe cognitive decline is marked by challenges with ADLs coupled with confusion and disorientation, making independent living a challenge.
- **Stage 6:** Severe cognitive decline includes a worsening of all previously stated challenges in addition to the onset of personality changes and difficulty recognizing family members and friends.
- **Stage 7:** Very severe cognitive decline marks the final stage as well as the most significant impairments to memory, communication, and motor control.

Early-Stage Functional Impairments

Although stages can provide an idea of functional impairment, it is important to realize that each individual with dementia can present with different and unique symptoms. Additionally, the length of each stage can vary considerably for each client. In the early stage, or stages 1 to 3²⁰ using the seven-stage model, the realization that something may be wrong begins to set in. Most individuals try to mask their symptoms through various compensatory techniques such as relying more heavily on phone reminders and post-it notes. Memory lapses or momentary confusion may occur, and individuals may begin to seek help for instrumental activities of daily living (IADLs) that involve more complex tasks.

Middle-Stage Functional Impairments

In the middle stage, or stages 4 to 5,²⁰ memory lapses and confusion increase, and poor judgment and even wandering may begin to become areas of concern. Memory deficits begin to involve personal information, such as home addresses and phone numbers, and important dates, such as birthdays and anniversaries. In dementia with Lewy bodies, more motor-related declines are present, and in frontotemporal (behavior variant) dementia, inappropriate behaviors begin to create additional functional obstacles. Overall, ADLs such as bathing, grooming, dressing, eating, transferring, and toileting begin to require assistance. IADLs such as communication, shopping, food preparation, housekeeping, laundry, transportation, medication, and financial management begin to become challenging as well. Sleep patterns may also become disrupted. In the middle stage of dementia, family and friends notice personality changes along with psychological challenges such as fear, depression, and paranoia. It is understandable, then, that social withdrawal tends to follow. In this stage, caregivers (e.g., care partners) typically begin to feel stressed and overwhelmed and experience feelings of burden and depression.

Late-Stage Functional Impairments

In the late stage, or stages 6 to 7,²⁰ people with dementia experience severe decline in both cognitive and physical function. Independence in all areas of life is severely impacted, including purposeful communication, eating, swallowing, bowel and bladder control, and mobility. Agitation and irritability are intensified, and individuals typically require maximum assistance with all ADLs. In this later stage, the focus of functioning turns to comfort and quality of life for the client, and support for caregivers.

Evaluation and Intervention of Functional Skill Deficits Secondary to Alzheimer Disease and Other Dementias

Assessment and Evaluation for Dementia

Occupational therapy (OT) assessment and evaluation should, as always, be client centered and involve the person with dementia, their caregiver(s), and any family members. Although others are helpful to have present during the initial evaluation, it is critical to empower the person with dementia to have an active role in this process. Typically, the evaluation is broken down into

assessments, including an occupational profile through observation and interview, followed by assessments for ADLs, cognition, and psychosocial and physical functioning. Prior to working with clients with dementia, it is critical to review their chart and identify any precautions or contraindications. In general, clients with dementia are at an increased risk for falls and are more easily overwhelmed and overstimulated. Unlike remedial techniques that are implemented when communicating with clients diagnosed with other neurological challenges such as brain injury or stroke, it is not useful or productive to argue with or attempt to orient clients with dementia who are disoriented and insist on things that are not reality based. Examples include time, date, season, and the current president. Attempts at orientation or disagreement with clients with degenerative neurological disease must be done so under extreme care because such attempts can lead to arguments that will increase anxiety, agitation, and paranoia. Assessments are invaluable in identifying these and additional areas that present challenges to people with dementia. The Assessment Table provides a selected list and description of appropriate assessments for dementia care.

Intervention Procedures for Impairments Associated with Alzheimer Dementia

Based on dementia stage, client strengths and weaknesses, and additional evaluation findings, occupational therapists develop treatment plans that address task simplification, remediation or compensation when possible, environmental modifications, health promotion, and caregiver training. The following outlines key interventions areas:

Task Simplification

Most clients with dementia are cared for in the home by family caregivers.¹ As dementia progresses, everyday tasks become more challenging, and both clients and caregivers will need to use adaptation, compensation, and task simplification. When simplifying tasks for clients with dementia and/or their caregivers, it's important to provide clear, concise verbal directions as well as visual and tactile cues when possible. Task simplification most often includes setup. For example, if engaging clients in meal preparation, therapists should arrange all food and materials in advance and in sequential order to promote function (Fig. 46-1). Similarly, if engaging clients in dressing, therapists should set up clothes in sequential order; clothing should be selected that is easiest to don, such as pullover shirts, elastic waistband pants, and slip-on shoes (Fig. 46-2). While setup is important, it is equally important to break down tasks into simple steps.²¹

Figure 46-1 Task simplification. When engaging clients in meal preparation, therapists should arrange all food and materials in advance and in sequential order to promote function.

Figure 46-2 Task simplification. When engaging clients in dressing, therapists should set up clothes in sequential order; clothing should be selected that is easiest to don, such as pullover shirts, elastic waistband pants, and slip-on shoes.

Environmental Modification

Environmental modifications are often necessary with the progression of dementia secondary to increased fall risk; however, it is important to consider when making modifications that familiar surroundings most optimally promote client function. Modifications that promote safety and mobility are outlined in Table 46-3. These modifications typically include adjustments to address vision and hearing loss, confusion, and visual-spatial challenges; it is equally important, however, to consider the importance of structured, predictable daily routines.²³

Table 46-3. Environmental Modifications that Promote Safety and Mobility

ENVIRONMENTAL MODIFICATION	DESCRIPTION
Reduce clutter	Declutter the environment by removing throw rugs, simplify and organize objects, place objects in sequence of use, and label objects when appropriate.
Improve lighting	Improve lighting during tasks and throughout walkways. Have the option of dim lighting for moments when bright lights may be overwhelming or overstimulating.
Decrease glare	Lighting can sometimes cause shadows that can be perceived to be confusing or even frightening. Check for glare throughout the home and reduce when possible.
Increase contrast	Utilize color contrast throughout all areas of the home. Toilet seats are commonly overlooked and are often white against a white background, making them appear to be the floor. Safe paint or tape can outline the seat. White coffee or tea cups are ideal along with dinner ware that is color contrasted to the table and food.
Arrange furniture	Furniture should be arranged in a manner that promotes clear and uncluttered walkways. Low stools present safety hazards.
Address wandering	Install items to deter, prevent, and monitor wandering such as disguising doors, installing open door alerts and security cameras, and implementing an ID system.
Address sound	Decrease noise that can be overstimulating, such as two televisions turned on at the same time or one turned on too loudly. Play client-preferred music softly in the background during meals and bathing to increase comfort and calmness.
Limit choices	Too many choices for meals, clothes, and so on can lead to being overwhelmed. Limit choices to two to three options both verbally and visually. Present food one item at a time. Use one- to two-step commands when cueing. Limited labeling can also provide visual cues for locating rooms and objects.
Use adaptive equipment	Use bathroom equipment such as a tub bench, toilet rail, grab bars, hand held shower, and a long-handled sponge. Tubing can be used to increase grip size of many items, such as toothbrushes, pens, combs, and utensils as well as deep plates/bowls.

Data from Fraker et al.²¹ and van Hoof et al.²²

Remediation

Typically, with degenerative neurological conditions, remediation of cognitive abilities is not a focus of treatment; however, research has shown improvement in cognition and quality of life for study participants with mild-to-moderate dementia after engaging in cognitive stimulation therapy (CST) for people using money, word games, present-day famous faces, and reality orientation boards. In this study, CST compared favorably with pharmacological treatments.²⁴ Restoration of physical function should be addressed in terms of range of motion (ROM), strength, and overall

endurance. Although remediation of physical function is possible, it is important that therapists take a gentle, structured approach and prevent overfatigue. A home program that is short and easy to follow, with appropriate and plentiful visual aids, will help facilitate goals centered on physical functioning. Home exercise programs, coupled with behavioral management training for caregivers, were shown to have significant improvements in patient physical functioning and depression, and decreased institutionalization.²⁵ Using client-centered tools, such as old family photo albums, and client-identified favorite music and television shows is another way to stimulate memory and discussion of past events because long-term memory remains intact longer than short-term memory. With this said, it is important to understand the degenerative nature of dementia and that although improvements can be made mentally and physically, the progressive nature of this disease will ultimately cause decline in all areas of functioning. Occupational therapists are assigned with the important role of intervening to improve and maintain daily functioning that enhances quality of life for as long as possible.

Compensation

While remediation, as discussed earlier, can be appropriate given each client's unique case, compensation tends to be a major focus of treatment, especially as it pertains to cognitive functioning and behavioral changes. Compensatory interventions should focus on identifying strengths and weakness of clients and caregivers; assessing levels of burden, depression, and quality of life; and developing treatment plans to provide education, training, and resources for modifying or adapting the identified occupations, client factors, and performance skills that impact overall occupational functioning.

Wellness and Health Promotion

Health promotion is important to address for both the care recipient and caregiver. Strengthening and maintaining health and wellness for both parties typically leads to enhanced occupational functioning. It is important to understand how clients and caregivers manage their stress in order to plan and provide appropriate training and resources. Wellness and health promotion includes examining and addressing self-management behaviors, such as good habits and routines, nutrition, and engagement in exercise and social activities.²⁶ Wellness and health promotion begins with awareness through proper education and resources.

Caregiver Training

More than 16 million caregivers provide informal, unpaid care for people with dementia.¹ In fact, more than half of informal, family caregivers of people with dementia help with transfers, toileting, bathing, grooming, and feeding.¹ Caregiving is an immense responsibility and can cause unhealthy levels of stress and anxiety.²⁷ Such anxiety, coupled with feelings of unpreparedness to deal with their loved one's newly challenging behaviors, presents uncomfortable and sometimes irritating situations. Research has shown that caregiver interventions can lead to increased ADL knowledge,²⁸ decreased burden, and improved quality of life.²⁹ The following areas of caregiver training are outlined as follows:

- Because many caregivers personalize the behavioral changes and verbal attacks of care recipients, it is critical to first educate caregivers about the neurological and physiological changes occurring in clients' brains. This will help caregivers understand that people with dementia do not have control over their behaviors. Next, it is critical to provide education and training in client ADL performance because over half of informal family caregivers provide assistance with ADLs.¹ As with all areas of functioning, it's important for caregivers to provide only assistance as needed to encourage client functioning as much as possible.
- Within caregiver training, it is also important to explain the degenerative nature of dementia and that, rather than correcting clients' incorrect statements, it is more beneficial to let such statements go to avoid confrontation. In the same manner, redirection of the client is a useful technique to avoid inappropriate or combative behaviors.
- Caregiver communication styles can influence the difference between successful and unsuccessful outcomes. In the early to early-moderate stages of dementia, clients realize their own memory challenges and often attempt to mask problems or become defensive about them. When communicating, it is critical to be positioned at eye level with the client, allow clients time to respond to questions, and help with word-finding only when it appears that assistance is welcome.
- Although bathing, grooming, and dressing are commonly performed daily, it is important to understand that bathing specifically can be extremely challenging for clients and there is no

reason why this activity needs to occur more than two to three times per week. People with dementia often experience fear of water, and although physical appearance is important, cleanliness can be achieved with sponge baths. It is important to ensure privacy, a softly lighted environment, warm water temperature, setup of all supplies prior to bathing, use of adaptive equipment as appropriate, and overall safety such as locks on medicine cabinets and an environment free of nearby electrical appliances. Educate caregivers to allow bathing to be relaxing and enjoyable, rather than rushed. Bathing is also an excellent opportunity to perform skin checks for breakdown and bruising. Once in the tub or shower, shampooing may become challenging, and therefore, this task can be performed separately on another day or at a sink while clothed. Techniques such as wearing a waterproof visor to prevent soap from entering the eyes or using a handheld shower may help reduce combativeness. Grooming can be completed while clothed and seated with assistance as needed. Proper nail care should be completed after bathing; if clients possess thick or difficult-to-trim nails, professional assistance should be obtained. Good oral hygiene, including flossing, is essential, and dentists exist who specialize in dental care for people with dementia. Hair combing and brushing are tasks that can be completed hand-over-hand, which helps to engage clients as their disease progresses. Limiting dressing and grooming supplies to two to three choices can also prevent clients from feeling overwhelmed. Dressing from a seated position and arranging clothing items in the order in which they need to be donned can also help with successful task completion. It is important for caregivers to take note of clothing items that are preferred by clients as well as clothing types that are comfortable and easiest to don and doff. Loose-fitting clothes, slip-on shoes, and clothing with larger fasteners are easiest to negotiate. Dressing can be a good time to perform ROM exercises accompanied by music to create a fun and carefree experience.

- Eating and/or feeding are also important to consider. With disease progression, people with dementia may not recognize hunger or thirst and may experience difficulty with eating activities. Common helpful strategies include eating in a calm environment in which clients are able to eat at their own pace, recommending that caregivers and clients eat together, serving only one food at a time, ensuring that clients use the bathroom before and after eating, serving food in bowls instead of plates (bowls are easier to retrieve food from), precutting foods in bite-size pieces before serving, and maintaining the same eating schedule for each meal and on each day of the week. Additionally, it is important to ensure that caregivers understand the importance of keeping clients' chins in a neutral and slightly flexed position when swallowing.
- Toileting and transferring are important considerations that impact many areas of daily living. A quick check of the environment can reveal safety hazards, such as throw rugs, low furniture, insufficient lighting, and cluttered pathways. Proper transfer training is essential and should include education about body mechanics for both clients and caregivers, as well as appropriate methods to transfer from beds, chairs, car seats, toilets, and showers/tubs. Caregivers should be able to both verbally instruct and demonstrate how to safely transfer clients from all areas of the home. A tracker for incontinence is important as is a schedule for toileting every 2 hours. Important transfer considerations include proper seat height and contrast, ability to undress before bladder voiding accidents occur, and whether bathrooms are organized and well lit. Important considerations for toileting during the evening are commode placement next to beds and sufficient lighting in hallways and bathrooms. Clients who are incontinent should be regularly checked for skin breakdown and placed on a proper skin care routine.
- Education about respite services and support groups is crucial as caregivers need breaks from the ongoing, everyday support they must provide to maintain the health and safety of the person with dementia. Respite programs provide breaks for caregivers to focus on themselves and other family members and friends, whereas support groups provide a forum in which to bond with other caregivers and learn about how others cope with similar daily challenges.

CASE STUDY

Patient Information

Donna is an active, 75-year-old white woman who lives in a two-story home in the west side of Detroit along with her 52-year-old daughter who works full time as a bank security guard, and 20-year-old granddaughter who attends college nearby. Donna's husband passed away many years ago. She held various jobs while growing up in the city, but then became and worked as a nurse for the majority of her life, eventually retiring at age 65. Donna was known for her high level of joy, care, and love that she provided to her patients. Her leisure interests include reading

the Bible, attending church, calligraphy, sewing, art, gardening, listening to Luciano Pavarotti, and the good company of family and friends. Donna has another daughter who lives in Georgia.

Donna is a smoker and has been her entire adult life. She has heart disease and high blood pressure for which she is being medically treated. Donna wears prescription lenses that just broke, and, in their place, she uses a magnifying glass. Her main source of income is social security, and she has Medicare along with supplemental insurance.

Reason for Occupational Therapy Referral

Donna's daughter, Carol, began noticing changes in her mother's ability to keep track of bills and appointments. Donna always prided herself on her home management and organization skills; however, in recent months, she reports noticing forgetfulness that is occurring more often and consistently, and changes in balance and overall endurance that impact her ability to perform ADLs and IADLs. More specifically, Carol reports that her mother has been experiencing difficulty getting ready in the morning, including occasional confusion between hot and cold water while bathing. Carol reports that Donna frequently becomes overwhelmed while dressing and sometimes dons inappropriate clothing for the season. Carol also reports that Donna's morning routine is taking notably longer than normal and that Donna appears exhausted afterward with an inability to make breakfast or do much of anything else. Carol also reports that her mother's personality has become somewhat inappropriate at times. Carol brought Donna to their family doctor who referred them to a neurologist. After meeting with the neurologist and based on medical history, physical examination, laboratory tests, and reported changes in thinking and daily functioning, a diagnosis of dementia was given without any specific type noted. As a result of the impact of Donna's newly diagnosed dementia on her daily living, the physician ordered an OT evaluation with recommendations for home adaptations.

Assessment Process and Results

An occupational therapist arrived at Donna's home approximately 1 month after diagnosis. Donna does not have a guardian or conservator. Prior to beginning the evaluation, the occupational therapist asked Donna whether she would like to answer the questions alone or have Carol present and contributing. Donna chose the latter, and all three sat down and began the evaluation process. The therapist used a top-down approach to begin the evaluation process and completed the Canadian Occupational Performance Measure (COPM); the Montreal Cognitive Assessment (MoCA); and functional screens for ROM, strength, and coordination. A home evaluation was also performed to ensure safety and accessibility within the home. Secondary to reported endurance and balance issues, the therapist issued the 6-Minute Walk Test (6MWT) for endurance and the Tinetti Balance and Gait Test. Findings revealed challenges consistent with Carol's reports about her mother's function.

Occupational Therapy Problem List

- **COPM:** Bathing is difficult due to confusion with hot/cold water. Dressing is overwhelming and confusing. Morning routine is exhausting and takes longer than reasonable. Donna is falling behind on mail organization, appointments, and bills. She reports being too tired for meal preparation.
- **MoCA:** Revealed moderate cognitive impairment (score = 23)
- **ROM, manual muscle test (MMT), and coordination:** ROM, MMT, and 9-Hole Pegboard assessment are within functional limits.
- **Home evaluation:** Closet is overwhelming with winter clothing mixed with summer and a great variety of choices. Bathroom is all white, has throw rugs, and is cluttered. Standard shower is present with no adaptive equipment. The rest of the home is accessible, although kitchen lights are dim and Donna has difficulty using the microwave because of small print.
- **6MWT:** Decreased endurance (score = 410 m; normal is 439–571)
- **Tinetti Balance and Gait Test:** Moderate risk for falls (score = 23)

Occupational Therapy Goal List

- Client will develop a binder/file system including mail, bills, and calendar with month-at-a-glance in order to increase independence in home management and organization skills.
- Client will perform a home exercise program focused on balance and endurance to improve physical functioning required for occupational performance.

- Client will safely and effectively distinguish the difference between the shower dial for hot and cold water.
- Client will perform 10 to 20 minutes per day of cognitive tasks along with her caregiver to provide daily cognitive stimulation.
- Client will engage in self-identified leisure tasks two to three times per week.
- Client and caregiver will demonstrate and implement energy conservation, task simplification, and environmental modifications to increase independence in ADLs and meal prep.
- Caregiver will correctly demonstrate and apply redirection techniques during communication challenges with her mom with 100% accuracy.
- Caregiver will contact the local Alzheimer's Association to receive resources, including support groups and respite care.

Intervention

1. The occupational therapist, client, and caregiver developed an effective, client-centered, and driven binder/file system so that Donna could organize her mail and bills, along with a calendar system that is visually organizing for the care recipient.
2. After client and caregiver education, Donna began a safe and efficient home exercise program for stretching, balance, and endurance.
3. The occupational therapist provided waterproof labeling on the shower dial to clearly delineate hot and cold water directions, and client education with return demonstration for safe use.
4. Donna began to perform cognitive tasks with her caregiver 10 to 20 minutes per day to provide daily cognitive stimulation, including tasks as outlined in CST guidelines (book is available for caregiver purchase, or therapists can provide tasks to perform based on CST), viewing family photos and recalling family members and events, and listening to enjoyable music such as Luciano Pavarotti. Daily cognitive stimulation activities were also used as a means to redirect smoking habits into meaningful and purposeful leisure pursuits and to implement health promotion education on smoking cessation.
5. The occupational therapist set up a small bin with client-centered leisure interests, including the Bible, the client's calligraphy set, sewing, and art and gardening supplies, to encourage leisure pursuits with her caregiver.
6. The occupational therapist provided education on energy conservation techniques, task simplification, and environmental modifications appropriate during morning ADLs and meal prep. These included setting up bathing supplies prior to bathing; limiting clothing options to two to three weather-appropriate outfits; laying out clothing in sequential order of donning; using high-contrast towels, handles, and toilet seat in her all white bathroom; having meals set up and ready to place in the oven or on the stove; clearly labeling (but not over labeling) drawers, cabinets, and refrigerator and freezer bins to decrease time spent seeking objects; identifying times of day that are more fatiguing than others; and planning structured days based on energy levels.
7. The occupational therapist provided caregiver education for and demonstration of positive, nonthreatening communication styles and redirection techniques to implement during communication challenges with her mom. Carol practiced performing these techniques during simulation opportunities with the therapist.
8. With the therapist's help, Carol contacted the local Alzheimer's Association to receive resources including information about support groups and respite care. This information is critical for Carol to have early on to address health and wellness for both herself and her mother, as well as to plan ahead for the future because she lives full time with her mother and is employed outside the home. This information will also be a source for future resources as Donna's dementia progresses and her occupational functioning declines. It will be important for Carol to plan for future systems to prevent Donna from wandering or answering the door and allowing strangers into their home.

Commonly Used Assessments in Dementia Evaluation

Instrument	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
------------	------------------	---------------------	----------	-------------	-------------	--------------------------

Instrument	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Disability Assessment for Dementia (DAD) ³⁴	Interview with the caregiver about the person with dementia's ADL performance over the past 2 weeks. Measures ADLs and IADLs in community-dwelling adults with dementia.	Approximately 15 minutes	Content validity established with experts and caregivers. Criterion-related (concurrent) validity established with the Rapid Disability Rating Scale-2 ($r = -0.85$, $n = 59$) and known groups. Construct validity established with MMSE ($r = 0.54$), $n = 55$.	Test-retest reliability intraclass correlation coefficient (ICC) = 0.96 ($n = 45$). Inter-rater reliability ICC = 0.95 ($n = 31$). Internal consistency Cronbach's alpha = 0.96 ($n = 59$).	Responsiveness of the DAD over a 1-year period and therapeutic sensitivity in pharmacological studies	Strengths: Measure of actual performance in ADL over a 2-week period. Assesses client's actual performance, not estimated capability. Considers sensorimotor disturbances that may influence performance. Weaknesses: Requires a 2-week period.
Executive Function Performance Test (EFPT) ³⁵	The EFPT is a criterion-referenced top-down assessment of executive function skills and covers five components of executive function throughout four domains, including initiation, organization, sequencing, safety/judgment, and termination.	30–45 minutes	Concurrent validity reports high correlation with the Functional Assessment Measure for clients with acute or chronic stroke and adequate-to-high correlation with the Assessment of Motor and Process Skills (AMPS) and Short Blessed. Construct validity with known groups discriminated between clients with stroke and health controls.	High internal consistency for total score and adequate-to-high internal consistency for tasks. Inter-rater reliability was high for total score and all tasks.	Not established	Strengths: Performance-based standardized assessment of cognitive function. Top-down approach to assessment compared to many other bottom-up approaches that analyze brain function. Weaknesses: Most studies were completed in samples of people with stroke. No normative data.

Instrument	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Performance Assessment of Self-Care Skills (PASS) ³⁶	The PASS is a performance-based criterion-referenced assessment consisting of 26 items ranging from functional mobility, personal self-care, IADLs with cognitive emphasis, and IADLs with physical emphasis. Can be given in total, alone or in combination. Two versions exist including one for home and one for clinic. Scored using a four-point (0–3) ordinal scale based on independence, safety, and adequacy.	Administration times range from 1.5 to 3 hours	Data are not available; however, the authors report content and construct validity.	Test-retest reliability for both the clinic and home version was high and ranged from ICC = 0.82–0.97) throughout independence, safety, and adequacy. Inter-rater reliability established as percentage agreement among examiners and ranged between 88% and 97% for both versions throughout independence, safety, and adequacy.	Not established	Strengths: No certification is required for administration and may be used in the home or clinic setting. Weaknesses: This test has a lengthy administration time and is not freely available.
Montreal Cognitive Assessment (MoCA) ^{37,38}	Designed as a rapid screening tool for mild cognitive assessment. Out of a score of 30, 26 or higher is considered normal.	Approximately 10 minutes	Concurrent validity was highly and positively correlated with the MMSE ($r = 0.867$, $p < 0.01$).	Cronbach's alpha was 0.884, high level of internal consistency. Inter-rater reliability was 0.966 ($p < 0.01$).	Detected 83% of participants with MCI and 94% with dementia	Strengths: Brief, useful screening tool to detect mild dementia and MCI. Weaknesses: Studies have had small samples with only 6-month follow-up. Conclusions are based on participants from a memory clinic.
Clinical Dementia Rating Scale (CDR) ³⁹	The CDR is a semi-structured interview that uses a five-point scale to assess cognitive and functional performance in the areas of memory, orientation, judgment and problem-solving, community affairs, home and hobbies, and personal care. Requires input from both the person with dementia and his or her caregiver.	Approximately 20–40 minutes. Administered to both the person with dementia and his or her caregiver.	Concurrent validity correlation was $r = 0.50$; Discriminant validity was strong.	Inter-rater reliability ranged from $r = 0.60$ – 0.80 .	Not available	Strengths: The CDR is noted as the best evidenced scale in a systematic review. Weaknesses: Time varies because caregiver/care recipient dyads are required for scoring.

Evidence Supporting Interventions for Clients with Dementia

Intervention	Description	Dosage	Participants	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
A structured occupational therapy program for older adults with dementia ³⁰	OT program included progressive muscle relaxation (10 minutes), physical exercises (10 minutes), personal care activities and household tasks (15 minutes), and cognitive exercises and recreation activities (10 minutes). Control group did not receive intervention.	Intervention included 10 treatment sessions of 70 minutes each over 5 weeks.	Seventy-seven participants attending a memory clinic were screened for dementia and were 60+ years old (36 = treatment group; 41 = control group).	Randomized controlled trial Level I	Novel OT program provided significant improvements in participants' physical and psychological domains as measured using the World Health Organization Quality of Life—BREF, compared to control.	Treatment group reported improved physical scores ($p < 0.0001$) and psychological scores ($p < 0.0001$).
Effects of community occupational therapy on quality of life, mood, and health status in patients with dementia and their caregivers ³¹	Community-based OT intervention	Ten 1-hour home-based OT sessions over 5 weeks	One hundred and thirty-five participants	Randomized controlled trial Level I	Improvement in participants' and caregivers overall quality of life was maintained 12 weeks postintervention.	People with dementia reported significantly higher quality of life ($p < 0.0001$) and general health status ($p < 0.0001$) at 6 and 12 weeks, respectively, postintervention, compared to control.
Tailored activities to manage neuropsychiatric behaviors in persons with dementia and reduce caregiver burden ³²	Tailored activity program to reduce behavioral disturbance and caregiver burden	Eight home visits by an occupational therapist. Client-centered intervention based on therapist assessment and client and caregiver feedback.	Sixty caregiver/care recipient dyads	Two-group, randomized, wait-list controlled pilot study Level I	Four months postintervention, caregivers reported reduced frequency of problem behaviors, less agitation and argumentation, and greater mastery and use of simplification techniques.	Caregivers reported a reduced frequency of behaviors ($p = 0.10$), greater activity engagement ($p = 0.029$), ability to keep busy ($p = 0.017$), less agitation ($p = 0.014$), and less argumentation ($p = 0.010$). Caregivers personally reported greater mastery ($p = 0.013$), self-efficacy, ($p = 0.011$) and use of simplification techniques ($p = 0.023$), compared to wait-list control participants.

Intervention	Description	Dosage	Participants	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Exercise plus behavioral management in patients with Alzheimer disease ²⁵	A home-based exercise program combined with caregiver training in behavioral management techniques	Dyads were seen in their homes for 12-hour long sessions, two times per week for the first 3 weeks, followed by weekly sessions for 4 weeks, and then biweekly sessions for 4 weeks. Three follow-up sessions were conducted over 3 months.	One hundred and fifty-three community-dwelling participants who met the National Institute of Neurological and Communicative Diseases and Stroke/Alzheimer's Disease and Related Disorders Association criteria for Alzheimer disease. Caregivers were spouses or adult relatives.	Randomized controlled trial Level I	Reduced functional dependence and delayed institutionalization for the treatment group as seen 3 months postintervention with participants having significantly fewer days of restricted activity and improved scores for physical role functioning and depression.	Fewer days of restricted activity ($p < 0.001$), improved physical role functioning ($p < 0.001$), improved depression scores ($p = 0.02$), and better physical role functioning scores ($p = 0.003$) with a trend for decreased institutionalization (19% vs. 50%); at 3 and 24 months postintervention.
Efficacy of an evidence-based cognitive stimulation therapy program for people with dementia ²⁴	CST for money, word games, and present-day famous faces as well as reality orientation board	Fourteen session program twice per week for 45 minutes per session over 7 weeks	Two hundred and one participants (115 = intervention group; 86 = control group)	Randomized controlled trial Level I	Intervention group significantly improved on Mini-Mental State Examination (MMSE), Alzheimer's Disease Assessment Scale—Cognition, and Quality of Life Alzheimer's Disease Scale, which compare favorably with pharmacological treatments in other studies. Gains in functional outcomes, communication, and anxiety and depression were modest.	MMSE ($p = 0.044$), Alzheimer's Disease Assessment Scale—Cognition ($p = 0.014$), and Quality of Life Alzheimer's Disease Scale ($p = 0.028$)
Evidence-based occupational therapy for people with dementia and their families: What clinical practice guidelines tell us regarding implications for practice ³³	Review of literature and guideline development for effective care within the scope of OT practice for people with dementia and their families focused on ADLs, quality of life, and carer impact	Five studies including 974 participants	Dosages varied between 5 and 10 visits over 5–6 months.	Meta-analysis Level I	OT interventions that were effective included environmental assessment, problem-solving strategies, carer education, and interactive carer skills training.	Positive ADL function (standardized mean difference [SMD] 0.17, 95% confidence interval [CI]: 0.02–0.33); carer impact revealed no significant effect (SMD – 0.15, 95% CI: – 0.32 to 0.02); quality of life for person with dementia was significant (SMD 0.62, 95% CI: 0.43–0.81).

Chapter 47

Cancer

Mary Vining Radomski Mattie Anheluk Ginger Carroll and Joette Zola

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe general information regarding cancer incidence, categories, and care.
2. Appreciate the contribution of occupational therapy to cancer rehabilitation, survivorship, and palliative care.
3. Identify occupational therapy–specific assessment and intervention approaches with this population.
4. Advocate for the provision of occupational therapy services for persons with cancer.
5. Identify interests and potential need for professional development in this practice area.

CHAPTER OUTLINE

Cancer: Background
Phases of the Cancer Journey
Occupational Therapy Evaluation and Intervention for People Living with Cancer
Conclusions and Recommendations
Case Study

TERMINOLOGY

Lymphedema: a buildup of lymph fluid in the fatty tissues under the skin that causes swelling; it is often a sequela to surgery and/or radiation that involves one or more lymph nodes and remains a lifetime risk for people living with cancer.

Metastasis: occurs when cancer cells migrate into the bloodstream or lymph system, travel to other parts of the body, and form new tumors.

Palliative care: an approach that aims to improve quality of life for families and patients facing life-threatening illness. It provides relief from pain and other distressing symptoms, support to help patients live as actively as possible, and coping and bereavement assistance.

Peripheral neuropathy: refers to numbness, tingling, and/or pain caused by nerve damage.

Survivorship: the cancer journey phase that begins as patients complete medical treatment and continues throughout the remainder of the patients' lives.

Cancer: Background

Roughly 19 million Americans are expected to live with cancer by 2024 as a result of early detection, effective treatments, and a growing aging population.¹ Cancer survivors face long-term side effects and health risks as a result of both treatment and ongoing fear of recurrence.² These challenges may interfere with activity and role performance, necessitating the services of occupational therapists.

The term *cancer* refers to a group of diseases in which abnormal cells divide without control, can invade nearby tissues, and travel through the blood and lymph systems to other body parts.³ Oncologists and pathologists classify cancer in order to specify a diagnosis, plan treatment, consider patient eligibility for clinical trials, and determine prognosis. For example, cancers are often classified by stage. Staging is the process of determining the severity of a person's cancer based on the degree to which a cancer has spread⁴ (Table 47-1). Common elements in most staging systems consider the primary tumor site, tumor size and number, spread into lymph nodes, and the presence or absence of **metastasis**.⁴

Table 47-1. Stages of Cancer (0–IV)

STAGE	DEFINITION
-------	------------

STAGE	DEFINITION
0	Abnormal cells are present but have not spread to other tissues. This stage is typically highly curable.
I	Cancer that is the next least advanced; patients often have good prognosis. This is referred to as early-stage cancer because a small cancer or tumor hasn't spread to lymph nodes or other body parts.
II–III	Cancer involving more extensive disease as indicated by greater tumor size and/or cancer spread to nearby lymph nodes, but not to other body parts.
IV	Cancer that has spread to other organs or body parts. This is referred to as advanced or metastatic cancer.

Cancers are also classified by the body location and tissue type from which the cancer originated (also called the primary site; e.g., breast cancer). Cancers that have metastasized to different body areas are named for the locations where the cancer originated and then spread (e.g., breast cancer with metastasis to the bones). In this chapter, six cancer types are described based on body location and which reflect diagnostic groups often seen by occupational therapists. Table 47-2 summarizes diagnosis-specific problems that occupational therapists address or consider when supporting improved occupational performance.

Table 47-2 Problems Relevant to Occupational Performance for Six Types of Cancer by Location

Location	Problems That May Interfere with Occupational Performance
Breast cancer	Weakness, fatigue, body-image issues, pain, lymphedema, limited range of motion (ROM), brachial plexus injury, cognitive inefficiencies
Lung cancer	Fatigue, dyspnea, weakness, limited ROM, limited endurance
Brain cancer	Cognitive problems, impaired vision and balance, decreased sensation, dysphasia, hemiparesis, impaired coordination, personality changes
Head and neck cancer	Limited cervical ROM, shoulder dysfunction, loss of scapular stability, difficulty swallowing, speech problems, stigma associated with disfigurement
Sarcoma	Possible amputation or issues associated with limb salvage, body-image issues, peripheral neuropathy, pain, fatigue, edema
Colorectal	Gastrointestinal problems (diarrhea, constipation, incontinence, bowel obstruction), physical and psychosocial challenges associated with managing an ostomy

Breast Cancer

As of 2018, there were more than 3.1 million breast cancer cases in the United States with over 260,000 new cases diagnosed each year,⁵ approximately 0.9% of which are diagnosed in men.⁶ Risk factors for breast cancer include age, heredity, physical inactivity, weight gain, use of hormone replacement therapy, and race.⁷ Treatment for breast cancer may include surgery, chemotherapy, radiation, and/or endocrine therapy.⁸

Lung Cancer

The two major types of lung cancer are non–small cell and small cell.⁹ Cigarette smoking is the leading cause of lung cancer, followed by environmental factors such as exposure to radon, secondhand smoke, and air pollution. Lung cancer is the deadliest form of cancer for both men and women.¹⁰ Lung cancer tends to be diagnosed at later stages when the cancer has metastasized and the individual's daily routines are affected by symptoms.

Brain Cancer

Each year, over 22,000 adults in the United States are diagnosed with a central nervous system tumor, most of which are brain tumors.¹¹ Metastatic brain tumors (those resulting from cancers that have spread from other body locations) occur more frequently than primary tumors, affecting 20% to 40% of cancer patients.¹² The most common types of primary brain tumors in adults are astrocytoma, meningioma, and oligodendroglioma.¹³ Glioblastoma multiforme, a type of astrocytoma, is the most common primary malignant brain tumor and the deadliest.¹⁴ The nature of functional deficits depends on brain tumor size and location.

Head and Neck Cancer

Head and neck cancer (HNC) describes malignant tumors that develop in or around the throat, larynx, nose, sinuses, and mouth. HNC accounts for about 4% of all cancers in the United States.¹⁵ Although younger people can develop the disease, most people are older than 50 years when

diagnosed.¹⁵ The causes may include smoking, excessive alcohol use, and the human papillomavirus.¹⁵ Treatment options include surgery, radiation therapy, chemotherapy, targeted therapy, or a combination of all—all of which may affect how a person feels, looks, talks, eats, and breathes.¹⁶

Sarcoma

Sarcomas are noncommon, malignant tumors that arise within bone and soft tissue. Soft-tissue sarcomas develop in fat, muscle, nerve, fibrous tissues surrounding joints, blood vessels, and deep skin tissues. Most sarcomas are found in the upper extremity (UE) and lower extremity (LE), but they can arise in any body part. Limb-sparing surgery is a common treatment for sarcoma, and amputation is now rarely needed.¹⁷

Colorectal Cancer

In 2018, within the United States, there were 43,030 new cases of rectal cancer and 97,220 new cases of colon cancer.¹⁸ Incidence is similar for both men and women, with increased risk for colon cancer in those aged 50 years and older.¹⁸ Treatment for colorectal cancer includes surgery, chemotherapy, and radiation.¹⁹ Decreased mobility and lowered activity levels can increase gastrointestinal issue risk (such as diarrhea) and caregiver burden.²⁰ Some patients must learn to care for a colostomy pouching system, which may be temporarily or permanently needed as a result of colorectal cancer treatment.²¹

Phases of the Cancer Journey

Patients and providers often use metaphors to describe the cancer experience. This facilitates communication using familiar experiences to represent unfamiliar medical concepts.²² Cancer **survivorship** is often framed as a journey, suggesting that the illness is part of a larger narrative within each person’s unique path.²²

Diagnosis

Often shocked by a cancer diagnosis,²³ patients shift their identity from a healthy to an ill person; rapidly gather information to make treatment decisions; and alter plans, activities, and roles to accommodate. The diagnosis may cause stress-related symptoms and/or emotional avoidance and withdrawal.²⁴

Medical Treatment

Medical therapies for cancer typically involve surgical tumor removal, chemotherapy, radiation, and/or immunotherapy. Cancer and its treatment have the potential to interfere with patients’ ability to perform activities of daily living (ADLs), instrumental activities of daily living (IADLs), and life roles (Table 47-3).²⁵ In addition to occupational therapy, the cancer rehabilitation team includes psychiatry, oncology nursing, psychosocial services, nutrition, pharmacy, pastoral care, physical therapy, speech-language pathology, lymphedema care, and fitness programs.

Table 47-3. Types of Cancer Treatment

TYPE OF CANCER TREATMENT	DESCRIPTION	SIDE/SECONDARY EFFECTS THAT MAY INTERFERE WITH FUNCTIONING
Surgery	Used to diagnose, treat, and prevent cancer	<ul style="list-style-type: none"> • Complications from surgery • Pain • Infection from wound site • Lymphedema
Chemotherapy	Medicines or drugs that are used to treat cancer; can be used to contain or slow tumor growth or kill cancer cells.	<ul style="list-style-type: none"> • Fever and chills • Nausea and vomiting • Hair loss • Fatigue • Sores in the mouth or throat • Constipation or diarrhea • Itching/rash • Muscle or joint pain • Memory changes
Radiation	The use of high-energy particles or wavelengths to kill the cancerous cells and shrink tumors	<ul style="list-style-type: none"> • Fatigue • Skin irritation at radiation site • Fever/chills

TYPE OF CANCER TREATMENT	DESCRIPTION	SIDE/SECONDARY EFFECTS THAT MAY INTERFERE WITH FUNCTIONING
Immunotherapy	A type of biological therapy that uses substances made from living organisms to treat cancer	<ul style="list-style-type: none"> • Skin irritation at needle site • Flulike symptoms • Swelling, weight gain

Adapted from the National Cancer Institute (2017). Types of cancer treatment.

Survivorship

For many people, the emotional relief of completing treatment may be accompanied by disequilibrium and fear of recurrence as they reorient their lives.²⁶ Many patients must manage long-term health consequences of cancer treatments and lingering problems with physical functioning, fatigue, and cognition as they attempt to return to “normal” life roles. Many people demonstrate resilience and report personal growth associated with cancer. A large number of people living with cancer, however, report poor mental and physical health-related quality of life compared to adults without cancer.²⁷

Palliative Care

Although most people who are diagnosed with cancer experience either a full recovery or live many years with cancer as a chronic condition,²⁸ those whose illness adversely affects daily functioning or is predicted to reduce life expectancy may receive **palliative care**. Palliative care is an interdisciplinary approach that optimizes quality of life and prevents or reduces suffering by addressing physical, emotional, spiritual, and social needs.²⁹ Palliative care is available from the time of diagnosis through cancer treatment and beyond, including the transition to end-of-life care and bereavement.²⁹

Occupational Therapy Evaluation and Intervention for People Living with Cancer

Occupational therapists employ a client-centered approach that is always central to occupational therapy services while considering the unique requirements of people with cancer. Patients with cancer have complex needs and priorities that can rapidly change, depending on illness severity, treatment response, and cancer stage. Patients often experience psychosocial, emotional, or existential distress that may impact their participation in therapy and daily occupations, and prompt a reevaluation of the roles and activities from which they derive life purpose.^{30,31} Especially during the treatment phase, patients tend to rely on health care providers, including occupational therapists, for information and emotional support.³² Finally, patients’ family members may have unmet needs of their own, including depression.³³ Occupational therapists revisit family members’ needs for information, support, and referral at various junctures of the illness trajectory.

Occupational Therapy Evaluation Procedures and Methods

The goal of the evaluation process is to develop the intervention plan, determine whether other services are needed, and begin to develop a therapeutic partnership. In this section, these processes are considered with specific implications for patients with cancer.

Initial Assessment Preparation

When a patient with cancer is referred to occupational therapy, the therapist obtains information from the medical record regarding the cancer diagnosis, including location, stage, diagnosis date, whether the cancer is a new diagnosis or recurrence, recent or current cancer treatment and side effects, and information about any comorbid conditions (e.g., arthritis, diabetes). Additionally, precautions such as immunosuppression, thrombocytopenia, isolation, and anemia are noted. Finally, the therapist reviews related documentation from other members of the medical or rehabilitation team to avoid service duplication.

Identify Patient Priorities and Resources

At the initial occupational therapy session, the therapist begins to learn more about the patient’s story. Patient priorities are identified along with the barriers, strengths, and resources that shape performance and possible progress. Therapists typically use structured interviews such as the Canadian Occupational Performance Measure³⁴ (COPM) to obtain information related to patients’ occupation-related goals and concerns. Therapists ask patients about the composition of their

social support network and allow the patients to determine whether and when to involve care partners in the evaluation process. These patient–therapist conversations are the foundation of both the assessment process and the development of therapeutic rapport.

Specify Problems and Impairments

Based on the abovementioned information, the therapist determines what if any impairment-specific assessments to administer to identify problem areas and establish baselines for progress and outcome measurement. Symptoms and impairments that are commonly assessed by occupational therapists with this population include fatigue, pain, cognitive functioning, range of motion (ROM), and physiological tolerance of activities. The examples of self-report instruments in the assessment table (at the end of this chapter) have established psychometric properties and are useful outcome measures for people with cancer. After administering symptom self-report questionnaires, therapists can then ask patients clarifying questions that will inform the intervention plan. For example, responses to a fatigue questionnaire may lead to a discussion about sleep hygiene or the impact of fatigue on home and work roles.

The evaluation approach for cognitive complaints will depend on the patient’s cancer location. For example, if the patient has cognitive or visual problems after surgical brain tumor resection, the cognitive evaluation will be similar to that used for patients with acquired brain injury (see Chapters 7, 9, 10, 36, and 37). If the patient reports concerns with memory and concentration after cancer treatment, a self-report questionnaire will help elucidate specific areas of concern and the extent of the problem.

Establish Goals for the Episode of Care

Occupational therapists collaborate with patients to establish therapy goals for the episode of care, which, in some instances, may be challenging. Patients who are in the midst of shock associated with a new diagnosis or have learned of a reoccurrence may not feel ready to set therapy goals. Occupational therapists may need to collaborate with other treatment team members during such time, including the patient’s family. Day-to-day performance may fluctuate due to fatigue, pain, and cancer treatment side effects, which may also lead to challenges with goal setting. Because patients’ goals and priorities may change rapidly, therapists must remain aware of patient’s priorities through frequent review and skilled communication.

Occupational Therapy Intervention Approaches

Occupational therapy intervention addresses a wide array of cancer-related problems (such as debility, fatigue, poor endurance, neuropathy, lymphedema, cognitive decline, UE impairment, balance, and pain)³⁵ and enables patients to learn to manage chronic symptoms or impairments as they resume occupational roles.³⁶

Arm function

Occupational therapists address limitations in arm function that result from cancer surgeries, especially for breast cancer, including restricted ROM, arm swelling, pain, numbness, peripheral neuropathy, and weakness.³⁵ Occupational therapists with specialized training in **lymphedema** management use techniques such as wrapping (Fig. 47-1), garment fitting, and teaching self-management techniques to treat lymphedema. Exercise as a means to help manage lymphedema is well documented, and therapists who are trained in lymphedema management can help assure that prescribed lymphedema garments do not restrict patients’ ability to effectively perform exercises.³⁷ An occupational therapy program for women with cancer-related lymphedema that incorporated exercise and education was found to result in improvements in UE swelling, arm ROM, quality of life, and mood.³⁸

Figure 47-1 An example of an upper extremity wrapping technique for lymphedema management performed by a certified lymphedema therapist. (© Allina Health System. Used with permission.)

Fatigue

Cancer-related fatigue (CRF) is a distressing symptom that often impacts the quality of life of many individuals with cancer during and after treatment. CRF is more than just a feeling of being tired and interferes with all aspects of daily life.³⁹ CRF is defined as an upsetting and enduring sense of physical, emotional, and/or cognitive exhaustion that impedes functioning and is inconsistent with recent activity levels. Seldom a solitary symptom, CRF involves concurrent symptoms such as pain, stress, low red blood cell count, and difficulty sleeping.⁴⁰ The multifactorial nature of CRF requires therapists to partner with the entire rehabilitation team to ensure that the emotional, cognitive, physical, and social aspects of CRF are addressed.⁴¹

The National Comprehensive Cancer Network (NCCN) recommends referral to occupational therapy for nonpharmacological CRF intervention.⁴⁰ These interventions emphasize physical activity and psychosocial and psychoeducational therapies. Recommendations also include the following self-management strategies⁴⁰: teaching patients to self-monitor fatigue levels, energy conservation, adaptive aide use, sleep hygiene strategies, arranging daily routines, and supporting participation in meaningful activities. Additionally, guidelines support the importance of normalizing CRF through patient and family education because symptoms can lead to fear of disease progression.⁴⁰ The occupational therapy literature further endorses the importance of exercise and other physical activity, problem-solving interventions, and cognitive-behavioral techniques for CRF.⁴² Occupational therapy fatigue management interventions that were developed for patients with other chronic conditions may be applicable to CRF.^{43,44}

Cognition

Cognitive changes occur in individuals with cancer as a consequence of the disease or cancer treatment. Patients with surgically resected brain tumors may experience cognitive decline similar to that of patients with other types of acquired brain injury. Occupational therapists use intervention approaches with these patients similar to those used for patients with stroke-related cognitive impairments (see Chapter 11). While patients with brain tumor experience cognitive limitations that are correlated with specific areas of brain damage, other patients (typically with breast cancer) may experience cancer-related cognitive dysfunction (CRCF; sometimes called chemobrain), which is thought to be multifactorial in origin. CRCF involves mild but disruptive changes in memory, executive functions, attention, and processing speed and has been reported in up to 30% of patients prior to any treatment and up to 75% of patients during or after treatment.⁴⁵ Possible mechanisms may be physiological (e.g., direct injury to brain tissue, oxidative stress and inflammation, cytokine dysregulation, microvascular injury) and/or psychological (e.g., styles of coping with stress, fatigue, depression).⁴⁶

CRCF can be acute or chronic and can affect quality of life and occupational performance related to ADLs, IADLs, and life roles. Cognitive effects can endure for years and adversely affect patients' quality of life and the ability to work and contribute to society.⁴⁷ Although there is still relatively little evidence to guide CRCF management, recent research supports the benefits of cognitive strategy training. Ferguson and colleagues found that intervention combining metacognitive strategy instruction (MSI) and cognitive-behavioral therapy (CBT) is feasible and can help patients with CRCF to manage cognitive challenges (see Evidence table at the end of this chapter).^{48,49} Wolf and colleagues used the Cognitive Orientation to daily Occupational Performance (CO-OP) approach, which included both global and domain-specific cognitive strategy learning. Participants experienced positive effects in subjective and objective cognitive performance and quality of life.⁵⁰ This chapter's Case Study illustrates how occupational therapists teach patients strategies to manage cognitive problems resulting from CRCF. There is no evidence to support the benefit or appropriateness of using commercial, computer-based cognitive exercises to improve everyday performance of people experiencing CRCF.

Peripheral Neuropathy

Chemotherapy-induced **peripheral neuropathy** (CIPN) describes sensory impairment of the peripheral nerves caused by neurotoxicity associated with many commonly used chemotherapy drugs. Symptoms vary depending on the severity and type of peripheral nerve involvement; people with prior neuropathy are more vulnerable. Patients report pain, numbness, and/or tingling. They may also experience cold intolerance. Motor symptoms occur less frequently and can include mild

weakness and decreased reflexes. Proprioception is often affected in the LE and is associated with balance and safety problems. Rarely, autonomic functions may be impacted, resulting in constipation and urinary and sexual complications. CIPN may increase fall risk and interfere with task performance because of balance and gait impairments, weakness, and sensory loss. Occupational therapists are included among the uniquely qualified rehabilitation professionals able to address both remedial and compensatory interventions to support patients impacted by CIPN.⁵¹

CIPN should be addressed early through a multidisciplinary approach, which may include a preventative approach before starting chemotherapy. For example, patients whose chemotherapy regimen puts them at risk for the development of neuropathy may prevent or lessen CIPN sensory symptoms by engaging in gentle movement like shoulder circles, marching in place, wiggling their toes, and performing sensory tactile stimulation (Fig. 47-2).⁵² Therapists should communicate with patients about their specific CIPN symptoms and the impact of these symptoms on daily life in order to guide interventions to improve safety, quality of life, and occupational function.⁵³ Therapists typically address the patient's unique functional and safety concerns (including fall prevention), adaptive equipment needs, psychosocial adjustment to the effects of CIPN, and physical performance needs.

Figure 47-2 An example of sensory tactile stimulation with mental awareness of where sensation feels “normal” and where it does not.

Patients with CIPN may have difficulty with buttoning, zipping, writing, cooking, sewing, home management tasks, exercising, and community mobility.⁵⁴ Occupational therapists use skill training and adaptive equipment to address these problems. Referral for driver's assessment and training may be indicated for some patients with CIPN with significant LE involvement.

Interventions targeting fall prevention commonly focus on functional mobility, ADL training, and home modification recommendations to support optimal engagement in daily-life roles. Stubblefield and colleagues proposed important home modifications and adaptive equipment needs.⁵⁵ Home modification recommendations may include maintaining clutter-free areas, removing throw rugs, using appropriate protection when handling hot and cold items, maintaining

safety with sharp objects, testing water temperature with thermometers or sensory-intact body areas, setting water heaters to below 120°F (49°C), and improving stairway safety through the installation of railings and lighting. Adaptive equipment may include built-up and nonslip handles, button hooks, and bathroom aides.

Interventions to improve physical performance can include edema control, exercise, pain management techniques, modalities such as transcutaneous electrical nerve stimulation (TENS) (if not medically contraindicated), and appropriate ROM and strengthening. Psychosocial adjustment can be enhanced through relaxation training and deep breathing.⁵⁶

Resumption of Everyday Activities and Roles

As described throughout this chapter, some patients living with cancer experience changed physical or cognitive capacities that interfere with the performance of everyday activities. Even patients with less obvious cancer-related disabilities may face challenges, resuming valued activities and roles related to exercise, work, nutrition, home and financial management, meal preparation, medication administration, and social activity.⁵⁷ Parents with cancer are typically very concerned about the welfare of their children and maintaining parenting activities.⁵⁸ Many patients worry about their ability to work; patients with cancer have lower employment rates and work fewer hours 2 to 6 years after diagnosis than adults of the same age.⁵⁹

The ultimate goal of all occupational therapy intervention is to support patients' engagement in valued activities and roles. To recap, this is accomplished through multiple approaches:

Skills Training and Equipment

As with other diagnostic groups, occupational therapists help reduce activity limitations by providing ADL, IADL, and transfer training to persons with cancer.³⁵ This may involve adaptive techniques, equipment, and optimizing access within the home, particularly for individuals receiving hospice or palliative care.⁶⁰ For example, a patient, Valeria, who was paralyzed by a spinal cord tumor, was taught to use adaptive dressing techniques similar to those used by patients sustaining traumatic spinal cord injury (see Chapter 39).

Strategy Instruction

Occupational therapists help patients learn and apply strategies to manage potentially chronic conditions such as CRF, CRCDD, and CIPN within the context of valued activities and roles. For example, Tom was concerned that CRF prevented him from interacting with his children at the end of a long workday. After exploring fatigue management strategies in occupational therapy, he shifted his work schedule so that he could engage in aerobic exercise (bike riding) with his daughters at the end of each workday.

Patients may also benefit from learning to use general strategies (not impairment specific) for goal setting and problem-solving, which enable them to address their own cancer-related concerns even after they have completed occupational therapy.^{61,62} For example, Lyons and colleagues taught patients with breast cancer to use a behavioral activation/problem-solving (BA/PS) strategy to help improve their performance of valued activities. Each week, participants selected an important but challenging activity to which they applied the BA/PS strategy, comprised of the following steps:

1. Determining why the activity was challenging
2. Setting a relevant 1-week behavioral goal
3. Creating and implementing an action plan
4. Reflecting on the outcome of the effort

A problem-solving procedure (identify solution, evaluate pros and cons, pick a solution) was inserted in the goal-setting process when participants did not immediately know which steps to take to meet their goals. Teaching patients to use general strategies such as BA/PS contributes to goal achievement and improvement in quality of life, coping, and planning for adults with cancer (see the Evidence table at the end of this chapter).^{62,63}

Interdisciplinary Rehabilitation Programs

Occupational therapists help patients resume roles and activities as part of multidisciplinary cancer rehabilitation programs, such as those designed to advance successful return to work through

education (including self-care), vocational counseling (such as gradual return to work), and/or physical exercise.⁶⁴

Supporting Wellness through Exercise

Exercise is important to long-term cancer self-management because it has beneficial effects on physical functioning, fatigue, and role and social functioning for patients actively receiving treatment for a variety of cancer types and those who have completed treatment.^{65,66} People living with cancer should aim to engage in 150 minutes of moderate-intensity aerobic exercise over 3 to 5 days per week and perform resistance training that involves major muscle groups at least 2 days per week.⁶⁷ Occupational therapists help patients restart or commence new exercise regimens that are tailored to their abilities and interests.⁴² Doing so involves helping patients evaluate their exercise options, and potential barriers and facilitators associated with establishing daily or weekly exercise routines. Clinicians may provide patients with a progressive walking schedule or help them explore activity options like yoga or Qigong. Patients who are severely deconditioned are often referred to specialized cancer exercise programs, but most patients engage in exercise programs in their homes or communities.

Conclusions and Recommendations

Patients benefit most from client-centered, context-informed, occupation-oriented approaches that assist them to overcome limitations posed by cancer-related impairments and to resume valued activities and roles. Occupational therapists who provide cancer rehabilitation services are privileged to share patients' uncertainty, sorrow, joy, and resilience in ways that expand and enrich their own growth and appreciation for the human experience. Beyond understanding content from this and other chapters in this textbook, occupational therapists who aspire to practice in this area must seek informal and formal ways to gain additional knowledge and expertise by, for example, reading the American Occupational Therapy Practice Guidelines for Cancer Rehabilitation⁶⁸ and/or becoming involved in the American Congress of Rehabilitation Medicine's Cancer Rehabilitation Networking Group.⁶⁹

Acknowledgments

Cynthia Cooper, MFA, MA, OTR/L, CHT, provided expert guidance on the peripheral neuropathy section, and we are most grateful.

CASE STUDY

Katerina is a 42-year-old Russian American woman who was diagnosed with stage II breast cancer. Acute treatment consisted of chemotherapy, single mastectomy with lymph node biopsy, and 5 years of hormone therapy. Reconstruction surgery is pending. Diagnostic brain imaging found no metastases. Katerina is married and has two young children. Her spouse travels for work, and she is responsible for childcare and household management. Katerina works part time as a high school paraprofessional.

Occupational Therapy Referral

An occupational therapy referral was made to address cognitive complaints affecting life roles.

Assessment and Treatment

At their first session, the occupational therapist conducted an informal interview to understand Katerina's prior level of function, current concerns, and limitations. Katerina's main concern was caring for her children. Most evenings, she had difficulty initiating anything. Her family had lost their evening routines, planning meals and cooking was difficult, and bedtimes were late and inconsistent. Katerina reported attention and memory errors. She missed several appointments owing to inconsistent use of her phone calendar. She was also distracted and reported losing her keys and purse. Katerina had started making lists but left them at home. Although she reported sleep problems resulting from arm discomfort, she refused medication to ensure that she could care for her children when her spouse traveled. Once approved by her doctor, Katerina wanted to return to work but worried that cognitive problems would be noticeable by coworkers. Additionally, she worried that she would not have sufficient energy to manage work and home.

Using the COPM,³⁴ Katerina identified her top priorities (average total performance score 5; satisfaction score 4):

- Consistent parenting
- Consistent household management
- Consistent care of self
- Energy to manage all of her life roles
- Information management plan for home and eventually for work

Katerina identified cognition and fatigue as interfering with optimal functioning, the latter of which was being formally evaluated in physical therapy. The occupational therapist administered the Functional Assessment of Cancer Therapy – Cognitive Function (FACT-Cog)⁷⁰ to understand and measure her cognitive concerns. Katerina's total score of 42/132 indicated that she perceived a decline in her thinking that affected her quality of life.

Finally, Katerina's UE was clearly swollen and reportedly painful. Appreciating the need for specialized expertise, the occupational therapist requested doctor's orders for an evaluation by one of the department's lymphedema specialists.

Occupational Therapy Problem List

- Disrupted sleep and fatigue
- Disrupted routines
- Decreased attention and memory
- Disorganized information management

Occupational Therapy Goal List

Katerina's occupational therapy goals (that follows) centered on cognition and fatigue management to improve care of others and self, appreciating that improvements were central to longer term aspirations to return to work.

- Consistently employ bedtime routines for herself and children, evidenced by going to sleep and waking at the same time 5 of 7 days, 4 of 4 weeks.
- Effectively manage fatigue throughout the day/week by prioritizing tasks and initiating breaks using smartphone alarm cues.
- Independently and consistently manage appointments on her smartphone calendar with alarms, evidenced by no missed appointments.
- Independently support her memory with notes/lists.

Intervention

Katerina attended five additional outpatient occupational therapy sessions over a 3-month period. In the first session, the therapist explained to her that many factors were competing for her cognitive energy. The therapist asked guided questions helping Katerina determine that sleep hygiene and consistent meal preparation were key preliminary priorities. In addition to providing sleep hygiene information, the therapist helped Katerina create a bedtime checklist that included preparing for the next day, transitioning away from electronics, and maintaining consistent bedtimes for everyone. The task of cooking was manageable, but Katerina struggled due to end-of-day fatigue. She was able to see the value in advanced meal planning and shared that she had considered online grocery shopping. For her homework, Katerina agreed to implement the bedtime checklists, plan 1 weeks' worth of meals, and trial online shopping.

During her second session, Katerina discussed her strategy use over the past week. She found the bedtime routines, meal planning, and online shopping beneficial and opted to continue them. Because Katerina still struggled to manage all of her life demands, the therapist introduced the concept of an "energy budget." Katerina was able to understand that she needed to manage her energy consistently and effectively to perform optimally. She could clearly see that taking breaks throughout her day could help her more successfully manage evening tasks. Katerina was not accustomed to taking breaks and knew that she would need time to change her behavior. With guidance from her therapist, she created a weekly activity template for reoccurring tasks to pace her chores throughout the day/week and decrease fatigue. Katerina observed that she wasted time and energy worrying about possible missed appointments. She

created a weekly and daily planning checklist to ensure that key tasks and family appointments were stored in her phone calendar with alarm reminders. This allowed her to observe her week in its entirety, consider her energy budget, and determine whether her plans were realistic and sustainable. Katerina’s homework for the week included implementation of weekly/daily planning procedures; following her activity template with adjustments to meet her energy needs; and continued use of sleep routines, meal planning, and online shopping.

The third session started with a weekly review and discussion regarding strategy use and effectiveness. Katerina was habitually using the bedtime routines, organizational checklists, and meal planning strategies. She had made meals 5/7 days last week with positive results. The daily/weekly routine list she developed was not working, and she was unable to complete listed tasks. The therapist introduced a prioritizing strategy to help Katerina identify the tasks and appointments that needed to occur and those she could postpone or delete. As she predicted, Katerina was not good at taking breaks. She set alarms on her phone but ignored them. With cues from her occupational therapist, Katerina understood that a break could be more than a nap and generated a list of 10 possible breaks she might take (e.g., 5-minute walk, deep breathing exercises) and agreed to implement these in the coming week. Katerina was overwhelmed and requested that her next appointment be conducted in 2 weeks to provide sufficient time to use the strategies and routines.

Katerina arrived at her fourth appointment appearing well-rested. She reported consistent sleep hygiene and improved sleep quality. She also consistently completed her daily and weekly routines. Katerina had recently attended several social events in which she had difficulty following multiple conversations and remembering things when interrupted. In anticipation of her next outing, she decided to rest prior to the event and store a list of attendees in her phone to remember names. The therapist and Katerina discussed different tasks she could practice over the next 2 weeks to challenge her activity tolerance and higher level attention skills. Katerina decided to volunteer at her children’s school 2 days per week for 4-hour time slots.

Session five began with a reflection of Katerina’s past 2 weeks. She remained consistent in her daily/weekly routines, reported feeling more energetic and mindful of managing her energy budget, and expressed that her confidence was higher after successfully volunteering in the classroom. Katerina did note some errors when she was interrupted, prompting her therapist to introduce information about attention levels and strategies she could use to manage classroom demands. Overall, Katerina reported feeling more confident in her ability to return to work, which would be determined with her physician at an upcoming appointment. Katerina and her therapist decided to schedule a follow-up session in 1 month. Her homework included continued strategy use and intentionally increasing her activities and attention demands during the day.

Katerina attended her final occupational therapy session 1 month later at which she reported independence and confidence in care of self, her children, and home tasks. She had increased her volunteer hours at the school to 4 hours per day, 4 days per week, and was tolerating it well. Katerina felt ready to return to part-time work. Her therapist helped her anticipate challenges she might encounter at work and identify strategies she could use to ensure accurate performance. For example, Katerina created an arriving-at-work and leaving-work checklist in order to reinstate these habit sequences. She blocked her lunch hours to ensure that she had time for proper nutrition and intentional rest. The COPM was readministered, and Katerina’s performance score had increased from 5 to 8; satisfaction score from 4 to 7. Her FACT-Cog had improved from 42 to 104/132. Katerina met her goals and was discharged.

Examples of Cancer-Specific Self-Report Assessments

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
--------------------------	------------------	---------------------	----------	-------------	-------------	--------------------------

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Functional Assessment of Cancer Therapy – Cognitive Function (FACT-Cog) ⁷⁰	To measure perceived cognitive issues specific to CRC and the impact on quality of life involving four subscales: perceived cognitive impairment (PCI), impact on quality of life, comments from others, and perceived cognitive ability (PCA)	10 min	Construct validity: Breast cancer survivors rated their cognition (47%) and quality of life (53%) as greater than 1 standard deviation below that of pre-chemotherapy control group. ⁷¹ Convergent validity: PCA scores appear to be highly correlated with objective neuropsychological performance in verbal memory and executive functioning in BCS. ⁷²	Acceptable levels of internal consistency for English- and Chinese-speaking patients (Cronbach's alpha 0.707–0.929) ⁷³ Acceptable test–retest reliability for English and Chinese versions (interclass correlations of 0.762 and 0.697, respectively) ⁷³	Minimal clinically important difference for breast cancer patients ranged from 6.9 to 10.6 points (4.7%–7.2% of the total score). ⁷⁴	Strengths: 37 items that describe functional cognitive concerns, developed for cancer population, short administration time. Limitations: Somewhat limited psychometric; variable association between self-report and performance on cognitive assessments.
National Comprehensive Cancer Network Distress Thermometer and Problem List (DTPL) ⁴⁵	To identify psychological distress	Approximately 5 min for patients to fill out; at least 10 min for provider to discuss responses with patient, if there are areas of concern	Convergent validity: Moderate positive correlation between DTPL and Brief Symptom Inventory ($r = 0.59$, $p < 0.001$) ⁴⁶	Acceptable test–retest reliability ($r = 0.800$, $p = 0.000$) ⁷⁵	77.1% sensitivity and 66.1% specificity to detect cancer-related distress; 80.9% sensitivity and 60.2% specificity to detect depression ⁷⁶ A cutoff score of 3 indicates patients with clinically elevated levels of distress. ⁷⁷	Strengths: objective, structured distress screening; consistent means for prioritizing and triaging to supportive care services ⁷⁸ Weaknesses: options provided in the Problem List may not encompass all critical issues experienced by patients; 0–10 scale may be too simplistic and does not give enough insight into patients' concerns ⁷⁸
Brief Fatigue Inventory (BFI) ⁷⁹	To assess the severity of fatigue, including interference in daily living	5 min	Construct validity: BFI was significantly correlated with both the Functional Assessment of Cancer Therapy (FACT) ($r = -0.88$, $p < 0.001$) and the Profile of Mood States (POMS) ($r = 0.84$, $p < 0.001$) Fatigue subscales.	High levels of internal consistency (Cronbach's alpha = 0.96)	There is evidence of BFI sensitivity as cancer patients reported a higher fatigue rating when compared to healthy control participants.	Strengths: Developed for cancer patients; short administration time; high construct validity and reliability. Weaknesses: Does not collect information such as the cognitive, affective, and somatic aspects of fatigue.

Evidence Table of Intervention Studies Supporting Occupational Therapy for Patients with Cancer

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Memory and attention adaptation training (MAAT) ³⁸	A brief CBT approach that included education about memory, attention, relaxation training, and a variety of other compensatory strategies	Breast cancer survivors, $n = 22$ (MAAT) and $n = 13$ (control condition, support therapy); Median age = 54.6 years; No significant difference in groups' age, education, or IQ.	Participants in both conditions received 8-weekly visits, 30–45 minutes each that were delivered via videoconference. Both treatments were delivered via videoconference.	Randomized controlled trial Assessed at baseline, after treatment, 2 months later Level I	MAAT participants made significant gains in self-reported cognitive impairments and cognitive processing speed at 2-month follow-up. Anxiety related to cognitive challenges decreased. Attended treatment for cognition via video teleconferencing that they may not have attended if they had to drive.	PCI: - Trend toward statistically significant group differences in PCI at posttest ($p = 0.09$) - Statistically significant differences in PCI at 2-month follow-up ($p = 0.02$) with a medium effect size ($d = 0.52$) Anxiety about cognitive problems: - Similarly, no significant posttest group differences with respect to anxiety and cognitive problems in daily life ($p = 0.77$) - Trend toward statistically significant differences in anxiety at 2-month follow-up ($p = 0.09$) with large effect size ($d = 0.90$)

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
One-to-one fatigue management course for people with chronic conditions ⁴⁴	Course consists of five modules: (1) Basics of Fatigue, (2) Communication and Fatigue, (3) Body Mechanics and Making the Most of Your Environment, (4) Analyzing and Modifying Activities, and (5) Living a Balanced Lifestyle. Participants were given homework to apply the principles learned to their daily life.	<i>n</i> = 49 (35 women and 14 men) from outpatient and community-based settings Ages 35–77 years (average 56.4); diagnosis of chronic disease (71.4% had a primary diagnosis of multiple sclerosis), moderate-to-severe fatigue.	1–2 hours for 4–6 sessions until all content was covered.	One-group, pretest–posttest, follow-up design Level III	Participants demonstrated a significant decrease in fatigue and increase in self-efficacy and quality of life, except in social well-being after taking the course.	Significant within-subjects effects were found for fatigue (FACIT-FS [<i>p</i> = 0.001]), quality of life (FACT-G total score [<i>p</i> = 0.021]), and self-efficacy (SEPECSA [<i>p</i> = 0.001]). Scores on three of the four FACT-G subscales were significant: Physical Well-Being (<i>p</i> = 0.002); Emotional Well-Being (<i>p</i> = 0.007); Functional Well-Being (<i>p</i> = 0.024). No significant within-subjects effect was found for the Social Well-Being subscale (<i>p</i> = 0.535).
Breast Cancer Recovery Program (BCRP) for lymphedema	Consisted of education regarding lymphedema management and instruction in relaxation techniques (deep diaphragmatic breathing, progressive muscle relaxation). Controls received usual medical care.	Women with stage I or II unilateral breast cancer–related lymphedema (BCRL) with ≥10% increased affected arm size compared with unaffected arm (16 in each group)	Ten biweekly, 1-hour sessions for 5 weeks	Randomized controlled trial Level I	Those receiving BCRP demonstrated significant treatment effects (extracellular fluid, arm flexibility, ROM, and mood) compared to controls.	Extracellular fluid in affected arm (measured via bioimpedance): <i>p</i> = 0.049, <i>r</i> = 0.43 Total shoulder active ROM: <i>p</i> = 0.034, <i>r</i> = 0.50 Mood as measured by Beck Depression Inventory: <i>p</i> = 0.03, <i>r</i> = 0.41 Quality of life as measured by SF-36: <i>p</i> = 0.03, <i>r</i> = 0.52 (general health)

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Behavioral activation and problem-solving (BA/PS) treatment ⁶⁷	The BA component involved a four-step process for goal planning and implementation. The three-step PS component was added when a participant had a goal, but did not know what action to take. Each week, participants applied BA/PS to 1–2 of their challenging activities to establish relevant weekly goals.	<i>n</i> = 31 women who self-reported functional limitations within 6 months of completing chemotherapy for stage I–III breast cancer (ages 18–60)	One-to-one telephone-delivered sessions (once per week for 6 weeks with 3-monthly follow-up sessions for study 1; 6-weekly sessions for study 2)	Two 1-group, pretest–posttest feasibility studies, the second of which included a no-treatment run-in phase Level III	66% of the participants completed all study activities and were highly satisfied with the intervention. Participants met 64% of the goals they set and showed pre–post improvements in quality of life, depression, anxiety, and coping.	Results of repeated-measures approach to linear-mixed modeling to explore main effects: Overall quality of life (<i>F</i> [5, 43.1] = 5.1, <i>p</i> = 0.001) Depression (<i>F</i> [5, 51.2] = 6.0, <i>p</i> < 0.001) Anxiety (<i>F</i> [5, 47.6] = 4.4, <i>p</i> < 0.002) Active coping (<i>F</i> [3, 31.7] = 4.9, <i>p</i> < 0.007) Planning (<i>F</i> [3, 36.0] = 4.1, <i>p</i> < 0.01) Reframing (<i>F</i> [3, 29.3] = 8.5, <i>p</i> < 0.001) Self-blame (<i>F</i> [3, 31.6] = 4.3, <i>p</i> < 0.01)

Burn Injuries

Rebecca Ozelie

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the differences between superficial, superficial partial-thickness, deep partial-thickness, and full-thickness burn injuries.
2. Explain the rationale for splinting and positioning programs for patients with burn injuries.
3. Identify occupational therapy interventions for each phase of burn recovery.
4. Describe potential complications after a burn injury and how they can impact occupational performance.
5. Discuss the effects of a burn injury on a patient's psychosocial functioning.

CHAPTER OUTLINE

Introduction
Burn Classification
Total Body Surface Area
Phases of Burn Management and Rehabilitation
Reconstructive Surgery
Return to Work
Special Considerations for Hand Burns
Future Directions
Case Study

TERMINOLOGY

- Antideformity positions:** positions opposite to common patterns of deformity used to prevent contractures.
- Blanching:** applying sufficient pressure to interrupt blood flow temporarily; used as an assessment of capillary flow rate.
- Debriding:** removing eschar and loose or necrotic tissue to prevent infection and promote healing.
- Dermis:** layer of skin below the epidermis that contains blood vessels, nerve endings, hair follicles, and sweat and oil glands; supports the regrowth of new epithelial tissue.
- Epidermis:** most superficial layer of the skin; acts as a barrier; it is continually sloughed and replaced.
- Pruritus:** severe itching of the skin.
- Total body surface area (TBSA):** assessment of the amount of injury to the skin after a burn injury.
- Wound contracture:** part of normal healing in which myofibroblasts in the wound bed contract to minimize the skin defect.
- Z-plasty:** surgical procedure in which a Z-shaped incision is made and tissue is transposed to increase tissue length.

Introduction

Approximately 486,000 burn injuries required medical treatment in the United States in 2016 and 3,275 people died from fire and smoke inhalation.¹ The ABA National Burn Repository from 2005 to 2014 reported the burn survival rate is 96.8%—the majority of burns in adults occur in males (68%); the most common cause of burns is fire/flame (43%); and most burns occur in the home (73%), followed by injuries in the workplace (8%).² Over 60% of patients with burn injuries are admitted to 128 regional burn centers designated by the American Burn Association; the remainder are treated at local or regional hospitals.¹ Therefore, every occupational therapist should understand the principles of care and rehabilitation of patients with burn injuries.

Burn Classification

In the past, burn depth was classified as first, second, or third degree. Today, the preferred classification terminology more accurately describes the level of cellular injury. The terms used are superficial, superficial partial-thickness, deep partial-thickness, and full-thickness (Fig. 48-1). Burns can have mixed depths, which necessitates that the burn team carefully assess the appearance and progress of each area of the wound site. Disruption of any portion of the skin has the potential to interfere with its normal functions, which include temperature regulation, fluid regulation, and its role as a physical barrier to infection.³ Occupational therapists may treat patients with all depths of burn injuries. It is important to differentiate and understand the implications of each classification in order to plan the most effective interventions as wound healing and long-term outcomes are often determined by burn depth.

Figure 48-1 Skin anatomy status postburns.

Superficial Burns

Superficial burns damage cells only in the **epidermis**⁴ (see Fig. 48-1). These injuries are dry, painful, and red. With a well-nourished and intact epithelial bed at the base of the hair follicles, these injuries heal spontaneously within approximately 7 days and leave no permanent scar. Sunburn is an example of a superficial burn.

Superficial Partial-Thickness Burns

Superficial partial-thickness burns damage cells in the epidermis and the upper level of the **dermis**.⁴ The most common sign of a superficial partial-thickness burn is intact blisters over the injured area.⁴ Hair follicles remain intact because these are found in the deeper layers of the dermis. In addition, these injuries are painful because of the irritation of the nerve endings in the dermal layer. Superficial partial-thickness burns usually heal spontaneously within 7 to 21 days and leave minimal or no scarring.

Deep Partial-Thickness Burns

Deep partial-thickness burns cause cell injury in the epidermis and severe damage to the dermal layer.⁴ These injuries appear blotchy, with areas of whitish color

interspersed throughout the wound, which is the result of damage to the blood vessels in the dermal layer.⁴ The injury site is painful. Spontaneous healing of deep partial-thickness burns is sluggish (3–5 weeks) because vascularity in the dermal layer is impaired. Therefore, the risk of significant scarring is increased. For this reason, deep partial-thickness burns are often grafted to expedite healing and minimize scarring.

Full-Thickness Injury Burns

In a full-thickness injury, both the epidermis and the dermal layer are destroyed.⁴ These wounds appear white or waxy because of the underlying adipose tissue and are inherently insensate because of the complete destruction of the dermal nerve endings.⁴ Full-thickness burns require surgical intervention, such as skin grafting, because there are no dermal elements to support the regrowth of epithelial tissue. Some burns, such as electrical burns, may damage structures below the dermis, including subcutaneous fat, muscle, or bone.

Total Body Surface Area

An estimation of burn wound size is defined as **total body surface area (TBSA)** is critical for effective early burn management. The burn percentage TBSA is used for the following:

- Calculating nutritional and fluid requirements
- Determining level of acuity to establish the level of medical treatment needed (e.g., admission to a burn center)
- Guiding clinical treatment decisions
- Predicting mortality outcomes

There are three common methods health care providers use to estimate a burn survivor's TBSA; the "rule of nines," the "rule of palms" and the "Lund–Browder chart." The rule of nines is a commonly used technique in adults (see Fig. 48-2). For example, if an adult received a burn that included the anterior and posterior surfaces of his right arm (9%), his anterior head and neck (4.5%), and his anterior chest (18%), then his TBSA affected would be 31.5%. To determine the TBSA of a burn injury in children and infants, a modification of this technique, the Lund–Browder chart, is used. In addition, in both children and adults, the palm method is also used to estimate TBSA. The palm method estimates that the palmar surface of one's hand is approximately 1% TBSA. These current methods do have some limitations and burn injuries are often over- and underestimated.⁵ This can lead to ineffective patient care and decreased burn unit efficiency. More technologically advanced methods are currently being used and studied. Recently, the use of three-dimensional imaging has been found to be superior to the rule of nines and palm method.⁶

Figure 48-2 Rule of nines.

Phases of Burn Management and Rehabilitation

Identifying specific phases of burn management helps to describe the role of occupational therapy (OT) for patients with burn injuries. These include the emergent, acute, and rehabilitation phases. Each of the phases, along with accompanying OT considerations, are described.

Emergent Phase

The emergent phase of a burn injury is considered to be from initial injury to approximately 72 hours after the burn.⁷

Medical Management

During the emergent phase, the medical team attempts to stabilize the patient. This may include fluid resuscitation, establishment of adequate tissue perfusion by means of mechanical ventilation, and achievement of cardiopulmonary stability. Associated injuries, such as fractures, are also evaluated and treated during this time.

Inhalation Injury

An important consideration in the emergent phase is the possibility of an inhalation injury. An inhalation injury damages the supply of oxygen to the body due to significant edema of the upper respiratory tract, chemical irritation of the lower respiratory tract, and injuries resulting from systemic effects of carbon monoxide and cyanide.⁸ Inhalation injuries are associated with the requirement of mechanical ventilation, secondary pneumonia, and acute respiratory distress syndrome.⁸ About 1 in 10 patients admitted to burn centers are reported to have an inhalation injury and those with inhalation injuries experience an increase in mortality rate.⁸ This increase in

mortality rates makes an accurate diagnosis and treatment imperative. A history of smoke exposure in confined spaces and prolonged rescue, singed eyebrows, soot around the nostrils, facial edema, and voice changes are some physical indications of an inhalation injury. Diagnosis is confirmed by analysis of arterial blood gases, chest radiographs, and fiberoptic bronchoscopy. Medical management of an inhalation injury often includes supportive respiratory care including mechanical ventilation and bronchial hygiene.

Compartment Syndrome

Circulation can be compromised when burn injuries encircle a body segment. This is due to the inelasticity of the eschar (burned tissue) combined with increased internal pressure within fascial compartments. Local increase in pressure within the compartments of the extremities compresses blood vessels and reduces blood flow,⁹ which results in what is known as compartment syndrome. If the pressure is not relieved, ischemia and necrosis may result. Symptoms of increased compartmental pressure include paresthesias, coldness, and decreased or absent pulses in the extremities. In the trunk, inelastic eschar can act as a corset, limiting lung expansion and preventing adequate respiration. Diagnosis of compartment syndrome is determined with use of Doppler ultrasound and pulse oximetry. Surgical intervention (escharotomy and/or a fasciotomy) is required to relieve the pressure and prevent tissue death (see Fig. 48-3). An escharotomy is a surgical incision through the eschar, whereas a fasciotomy is a deeper incision extending through the fascia.

Figure 48-3 Fasciotomy.

Dressings

After the initial burn assessment, the medical staff will clean, debride, and dress any wound areas (see Fig. 48-4). The functions of dressings include protecting the wound against infection, maintaining a protective environment, and facilitating normal wound healing. With dressings, topical agents are used and can vary widely, although most are wide-spectrum antimicrobials. Examples include agents that contain silver (Aquacel AG), nano-crystalline silver (Acticoat), cadexomer iodine (Iodosorb), or synthetic antimicrobial (LLKKK18).¹⁰ These antimicrobials serve to keep the level of bacterial colonization of a wound at a manageable level. It is also a common practice for wounds to be debrided or excised to remove devitalized tissue from the wound site. Debridement or excision of the wound is done by medical personnel. Debridement of blisters is controversial. Leaving blisters intact is thought to provide a positive wound

healing environment, reduction in pain, and enhanced cell proliferation.¹¹ Those in favor of **debriding** blisters by eliminating the underlying fluid feel that the fluid can serve as a medium for bacteria.¹² The medical personnel will also make the decisions as to what dressing and topical agent is most appropriate for each patient. Although it is often the nursing staff who change the dressings, it is appropriate for occupational therapists to routinely or periodically participate in dressing removal and application as it provides opportunities to view the healing wounds. This allows the therapist to monitor healing and adjust the therapy program accordingly.

Figure 48-4 Wound cleaning and dressings.

Infection Control

One of the functions of the skin is to act as a barrier against infection.¹³ Therefore, a patient with a burn injury is highly susceptible to infection, and infection is the most common cause of morbidity and mortality in patients with burns.¹⁴ It is essential that all staff, family, and visitors adhere to strict infection control procedures. This includes washing hands frequently, using gloves when necessary, and avoiding cross-contamination through instruments and equipment.

Contracture Formation

Patients with burn injuries are at significant risk for contractures. Contractures tend to occur in predictable patterns, usually flexed, shortened positions (e.g., elbow flexion, shoulder adduction, or knee flexion) and can considerably limit the patient's ability to perform activities of daily living (ADLs). The shoulder has been found to be the most frequently contracted joint followed by the elbow, wrist, ankle, and knee.¹⁵ In a recent Burn Model System National Database study, 33% of burn survivors developed at least one contracture with an average of three contractures per person.¹⁵ Contractures are defined as abnormal shortening of muscle tissue, rendering the muscle highly resistant to stretching. It can be caused by fibrosis of the tissues supporting the muscle or the joint. It is important to note that **wound contracture** is a normal physiological response of the initial wound closure and healing process and subsequent scar contracture may occur as the scar matures.¹⁶ Research of the biological principles of

scar and contracture formation suggest forces applied to wounds as they heal will increase fibrosis and therefore contracture formation. Kwan and Tredget¹⁶ advise that relieving forces to healing wounds may reduce scarring and contractures.

OT during the Emergent Phase

During the emergent phase, the occupational therapist performs an initial evaluation of the patient's needs. A full evaluation may be deferred until after the emergent phase, when the patient is more medically stable. During the screen, the therapist notes the distribution of the burn, burn type and depth, and which joints are involved. This allows the occupational therapist to establish an appropriate splinting and positioning program. It is also during this time that the therapist begins completing an occupational profile of the patient to determine preadmission functional status, roles, interests, and social supports.

OT intervention in the emergent phase focuses on the prevention of early contracture formation through the use of splints and positioning programs. It is ideal to initiate OT intervention as early as 24 to 48 hours after burn because collagen synthesis and contracture formation begin during the initial response to a thermal injury.¹⁷

Splinting

Ideally, splints are fabricated and applied in the initial visit, and a positioning program is established and communicated to the team. Table 48-1 describes common contracture patterns, antideformity positions, and appropriate splints. Generally, any joint involved in a superficial partial-thickness injury or worse has the potential for contracture and is usually splinted. Splint wearing times are determined by the patient's tolerance to the splint and functional ability to use the involved extremity. That is, a decrease in active movement of the involved limb indicates the need for increased splint wearing time to prevent potential contractures. For example, a heavily sedated patient cannot perform active movement and therefore requires splinting at all times, except for therapy and dressing changes. An alert patient who can use his or her affected extremity for functional tasks, such as self-feeding or prescribed exercises, may require the use of splints only at night. Splints are applied over the burn dressing and secured with either gauze wrap or Velcro straps. Although splinting is considered the standard of care in burn treatment, there is a paucity of evidence to support its use.¹⁸ Validation of the practice of splinting for the prevention of contracture is a research area that may be addressed by occupational therapists in the future.

Table 48-1. Anticontracture Positioning by Location of Burn

LOCATION OF BURN	CONTRACTURE TENDENCY	ANTICONTRACTURE POSITIONING AND/OR TYPICAL SPLINT
Anterior neck	Neck flexion	Remove pillows; use half-mattress to extend the neck; neck extension splint or collar
Axilla	Adduction	120° abduction with slight external rotation; axilla splint or positioning wedges; watch for signs of brachial plexus strain
Anterior elbow	Flexion	Elbow extension splint in 5°–10° flexion
Dorsal wrist	Wrist extension	Wrist support in neutral
Volar wrist	Wrist flexion	Wrist cock-up splint in 5°–10° extension
Hand dorsal	Claw hand deformity	Functional hand splint with MP joints 70°–90°, DIP joints fully extended, first web open, thumb in opposition (safe position; see Chapter 37)
Hand volar	Palmar contracture cupping of hand	Palm extension splint MPs in slight hyperextension
Hip-anterior	Hip flexion	Prone positioning; weights on thigh in supine; knee immobilizers

LOCATION OF BURN	CONTRACTURE TENDENCY	ANTICONTRACTURE POSITIONING AND/OR TYPICAL SPLINT
Knee	Knee flexion	Knee extension positioning and/or splints; prevent external rotation, which may cause peroneal nerve compression
Foot	Foot drop	Ankle at 90° with foot board or splint; watch for signs of heel ulcer

MP, metacarpophalangeal; DIP, distal interphalangeal.

Positioning

Antideformity positioning, which is used as an adjunct to splinting for prevention of contractures, can be initiated in the first visit. For example, if a patient is unable to be fitted with a custom wrist extension splint, supporting the hand on a rolled pillow can, at least temporarily, maintain appropriate joint position. Another example is removing pillows under the patient's head to limit the amount of neck flexion and potential for contracture. Positioning to elevate the upper extremities can also help to minimize upper extremity edema. Elevation can be done with foam wedges, pillows, or specialized arm troughs attached to the bed. A risk of elevating the upper extremity is the potential for brachial plexus strain.

Acute Phase

The acute phase begins after the emergent phase and continues until the wound is closed, either by spontaneous healing or skin grafts.⁷ The acute phase can last several days to several months, depending on the extent of the burn and the amount of grafting required. For example, a patient with a 10% TBSA may have an acute phase of 1 week, during which the patient is mobile and undergoes one excision and grafting procedure. However, a patient with a 70% TBSA burn may be in the acute phase for several weeks, during which the patient is in an intensive care unit and undergoes many grafting procedures to close the wounds.

Support and Psychosocial Adjustment in the Acute Phase

Most patients with burn injuries report some symptoms of anxiety, depression, and even posttraumatic stress disorder after injury.¹⁹ Several factors have been identified as risk factors for poor adjustment and postinjury onset of psychological disorders. These include preburn affective disorders, burn injury size and location, level of pain, dispositional variables, and avoidance of coping.¹⁹ The psychosocial challenges of burn patients vary as the patient moves through each stage of physical recovery.²⁰ Patients in the acute stage deal with issues of depression and anxiety and may begin to exhibit signs of both acute and posttraumatic stress disorder. Also at this time, any preinjury psychopathology may become more apparent.²⁰

LeDoux et al.²¹ state that the burn team can foster healthy coping strategies while working with the burn patient by using the following techniques:

1. Identify strengths that each patient can emphasize, reminding him or her of the strength already involved in surviving a painful and frightening experience.
2. Validate sadness and fear.
3. Assist patient to achieve goals; this helps to show hope for the future.
4. Instill a belief that the patient can succeed.

It is also important to note that persons with burn injuries have been found to have a higher rate of mental illness before their burn injury.²² This knowledge should cue occupational therapists working with patients with burns to critically assess for psychological needs, develop a plan of care, and work interprofessionally to meet the needs of their patient.

Team Communication

Communication with all members of the team, including the patient and the patient's family and/or support system, throughout hospitalization is essential. During this acute phase, collaboration between the occupational therapist and the burn team is essential for several reasons, including the following²³:

1. Alerting the team to developing contractures and response to therapeutic intervention
2. Planning for perioperative splinting
3. Clarifying range-of-motion orders based on graft integrity
4. Teaching the team about environmental modifications or communication systems
5. Advocating on the patient's behalf regarding eventual outpatient needs

Medical Management

Skin grafting, which occurs primarily in the acute phase when the patient is medically stable, is required when the dermal bed is sufficiently destroyed to prevent or significantly impair spontaneous regrowth of the epithelial tissue.²⁴ Skin grafting is generally performed for all full-thickness burns and for large, deep partial-thickness burns. Skin grafting entails both excision of necrotic (dead) tissue and the placement of skin or a skin substitute over the wound bed.

Types of Grafts

A variety of grafting procedures are available. According to the size of the burn, availability of donor sites and medical stability of the patient, the team may opt to use one or more of the graft types described below.

- **Autografts:** Skin harvested from an unburned area of the patient is an autograft. Split-thickness autografts are considered the current gold standard.²⁵ Split-thickness autografts are taken at the level of the mid-dermis and allow for regeneration of epidermis. Donor sites are ideally selected for the best match of color and texture to the affected area. Donor sites may produce scarring and can be painful. Donor sites often will require scar management techniques similar to the burn site. The harvested skin can be left as a solid sheet (sheet graft) or perforated to increase the surface area (meshed graft) (see Fig. 48-5). Meshing allows the surface area of the harvested skin to cover up to one and half to nine times the original area.²⁶ Both sheet and meshed grafts have advantages and disadvantages. A sheet graft has the best cosmetic outcome and is thus preferred for the face and hands.²⁷ Infection and the development of hematoma under a sheet graft, however, can cause complete graft loss and require regrafting. A meshed graft may be less cosmetically appealing as the meshed pattern is retained permanently and can result in severe scarring.²⁸ The meshed graft is advantageous, however, as it covers large areas when the donor site is limited and allow drainage of blood and exudate, which prevents hematomas and improves graft adherence.²⁷

Figure 48-5 Meshed graft to lower extremity.

- **Skin substitutes:** In cases of extensive burn injuries, where there is not sufficient donor skin to cover all of the affected area with autograft, the burn team may opt to use a variety of skin substitutes. These skin substitutes can be either biologic, such as allografts or xenografts (from cadaver and bovine skin, respectively), or synthetic, such as Biobrane comprising nylon and silastic. These dressings aid in wound management by decreasing infection, stimulating healing, preparing the wound bed for autograft skin, decreasing pain, and protecting exposed tendons, nerves, and blood vessels.²⁹

OT during the Acute Phase

During the acute phase, the occupational therapist performs a detailed initial evaluation. This includes a thorough chart review including a review of the past medical history. Associated diagnoses that may limit occupational performance, such as psychiatric illness, diabetes, or lung disease, are to be accounted for during OT treatment planning. Areas specifically assessed by the occupational therapist during the initial evaluation include client factors (e.g., mental functions, cognitive skills, communication and social skills, sensory functions, neuromusculoskeletal and movement-related functions, joint mobility/stability, and muscle strength/tone/endurance) and ADL and instrumental activities of daily living (IADL) performance. It is important to document specific range-of-motion (ROM) and manual muscle test (MMT) measurements for any involved joints as a baseline during the evaluation. This will allow the clinician to reassess and document progress along the course of treatment.

Evaluation can consist of standardized outcome measurements such as the Patient and Observer Scar Assessment Scale, the Disabilities of the Arm, Shoulder, and Hand Score (DASH), the Brief Burn Specific Health Scale (BSHS-B), the ICF Core Sets for Hand Conditions, the Jebsen–Taylor Hand Function (JTHF) Test, observation during task performance, and interviews with the patient and family. The potential for permanent scarring and disfigurement may cause significant anxiety and limit the patient's ability or motivation to participate in rehabilitation. Thus, early assessment of the patient's support systems allows the therapist to identify resources that may aid in early patient motivation and goal setting.

Because of the acute medical nature of many burn injuries, OT intervention in the acute phase may focus on client factors such as ROM and strength. These can be

addressed through preparatory methods and tasks such as continued splinting, positioning, therapeutic exercise, and through occupations and activities. Whenever possible, activities in treatment should reflect each patient's interests and occupations. Other potential treatment activities include environmental modifications, pain remediation, and patient and family education. In the acute phase, the individual's ability to participate in treatment related to self-care and functional retraining is often limited by complex medical issues. These areas are addressed in more detail during the rehabilitation phase.

Splinting and Positioning

During the acute phase, the splinting and positioning programs established in the emergent phase are continually monitored and adjusted. Splinting schedules are adjusted according to the individual's ability to participate in activities. For example, if a patient consistently uses an affected elbow for self-feeding and ADLs during the day, decreasing the wearing time for the elbow splint to nights and rest periods is appropriate. It is imperative to check all splints often to ensure proper fit and function.¹⁷ In addition, teaching the nursing staff and family members proper fit and application of splints can help decrease the potential for complications.

Exercise and Activity

In the acute phase, splinting and positioning are used in combination with exercise and activity.³⁰ Exercise is especially important to control edema, prevent muscle atrophy, tendon adherence, joint stiffness, and capsular shortening, and improve pulmonary function.^{17,31} Exercise can improve muscle endurance and cardiopulmonary fitness, which are essential components of health.³² Early incorporation of exercise and activity has also been found to reduce intensive care unit and hospital length stay, as well as improvements in ROM of joints.³³ Exercise types include passive ROM, active ROM, active assistive ROM, and functional activity. If the patient cannot participate in active exercise or activity because of poor medical status or impaired level of alertness, passive ROM is indicated. Active exercise is encouraged whenever possible,³⁴ and it is the role of the therapist to guide the patient toward function. Within a single treatment session, a patient may participate in all of these forms of exercise. Functional activities may be used to improve active ROM. For example, completing a meal preparation activity can be meaningful, fun, and easily adapted by changing height and distance of objects to meet upper extremity ROM goals. Contraindications to exercise include exposed tendons, recent autografts (~5–10 days), acute medical complications, and fractures.^{7,17} In addition, periodic inspection of the wound by the occupational therapist is essential to determine the status of wound healing and skin integrity as related to tolerance of the exercise program.

Perioperative Care

The 5 to 10 days after a skin graft procedure is the perioperative period. A patient with a large burn injury may make many trips to the operating room for skin grafting. Each surgical procedure begins a new perioperative stage. For example, a patient needing grafting on the trunk, arms, and legs may make three trips to the operating room, with each successive area requiring proper perioperative care. The role of the occupational therapist in the perioperative period is to fabricate custom splints to immobilize the newly grafted areas in antideformity positions. Ideally, splints are fabricated immediately prior to or during surgery and applied at the conclusion of the surgery. These splints usually stay in place, along with the primary dressing, for 5 to 10 days.^{7,17} During this time, ROM exercises are contraindicated to allow for graft adherence. After the primary dressing is removed, the burn team assesses the graft

adherence, and a determination is made regarding the appropriateness of resuming exercise.

Pain Management

The occupational therapist must address pain issues that arise during treatment. Patients can experience both the acute feelings of pain and secondary morbidities of pain such as long-term anxiety and posttraumatic stress³⁵ and even delayed wound healing.³⁶ Many patients in intensive care cannot verbalize a subjective response to manipulation, such as during dressing changes or exercise. In these cases, the therapist monitors objective responses to pain, such as blood pressure, heart rate, and respiratory rate, and adjusts the treatment accordingly. The time of therapy sessions should be considered to allow pain medication to be administered prior to treatment. Decreased repetitions and increased rest breaks during exercise sessions may also be appropriate. Other techniques used to manage pain throughout recovery include distraction strategies, relaxation techniques, and preparatory information (informing/preparing the client regarding procedures to be performed). The use of virtual reality as a distraction has also been found to be a safe, low-cost, effective pain reduction technique.³⁷

Environmental Adaptation

Beginning in the acute phase and throughout recovery, the occupational therapist may provide environmental adaptations to facilitate the patient's independence in identified occupations. Modified call buttons and bed controls, voice-activated communication systems, modifications to phones and laptops, and modified utensils (Fig. 48-6) and self-care items are examples of these environmental adaptations. These modifications can increase a patient's sense of control and independence. The development of environmental modifications is limited only by the patient's motivation and the therapist's creativity.

Figure 48-6 Modified utensils to facilitate independence.

Patient and Family Teaching

The occupational therapist provides members of the patient's support system with education regarding ways to interact with and support the patient during recovery. They may be encouraged to make recordings and posters or to bring in favorite music or foods. They may need to learn new ways to touch or comfort their loved one. In addition, the family and friends provide a source of information regarding the patient's roles, habits, routines, and available community resources if the patient cannot

communicate this information. An educated family and/or support system can be an important asset for ensuring follow-through of the rehabilitation program.

Discharge Planning

Because hospital stays are generally short, discharge planning begins as soon as possible after admission. Many patients in the acute phase are either discharged directly home or to a rehabilitation unit. Elements to consider during discharge planning are the availability of community resources for outpatient or follow-up care, support systems available to the patient, and physical demands of the home environment. When patients who have sustained major burns cannot return to the hospital where they received acute care, it is important for the inpatient occupational therapist to establish a relationship with a therapist in the patient's community to ensure continuity of care throughout the rehabilitation phase. Whenever possible, all authorization from third-party payers should be established prior to discharge to avoid delays in the initiation of outpatient therapy. If a patient cannot be discharged directly to home, transfer to an inpatient rehabilitation facility is appropriate, and early communication with the receiving therapist is necessary to ensure continuity of care.

Rehabilitation Phase

The rehabilitation phase follows the acute phase and continues until scar maturation.³⁸ Scar maturation can take 6 months to 2 years.³⁸ It is considered complete when the scar becomes pale and the rate of collagen synthesis stabilizes.⁷ The level of direct involvement of the occupational therapist during this extended time is varied. It may range from daily inpatient treatment to weekly outpatient treatment to annual clinic visits.

OT during the Rehabilitation Phase

During the rehabilitation phase, the occupational therapist continues to assess capacities and abilities such as ROM, strength, activity tolerance, sensation, and scar management. In addition, outcome measures specific to ADLs and IADLs, fine motor control, and upper extremity function are valuable in guiding treatment planning and preparing for discharge. The overall goal of OT intervention during this phase is to facilitate the patient's return to his or her previous level of occupational performance. Patients are encouraged to take increasing responsibility for their care, including collaborating to establish meaningful goals.

Range-of-Motion

In the rehabilitation stage, the patient continues to benefit from daily stretching routines established in the acute phase of care. In the early part of this phase, the rate of collagen synthesis is increased, requiring the patient to stretch frequently throughout the day. Aggressive contraction can continue for months after injury.³⁹ At all times, skin integrity must be monitored during stretching to prevent tearing. Massage using a non-water-based cream should precede stretching to help prevent dry skin from rupturing.³⁸ An appropriate stretch consists of bringing the tissue to the point of **blanching**, or becoming pale, and holding it in that position for several seconds. The patient should report tension but not pain. Overzealous stretching can result in tissue tears and edema, which increase joint stiffness. The recommended hold time of stretching exercises has been reported in the literature in varying amounts of time. One study recommends 30 to 60 seconds of hold time to be effective in improving ROM and functional recovery.⁴⁰ Another study recommended more than 3 minutes of hold time.³⁹ Longer hold times are thought to be potentially more beneficial but can lead to therapist fatigue, which can affect the consistency and patient's tolerance.³⁹ Each area of contracture is treated for at least 3 minutes per session. This yielded significant

improvements in joint ROM.³⁹ Stretching should be initially performed by an occupational therapist. With training, the patient and/or caregiver can also be educated to complete the ROM exercises.

Strength

Resistive exercise and graded functional activities can improve strength. Patients may be taught an independent exercise program with resistive rubber ribbon or tubing, such as Theraband, to increase proximal upper body strength. Functional activities can also be graded to increase strength. For example, patients may gain strength as they perform self-care activities with increasing demands, as when progressing from sitting to standing for oral facial hygiene activities.

Activity Tolerance

A key feature of rehabilitation is mobilizing the patient as much as possible, thereby increasing his or her activity tolerance. For an inpatient, this includes increased time spent out of bed and trips to the gym and off the medical unit. With careful monitoring by the occupational therapist, activity time should be increased if there is no evidence of fatigue. Fatigue can be monitored by patient self-report and clinician observation. For inpatient and outpatient rehabilitation, this may also include facilitating patients resuming leisure activities and going on community outings.

Sensation

Newly healed skin and grafted skin may be hypersensitive, which can significantly limit functional performance. Hypersensitivity can be addressed effectively by systematic desensitization. This can be achieved by asking the patient to manipulate objects with varying textures in the environment. Initially, the patient practices holding soft textures, such as cotton balls or lambswool, and then progresses to manipulating objects with rougher textures, such as Velcro or burlap. A formal system such as the Downey desensitization program can also be used.

Coordination

Coordination can be impaired by a variety of factors, including limited ROM, strength, or sensation. Coordination can be improved through the use of selected progressive tasks designed to challenge the patient's skills. For example, a patient may be asked first to take lids off large jars and then smaller containers. The patient may also trace large letters or patterns before attempting a fine motor writing task such as working on a crossword puzzle.

Scar Management

Scar tissue formation is a natural response to wound healing.⁷ It begins in the emergent phase and may take up to 2 years to mature.⁴¹ A hypertrophic scar is an aberration of the normal healing process and presents as a red, raised, and inelastic scar¹⁷ (Fig. 48-7). A hypertrophic scar contains an increased number of fibroblasts as compared to normal skin, and the collagen fibers are arranged in a nodular as opposed to parallel fashion.⁴² The cause is thought to be a disruption in the balance between collagen synthesis and lysis.⁷ The tendency for hypertrophic scarring is unique to each individual, although it tends to form over extensor joints and areas of high tension. In general, patients with large amounts of pigment in the skin and young patients are most prone to hypertrophic scarring. In addition to being cosmetically unappealing, hypertrophic scars can limit functional skills by restricting joint ROM.

Figure 48-7 Keloid and hypertrophic scars.

Keloids are another type of scars (see Fig. 48-7). Unlike hypertrophic scars, these can appear years after the initial injury and extend beyond the site of injury.⁴³ Keloids are often painful, will not improve with time, most common in darker skin types, and may have a genetic predisposition.⁴⁴ Keloids can be excised but have a high recurrence rate following surgery.⁴⁴

Objective quantification of scars is limited and conflicting measures are used in the literature. The Patient and Observer Scar Assessment Scale and the Vancouver Scar Scale are the most widely used scar assessment tools.⁴⁵ The Patient and Observer Scar Assessment Scale has an observer scar assessment scale and a patient scar assessment scale and the Vancouver Scar Scale is used to rate the pliability, vascularity, height, and pigmentation of scars.⁴⁶ Other assessments include the Patient and Observer Scar Assessment Scale⁴⁷ and the Matching Assessment of Scars and Photographs.⁴⁸

The occupational therapist attempts to prevent or limit the development of hypertrophic scars. Treatment methods include a combination of techniques, including massage, pressure therapy, and the use of specialized inserts.

MASSAGE

Scar massage is frequently used to improve functional and cosmetic outcomes of scars. A systematic review found that there is preliminary evidence that scar massage may be effective in reduction of scar height, vascularity, pliability, pain, **pruritus**, and depression.⁴⁹ It is thought that scar massage causes mechanical disruption of the increased fibrotic tissue of the scar.⁴⁹ This can result in an improved cosmetic appearance and improvement in the elastic properties of the scar. Scar massage is initiated when it is determined that the burned area is closed and can withstand slight friction. Newly healed skin can be fragile and susceptible to lesions and blistering.⁵⁰ There is no set protocol for scar massage. Literature reports scar massage ranging from 10 minutes twice daily to 30 minutes twice weekly.⁵¹ It should be applied with deep pressure (enough to blanch the scar temporarily) in either a circular pattern or

perpendicular to the long axis of the scar (Fig. 48-8). Lubricant should be used during scar massage to reduce friction. Perfume-free lubricants with high water content are preferred to decrease potential irritation and provide moisture to newly healed skin. Initially, scar massage is the responsibility of the occupational therapist so that skin integrity and tolerance can be monitored. Once an established routine has been developed, the therapist should teach the patient and/or caregivers to assume responsibility for daily scar massage.

Figure 48-8 Scar massage.

PRESSURE THERAPY

Pressure therapy has been considered a critical component of scar management since the 1970s.⁵² It is thought that pressure can control collagen synthesis, facilitate scar maturation, and reduce scar redness by limiting the supply of blood, oxygen, and nutrients to the scar tissue.⁵³ The use of pressure therapy within a designated range of 15 to 25 mm Hg of pressure has been found to improve Vancouver Scar Scale score, pigmentation, redness, and scar brightness.⁵⁴ The occupational therapist initiates the application of gentle pressure via Tubigrip, elastic bandage wraps, Coban, or Isotoner gloves once the skin is mostly healed with no more than quarter-sized openings remaining or as indicated by the physician. Initially, pressure dressings are applied for 2-hour intervals. Wearing time is gradually increased in 2-hour increments until 23-hour wear is tolerated. Tolerance is determined by lack of blisters or new open areas. At this point, increased pressure using customized products such as Tricolast or Bioconcepts garments are indicated (Fig. 48-9). The most common amount of pressure used in practice is 15 to 25 mm Hg. Higher pressures have been found to have an increased effect, but pressures of 40 mm Hg and above induce discomfort and potential harm to the patient.^{52,55} Pressure less than 15 mm Hg appear to have no or poor effect on scars.^{53,56,57} Pressure garments should be worn for a minimum of 23 hours a day and for 6 to 12 months or until scar maturation.^{44,58} It is customary to only remove the pressure garments for skin care, hygiene, and cleaning of garments.

Figure 48-9 Custom pressure garments.

Custom garments cause notable shearing during application and removal and thus should be used only when the skin is healed sufficiently to withstand these forces. A skilled therapist should assist with application and removal of the garments until other staff, family, friends, and the patient have had extensive training. The therapist's role is to initiate the ordering of custom garments and oversee their use. Prolonged use of pressure therapy may result in heterotopic ossification, muscle atrophy, joint stiffness, and impaired skin perspiration.⁵⁹ Most providers of custom garments send trained personnel to measure the patient for custom fitting. For facial burns, the patient may use a transparent facial orthosis secured by elastic straps to provide even pressure distribution. These orthoses are usually fabricated by a specially trained orthotist at the request of the medical team.

Silicone products are also often used in conjunction with pressure therapy. Silicone products can include topical silicone gels, silicone gel sheets, silicone sprays, and silicone oils. It is thought that silicone reduces transepidermal water loss and can normalize the cellular process of the skin, reducing collagen production.^{60,61} Silicone gel sheets are typically worn 12 to 24 hours per day and removed for bathing and skin care activities. Skin should be monitored for potential maceration or breakdown. Scar elasticity, redness, thickness, and itching have been shown to be improved after the use of silicone products.⁶²

INSERTS

Inserts are also often used in conjunction with pressure garments. They may be constructed from products such as Otoform or closed cell foam (Fig. 48-10). Their purpose is to increase pressure in concave areas, such as the web spaces and the sternoclavicular depression. Silicone inserts have also been demonstrated to be effective in improving pliability, thickness, and pain in hypertrophic scars.⁶² The design of a scar management program is determined by the available resources, careful clinical observation, and the patient's ability to comply with the program. Periodic outpatient visits to OT or an established burn clinic throughout the rehabilitation phase allow for monitoring and adjustments of the scar management program.

Figure 48-10 Web space inserts.

Self-Care and Home Management Skills

If neuromuscular limitations impede the patient's performance of functional tasks, the therapist may provide adaptive equipment, such as built-up handles for impaired grasp or long-handled utensils for decreased elbow flexion. Teaching adaptive techniques, such as performing certain activities unilaterally, may also improve independence with ADLs and IADLs.

Patient and Family Teaching

Patients and their family members should understand the rationale for each of the splints and techniques used in their care. They participate in the development of goals, so that they are invested in achieving them. Skin care is an important element in discharge teaching. Patients should practice monitoring their skin for breakdown and caring for their skin, including the daily use of a moisturizer and sunscreen. In addition, patients should have a basic understanding of wound healing and tissue response to exercise and scar management techniques.

Support and Psychosocial Adjustment during the Rehabilitation Phase

Although the patient and family typically focus on survival immediately after injury, many other issues may arise during rehabilitation. Patients face challenges related to their medical/physical wellbeing, psychological health, and functional skills and performance.⁶³ The increase in activity in the rehabilitation phase not only assists physical rehabilitation but also helps patients discover how their injury may affect their daily lives. Emotional reactions to the realization of loss may produce a wide range of behaviors, such as crying or expressions of anger. In addition, guilt or embarrassment regarding the injury may lead the patient to withdraw. It is also reported that burn survivors may experience posttraumatic stress disorder, depression,

and social withdrawal.⁶⁴ Incidence of posttraumatic stress disorder 1 year after burn range from 18% to 45%.⁶³

Evidence suggests that the psychological effects of burns may continue to increase in importance after discharge.⁶³ It has also been found that the process of recovery is not a simple or direct path.⁶³ Each burn survivor needs to be treated in a client-centered manner to provide the most appropriate care to address any psychosocial concerns.

One of the most difficult challenges for the burn therapist is caring for patients as they grieve for a functional limitation or alteration in body image.²³ The occupational therapist supports the patient by encouraging questions and verbalization of feelings about the burn injury.²³ The occupational therapist also chooses treatment activities to restore confidence and self-esteem. Group activities provide opportunities for socialization and sharing of concerns in a safe environment.⁶⁵ Given the extensive contact with the patient throughout all phases of recovery, the occupational therapist is in a unique position to identify and address psychosocial issues, but collaboration with other specialists on the burn team (e.g., nursing staff, family members, social workers, and psychologists) is essential.

Potential Complications

In addition to the potential for soft tissue contractures and loss of joint ROM, other complications may occur in any phase of burn recovery. These are listed below.

Pruritus

Pruritus (persistent itching) is a common complication after sustaining a burn injury.⁶⁶ Historically, it was thought that pruritus would improve over time as the burn injury heals. Evidence now shows that pruritus can last for several years^{67,68} and can significantly affect burn survivors' quality of life.^{67,68} The 5D and Leuven itch scales are two reliable and valid scales that can be used with burn survivors with pruritus.⁶⁹ The "Itch Man Scale" can be used with children and is also found to be valid and reliable.⁷⁰ The use of compression garments, scar massage, skin moisturizers, cold packs, and medications such as antihistamines or steroids may help alleviate itching.

Microstomia

Patients with facial burns in the area of the mouth are at risk for oral commissure contracture (microstomia),³⁸ which is tightening of the musculature around the lip area that limits mouth opening. In extreme cases, urgent surgical revision is required. This risk is exaggerated if the patient has undergone prolonged periods without eating or speaking because of intubation or respiratory compromise. In addition to daily scar massage, the therapist can teach the patient facial stretching exercises, such as yawning or grinning widely and pursing lips together. The exercises can be combined with the wearing of a microstomia splint to stretch the oral commissure. The splint may be worn as tolerated, usually starting with 10 minutes and gradually increasing to 60 minutes twice a day. These devices can be purchased commercially or fabricated by a skilled occupational therapist or in collaboration with a speech and language therapist. Additionally, the therapist can use stacked Popsicle sticks to facilitate increased vertical opening of the mouth. The cognitive level of the patient is an extremely important factor in use of a microstomia device because of the risk of an unexpected airway emergency. For example, a heavily sedated or confused patient may attempt to swallow the device.

Heterotopic Ossification

Heterotopic ossification, or myositis ossificans, is the development of new abnormal bone in soft tissues that normally do not ossify. It occurs in 0.2% to 4% of patients with major burns.⁷¹ Burn size and depth are significant predictors of heterotopic

ossification.⁷¹ The most common location in the burn-injured population is the elbow, followed by the shoulder and hip.⁷² Heterotopic ossification can be a debilitating complication of a burn injury and can cause pain, swelling, and rapid loss of ROM and functional use of the area impacted. Symptoms that the therapist may note include a hard-end feel when completing ROM, redness in the area, and/or the area may be warm to touch. The therapist must be aware of the symptoms and alert the team so a formal diagnosis can be determined by radiography. The medical team can then discuss the treatment of prophylaxis options and/or surgical excision. In addition, it is important to consult with the medical team to determine the recommendation for ROM. There is conflicting evidence about the effect of ROM on the progression of heterotopic ossification. Some evidence find that aggressive ROM can exacerbate heterotopic ossification and others find that heterotopic ossification progresses due to a lack of ROM.^{73,74}

Heat Intolerance

Heat intolerance is caused by loss of sweating because split-thickness skin grafts typically do not contain sweat glands. To compensate for this, patients may sweat excessively in remaining unburned areas. Patients in extremely hot climates may require additional air conditioners in the home to maintain comfort.³⁸ The lack of sweat glands also makes healed grafts susceptible to extreme dryness⁷ and patients are encouraged to use moisturizing cream often throughout the day. A heat acclimation regimen has also been found to improve heat tolerance in burn survivors.⁷⁵ Note: this should only be performed by a skilled clinician under the direction of medical personnel.

Reconstructive Surgery

An important element in burn recovery is the planning and execution of reconstructive procedures. Despite diligent efforts by the burn team and patient, contractures may develop. Reconstructive surgery can be useful in correcting these deformities. Surgery is typically performed once the scar tissue is mature; however, it may be necessary to perform reconstructive surgery before scar maturation if a severe functional deficit is present.⁷⁶ For example, an axillary contracture, which limits abduction to 80°, may significantly interfere with dressing and hygiene. A surgical procedure, a **Z-plasty**, can be performed to elongate soft tissue.⁷⁶ A skin graft to cover the deficit may be necessary once the contracture is released. Fifteen percent of patients who sustain hand injuries require reconstructive surgery.⁷⁷ Reconstructive surgery is most often performed on contractures of the little finger and web space.⁷⁷

OT Related to Reconstructive Procedures

When results of a functional assessment or outcome measure suggest that the patient's progress toward his or her goals has ceased because of a contracture, the occupational therapist communicates this information to the burn team. Possible recommendations from the burn team may include the need for surgical release of the contracture.

Postoperatively, the occupational therapist provides a custom splint to immobilize and protect the graft in its new lengthened position. After approximately 10 to 14 days, the therapist initiates an exercise program beginning with gentle active ROM and progressing to more aggressive exercise and activity as skin integrity tolerates. Pressure therapy over the newly grafted area minimizes scarring. This includes the use of a pressure garment and an insert fabricated to match the contours of the new graft.

Return to Work

Returning to work before final scar maturation preserves function and improves the patient's self-concept.³⁸ However, only one-third of burn patients return to previous work roles⁷⁸ and approximately 28% will not return to any form of employment.⁷⁹ This makes it important for occupational therapists to address return to work throughout all phases of care. During the initial evaluation in the acute phase, the occupational therapist gathers information regarding the work history of the patient and specific job demands the patient previously was required to complete. With this information, the occupational therapist can guide treatment activities to prepare for return to the previous level of functioning. For example, if the patient was employed as a mechanic prior to injury, tool use should be incorporated into treatment activities as soon as possible. Patients may require job retraining if the extent of the injury renders the original job demands now unrealistic. In this case, the occupational therapist works with the patient and employer to explore appropriate job modifications.

In addition to physical limitations, burn survivors may encounter psychosocial barriers to returning to the work. These include nightmares, flashback, and concern regarding appearance and depression. Patients exhibiting these symptoms may benefit from psychological intervention that, when started early in their recovery, may enable them to return to work sooner.⁸⁰ It is also important to acknowledge if the burn injury happened at work and the effect of returning to the place of injury may have on the patient.

Special Considerations for Hand Burns

The hand is involved in more than 90% of all burns.⁸¹ Hand burns can result in significant functional limitations and poor aesthetics. The high rate of injury to the hand is because individuals often use their hands to protect themselves or to extinguish the fire.⁸² Dorsal hand burns occur more frequently than palmar injuries.⁸³ Significant edema frequently occurs in response to thermal injury. This pulls the hand into a position of deformity⁸⁴ characterized by thumb adduction, digital metacarpal hyperextension, interphalangeal joint flexion, and flattening of the palmar arches. If this position is maintained, the result is joint contracture and severe functional limitation; thus, it is imperative that aggressive interventions should be initiated early.⁸²

Evaluation of Hand Burns

A comprehensive hand evaluation includes determination of whether ROM limitations are due to joint stiffness, intrinsic muscle tightness, extrinsic muscle tightness, or inelasticity of skin. Other factors that limit hand flexibility and decrease ROM include pain, bulky dressings, edema, exposed tendons, and the presence of eschar, which is inelastic. Once the clinician determines the cause of ROM limitations, an effective treatment plan can be devised. The Hand Burn Severity score is a simple assessment measure that has been found to be a valid and reliable measure that can assist with stratifying severity and assist with reporting outcomes.⁸⁵

Treatment of Hand Burns

The occupational therapist must provide appropriate splinting and exercise programs to prevent contracture and expedite functional use of the burned hand. The recommended splinting position of the hand is described in Table 48-1. It is commonly referred to the intrinsic plus position. In this position, the collateral ligaments of the metacarpophalangeal (MP), proximal interphalangeal (PIP), and distal interphalangeal (DIP) joints are positioned at length, preventing ligamentous contracture so that maximum digital ROM is preserved.

Two distinct options exist for thumb position. Radial abduction maintains the first web space at maximum length. Palmar abduction is preferred, however, because this is a position of function. Hand burns are typically dorsal. When present, a deep palmar burn can lead to palmar contracture. In this case, a volar hand extension splint is appropriate. When using this position, careful monitoring of MP flexion is critical to prevent shortening of the collateral ligaments. Unfortunately, evidence is lacking regarding specific splint positions and schedules. According to Richard and Ward,¹⁸ “Controversy about splinting in burn care is not based on the rationale for and success of splinting, but exists because of the paucity of validation of its use” (p. 392). A list of splinting options for the conditions previously discussed follows.

- **Dynamic PIP extension splint such as LMB, or banana splints, for PIP stiffness:** Start 10 minutes three times a day, increase wearing time as tolerated, not to exceed 60 minutes at a time.
- **Dynamic flexion splint in which the MPs are blocked in full extension while the DIPs are passively flexed** (for intrinsic muscle tightness): Start 10 minutes three times a day, increase wearing time as tolerated, not to exceed 60 minutes at a time.
- **Forearm-based dynamic flexion splint that offers composite MP-DIP flexion** (Fig. 48-11) (for extrinsic extensor tightness or inelastic skin that limits composite flexion): Start 10 minutes three times a day, increasing as tolerated but not to exceed 40 minutes.

Figure 48-11 Forearm-based dynamic flexion splint.

- **Volar forearm-based static extension splint** (for extrinsic flexor tightness): Wear at night.
- **Forearm-based dynamic extension splint** (for extrinsic flexor tightness): Wear periodically during the day, starting with 10 minutes three times per day and progressing to 45 minutes as tolerated.

Often, individuals do not present with a single limitation; rather, a combination of factors limits the individual’s ROM. The clinician must determine which factor is the primary source of dysfunction and treat accordingly. Appropriate splints are always used in conjunction with active and passive ROM, edema management, therapeutic exercises, functional activities, and scar management techniques. Splints should never be used to the extent that they limit or prevent performance of ADLs or functional activities.

Potential Complications of Hand Burns

Normal hand anatomy can be characterized by a balance of levers and pulleys that work harmoniously to achieve motion. Damage to this balanced and complex network can result in significant functional limitations.

Extensor Tendon Injury

Extensor tendon injury is often associated with dorsal hand burns because they lie superficially on the dorsal aspect of the hand. Dorsal skin is thin and flexible, which

provides little mechanical protection.⁸⁶ Because of the close proximity of structures, the formation of scar tissue can greatly limit tendon excursion and create imbalance. This can result in contracture development. Boutonniere and swan-neck deformities (Fig. 48-12) are the result of extensor tendon damage.^{81,87} It is recommended that customized splints are applied as soon as possible.

Figure 48-12 Boutonniere deformity.

Web Space Contractures

Web space contractures can be due to overgrafting of the web spaces, muscle shortening (contracture of the adductor pollicis brevis resulting in a first web space contracture), joint stiffness, or skin graft contracture in a normal response to tissue healing. Splints, scar management, and exercise are effective treatment modalities. First web space contractures (between the thumb and index finger) respond well to a web space C-splint that is lined with Otoform, a silicon gel sheet. This is usually worn at night for 6 to 8 hours. During the day, the individual performs stretching, massage, and functional activities that encourage full ROM of the affected area. For example, an individual with a first web space contracture is asked to pick up containers or game pieces of various sizes, using palmar abduction to promote full abduction of the thumb. A dynamic splint with an insert that exerts pressure over the second, third, and fourth web spaces can be appropriate for digital web space contractures. Another option is the addition of web space inserts under a pressure garment or Isotoner glove.

Future Directions

Exciting progress has occurred in regards to reconstruction techniques for the burn patient. To date, 37 successful face transplants have occurred worldwide,⁸⁸ and patients have undergone unilateral and bilateral hand transplants as well. The major goals of face and hand transplants include functional and sensory improvements; however, the potential impact they have on an individual's life satisfaction, body image, and social interaction cannot be overlooked.

The use of stem cells for wound healing is another exciting advancement in burn care. Various types of stem cells are being studied and used to treat fibrosis, scarring, and wound contractures.¹⁰ Recently, 80% of a child's epidermis was able to be regenerated with the use of genetically modified epidermal stem cells. Two years after transplant, the child presents with high-quality functional skin.⁸⁹ The possibilities for the application of stem cells in burn care are vast and present promising solutions to wound care.

The application of 3D scanning and printing for the treatment of burn contractures is also a new advancement seen in burn care. The use of 3D scanning and printing allows

for potentially increased customization, production speed, and cost effectiveness of splints.⁹⁰

CASE STUDY

Patient Information

Nancy is a 42-year-old woman who sustained a 45% total body surface area (TBSA) burn as a result of a house fire. She presented to the emergency department with superficial and superficial partial-thickness burns to her face and neck and deep partial- and full-thickness burns to bilateral upper extremities and hands (dorsal aspect only), chest, and proximal aspect of her bilateral lower extremities. She also sustained an inhalation injury and was intubated and sedated. She was admitted to the intensive care unit. No significant medical history was reported. Split-thickness skin grafts (STSGs) were performed to her chest and upper thighs 3 days after admission. STSGs were performed to her arms and hands 10 days after admission. After skin grafting was complete, Nancy was extubated and moved to a private room. She was on a regular diet and could walk independently. She was noted to be withdrawn and was concerned regarding her ability to care for her 3-year-old daughter. Her husband and sister were present and supportive throughout her hospitalization.

Reason for OT Referral

Nancy was referred to OT during the acute phase to prevent contractures that might result in impairments in occupational functioning, to provide patient and family education, and to address psychosocial sequelae related to the burn injury.

Assessment Process and Results

The occupational therapist completed the following assessments related to Nancy's condition:

- Assessment of wound healing: Immature scar noted on bilateral forearms and dorsum of both hands
- Assessment of cognitive/social status: Awake and alert for several short periods throughout the day; also noted to appear withdrawn, not seeking social interaction
- Biomechanical assessment: ROM and MMT: Decreased elbow flexion, decreased grasp (metacarpophalangeal [MP] flexion limited), and decreased upper extremity strength bilaterally
- Role and interest assessment: Ability to care for daughter is of primary importance
- Functional assessment: Observed having difficulty using utensils, requires assistance for all ADLs, unable to use nurse call button, and observed to fatigue easily

OT Problem List

- Decreased ADL and IADL independence
- Decreased strength and ROM in bilateral upper extremities
- Withdrawn behavior
- Activity tolerance limited to 5 minutes

OT Goal List

- Participate in splinting and positioning regimen without signs of skin irritation to increase upper extremity functional use during ADLs.
- Complete bilateral upper extremity active and passive ROM exercises to increase ROM and endurance required for ADL performance.
- Increase right digit 2 to 5 MP flexion from 40° to 50° to improve ability to grasp utensils independently.
- Self-feed with modified independence and adaptive equipment as needed.
- Comb daughter's hair for 5 minutes in unsupported short sit at the edge of the bed with distant supervision.
- Participate in burn survivor support group 3 opportunities to increase knowledge of burn recovery process and address anxiety and withdrawal.

Intervention

OT provided six to seven times a week for 60 minute sessions. Bilateral elbow and hand splints were fabricated. Adaptive equipment, including a modified call button, built-up utensils, bath mitt, and modified long-handled sponge were provided. The therapist encouraged the family to bring in recordings and videos of get-well messages that Nancy could listen to. Nancy was taken to the therapy gym as much as possible and private time with her daughter was added to her daily schedule.

As the scars matured, Nancy was provided with both verbal and written instructions regarding scar management and skin care. As discharge neared, outpatient OT was arranged for three times per week with plans communicated regarding need to fit for pressure garments.

Evidence Table of Intervention Studies for Burn Injuries

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Early inpatient rehabilitation on burn survivors' functional outcomes and resource utilization ⁹¹	A burn center and an inpatient rehabilitation hospital merged. Study evaluated effect of merger on burn survivors' functional outcomes and resource utilization	About 138 burn survivors (60 — transferred to rehab before merger, 78 — transferred to rehab after merger)	Merger of a regional burn center and a rehabilitation hospital	Retrospective analysis of two groups, Level II	Patients who received early inpatient rehabilitation had significantly shorter burn center length of stay (LOS), shorter wait time for rehab, and improved resource utilization	Patients transferred after the merger had significantly shorter burn center LOS (28.5 ± 20.9 days vs. 38.8 ± 34.2 days, $p = 0.043$), and shorter waiting time for rehab (0.7 ± 1.1 days vs. 1.5 ± 2.3 days, $p = 0.010$) than patients transferred before the merger

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Recovery of postburn hypertrophic scars in a monitored pressure therapy intervention program ⁹²	All subjects treated with a 6-month pressure therapy program using the Smart Pressure Monitored Suits	About 34 patients with 65 hypertrophic scars	Patients divided into early treatment group (prescribed pressure therapy within 60 days of injury) and late intervention group (prescribed pressure therapy 61 days or more after injury)	Longitudinal cohort design, Level III	Hypertrophic scars improve in appearance, pain and itch with monitored pressure therapy. Early application of pressure therapy may facilitate better outcomes as evidence by faster recovery than those in late intervention group	The early group demonstrated superior effect in improving scar lightness, yellowness ($p < 0.01$), thickness ($p < 0.01$), pigmentation score ($p < 0.05$), and pain score ($p < 0.01$) than the late group in comparison between the two groups at similar postburn timing
Effectiveness of early stretching exercises for ROM in the shoulder joint and functional recovery in patients with burns ⁹³	Intervention group received standardized protocol of stretching for 14 days. Control group received usual protocol	Patients with 10%–45% TBSA burns involving the axilla group were randomized into intervention ($n = 110$) and control groups ($n = 110$)	Intervention group received stretching exercises within 48–72 hours postinjury. The number of repetition was increased gradually over 3 days beginning with five reps and progressing to 20	Randomized controlled trial, Level I	Early sustained stretching exercises significantly improves the ROM and functional recovery of the shoulder joint after a severe burn injury	There is a significant beneficial difference ($p = <0.0001$) in ROM and functional recovery between the intervention and control group

ROM, range-of-motion; TBSA, total body surface area.

Chapter 49

Chronic Pain and Fibromyalgia

Sharon A. Gutman and Lee Ann Westover

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Understand the multifactorial and interconnected contributing factors to chronic pain syndromes.
2. Understand how chronic pain syndromes commonly affect clients' participation in desired daily life activities.
3. Understand traditional medical management of chronic pain syndromes.
4. Understand how occupational therapists evaluate functional skill deficits and occupational restrictions occurring secondary to chronic pain.
5. Understand how occupational therapists provide intervention to reduce pain and enhance participation in clients' desired daily activities.

CHAPTER OUTLINE

Chronic Pain and Fibromyalgia: Definition, Prevalence, and Background
Functional Impairment in Daily Occupation Secondary to Chronic Pain
Evaluation of Functional Skill Deficits Secondary to Chronic Pain
Intervention of Functional Skill Deficits Secondary to Chronic Pain
Case Study

TERMINOLOGY

Body mechanics: the proper positioning of the body during daily activities to avoid injury and pain.

Central sensitization (CS): a central nervous system (CNS) condition that may account for the development and maintenance of chronic pain syndromes; in CS, a phenomenon referred to as wind-up occurs in which the CNS becomes highly reactive to any touch stimulus, resulting in feelings of pain from non-noxious stimuli.

Chronic pain: pain that is persistent or recurring for longer than 3 months; etiology may or may not be known.

Energy conservation: the arrangement of desired daily life activities over the day or week for the purpose of preserving patient stamina, preventing fatigue, and minimizing joint stress and pain; also involves the idea that energy expenditure can be reduced in any one activity.

Fibromyalgia (FM): widespread pain with tenderness and stiffness that is independent of a specific injury or lesion; etiology is largely unknown but may relate to CNS-processing problems.

Guarding behaviors: the adoption of dysfunctional behaviors such as bracing, posturing, and limping in an effort to protect a painful body region; commonly leads to additional musculoskeletal problems resulting from the overuse of certain muscle groups and body positions.

Low back pain (LBP): pain located between the margins of the lower ribs and crease of the buttocks; etiology may or may not be known but is commonly caused by neuroanatomical conditions, including radiculopathy, spinal stenosis, herniated spinal disks, and spinal compression and fractures.

Physical agent modalities: interventions and technologies that use force or energy to promote the healing process and reduce pain.

Work simplification: the arrangement of tools and steps in an activity to reduce pain and energy expenditure.

Chronic Pain and Fibromyalgia: Definition, Prevalence, and Background

Chronic pain and related disorders may affect as many as 20% of the global population and is attributable to 15% to 20% of physician visits worldwide.¹ The prevalence of individuals experiencing chronic pain is estimated to be as high as 36% in European households and 43% in US households.² In 2018, the World Health Organization (WHO) released the *International Classification of Diseases, 11th edition (ICD-11)*, which includes a revised definition of chronic pain.¹ This revised definition is intended to better reflect the epidemiology of chronic pain than previous versions and identifies chronic pain as a global health care problem.² Chronic pain is now defined in the *ICD-11* as persistent or recurring pain lasting longer than 3 months.¹ This definition includes seven optional specifiers for chronic pain. *Chronic cancer pain* was introduced and can include pain from the cancer itself or related to treatment. *Chronic postsurgical and post-traumatic pain* occurs after surgical procedure or tissue injury, including burns. *Chronic neuropathic pain* is caused by injury to or disease in the somatosensory nervous system. *Chronic headache and orofacial pain* is defined as head, mouth, jaw, or face pain that occurs approximately 50% of days for 3 months. *Chronic musculoskeletal pain* includes direct pain sensation in the musculoskeletal system, but *chronic visceral pain* is often perceived as referred pain from origins in other internal organs.

The etiology of many forms of chronic pain is currently unknown; thus, the final specifier of *chronic primary pain* was newly introduced to reflect such. Chronic primary pain includes the common conditions of back pain (not otherwise attributed to musculoskeletal or neuropathic causes), fibromyalgia (FM), chronic widespread pain, and irritable bowel syndrome. Chronic primary pain is defined as occurring in one or more anatomical areas and is associated with functional impairment and emotional distress—such as difficulty with performance of activities of daily living (ADLs) and participation in life roles. Details on rheumatic pain can be found in Chapter 42. This chapter focuses primarily on chronic low back pain (LBP) and FM.

Fibromyalgia: Prevalence, Etiology, Diagnosis, and Medical Management

Prevalence

Fibromyalgia (FM) syndrome is one of the most common chronic primary pain conditions.³ FM is defined as widespread pain with tenderness and stiffness, independent of specific injury or lesion.^{3,4} Depending on diagnostic criteria and geographic location, the prevalence of FM is reported as ranging from 0.2% to 13% worldwide.^{3–7} Women appear to be affected by FM significantly more than men, with as many as 2 women experiencing FM for every 0.15 men.^{3,6} The prevalence also appears to increase with age, with reports of maximum occurrence over the age of 60,⁶ and up to 7.4% of women over 70 experiencing FM.³

Etiology

The etiology of FM is largely unknown, which has contributed to difficulty diagnosing and treating the syndrome.^{6–8} Abnormalities in central nervous system (CNS) pain processing are a hallmark, and as such, FM is referred to as a *centralized pain state*.^{6,7} Even gentle touch is often experienced by FM patients as pain. Afferent pain signals appear to be amplified within the spinal cord, but psychosocial and environmental factors may also contribute to the amplification. These can include stressors related to acute pain, psychosocial stress, certain infections, trauma, and deployment to war. Brain regions involved in processing pain and emotion are implicated via functional magnetic resonance imaging, for instance, the amygdala, thalamus, and insula.⁶ Patients who develop FM often have a personal and/or family history of chronic pain or pain syndromes.^{6,7} Functional and cognitive impairments are common symptoms of FM and can include depression, anxiety, obsessive–compulsive disorder, post-traumatic stress disorder, sleep participation deficits, fatigue, headaches, paresthesia, and/or psychosis.^{3,4,7}

Diagnosis

A diagnosis of FM is considered whenever widespread pain is not explained by other illness or injury.^{6,7} Lab testing will not contribute to diagnosis—rather, clinicians rate sensitivity of 18 body sites, with 11 sensitive sites resulting in a diagnosis of FM; 25% of FM patients, however, do not experience the requisite tenderness in all 11 sites.⁶ A psychosocial questionnaire is used in conjunction with touch sensitivity ratings to determine whether patients experience deficits in sleep participation and cognition.

Medical Management

FM is treated by combining pharmacological and nonpharmacological methods, and team-based strategy is recommended.⁷ Pharmacology can be helpful, but psychosocial and functional

interventions are considered central to treatment. Opioids are not effective with this population. Improved function and participation should be the primary focus for clinicians. Patients are encouraged to participate in education about the illness and importance of active participation in treatment. Diagnosis itself has proven to be helpful for many patients. Interventions should also be delivered to support sleep participation, stress management, and exercise. The strongest evidence supports education, cognitive-behavioral therapy (CBT), and exercise, but limited evidence also supports the use of alternative therapies like Tai Chi, yoga, acupuncture, myofascial release, and chiropractic. These interventions are also thought to contribute to an internal locus of control and can be implemented freely, as long as they do not cause harm to the patient.

Low Back Pain: Prevalence, Etiology, Diagnosis, and Medical Management

Prevalence

Low back pain (LBP) is the global leading cause of lost workdays due to disability.⁹ Up to 540 million people, or 7.3% of the global population in 2015, were affected by LBP at any one time.¹⁰ Rate of occurrence is estimated to be heightened in low- and middle-income countries as a result of population growth and lack of resources.⁹ During the first decade of life, LBP occurrence is low. During adolescence, however, prevalence rises steeply to an estimated 37% to 40% of children ages 9 to 14.^{10,11} The prevalence of LBP peaks in middle adulthood, and most adults report experiencing LBP at some point. LBP is experienced more frequently in women than in men. As people age, LBP more frequently leads to deficits in activity participation. LBP is defined by pain between the margins of the lower ribs and the crease of the buttocks.¹⁰ As such, it is not a disease, but a symptom attributable to many possible causes.

Etiology

LBP resolves in 80% to 90% of individuals within 6 weeks. Pain that does not resolve in approximately 12 weeks is considered chronic and occurs in 5% to 10% of patients. At least one study found that back pain due to a specific pathoanatomical cause may occur in less than 1% of LBP patients in primary care.^{9,10} Common identifiable conditions that cause LBP are as follows:

- **Radiculopathy (RP)** occurs with nerve-root involvement and is commonly referred to as sciatica.¹² RP is expressed as electric or shooting pain in the legs that may worsen with back pain, sneezing, straining, or coughing. RP is commonly caused by disk herniation and inflammation.
- **Spinal stenosis** is back pain or discomfort while standing still or walking that affects one or both legs.^{9,12} It is frequently caused by bulging disks, narrowing of foramina or spinal canal, or other degenerative conditions (Fig. 49-1).

Figure 49-1 Spinal stenosis. Central stenosis (*top, left, and right*) usually develops at the disk level from a bulging disk with facet joint overgrowth from the inferior articular process of the lumbar vertebrae and thickening and redundancy of the ligamentum flavum. Lateral stenosis (*bottom, left, and right*) includes both the lateral recess and foraminal stenosis resulting from overgrowth from the superior articular process of the vertebra and other degenerative changes similar to those of central stenosis. Lateral recess stenosis affects the spinal nerve root at the disk level.

- **Facet joint pain or facet arthropathy** is caused by arthritis and/or inflammation in the spinal joints. This type of pain worsens with spinal extension.
- **Spondylosis** involves age-related degenerative spinal column changes. These can include disk compression, arthritis, or osteophyte formation.
- **Spondylolisthesis** occurs when one lumbar vertebra displaces or slides over another; can lead to spinal stenosis.
- **Herniated nucleus pulposus** occurs when the outer layer of the intervertebral disk—the annulus—breaks down. This exposes the innervated inner core, the nucleus pulposus, and releases inflammatory agents that cause pain. The rupture of the annulus is often caused by stress (Fig. 49-2).

Figure 49-2 Herniated nucleus pulposus. Cross-sectional anatomy of the cervical spine depicting several pathological states: hypertrophy of the uncovertebral joints, hypertrophy of zygapophyseal joints, and herniation of the nucleus pulposus.

- **Compression and stress fractures** are commonly caused by arthritis, trauma, or repetitive strain (Fig. 49-3).

Figure 49-3 Spinal compression and fracture. Compression fracture. A compression fracture is a wedge-shaped fracture (also called wedge fracture) of the vertebral body involving the anterior column. It occurs in the thoracic and lumbar region, most often in the midthoracic and midlumbar region. Compression fractures can occur with minor trauma in older patients with osteoporosis and in younger people with significant trauma.

- **Nonspecific LBP** has no identifiable, specific cause and may represent 90% or more of LBP cases.¹¹

Risk Factors

Risk factors for all LBP include frequent physical behaviors associated with work, such as twisting, lifting, bending, repetitive motion, vibration, and static postures.¹³ Psychosocial factors, such as depression, cognitive impairment, stress, and job dissatisfaction, also increase LBP risk. Smoking and obesity are also risk factors.¹⁰

Medical Management

Surgery for spinal conditions should be considered only when strictly necessary, because it is the most invasive treatment option with potential for complications.¹⁴ For many conditions, however, surgery offers the most complete resolution of symptoms in the shortest amount of time.

- **Laminectomy or decompression surgery** involves the removal of the vertebral lamina, which forms the posterior of the spinal canal. This relieves pressure on the spinal cord or nerve roots in the case of stenosis.¹⁵
- **Spinal fusion** may be conducted in cases of degenerative disk disease, fracture, spinal instability, or herniated disk. Two or more vertebrae are permanently connected and immobilized relative to each other, often using a combination of screws, rods, and bone graft.
- **Disk dissection or discectomy** removes all or part of a damaged intervertebral disk secondary to disk herniation.
- **Vertebroplasty and kyphoplasty** are outpatient procedures in which cement is injected into vertebrae to stabilize them after a fracture.

Medication can also be helpful in relieving LBP pain and inflammation:

- **Opioids or muscle relaxants** for pain control should be limited and used only after other medications are shown to be ineffective.^{9,11,13,14,16} Opioids carry a serious risk of addiction that outweighs potential benefits.
- **Nonsteroidal anti-inflammatory drugs (NSAIDs)**,^{11,13,14,17} work well with a number of back pain conditions, but are not as effective in neuropathic pain from compression or herniated disks.¹⁶
- **Anticonvulsant or antiseizure** medications, such as gabapentin (Neurontin), carbamazepine (Tegretol), and lamotrigine (Lamictal), are often effective against neuropathic pain. These drugs inhibit electrical signals within the CNS.

Central Sensitization

Central sensitization (CS) is a CNS condition that may account for the development and maintenance of chronic pain syndromes. In CS, a phenomenon referred to as *wind-up* occurs in which the CNS becomes highly reactive to any touch stimulus, resulting in feelings of pain from non-noxious stimuli.¹⁸ This persistent state of CNS reactivity reduces the threshold for pain tolerance and maintains pain syndromes after anatomical injury has resolved. In CS, patients experience two primary symptoms: *hyperalgesia* and *allodynia*.¹⁶ Hyperalgesia is increased sensitivity to painful stimuli. Allodynia is the experience of pain sensation from stimuli that should not result in pain, such as light touch. Sometimes, patients who experience CS also experience sensitivity to other sensory stimuli,¹² including sensitivity to light, odor, and sound. CS may also result in cognitive impairment, including attentional or memory deficits, and emotional distress such as anxiety.^{19,20} CS may play a role in many conditions, including FM, LBP, arthritis, headaches, and neuropathic pain.^{18,21,22} Up to 50 diagnoses may fall under this umbrella.^{21,22} Medical management of CS targets the CNS. As such, anticonvulsant medications and antidepressants are more effective than other pain medications.²¹

Functional Impairment in Daily Occupation Secondary to Chronic Pain

The wide range of symptomatology accompanying chronic pain presents barriers to independence, role fulfillment, and occupational participation. Daily routines are interrupted, as are physical activity and even social identity.^{2,10,23,24}

Activities of Daily Living

Up to one in three individuals who experience chronic pain are less able to maintain independence than those without it.² Pain, fatigue, and the effects of resultant depression and anxiety can impact both motivation and performance levels. Reduced ability to participate in hygiene and bathing is commonly described in the literature.^{2,24} Other ADLs that are typically adversely impacted by chronic pain include dressing, functional mobility, and sexual activity.²

Instrumental Activities of Daily Living

Instrumental activities of daily living (IADLs)—such as meal preparation, home maintenance, shopping, driving and community mobility, work, school, and religious participation—are noted in the literature as being negatively impacted by pain caused by the same physical, cognitive, and emotional factors described earlier.² Performance of IADLs, care of others, care of pets, and child-rearing are often limited.^{2,10,24} Health management is also identified in the literature as an area of dissatisfaction for individuals with chronic pain.^{2,10} In one study, up to 39% of respondents perceived their physician to view their pain without seriousness and reported that their pain was inappropriately medically managed.² Numerous health care appointments and procedures, even when care is adequate, interrupt the ability to participate in desired daily activities and require functional cognitive skills, including organization, attention to detail and concentration, planning, problem-solving, and decision-making.

Work and Education

Disruption to work participation is perhaps the most widely cited deficit area in the chronic pain literature. Individuals' ability to work affects not only their own financial health, but the larger productivity of society. Up to two-thirds of people with chronic pain are less able to or cannot work outside the home.² One in four chronic pain patients must change jobs secondary to pain, and one in five are reported to be unemployed. Impaired job performance occurs frequently, which, in turn, may increase disruption of co-workers' performance. The incidence of job loss for individuals with chronic pain increases as much as seven times after clinical onset. Individuals who experience chronic pain are less likely to attend and complete college, and are more likely to retire early, which adversely impacts lifetime earnings.^{2,10}

Other Occupational Domains

Disrupted rest and sleep is an occupational domain widely addressed in chronic pain literature, regardless of specific diagnosis, and results from pain-related fatigue, increased nighttime awakenings, and reduced total sleep time.²⁻⁴ Leisure participation is reported to be as disrupted as participation in education and work.^{2,10,24} Secondary to impairment in the abovementioned domains, social relationships become strained or broken, and participation in social activities is reduced.^{2,24} Social identity changes in turn, because of difficulty fulfilling expected social roles—in particular, in societies with more physically demanding living conditions.¹⁰

Evaluation of Functional Skill Deficits Secondary to Chronic Pain

Occupational therapists may treat patients whose chronic pain is the primary (e.g., LBP, FM) or secondary diagnosis (e.g., pain secondary to traumatic brain injury). In many instances, chronic pain may be reported first to the occupational therapist who is treating the patient for another medical reason. When chronic pain is first detected by therapists, patients should be referred to their primary care physicians to determine, if possible, the causes and appropriate treatment. Chronic pain is multifactorial and has physical, cognitive, and psychosocial contributing factors.²⁵ The experience of chronic pain must be understood and assessed as a cycle in which daily stress, mood alterations, disrupted sleep, and physical activity or inactivity all interact to impact pain level.

Patient History

A number of screens and evaluations are available to assist therapists in the assessment of chronic pain syndromes. Pain should first be assessed by taking a patient history with regard to the following factors: (a) location including the site(s) of origin and whether and where radiating pain exists; (b) whether the patient can identify onset and causes (e.g., injury secondary to improper lifting); (c) whether pain is experienced as persistent or intermittent; (d) identification of pain sensory experiences, such as burning, throbbing, shooting, stabbing, tingling, or electrical (referred to as pain quality); (e) possible factors that cause pain exacerbation and relief; (f) pain intensity throughout the day and in relation to specific activities; and (g) previously attempted pain interventions.

Occupational Profile

Once the abovementioned factors are understood, chronic pain should be assessed to determine its impact on daily function using an occupational profile. Occupational profiles allow therapists to gain an understanding of the ways in which chronic pain has disrupted a patient's occupational roles and the ADLs supporting those roles. Occupational profiles also help therapists to understand how the experience of chronic pain has impacted patients' psychosocial health, daily mood, sleep

patterns, daily stressors, and quality of life. It is important for therapists to understand that factors such as depression, disrupted sleep, and stress—which commonly accompany chronic pain—must be assessed and addressed in treatment for optimal effectiveness. Chapters 51 and 52 provide information regarding the assessment and treatment of depression, disrupted sleep, and stress—which must be disentangled from the physical mechanisms that may contribute to chronic pain.

Pain Diaries

Often, patients have not connected their experience of pain to sleep patterns, mood, physical activity level, stress, and diet and nutrition. In such cases, patients should be instructed to maintain a pain diary for 1 to 2 weeks in which they record:

- Pain occurrence
- Pain intensity and duration
- Pain quality
- Possible identifiable triggers
- Physical activity level
- Movement patterns used in specific activities
- Mood and stress level
- Sleep quality during the previous night
- Food intake (quality and quantity)
- Reactions to heat/cold or humid weather

This collection of data over 1 to 2 weeks allows patterns to be discerned regarding the experience of pain, and the environmental and internal stressors that may contribute to pain exacerbation or relief (see Box 49-1). Such information is critical to help patients begin to understand the interrelationship between the internal experience of pain and the external conditions that may heighten or decrease the pain experience. Without this understanding, both therapists and patients will not have sufficient knowledge to develop interventions that effectively begin to alter the pain cycle.

Box 49-1

Pain Diary

Date	Pain Occurrence	Pain Intensity and Duration	Pain Quality (Throbbing, Aching, Stabbing, Shooting, Burning, Tingling, and Electrical)	Possible Triggers	Activity Level Preceding Pain	Movement Patterns Used in Specific Activities Preceding Pain	Sleep Quality Previous Night	Food Intake (Type and Quantity) ^a	Weather (Hot, Cold, and Humid)
Morning 6:00– 11:59 am									
Afternoon 12:00– 4:59 pm									
Evening 5:00– 11:59 pm									
Sleep time 12:00– 5:59 am									

^a Note the intake of alcohol, caffeine, refined sugars, gluten, dairy, processed meats, corn and vegetable oils.

Visual Analog Scales

Visual Analog Scales (VASs) (also referred to as verbal or numeric rating scales) are self-report measures that allow patients to rate their pain on a continuum using numbers, qualitative descriptors, and emoticons as anchors (see Box 49-2).²⁶ These types of measures allow patients to document their pain level either in the present moment or as it occurred over the past week. Although VASs are easy to use, they do not allow consideration of pain with regard to changing intensity and duration—a critical factor since most patients experience chronic pain as a changing

rather than stable phenomenon. VASs also do not allow for the rating of pain to be considered in relation to the internal and environmental factors noted earlier. As a result, VASs tend to oversimplify the pain experience, which then frequently leads to an oversimplification of intervention and a failure to address the multiple contributing factors of pain.

Box 49-2

Visual Analog Scales

Please rate your pain level in the past week.

0 1 2 3 4 5 6 7 8 9 10

No pain Moderate pain Severe pain

Please rate how much pain has interfered with daily life activities in the past week.

0 1 2 3 4 5 6 7 8 9 10

No interference Moderate interference Severe interference

Pain Disability Index

The Pain Disability Index (PDI)²⁷ is a 7-item, 10-point, self-report Likert scale, where 0 = no disability and 10 = worst disability as a result of pain. The scale allows patients to rate their pain level in seven categories: family and home responsibilities, recreation and leisure activities, social activity, occupations related to work (including paid and volunteer work), sexual activity, self-care activities, and life support activities (e.g., eating, sleeping, breathing). The scale yields a total possible score ranging from 0 to 70, with higher scores indicating greater disability secondary to pain. The PDI has been found to be able to discriminate between patients having high and low pain levels²⁷ and possesses high test–retest reliability (intraclass correlation coefficient [ICC] = 0.83)²⁸ and internal consistency (alpha = 0.86).²⁹ The PDI allows therapists to identify activities in which patients report experiencing heightened pain in order to address those areas and document change over time.

Brief Pain Inventory

The Brief Pain Inventory (BPI) is a self-report measure that allows patients to document pain level in general life activities and is available in short (9 items) and long (17 items) versions.³⁰ Although initially developed for patients with pain secondary to cancer, the assessment is now commonly used for patients with chronic pain resulting from multiple causes. The scale includes the ability for patients to pinpoint their pain location on front and back anatomical diagrams. Both versions allow patients to rate their pain level from least to worst on a 10-point Likert scale in the last 24 hours and on average. Seven questions ask patients to report to what degree pain has interfered with their general activity, mood, walking ability, normal walk, relations with others, sleep, and enjoyment of life (0 = does not interfere, 10 = completely interferes). The BPI yields two scores: a pain severity score (with a total score ranging from 0 to 40) and a pain interference score (with a total score ranging from 0 to 70). Test–retest reliability was found to be high for both pain severity and pain intensity ($r = 0.80$, respectively).³¹ Internal consistency was also found to be high for both pain severity and pain intensity, with alpha coefficients ranging from 0.81 to 0.89 and 0.88 to 0.95, respectively.³² Construct validity was also found to be high.³³ Although the BPI allows therapists to understand a patients' pain with regard to severity and interference in general life activities, it does not allow for an in-depth assessment of pain interference in the common basic ADLs and IADLs that occupational therapists typically assess.

Canadian Occupational Performance Measure

The Canadian Occupational Performance Measure (COPM) is a 5-item, 10-point rating scale (1 = most important, 10 = least important) designed to be completed conjointly by a therapist and participant and requires approximately 30 minutes to administer.^{34,35} Although the scale was not designed to measure pain specifically, it can be modified to assess the patient's most important daily activities impacted by pain. Patients can be asked to identify the five most critical activities that are adversely impacted by pain in the areas of self-care, productivity (e.g., work, volunteerism, home management), and leisure. After the identification of five problems, participants are asked to rate both performance and satisfaction levels of the identified activities on a 10-point scale (1 = not satisfied; 10 = extremely satisfied). An open-ended narrative section is provided to allow therapists to record participant comments. The COPM is intended to be used pre- and postintervention to determine whether intervention impacted participants' perceived performance and satisfaction levels in identified areas. Test-retest reliability was reported to be high for both performance and satisfaction sections ($r = 0.89, p < 0.001$; $r = 0.88, p < 0.001$, respectively).³⁶ Inter-rater reliability was reported to be moderate for both performance and satisfaction sections (ICC = 0.67, $p < 0.05$; ICC = 0.69, $p < 0.05$, respectively).³⁷ Convergent validity with the Disability and Impact Profile was found to be moderate ($r = 0.74, p < 0.05$).³⁸

Intervention of Functional Skill Deficits Secondary to Chronic Pain

Occupational therapists treat patients with chronic pain as part of an interprofessional team that includes primary care physicians, pain management specialists, nurses, physical therapists, nutritionists, and psychologists. The intervention goals of occupational therapy (OT) in the treatment of chronic pain syndromes are to help patients learn to effectively manage their pain to participate in desired ADLs. Intervention consists of education and lifestyle modification, pain reduction, and activity adaptation.

Client Education and Lifestyle Modification

As noted previously, effective pain management is best achieved when pain is understood and addressed as having multiple and interrelated physical, cognitive, and psychosocial contributing factors. It is critical to help patients understand that the experience of pain is impacted by daily stress, mood, sleep quality, physical activity, movement patterns in daily activities, and physiological reactions to heat and cold. Patients should be instructed to complete a pain diary for 1 to 2 weeks, after which therapists should help patients identify patterns between their experience of pain and the above-noted factors. Once such patterns have been identified, therapists can help patients make lifestyle changes to effectively manage pain over time.

Sleep

Poor sleep quality includes difficulty falling asleep, frequent awakenings, and insufficient total sleep time (<7–8 hours). Poor sleep quality is associated with reduced tissue repair and heightened pain levels.³⁹ It is important for patients with chronic pain to maintain regular sleep-wake times and attempt to gain 7 to 8 hours of sleep per night. Chapter 51 details intervention strategies that therapists can use to help patients enhance sleep quality. Therapists can also additionally help patients make changes to mattresses and sleep positions to reduce pain. For example, mattresses or mattress toppers that conform to the body and cushion bony prominences and painful regions should be adopted. Adjustable beds that can raise and lower the trunk and lower extremities can also help in pain reduction. When adjustable beds are not feasible, pillows can be used to position the body to reduce pain. For example, pillows should be evaluated to ascertain that they maintain the head and neck in a neutral aligned position that reduces rotational forces. Patients with LBP who sleep in a supine position often find that placing a pillow beneath the knees alleviates pain. Patients who sleep on their side should position a pillow between their knees to avoid internal rotation of the hips. Side-sleeping patients may also find that resting one arm across a pillow positioned at chest level reduces shoulder internal rotation and can alleviate pain.

Stress and Mood

The experience of pain activates sympathetic nervous system responses, including accelerated heart rate, increased blood pressure, and shallow respiration. Stress occurring as a result of normal ADLs commonly increases sympathetic nervous system responses, physiological inflammatory responses, and muscular tightening or guarding that can trigger pain phenomena.⁴⁰ It is critical for patients to understand the relationship between stress and pain for effective management over time. Therapists must assist patients to identify common life stressors and problem solve ways to reduce daily stress through lifestyle changes and stress reduction techniques. Lifestyle changes may involve activity

simplification and pacing in daily occupations (discussed later). Stress reduction techniques can include deep breathing exercises, guided meditation and visualization, and progressive muscle relaxation. These techniques help patients to increase parasympathetic responses, including the secretion of hormones that reduce heart rate and blood pressure, and to facilitate states of emotional calmness.⁴¹ Such techniques should become part of the patient's daily routine for effective pain management over time. Stress reduction techniques also include CBT in which patients are taught to rethink and reframe their typical thoughts to stressful situations so that such situations are no longer perceived with as great anxiety.⁴² CBT is an involved practice that requires patient training over several months. Although occupational therapists can integrate CBT into sessions, patients should be referred to CBT specialists for appropriate training.

Physical Activity

Patients with chronic pain syndromes are at risk for reduced activity levels and inactivity that can commonly contribute to increased weight gain, muscle atrophy, and loss of strength and endurance needed for typical daily occupations. Because patients fear pain sensations, they commonly adopt **guarding behaviors**, such as bracing, posturing, and limping. Such dysfunctional behaviors often contribute to additional musculoskeletal problems resulting from the overuse of certain muscle groups and body positions in an attempt to avoid pain. Therapists should help patients recognize guarding behaviors and substitute their use with functional movement. Patients with chronic pain who avoid activity can learn to adopt alternative movement patterns to accomplish desired occupations (discussed in section on Body Mechanics). Patients should also be encouraged to progressively challenge their perceived physical limitations, as many patients will stop activity participation because they anticipate painful responses that may subside as more effective pain management strategies are learned. A daily routine of low-impact exercise and participation in occupations should be customized for each patient with specified dosages throughout the day. Exercise and occupational participation routines should be sufficiently gentle to avoid pain but rigorous enough to maintain joint range of motion (ROM), strength, endurance, and appropriate weight.

Responses to Climatic Changes

Many studies have documented an association between orthopedic and rheumatic pain and weather changes—particularly humidity, heat, cold, and barometric changes.^{43–45} Such climatic conditions may alter fluid levels that line and lubricate joints, leading to increased inflammation. Humidity and barometric changes, in particular, may cause the tendons, ligaments, and muscles to expand, thus exacerbating inflammation and pain. There is also evidence that pain thresholds decrease in cold temperatures, causing heightened pain perception. Pain responses to humidity, heat, and cold should be part of patient education along with strategies to reduce pain when such climatic conditions occur. Strategies include (a) the use of bed and chair pads with options for heat and massage (which can be used in car, work, and home intermittently during the day and evening); (b) dressing in layers appropriate for the transition between indoor and outdoor activities throughout the day; (c) using thermal insulated gloves, hats, and shoes for cold temperatures and loose-fitting clothing of natural materials (e.g., cotton) to maintain cooler body temperatures in hot weather; (d) when possible, transferring activities from outdoor to indoor temperature-controlled environments during hot and humid weather; and (e) using over-the-counter pain patches and devices as needed.

Food Intake and Weight Control

Patients with chronic pain syndromes are at risk for gaining weight as a result of activity reduction and inactivity, and depression-related overeating. Overweight conditions exacerbate pain because of the increased demand on the musculoskeletal system.⁴⁶ Information regarding food intake and weight control should be part of client education, and patients should be assisted to understand their ideal weight, healthiest foods for weight management, portion control, and foods having inflammatory properties that should be avoided. Patients should also be assisted to develop a regular food intake schedule of well-proportioned, healthy meals. Occupational therapists can provide education regarding food intake collaboratively with nutritionists, nurses, and primary care physicians.

Body Mechanics

Body mechanics involve the proper positioning of the body during daily activities to avoid injury and pain. Patients with chronic pain syndromes should receive education regarding both the anatomy of the spine and extremities, and their proper positioning during movement to maintain health. Patient understanding of body mechanics is critical for effective long-term pain

management. Patients should be provided with the opportunity to practice body mechanics within self-identified desired occupations, and relative to static and dynamic postures and transitional patterns (e.g., sit-to-stand). General principles of body mechanics involve the following:

- Maintaining a straight back and upright posture
- Carrying objects close to the body
- Lifting with the lower extremities while maintaining a wide base of support
- Avoiding rotational and compressional movements of the spine

Activities Performed in Standing

To reduce back pain for activities performed in prolonged standing—such as washing dishes at a sink and brushing teeth—patients should stand upright with their bodies facing the activity (and avoiding spinal rotation and flexion). The patient can lean against the stable counter and rest one foot on a low stool or cabinet base to achieve a posterior pelvic tilt (Fig. 49-4). Patients can also rest one upper extremity on the counter to support the spine. Patients should be instructed to turn their bodies as one unit while maintaining the spine in a neutral position. The use of an antifatigue mat may also help to reduce lower extremity and back pain.

Figure 49-4 To reduce back pain for activities performed in prolonged standing—such as washing dishes at a sink and brushing teeth—patients should stand upright with their bodies facing the activity (and avoiding spinal rotation and flexion). The patient can lean against the stable counter and rest one foot on a low stool or cabinet base to achieve a posterior pelvic tilt.

Transitioning to Sit

When transitioning to sit from a standing position, patients should lower their bodies by flexing the knees and hips without bending the spine (Fig. 49-5). The patient's hands should be placed on the chair armrest to guide the descent and support the trunk. Chairs with raised seats are recommended because they require less muscular strength, which reduces spinal column stress and pain. A slightly reclined sitting posture is preferred for prolonged sitting. When seated to work at a table, patients should avoid bending over the work by moving the chair close to the work and raising or inclining the work surface as needed.

Figure 49-5 When transitioning to sit from a standing position, patients should lower their bodies by flexing the knees and hips without bending the spine. The patient's hands should be placed on the chair armrest to guide the descent and support the trunk.

Bed Positions

When lying in bed, the ideal posture to decrease pressure on the spine is supine with the knees flexed. A pillow should be placed under the knees to maintain their flexed position (Fig. 49-6). For patients who sleep on their side, a pillow should be placed between the legs with the knees slightly flexed to reduce hip internal rotation (Fig. 49-7). A pillow can also be placed at chest level with one upper extremity draped across to prevent shoulder internal rotation. When rising from bed, patients should log roll to the edge of the bed, allow both lower extremities to descend to the floor, and use their upper extremities to support the trunk to rise to an upright seated position (Video 49-1). A small bedrail can be used for patients with decreased upper extremity strength. When entering bed, patients should maintain a straight back and use their arms as support on the bed surface (or bedrail) to lower their body to a seated position on the edge of the bed. Once seated, the patient can raise the lower extremities to the bed while lowering the trunk to a supine position (Video 49-2).

Figure 49-6 When lying in bed, the ideal posture to decrease pressure on the spine is supine with the knees flexed. A pillow should be placed under the knees to maintain their flexed position.

Figure 49-7 **A.** For patients who sleep on their side, a pillow should be placed between their legs with the knees slightly flexed to reduce hip internal rotation. **B.** A pillow can also be placed at chest level with one upper extremity draped across to prevent shoulder internal rotation.

Toilet Use

 The body mechanics used to sit down on a toilet seat are similar to lowering oneself to a chair. Raised toilet seats and grab bars can be used to help rise from and sit down onto toilets (Fig. 49-8). When performing hygiene tasks after toileting, patients should be taught to reach between the legs rather than rotating the spine. A long-handled tissue paper holder can be used to extend reach if needed. When flushing the toilet, patients should rise from the toilet and stand, turn their bodies as a unit to face the lever (avoiding rotational trunk movement), and move as close as possible to the lever to reduce reaching. Patients can also use grab bars to support their trunk when flushing the lever (Video 49-3).

Figure 49-8 The body mechanics used to sit down on a toilet seat are similar to lowering oneself to a chair. Raised toilet seats and grab bars can be used to help rise from and sit down onto toilets.

Activities Requiring Bending and Reaching: Laundry, Dressing, and Cleaning

For tasks that require excessive reaching and bending of the spine—such as sweeping, vacuuming, retrieving laundry from a machine, and reaching into a closet—patients should be taught to position the body close to the task and maintain the spine in a neutral position. For front-loading laundry machines, patients should sit on a stool facing the machine to retrieve clothing items. For top-loading laundry machines, patients should stand close to the machine and lean against it (Fig. 49-9). One upper extremity can be positioned on the machine's top surface to support the trunk, while the other extremity retrieves the clothing. If the trunk must be flexed to reach fully into the laundry basin, one leg can be extended at the hip to reduce back strain. Clothing should be retrieved in small handfuls to reduce load on the shoulders and back, and ideally placed on a 36-inch (92-cm) or higher table to fold. Folded laundry can either be carried in small bundles held close to the body or placed in rolling laundry carriers to be transported to closets and drawers. Carrying large laundry baskets should be avoided.

Figure 49-9 **A.** For top-loading laundry machines, patients should stand close to the machine and lean against it. One upper extremity can be positioned on the machine's top surface to support the trunk, while the other extremity retrieves the clothing. **B.** If the trunk must be flexed to reach fully into the laundry basin, one leg can be extended at the hip to reduce back strain.

Dressing should be achieved through movements that maintain the back in a neutral position with avoidance of spinal flexion and rotational movements. Patients can sit in a chair to dress the trunk and upper extremities. The lower extremities can be dressed using a dressing stick, sock aid, and long-handled shoehorn. Clothing should be laid out nearby in an easy-to-reach location that does not require excessive reaching or bending.

When tools are used in activities, such as brooms and vacuums, they should be moved at short distances from the body to avoid excessive reaching that could trigger pain. Patients should move their bodies as a unit and avoid flexion and rotational spinal movements. Reachers can be used to retrieve light objects from closets and cabinets. Long-handled telescoping sponges and mops can be used to reduce bending and reaching while cleaning.

Lifting and Carrying Objects

Ideally, lifting objects from the floor should be avoided or accomplished using a reacher. When lifting objects is necessitated by work or child-rearing demands, patients should be taught to face the object and lower both knees in a semi-squat position toward the floor while maintaining a straight back and posterior pelvic tilt (Fig. 49-10). When lifting large or heavy objects, or a small child, patients should add more central support by lowering one knee to the floor (half-kneeling) so that the body is close to and facing the object. The goal is to bring and keep the weighted mass as close to the body's center of gravity as possible. Once the object or child is grasped securely, the knee on the floor helps push the body up and then both legs extend to lift the weight. The patient should be instructed to lift to an intermediate height, such as a chair, if possible, rest briefly, and then lift to carry.

Figure 49-10 **A.** When lifting objects is necessitated by work or child-rearing demands, patients should be taught to face the object and lower both the knees in a semi-squat position toward the floor while maintaining a straight back and posterior pelvic tilt. **B.** When lifting large or heavy objects, or a small child, patients should add more central support by lowering one knee to the floor (half-kneeling) so that the body is close to and facing the object. The goal is to bring and keep the weighted mass as close to the body's center of gravity as possible. **C.** Once the object or child is grasped securely, the knee on the floor helps push the body up and then both legs extend to lift the weight.

Patients must learn to carry light, well-balanced loads of laundry, groceries, and parcels close to the body with straight spinal alignment. Infants should be transported in front or back baby carriers or strollers. Through practice sessions, patients learn their safe load tolerances over given distances and time. It is important that practice employ common items, such as a half milk gallon (which weighs 4 pounds) or a gallon of bottled water (which weighs 8 pounds).

Driving

Transferring in and out of a car is similar to rising from and sitting on a chair. The car seat may need to be adjusted backward to allow sufficient space for transfers. The seat height should also be raised fully to reduce load on the spine and upper extremities when entering and exiting the car. Transfers should be performed with a straight back and the body moved as a unit to avoid rotational forces on the spine. Once seated, the car seat can be adjusted so that the hips are no higher than 90° (no higher than the knees) to avoid back strain. The car seat and steering wheel angle should be positioned to accommodate the size of the driver. An adjustable lumbar support may be available in some cars, or a lumbar roll can be used to provide additional low back support. When drivers are traveling for extended periods, rest breaks should be scheduled to allow position change and body stretches. Seats can also be reclined to decrease spinal compression that occurs from sitting upright for prolonged periods. Commercial car pads with options for heat and vibrating massage are available that can be placed in the driver's seat and plugged into lighters.

Computer Use at a Desk

Chapter 21 provides detailed information regarding the use of ergonomics to modify the computer desk area to reduce injury and pain. Primary principles include the following:

- The chair height and angle should be adjusted to maintain a neutral spinal position (avoiding spinal flexion and rotation).
- The monitor, keyboard, mouse, and work implements should be placed in close proximity to reduce reaching, bending, and rotational movements. Monitors should be at eye level to maintain the neck in a neutral position.

Patients should be taught to avoid prolonged sitting, which can increase spinal compression and load on the neck and shoulders. Some desks are adjustable and provide the option to become standing workstations. Standing for long periods without breaks, particularly on hard surfaces, however, can be associated with leg, low back, and foot pain. Hedge⁴⁷ recommends a combined sit–stand–walk movement routine involving sitting for 20 minutes, standing for 8 minutes, and walking for 2 minutes. Simply moving from a prolonged sitting to a prolonged standing position will not effectively prevent or reduce pain.

Energy Conservation and Work Simplification

Energy conservation is the arrangement of desired ADLs over the day or week for the purpose of preserving patient stamina, preventing fatigue, and minimizing joint stress and pain. Energy conservation also involves the idea that energy expenditure can be reduced in any one activity. **Work simplification** is the arrangement of tools and steps in an activity to reduce the amount of energy expended. The experience of chronic pain, particularly FM, is fatiguing, and patients commonly report that, as a result of pain, they do not have the energy desired for daily occupational participation.⁴⁸ Patients with FM also report that when they attempt to carry out large amounts of activities in 1 day, they commonly experience debilitating fatigue and energy depletion over the next 1 to 3 days. It is critical for therapists to help patients understand this pain-related phenomenon and prevent severe fatigue by pacing desired occupations over the day or week and adopting work simplification principles. The following provides general guidelines for energy conservation and work simplification:

General Guidelines

- Plan activities for each week to avoid completing too many in 1 day.
- Pace needed activities for each day so that rest periods are maintained between activities. Maintain a slow and steady pace; avoid rushing.
- Break large tasks into smaller ones that can be divided throughout the day.
- Maintain all supplies for daily activities in the location where each activity is to take place.
- Sit whenever possible, but avoid prolonged sitting. Whenever feasible, use the guide of 20 minutes sitting, 8 minutes standing, and 2 minutes walking.

Self-care and Dressing

- Sit to perform self-care when possible.
- Use a shower bench and handheld shower head instead of standing.
- Don a terry cloth robe after showering instead of using a towel to dry off.
- Lay out clothing the night before. Dress in sitting using a reacher, dressing stick, sock aid, and long-handled shoehorn.
- Wear loose-fitting clothing that is easy to don. Use clothing with zippers and Velcro instead of buttons. Use slip-on shoes or elastic shoelaces.

Meal Preparation

- Gather all supplies before starting.
- Sit when possible.
- Use lightweight cookware and dishes.
- Divide cooking tasks into smaller ones that can be paced with rest periods.
- Make large meals that can be frozen and used throughout the week.
- Use preprepared or delivered meals.
- Use paper plates and cups to eliminate dishwashing.
- Drag or slide heavy objects across the counter rather than lifting.
- Fill large pots on the stove with water from a pitcher rather than carrying heavy pots with water filled from the sink.
- Use electric appliances such as can openers and dishwashers. Allow dishes to air dry.

Cleaning and Housework

- Pace cleaning and housework activities over the week instead of 1 day.
- Use long-handled telescoping mops and sponges to avoid bending and reaching.
- When vacuuming, sweeping, or dusting, maintain the tool close to the body taking small steps to reduce bending and reaching.

Shopping

- Prepare a list of needed items before going to the store. List items by store layout to reduce needed walking.
- Use a wheeled store cart instead of carried basket.
- Pack grocery bags lightly to avoid heavy lifting.
- Avoid shopping at peak hours when stores are busiest. Use a delivery service if feasible.

Strength and Endurance Training

Because patients with chronic pain commonly fear exacerbation of their discomfort, they are at risk for reduced activity or inactivity, resulting in loss of strength, endurance, and ROM. Reduced muscular strength and ROM of the structures surrounding painful regions can further exacerbate pain syndromes. For example, loss of strength in the core muscles surrounding herniated lumbar disks places greater demand on the spinal column during movement and can increase pain. For these reasons, patients with chronic pain syndromes should be placed on slow, controlled, and graded strength and endurance training programs to prevent deconditioning. Interventions should begin as gentle and slow-paced activities that are initially graded to match and then gently challenge the physical and emotional abilities of each patient. Interventions should also be embedded within meaningful functional activities to each patient, such as pushing and pulling a vacuum cleaner, standing while folding laundry, and carrying weighted grocery bags. Activities can be progressively increased in time, repetitions, distances, and weight in accordance with each patient's tolerance and progress. Proper body mechanics should be emphasized in all strength and endurance training activities. Aquatic therapy is particularly beneficial for patients with chronic pain because water's buoyancy decreases gravitational forces on muscles and lessens spinal compression. Water also provides resistance helpful to build muscular strength and endurance in a gentle way over time.

Adaptive Equipment

Adaptive equipment for patients with chronic pain is recommended to reduce energy expenditure, joint strain, and spinal rotation and flexion. Chapter 42 details adaptive equipment to preserve joint integrity of patients with rheumatoid and osteoarthritis. The following are the most commonly

recommended adaptive equipment and supplies for patients with FM and chronic pain secondary to orthopedic conditions:

- Shower benches, grab bars, handheld shower heads, long-handled bathing sponges and brushes
- Stools on which to sit while performing self-care at a sink, meal preparation at a kitchen counter, and household activities such as folding laundry
- Long-handled telescoping dusters, mops, and sponges
- Reachers, dressing sticks, sock aids, long-handled shoehorns, and elastic shoelaces
- Grab bars, toilet safety frames, raised toilet seats, and long-handled tissue wipes

Physical Agent Modalities

Physical agent modalities are interventions and technologies that use force or energy to promote the healing process and reduce pain. In OT, physical agents are commonly used as a precursor to interventions involving occupational participation in patient-identified desired daily activities. Physical agents can increase soft-tissue elasticity and joint flexibility and reduce painful regions in preparation for the engagement in functional activity.⁴⁹ Chapter 24 provides an exhaustive detail of available, commonly used physical agent modalities. There are several commonly used physical agents in the treatment of chronic pain (discussed later). It is important for therapists to obtain appropriate training in physical agent use and adhere to the licensing regulations of their state or municipality.

Hot Packs

Hot packs are a form of thermotherapy that provide a moderate dose of moist heat that can be applied to a painful region.^{48,49} Hot packs are indicated for chronic conditions and should not be used for acute conditions because of heat's potential to increase inflammation. Hot packs should never be placed directly on skin; instead, dry padding should be used between hot packs and skin to avoid burns (Fig. 49-11). The patient's skin should be checked after 5 minutes of application for redness, blistering, or potential burns, and the patient asked about his or her comfort level. Generally, hot packs should be left on for 15 to 20 minutes to achieve a therapeutic effect.

Figure 49-11 Hot packs are a form of thermotherapy that provide a moderate dose of moist heat that can be applied to a painful region. Hot packs should never be placed directly on skin; instead, dry padding should be used between hot packs and skin to avoid burns.

Cold Packs

Cold packs are a form of cryotherapy that conduct heat out of the body and into the cooling agent.^{48,50} Cold packs can be used in the management of acute inflammation and chronic pain. Some patients with chronic pain have heightened responses to cold sensations and cannot tolerate any form of cryotherapy. Dry padding should be used between cold packs and skin to avoid irritation. Therapists should monitor patients' skin and response to the modality. Cold packs should generally be applied for approximately 10 to 15 minutes.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) uses surface electrodes placed over the area of pain to stimulate afferent sensory nerve fibers to modulate pain perception (Fig. 49-12).^{48,51} TENS can be used to manage pain in musculoskeletal disorders, presurgically and postsurgically, and for both acute and chronic pain. Optimal electrode placement should correlate with pain structures and sources and can include dermatomes, and motor, trigger, and acupuncture points. Treatment time varies between 30 and 60 minutes. Home TENS units can be used as needed or on a three to four times daily schedule.

Figure 49-12 Transcutaneous electrical nerve stimulation uses surface electrodes placed over the area of pain to stimulate afferent sensory nerve fibers to modulate pain perception.

Biofeedback

Biofeedback uses surface electrodes and instrumentation to measure and display physiological body responses, including respiratory, cardiovascular, and neuromuscular.^{48,52} The feedback provided through this technology measures activity in the neuromuscular system and can be used for motor reeducation and the retraining of functional movement to both (1) reduce pain and (2) improve functional movement in daily activities. For chronic pain, biofeedback provides information related to hyperactive muscle contraction (spasm), alerting patients to consciously relax those muscle groups. Biofeedback provides immediate feedback (auditory or visual), allowing patients to objectively measure, determine, and quantify muscle activity and track motor performance changes.

Complementary and Alternative Therapies

A range of complementary and alternative therapies are increasingly used to treat chronic pain syndromes with evidence for effectiveness. These include acupuncture,⁵³ acupressure,⁵⁴ Tai Chi,⁵⁵ meditation,⁵⁶ integrated yoga,⁵⁷ and energy healing⁵⁸ (e.g., Reiki, therapeutic touch, Qigong, craniosacral therapy). Most of these therapies require training, and some require certification (e.g., acupuncture). Of these therapies, occupational therapists with training could provide meditation instruction, integrated yoga and Tai Chi, and energy healing. Meditation involves a focus on deep breathing and quieting of racing thoughts in the mind that induce states of stress. A daily practice of meditation can help patients with chronic pain to reduce stress levels that may heighten muscle spasms and physiological inflammatory responses. Progressive muscle relaxation, which can be practiced as a form of meditation, directly helps patients to systematically reduce tension held in all muscle groups of the body. Other forms of mediation include visualization and guided imagery in which a narrator provides guidance to release stressful thoughts and muscle tension, often against a background of calming music. Meditation for patients with chronic pain should not be performed in the traditional lotus position (sitting cross-legged with the feet resting on the floor or thighs), but rather seated in a chair or supine with a bolster beneath the knees.

Integrated yoga is a form of yoga in which typical yoga poses are modified to reduce joint stress, maintain the spine in a neutral position (avoiding spinal flexion and rotation), and maintain the hips in positions of $<90^\circ$ flexion. One form of integrated yoga is chair yoga in which patients perform poses while seated in a chair or in standing using the chair for support. Integrated yoga combines traditional gentle rehabilitation stretching exercises with modified yoga poses. Integrated yoga can help patients with chronic pain to maintain flexibility while using muscle groups in a gentle, low-impact manner.

Energy healing is the restoration of a patient's biofield through the channeling of what in the East is referred to as vital life force energy (i.e., Chi, Qi, and Prana). The human biofield is an electromagnetic field that surrounds and permeates living organisms.⁵⁹ Traditional Eastern biofield practitioners maintain that disease begins in the biofield as energetic imbalances. The objective of energy healing is to restore a patient's energy flow and release blockages that may impede healing processes. Such practices emphasize the idea that the body holds an innate intelligence and that the body's auto-healing response can be promoted through a practitioner's hands-on channeling of vital life force energy. A growing body of research has demonstrated support for the effectiveness of energy healing practices in various conditions, including chronic pain.

The use of complementary and alternative therapies in the treatment of chronic pain has become an important adjunct to pain medication, which, over time, has been shown to cause negative side effects, including digestive problems, liver toxicity, kidney damage, muscular atrophy, and cognitive deficits.⁶⁰

CASE STUDY

Patient Information

Nalani is a 46-year-old female of Pacific Island descent who received a diagnosis of FM 1 month ago. Symptoms include widespread musculoskeletal pain; severe fatigue, particularly after highly active days; disrupted sleep; and cognitive problems, including short-term memory deficits and difficulty concentrating. Nalani has worked full time as a nurse in a pediatric physician's practice for 12 years, but as a result of FM symptoms, has been forced to reduce her hours to part time.

Reason for Occupational Therapy Referral

Nalani was referred to OT to address pain and fatigue that have been interfering with basic ADLs and IADLs.

Assessment Process and Results

Through a patient history and the completion of a 1-week pain diary, the following information was obtained regarding Nalani's pain experience:

- Nalani experienced pain and tenderness at her cervical area, on her back across and between both scapulae, at her lumbar spine, above each iliac crest, across both sacral indentations, and at each hip and buttock area. Occasionally, pain was experienced in both knees.
- Nalani stated that pain onset began approximately 5 years ago after she sustained a car accident in which she injured her neck and, at the same time, lost her mother to cancer.
- Her pain was experienced as intermittent with worse pain reported in the early morning and after busy days at the pediatric practice. Pain was reported as aching and throbbing.
- Nalani reported that hectic days, stress, lack of sleep, and humid and cold weather exacerbated her pain level.
- Relief could sometimes be found after spending 1 to 2 days in bed.

Through an occupational profile, it was determined that many of Nalani's desired ADLs had become disrupted and difficult to complete, including showering, meal preparation, laundry, cleaning, grocery shopping, and work. Because of pain and decreased energy, she would commonly forgo laundry and cleaning for a month and then spend an entire day completing these activities, causing debilitating pain and fatigue for 2 days afterward.

COPM scores before intervention were reported as follows:

- Showering: Performance = 2, Satisfaction = 2
- Meal preparation: Performance = 3, Satisfaction = 2
- Laundry: Performance = 1, Satisfaction = 1
- Cleaning: Performance = 2, Satisfaction = 2
- Grocery shopping: Performance = 4, Satisfaction = 3
- Work: Performance = 5, Satisfaction = 5

Occupational Therapy Problem List

- Pain and tenderness in the neck, shoulders, low back, hips/buttocks, and knees that interferes with participation in desired ADLs
- Severe fatigue after showering, meal preparation, laundry, cleaning, grocery shopping, and often work
- Debilitating fatigue after overactivity, commonly resulting in 1 to 2 days of bed rest

Occupational Therapy Goal List

- Provide education about the relationship between sleep, activity level, climatic changes, and pain level.

- Provide education in and practice opportunities to use appropriate body mechanics in desired ADLs to reduce and prevent pain.
- Provide education in and practice opportunities to use energy conservation, work simplification, and adaptive equipment in desired ADLs to reduce and prevent fatigue and pain.
- Begin a slow, gentle, low-impact, progressively graded strength and endurance training program as tolerated by the patient.
- Provide education in and practice opportunities to use guided imagery and progressive muscle relaxation as forms of meditation.
- Use physical agent modalities as a precursor to occupational participation during OT intervention sessions. Provide education about hot packs and TENS units for home use.

Intervention

Intervention began by helping Nalani understand the relationships between sleep disruption, stress levels, physical exertion, and climatic conditions. Nalani was assisted to learn sleep strategies, her mattress was replaced with a softer memory foam mattress that contoured to her body and relieved pressure on bony prominences, and her pillow was replaced with one that prevented her neck from positions of flexion and rotation. A pillow was also used beneath her knees to relieve low back strain.

Nalani also received instruction in and opportunities to practice meditation in the forms of guided imagery and progressive muscle relaxation. She was given meditation videos and placed on a home meditation schedule of 5 days per week for 20-minute sessions.

The therapist and Nalani also spoke about the impact of humidity and cold on her pain levels, as she identified these as stressors. Strategies to deal with these specific weather conditions were discussed, including dress and the adoption of a dehumidifier.

Because Nalani reported that increased activity levels exacerbated pain and fatigue levels, energy conservation and work simplification strategies were taught and practiced within the specific ADLs that she identified as most important. All desired daily activities were scheduled over the week in intervals so that they could be slowly accomplished leaving time for rest periods. All large tasks, such as meal preparation, were broken down into smaller more manageable ones that could be paced over the day or week. Nalani was also encouraged to prepare a larger amount of food on the weekend that could be frozen and used over weekdays.

Recommended adaptive equipment and supplies to reduce fatigue and pain included (1) a shower bench and handheld shower head, shower grab bars, and long-handled bathing sponge; (2) a long-handled telescoping duster, mop, and sponge; (3) a reacher, dressing stick, sock aid, long-handled shoehorn, and elastic shoelaces; (4) grab bars at the toilet and a raised toilet seat; (5) a stool on which to perform self-care and meal preparation; and (6) lightweight cookware and dishes.

Nalani was also taught appropriate body mechanics with opportunities to practice these in the specific activities of showering, grooming at the bathroom sink, meal preparation, laundry, cleaning, and carrying grocery bags and work-related medical supplies.

A gentle, slow-paced, low-impact strength and endurance training program was begun and progressively graded in accordance with Nalani's tolerance. All training was embedded within desired daily activities, such as vacuuming; making a bed; carrying grocery bags; and retrieving, folding, and transporting laundry.

Hot packs were used at the beginning of each therapy session to loosen soft tissue and reduce pain at the low back and shoulders. Nalani also received instruction in hot pack and TENS unit for home use. Cold packs were contraindicated because Nalani reported that cold commonly induced pain and tenderness.

At the end of 3 weeks, Nalani reported that she was better able to participate in desired occupations with less pain and fatigue. She had begun to gradually increase her work hours with the support of her employer who provided work accommodations, including 10-minute rest periods each hour, the use of a wheeled cart to transport medical supplies, and the ability to use a stool while taking patient vitals.

COPM scores at intervention end were as follows:

- Showering: Performance = 5, Satisfaction = 6
- Meal preparation: Performance = 6, Satisfaction = 6
- Laundry: Performance = 5, Satisfaction = 3
- Cleaning: Performance = 7, Satisfaction = 8
- Grocery shopping: Performance = 6, Satisfaction = 6
- Work: Performance = 7, Satisfaction = 8

Evidence Table of Intervention Studies for Chronic Pain and Fibromyalgia

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Lifestyle Redesign, a treatment method focused on development of healthy habits and routines for self-care ²³	Treatment includes education, self-analysis of occupation, problem-solving, development of motivation, and behavioral change. Treatment is driven by progression of modules.	Forty-five chronic pain patients (32 women, 12 men); most common diagnoses included lumbago, myalgia (e.g., FM), and complex regional pain syndrome.	Mean number of OT treatments per patient = 9.04; mode = 8 sessions; mean duration of therapy = 18 weeks	One group pretest and posttest design Level III	Significant effect on quality of life, self-efficacy, and functional abilities; no significance in pain reduction.	COPM indicated increase in performance and satisfaction of performance ($p < 0.001$); Short form: 36 quality-of-life measure indicated increased role participation secondary to physical and mental health ($p = 0.0013$ and $p = 0.0041$) and increased social functioning ($p = 0.0004$). Pain Self-Efficacy Questionnaire indicated increased functional ability despite pain ($p = 0.0030$).

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Integrated care team to reduce disability from chronic low back pain in working and private life, vs. treatment as usual ⁶¹	In the integrated care team, a physician supervised a workplace intervention and graded activity program, including cognitive-behavioral principles. The team consisted of a physician, a medical specialist, an occupational therapist, and a physical therapist. The care team and patient shared a common goal of return to work and occupational function. They communicated closely throughout treatment via email, letters, and a conference call every 3 weeks.	Adults aged 18–65 years with LBP, had LBP for >12 weeks, were in paid work for at least 8 hours a week, and were absent or partially absent from work. These were assigned to integrated care intervention group ($n = 66$; 37 men and 29 women) and treatment as usual control group ($n = 68$; 41 men and 27 women).	Average duration of integrated care was 67 days. Median number of team consultations: physician 2.2; occupational therapist 2.4; physical therapist 6.5 individual, and 11.6 group sessions.	Randomized controlled trial Level I	Reduced time-out of work, reduced sick days, and increased occupational function for those in the integrated care group	Time before return to work was significantly shorter for integrated care group (88 days in the integrated care group and 208 days in the control group; log-rank test, $p = 0.003$). Median number of sick days in 12-month follow-up period were significantly fewer (82 in the integrated care group and 175 in the control group; Mann-Whitney U test, $p = 0.003$). After 12 months, the integrated care group experienced a significantly higher level of functional status ($p = 0.01$).
Occupational therapy interventions for adults with fibromyalgia ²⁴	Systematic review. Included studies were peer-reviewed and conducted between 2000 and 2014 and featured an intervention approach. Studies were not all conducted by occupational therapists, but fall within the practice domain of OT.	Forty-two articles were reviewed in the areas of cognitive-behavioral ($n = 3$), self-management ($n = 2$), relaxation and stress management ($n = 5$), and emotional disclosure ($n = 3$). Included studies featured adult populations with FM diagnosis.	Dosage varied by study.	Systematic review Level I	Strongest evidence supports physical activity to improve pain and function, moderately strong evidence supports multidisciplinary interventions for reducing pain and depression, improving function. Some evidence indicates that CBT facilitates pain reduction, and improved mood and function. Low-quality evidence supports mindfulness-based stress reduction for short-term benefits.	No statistical analysis

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Yoga of awareness program to manage fibromyalgia ⁶²	Manualized gentle yoga poses, meditation, breathing exercises, group discussion, and study of yoga principles to develop coping skills. The program was delivered by a certified yoga teacher.	Participants were all females 21+ years old. All had diagnosis of FM for at least 1 year and had adhered to medical treatment regimen for >3 months. These were assigned to yoga intervention group ($n = 25$) and waitlist control group ($n = 28$).	Classes were conducted once a week for 8 weeks. Classes lasted 120 minutes and included 7–12 participants. Each class included 40 minutes of stretching, 25 minutes of meditation, 10 minutes of breathing techniques, 20 minutes of coping education, and 25 minutes of group discussion.	Randomized controlled trial Level I	Yoga participants experienced reduced symptoms, pain, fatigue, stiffness, depression, anxiety, tenderness, and environmental sensitivity. They also experienced improved social and activity engagement, memory, and balance.	Significant benefit for yoga group shown in pain, fatigue, stiffness, sleep, depression, memory, anxiety, tenderness, balance, and environmental sensitivity as assessed by Fibromyalgia Impact Questionnaire–Revised ($p = 0.003$). Via diary, yoga group also demonstrated significant improvement in the areas of pain ($b = -1.47, t = -5.90, p < 0.0001$), fatigue ($b = -1.68, t = -6.23, p < 0.0001$), emotional distress ($b = -1.34, t = -4.92, p < 0.0001$), vigor ($b = 0.92, t = 3.62, p = 0.0005$), success at acceptance ($b = 1.20, t = 5.10, p < 0.0001$) and relaxation ($b = 1.38, t = 4.36, p < 0.0001$).

Chapter 50

Human Immunodeficiency Virus

Gayle J. Restall

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Understand the social and epidemiological history of HIV/AIDS in the United States, focusing on the populations most prevalently infected.
2. Summarize the natural history of HIV and its concomitant medical and social trajectories.
3. Extrapolate the effects of HIV/AIDS on the occupations of people living with HIV/AIDS.
4. Select tools and assessment strategies to ascertain the occupational needs of individuals living with HIV/AIDS.
5. Describe intervention strategies to maintain, restore, and promote meaningful occupations of individuals living with HIV/AIDS.

CHAPTER OUTLINE

Description of Human Immunodeficiency Virus
Functional Impairment in Daily Occupation
Evaluation and Intervention of Functional Skill Deficits Secondary to Human Immunodeficiency Virus
Case Study

TERMINOLOGY

Cultural safety: the creation of environments in which people feel safe and are not assaulted for who they are and what they need; it involves respect, shared meaning, knowledge, and experience¹; to attain cultural safety, occupational therapists must understand their own positionality, and the social and historical context in which clinical encounters occur.

HAART: an acronym for highly active antiretroviral therapy, which is a combination of pharmaceutical interventions configured to act on HIV at different points of reproduction of the virus.

Health inequities: unfair and unjust systematic differences in the health status of groups of people as the result of social factors, including ethnicity, gender, education, employment, and socioeconomic status.

Opportunistic infections: infections that occur when organisms that are normally not harmful become pathogenic when the body's immune system is compromised.²

Retrovirus: a virus that can make copies of itself in host cells because it has an enzyme called reverse transcriptase that enables transcription of RNA to DNA.²

Description of Human Immunodeficiency Virus

Introduction

Human immunodeficiency virus (HIV) is a **retrovirus** that attacks the immune system and over time leads to acquired immunodeficiency syndrome (AIDS)—a condition in which progressive immune system failure allows fatal **opportunistic infections** to thrive in the human body. The symptoms associated with HIV were first described in 1981,³⁻⁵ and later in 1993, AIDS was officially defined.⁶ Surveillance systems for both HIV and AIDS have been established and revised in the United States^{7,8} and internationally.^{9,10} HIV/AIDS is regarded as a global pandemic because it has dramatically affected nations and populations throughout the world. Initially a fatal diagnosis, life expectancies have increased as a result of advances in medical management; HIV/AIDS is now considered a chronic disease.¹¹ Primary, secondary, and tertiary prevention strategies continue to be important to prevent the spread of the virus, prevent AIDS-related deaths, and support patients' ability to successfully age with HIV. The experiences and life trajectories of people aging with HIV are influenced by multiple health and social factors. The

biological and physical aspects of HIV/AIDS have been systematically studied and documented, but the more variable social trajectory continues to be shaped by the sociopolitical context in which individuals experience the disease. Consequently, quality of life after diagnosis is highly contingent on resources, supports, and access to relevant treatment. Occupational therapists can provide valuable programs and services to improve the lives of people with HIV/AIDS.

Epidemiology

HIV/AIDS Globally

According to the World Health Organization (WHO), 36.7 million people were living with HIV/AIDS in 2016.¹² Of those living with HIV/AIDS, 17.8 million were women aged 15 years or older, whereas 2.1 million were children and adolescents under the age of 15. Approximately 1.8 million new HIV infections occurred in 2016, representing a decline of 16% from 2010 estimates.¹² Changes in the annual number of new infections between 2010 and 2016 varied among global regions with the steepest declines in eastern and southern Africa (29%), as compared to 60% increases in eastern Europe and central Asia. In comparison, North America and western and central Europe experienced a 9% decline in annual rates of new infections. Estimates of the extent of the global HIV/AIDS pandemic are complicated by differences in surveillance methodology. Nevertheless, annual AIDS-related deaths peaked at around 1.9 million in 2005 and fell to 1.0 million in 2016. The decline in deaths has been attributed primarily to antiretroviral therapy (ART). Despite substantial declines, AIDS-related illnesses continue to be the leading cause of death worldwide for women aged 15 to 59 years.¹²

Populations and subgroups most affected by HIV/AIDS vary greatly by country and prevailing social, economic, and political conditions; however, the WHO has identified five key populations that are at increased risk of contracting HIV: men who have sex with men, people who inject drugs, people in prisons and other closed settings, sex workers, and transgender people.¹³ These populations are not mutually exclusive and often experience social contexts that increase their vulnerability

In 2014, the WHO advanced the 90-90-90 targets for ending the AIDS epidemic: (1) 90% of people with HIV know their HIV status, (2) 90% of people diagnosed with HIV receive ongoing ART, and (3) 90% of people receiving ART have viral suppression.¹⁴ The WHO predicted that achieving these targets would prevent HIV-related illnesses, AIDS-related deaths, and new HIV infections, ending the AIDS epidemic by 2030. Acknowledging the social, political, and economic drivers of both the HIV epidemic and the response to HIV, the Joint United Nations Programme on HIV/AIDS (UNAIDS) has stressed the importance of multisectoral collaboration to address factors including inequality, poverty, education, economic growth, peace, safe cities, **cultural safety**, and healthy living.¹⁵

HIV/AIDS in the United States

At the end of 2015, 973,846 people were living with a diagnosis of HIV in the United States, and approximately 15% more were infected but undiagnosed.¹⁶ Incidence rates of new infections have decreased by 8% from 2010 to 2015.¹⁶ Despite these advances, HIV/AIDS remains a significant cause of death in the United States. In 2016, the most frequent modes of transmission for new HIV diagnoses were male-to-male sexual contact (67%), heterosexual contact (24%), injection drug use (6%), and combined male-to-male sexual contact and injection drug use (3%).¹⁶ From 2011 to 2015, males accounted for 81% of new diagnoses.¹⁶ At the end of 2015, 71% of males living with HIV 13 years of age and older were believed to have contracted the virus through male-to-male sexual contact. In contrast, 87% of new diagnoses for females 13 years of age and older were attributed to heterosexual contact.¹⁶ Blacks/African Americans have the highest prevalence rates of HIV infection among racial and ethnic groups. In 2016, women accounted for 19% of new diagnoses, 61% of whom were black/African American.¹⁷ Drug therapies administered during the perinatal period have substantially reduced transmission from mother to child. HIV infection rates among infants have diminished, with 99 new diagnoses of perinatal HIV transmission in 2016.¹⁸

Etiology

HIV is a retrovirus that results in a gradual deterioration of the immune system. Once the virus enters the human body, it overwhelms the CD4+ T cells that usually defend the body against viruses. HIV converts its own RNA into a form that can be recognized and replicated using the

DNA of the host, a process called transcription. Once emitted into the cytoplasm of the cell, this reconfigured virus translates itself prolifically, producing new copies and long chains of viral proteins that mature into new infectious particles that are emitted into other cells. The damage to the immune system makes it increasingly difficult for the body to resist other infections and diseases, and the person becomes more susceptible to opportunistic infections.² HIV is transmitted through person-to-person contact with blood, semen, pre-seminal fluid, rectal fluids, vaginal fluids, and breast milk. Studies have shown that HIV does not live long outside the body and is not spread through contact with saliva, sweat, or tears, or through air or water.¹⁹ HIV status is confirmed by blood tests such as nucleic acid tests, antigen/antibody tests, and antibody tests. Rapid screening tests, oral antibody self-tests, and home collection tests are becoming increasingly available and, if positive, need to be followed by a confirmatory test.²⁰ Universal screening programs have been advocated because many people living with HIV remain undiagnosed.

It is rare for health care providers to contract HIV through patient contact. In these cases, transmission is most likely to occur as a result of a piercing from a contaminated needle or other sharp item.²¹ Precautions are advised if the provider is handling blood and blood products, regardless of whether HIV infection or risk status is known.²² Universal precautions include using barriers such as gloves and masks, washing skin that comes in contact with bodily fluid, and safe and careful disposal of sharps. Special care should be taken to avoid exposing HIV-positive persons to infectious agents because their compromised immunity makes them more vulnerable to opportunistic infections that can cause serious health consequences.

Course, Prognosis, and Contextual Factors

Different strains of HIV have been identified.²³ Viral load and strength of a particular HIV strain have been associated with the rate of disease progression. HIV-1 is the most common strain in the United States and worldwide, and is associated with a more rapid progression than the HIV-2 strain found in some areas of West Africa. Some people seem to be resistant to rapid translation of the virus, and there is a minority of individuals who do not progress through clinical stages even without being on ART.²³ Concurrent diseases or poor health status before infection can increase vulnerability and complicate medical interventions. Early detection of infections and adherence to medication regimens can prevent or slow the virus from usurping the immune system in people who respond positively to medications.

Sociopolitical Context of HIV/AIDS

HIV infection is most frequently attributed to unprotected sexual intercourse. Globally, infections rates are highest among women who have sex with men. People experiencing poverty in poorly resourced countries are more vulnerable to the spread of HIV. According to 2015 data, sub-Saharan Africa represented 66% of new HIV infections worldwide, 47% of which were women aged 15 years and older.²⁴ In the United States, HIV is still most prevalent among men who have sex with men; however, the incidence of infection attributed to heterosexual sex is rising. HIV disproportionately affects minority groups, particularly African Americans.¹⁷ The distribution of HIV represents an alarming health disparity globally and in the United States.

Stigma and Discrimination

HIV is a highly stigmatized health condition. In North America, men who have sex with men, people of color (Black/African American, Hispanic/Latino, and Indigenous), transgender women, injection drug users, and sex workers are overrepresented in the population of people living with HIV. People associated with socially stigmatized identities, in addition to HIV, can have compounded experiences of oppression. Crenshaw initially coined the term intersectionality to describe how being a woman and being black intersected in the experiences of oppression.²⁵ Since that time, intersectionality has become an important way of conceptualizing people's experiences resulting from multiple stigmatized identities. Occupational therapists need to recognize and understand the ways that people living with HIV can experience intersecting forms of stigma and discrimination. Therapists need to develop cultural humility and implement culturally safe practices to promote productive therapeutic relationships based on inclusion, trust, and respect.²⁶ Therapists also need to identify and respond to **health inequities** that result from historical and current injustices, diverse identities, living arrangements, and access to opportunities that promote health and well-being. Ensuring knowledge of and linkage to external health, social, and peer support services, and advocacy for fair and just policies and practices are important strategies.

Because of the risks for discrimination within the environments in which people with HIV live, work, spend leisure time, and build meaningful relationships, disclosure of HIV status can be a complex decision. The criminalization of HIV nondisclosure, in situations in which HIV transmission is likely, is embedded in laws in many jurisdictions and further compounds disclosure decision-making. Despite the lack of evidence that HIV nondisclosure laws have reduced transmission rates, and in the context of successful prevention and treatment, these laws persist.²⁷ People living with HIV have protections under anti-discrimination legislation, and occupational therapists should be aware of these protections and connect people with resources to help them understand their confidentiality rights. Efforts to reduce HIV-associated stigma are important to promote prevention, testing, and linkage to care.

Signs and Symptoms

Without treatment, people with HIV typically progress through stages.¹⁹ Stage 1 is the acute infection period in which people with HIV are highly infectious. Within 2 to 4 weeks of initial exposure, most, although not all people infected with HIV experience flulike symptoms, such as fever, headache, chills, rash, sore throat, fatigue, mouth ulcers, and enlarged lymph nodes. Until the body's immune system is depleted of resources to combat the virus, the infected person may not experience further symptoms. Many people remain unaware that they have the virus.²⁰ Stage 2 is the chronic stage in which the virus is active but reproduces at low levels, leaving the individual with few symptoms; however, the virus can still be transmitted during this stage. For some people who are not taking medications, this stage may last up to a decade or be much shorter. For many people with HIV who take ART medications as prescribed, this stage may last several decades. In addition, with medications, people's viral load can be suppressed to very low levels with much less likelihood of virus transmission. Stage 3 is AIDS; symptoms include weakness, weight loss, chills, fevers, sweats, and swollen lymph glands. A diagnosis of AIDS is made when a person with HIV has a CD4 count less than 200 cells per mm³ or has an AIDS-defining condition that includes opportunistic infections and life-threatening cancers.²⁸

As the disease progresses, people with HIV often experience HIV-associated neurocognitive disorders (HANDs), characterized by impairment with memory, concentration, attention, and motor skills. The symptoms have been classified into three conditions according to symptom severity and functional impairment:

- Asymptomatic neurocognitive impairment (ANI)
- HIV-associated mild neurocognitive disorder (MND)
- HIV-associated dementia (HAD)²⁹

People living with HIV experience higher rates of mental health conditions than the general public.³⁰ These conditions can include depression, anxiety, and post-traumatic stress disorder. In addition, stressful life situations, HIV infection, opportunistic infections, and/or some medicines used to treat HIV may contribute to the development of mental health conditions.

Aging with HIV

The success of current medication regimes has meant that many people with HIV are living long-term. People aged 50 years and older account for approximately 45% of Americans living with HIV and comprise two distinct groups.³¹ One group consists of people newly diagnosed. In 2015, 17% of new HIV diagnoses in the United States were attributed to people aged 50 years and older.³¹ The second group consists of people living long-term with HIV as the result of successful treatments that have transformed HIV into a chronic health condition. This latter group comprises the majority and will continue to increase in numbers, presenting unique and not yet fully understood challenges to HIV intervention for successful aging.

People aging with long-term HIV are at higher risk of co-occurring chronic health conditions, including cardiovascular disease, some cancers, kidney disease, liver disease, cognitive impairment, frailty, and bone disease.^{32,33} These comorbid conditions tend to occur at younger ages and with greater frequency as compared to the general population and may be related to multiple social and other risk factors, in addition to the direct effect of HIV and antiretroviral treatments.³¹ As people living with HIV age, co-occurring chronic health conditions can increase the risk for and experience of functional impairments that can restrict engagement in meaningful activities. Promoting physical and psychosocial well-being should be a priority with attention to early and sustained treatment; control of risk factors; addressing health disparities through health

care, and health and social policy initiatives; strategies to reduce stigma and discrimination; interventions to promote health such as physical activities; and social support networks.³¹ People living with HIV have identified the importance of maintaining social support networks, taking responsibility for their health, assuming a healthy lifestyle, and taking part in meaningful activities important to aging well.³⁴

Medical Management

The best treatment for HIV is prevention. Prevention strategies entail raising public awareness, providing education, and promoting individual behaviors that avoid risk or minimize harm. Proper and consistent condom use during anal and vaginal sex is an important universal prevention strategy. For people who use injection drugs, harm reduction strategies have been shown to be safe and effective, and include needle and syringe exchange programs, and opioid substitution treatments.^{35,36}

Pre-exposure prophylaxis (PrEP)—a combination of two antiretroviral drugs (tenofovir disoproxil fumarate and emtricitabine)—is an option for those at high risk, including HIV-negative partners in serodiscordant relationships, injection drug users who share needles, and people who frequently have unprotected sex.^{37,38} For individuals who are at incidental risk for exposure to HIV, such as occupational exposure when handling blood products or after sexual assault, postexposure regimes of antiretroviral medications started as soon as possible and within 72 hours with follow-up are recommended.^{39,40}

Advances in pharmaceutical interventions have increased survival and extended years of quality life. ART consists of a combination of pharmaceuticals to treat HIV and should be started as soon as possible. Currently, there are seven classes of drugs used to treat HIV, and most people take a combination of three drugs from at least two drug classes. Combination therapies, called highly active antiretroviral therapy (**HAART**), are aimed at preventing HIV from reproducing itself, thus reducing the loss of CD4 cells that have the important function of helping the body to fight infections.⁴¹ Thus, ART medications can maintain or increase the CD4 cells in the system while reducing viral load (Fig. 50-1). Consistent use of ART medications, in many people, can suppress viral loads to levels that are essentially undetectable by HIV viral load tests.²⁸ In addition, there is now a convincing body of evidence that a person with sustained undetectable viral loads cannot transmit the virus through sexual contact.^{42,43} Long-term use of HAART is associated with side effects, including fat redistribution, liver damage and disease, insulin resistance, osteoporosis, nervous system effects, and psychiatric disorders.⁴¹ Despite such side effects, these medications have clear advantages for increasing life expectancy of people living with HIV and for preventing the virus' spread.

Figure 50-1 A. Natural progression of human immunodeficiency virus (HIV) infection. B. Progression of HIV infection with highly active antiretroviral therapy (HAART).

Mother-to-child transmission of HIV during pregnancy, childbirth, and breastfeeding can also be prevented. Mothers taking HIV medications throughout pregnancy, labor, and delivery; who provide HIV medications to their baby for 4 to 6 weeks; and who do not breast feed or pre-chew their baby's food, have reduced the risk of transmission to approximately 1%.¹⁸ The Centers for Disease Control and Prevention recommend that all pregnant women be routinely tested for HIV.

Functional Impairment in Daily Occupation

The symptoms and impairments resulting from HIV and its treatments, as well as sociopolitical barriers such as poverty and discrimination, can affect many aspects of people's lives, including their ability to engage in meaningful activities and social roles. Understanding the complexity of these roles for a client with HIV is important in establishing a baseline for decision-making and intervention. Understanding clients' goals, strengths, and resources is a vital starting point for promoting mastery and resiliency.

Depending on the person's symptoms and impairments, daily activities may be affected, including walking, transfers, and basic self-care, and household responsibilities such as shopping, meal preparation, and budgeting. Social roles, such as parenting, home management, work, and school, and relationships with family, friends, neighbors, and co-workers may also be affected. Psychosocial factors such as uncertainty about the future and concerns about HIV status disclosure to sexual partners, family, co-workers, and others may produce additional strain on social roles. Negotiating a complex health and social care system may create barriers to obtain needed supports and resources. Poverty, lack of safe and affordable housing, and food insecurity can pose additional challenges. For some, the social assistance surrounding HIV care may present new resources and supports.

Evaluation and Intervention of Functional Skill Deficits Secondary to Human Immunodeficiency Virus

A growing body of professional literature attests to successful and potential contributions of occupational therapy in addressing the functional needs of people with HIV/AIDS. Greater understanding of the complexity of need has resulted in the development of frameworks that highlight how people living with HIV experience episodic disability.⁴⁴ In addition, models of service delivery emphasize the important roles that occupational therapists can assume to support

people living with HIV to participate in desired activities and social relationships.⁴⁵ Holistic approaches that are client centered, strengths based, and culturally safe and that consider clients' personal and environmental factors are vital in clinical practice with this diverse population.¹⁸ Occupational therapy–related research has largely focused on the needs and experiences of people living with HIV, including the experiences of women,⁴⁶ people working or desiring return to the workforce and other productive occupations,^{47,48} and aging with HIV.³⁴ Literature reviews have highlighted recommendations for occupational therapists' contributions to evidence-based self-management interventions⁴⁹ and rehabilitation for comorbidities experienced by people living with HIV.⁵⁰ Evidence supporting the effectiveness of occupational therapy interventions for people living with HIV are less common and have focused on resumption of work and volunteer roles, and case studies of individualized home interventions (see Evidence Table at the end of this chapter).^{51–54}

Occupational therapy interventions for HIV/AIDS can be enhanced by the use of instruments that both address underlying client abilities supporting occupational performance and measure therapy outcomes. Based on assessment outcomes, occupational therapists can recommend lifestyle modifications and compensatory strategies to cope with symptoms. O'Brien et al. compiled a summary review of instruments used to describe disability as experienced by people with HIV that occupational therapists may find useful in their work.⁵⁵ Worthington et al. reviewed instruments and evidence specific to workforce participation, some of which address occupation.⁵⁶ The HIV Disability Questionnaire⁵⁷ is a promising instrument for measuring the multiple dimensions of disability, including symptoms and challenges to daily activities and social inclusion. There are also quality-of-life measures applicable to people living with HIV that have established psychometric properties.⁵⁸

Occupation Specific Assessments

Occupational therapists can use both qualitative and quantitative assessments to determine the occupational needs of persons with HIV/AIDS. The following are general assessment tools that can provide an overview of occupational performance issues specific to an individual. Given the diversity of people living with HIV, occupational therapists should always consider the cultural appropriateness of a specific assessment tool and process.

Qualitative Assessment Strategies

Each theoretical model of occupation is associated with instruments and strategies for framing occupation. An array of qualitative tools reflecting the naturalistic paradigm can be useful to reveal the nature of experience—in this case, how individuals experience HIV. Among these strategies, semi-structured interviews can elicit narrative reflecting occupational participation. One published narrative tool is the *Occupational Performance History Interview II*.⁵⁹ This tool is used to probe how a given illness, condition, or untoward event shaped or altered a person's occupations. These narrative data can be analyzed in a number of ways and used to generate plans and strategies for reconstructing occupation. Two other instruments, the *Occupational Self-Assessment*⁶⁰ and the *Worker Role Interview*,⁶¹ may also be useful.

Quantitative Assessment Strategies

Quantitative strategies are useful when the phenomenon in question is well defined and the query is focused. An example of a quantitative criterion-referenced tool useful for people with HIV is the *Assessment of Motor and Process Skills* (AMPS).⁶² This instrument enables the therapist to observe the person with HIV engaging in familiar tasks, quantify and compare the person's occupational performance, and recommend strategies and supports necessary for safe living. Using the international AMPS database, Merritt et al. found evidence for use of the AMPS as a valid measure of activities of daily living (ADLs) among people with HIV, including use as a potential tool to identify the need for community-based supports.⁶³ The Canadian Occupational Performance Measure provides the opportunity for people living with HIV to identify, prioritize, and self-assess their occupational performance needs and goals.⁶⁴ This instrument uses a client-centered approach to guide treatment priorities and measure outcomes.

In addition to these comprehensive measures of disability, quality of life, and task and occupational performance, the assessment of specific challenges to occupations affected by HIV/AIDS symptoms can be helpful for intervention planning. At times, it can be difficult to distinguish symptoms associated with HIV/AIDS from those related to treatment. Nevertheless, all symptoms can impact quality of life. Since the 1990s, over 30 indices have been designed that

capture both severity level and the individual's experience of HIV symptoms and effects.⁵⁵ Combined with other data, a symptom index informs the occupational therapist and other health providers so they may help the person with HIV to manage symptoms.

Assessment and Intervention for Common Signs and Symptoms

Psychosocial

Awareness of the psychosocial trajectory is equally important in the treatment of people with HIV/AIDS. As with any serious illness, initial diagnosis is usually followed by a grief response. Education is vitally important at this time. People living with HIV may experience symptoms of anxiety and depression.⁶⁵ Depression is common initially and intermittently throughout the disease process.⁶⁶ As the disease progresses, neurological changes and medication side effects may predispose the person with HIV to mood swings, prolonged depression, and cognitive impairment. Occupational therapists should be prepared to screen for depression and conduct further assessment and referral as necessary. Suicide risk should be assessed and protocols followed. In a literature review examining depression in people living with HIV, Nanni et al. recommended short, validated depression screenings.⁶⁶ The therapist should be aware that people living with HIV commonly report mild-to-severe symptoms of loneliness.⁶⁷

To address HIV psychosocial manifestations, the occupational therapist should explore whether the person is receptive to linking with a peer outreach worker who can provide information about HIV and helpful resources. In addition, many people living with HIV place importance on peer-mentoring others living with HIV.⁶⁸ Cognitive-behavioral interventions may be helpful,⁶⁹ and work and volunteering can provide social support networks. However, as people age with HIV, they may become more isolated as their social networks decrease. Connecting with others with whom people feel comfortable sharing feelings and obtaining advice can have a positive impact.⁶⁶ Occupational therapists should be prepared to employ psychosocial strategies to address depressive and anxiety symptoms or refer to appropriate professionals. Therapists have an important role in facilitating resiliency and promoting the development of social support networks and participation in family and community life.

Stigma, prejudice, and discrimination can be some of the most challenging obstacles for people living with HIV and can result in ongoing stress and limitations to social participation.⁷⁰ Confronting stigma on a daily basis can have negative effects on emotional and physical well-being. Occupational therapists can provide education within families, workplaces, health and social care organizations, and communities to dispel myths and misunderstandings about the transmission of HIV, reinforce the human rights of people living with HIV, and suggest ways to reduce the oppression of people affected by intersecting forms of stigmatization.

Fatigue

Fatigue, in contrast to tiredness, can be pervasive and persistent, contributing to difficulties in occupational engagement. Fatigue can affect people with HIV even when they are healthy and stable. There may be many explanations for the causes of fatigue in HIV, including depression, stress, the medical condition, and pharmacotherapies for HIV.⁶⁹ Whatever the source, fatigue can be disabling. Jong et al. identified several assessment tools available for assessing fatigue.⁷¹

With a clear understanding of the client's fatigue, the occupational therapist can assist in selecting appropriate strategies. Lifestyle counseling that addresses sleep hygiene, nutrition, activity level, and stress management can be helpful. Work simplification and energy conservation can be applied to many roles, including home management and work. The occupational therapist can help the person with HIV to establish role priorities, reserving time and energy to attend to personal health needs. This may entail negotiating and relinquishing some responsibilities and tasks to others, or arranging for support, such as homemaker services or workplace accommodations.

Pain

Pain is an important consideration for people living with HIV. Persistent pain can limit participation in and enjoyment of meaningful activities and roles. Occupational therapy is a recommended nonpharmacological intervention for chronic pain.⁷² A number of tools are available to occupational therapists to screen and assess pain experiences. After careful evaluation, occupational therapists can implement ergonomic and graded activity interventions, and recommend activity modification to promote tolerance and pacing.⁷³

Neuropathy

Neuropathies are a manifestation of HIV and a side effect of ART medications. Peripheral sensory polyneuropathy is common and can result in pain, numbness, poor balance, difficulties with fine motor control, and risk of thermal injury. Fine motor, sensory, coordination, and balance assessments can highlight the extent of deficits. Home and community assessments can highlight potential injury risks. Occupational therapists can prescribe equipment and suggest compensatory strategies and environmental modifications to reduce injury risk and improve function. For example, mobility aids may be helpful in reducing fall risk. Removing hazards that can cause tripping and installing safety rails in the bathtub to increase safe transfers are potential home adaptations. Teaching awareness and compensatory techniques for meal preparation and self-care can help prevent knife wounds and thermal injuries.

Neurocognitive Disorders

A substantial number of people living with HIV will develop neurocognitive disorders over their lifetime.⁷⁴ The more severe form of HAND, HAD, can cause significant functional impairment. However, even the MND subtype can affect the ability to carry out daily activities. Occupational therapists can choose from a variety of standardized assessments to evaluate cognition with careful consideration of the cultural and linguistic appropriateness of the instrument. In addition, functional assessments can be used to evaluate functional task performance. Ranka and Chapparo illustrated the use of the *Perceive, Recall, Plan, and Perform System of Task Analysis* to assess the cognitive strategies needed to perform everyday tasks with a man with HAD.⁷⁵ Askari et al. have completed preliminary work to develop an HIV-specific cognitive assessment.⁷⁶ Based on assessment results, personalized cognitive rehabilitation strategies that have shown promise for other forms of mild dementia may be appropriate.⁷⁷

Prevention Strategies throughout the Disease Trajectory

Occupational therapy for people living with HIV requires a holistic approach. As previously noted, some cohorts of people with HIV have experienced oppressions that have hindered the achievement of their occupational potential, and their engagement in valued activities and social roles. These oppressions have sociopolitical implications, and occupational therapists should be aware of this context. Interventions must be customized and responsive to the needs and priorities of individuals within their environments. Policy and social structures that perpetuate oppressions should be challenged. Primary, secondary, and tertiary prevention strategies are important.

Primary prevention of the spread of HIV is vital. Promotion of routine testing to detect HIV infection early, and linkage with care to initiate and maintain HAART, can help prevent transmission of the virus and slow disease progression. In the early stages of HIV infection, it is important that people resume or establish routines, habits, and behaviors that preserve health. Occupational therapists can assist individuals to plan and schedule medication management and health care appointments into their habits and routines.

Secondary prevention of complications resulting from living long term with this chronic health condition can include:

- Lifestyle counseling and self-management interventions
- Linking people with appropriate peer supports
- Referral to harm reduction programs
- Implementation of psychosocial interventions

If symptoms progress, the person with HIV can face challenges in work, parenting, self-care, and other occupational pursuits. At this time, it is common for people to experience periods of good health interspersed with periods of disability that disrupt routines and occupational roles. Whether the patient is a child or an adult, preserving and adapting occupational roles is critically important for both physical and mental health. Role exploration may be important for people who wish to assume new productive roles and habits. Additional strategies important to secondary prevention may include:

- Parenting classes
- Practicing independent living skills
- Job training/retraining

- Exploring play, leisure, and social activities
- Supporting self-advocacy
- Advocacy for access to needed supports and services
- Interventions to reduce intersecting forms of stigma and discrimination

Tertiary prevention of ongoing disability can be addressed through rehabilitation strategies to treat specific symptoms and comorbid conditions. Therapy may entail:

- Lifestyle counseling and disease self-management education
- Assessing the need for and supporting the negotiation of workplace accommodations
- Identifying ways to adjust routines and habits to maintain valued activities and roles, such as parenting, home management, volunteering, relationships, and leisure activities
- Interventions and supports to address psychosocial stresses associated with social and functional losses, disclosure decision-making, pervasive intersecting forms of stigma and discrimination, and negotiating sexual relationships

People aging with HIV/AIDS may experience increases in sensory deficits, muscle weakness, pain, fatigue, incoordination, compromised memory, and other sequelae that can compromise occupational roles. At this stage, tertiary prevention may entail:

- Environmental adjustments
- Teaching adaptive strategies
- Recommendation and provision of assistive devices and/or personal assistance
- Changes in living arrangements
- Engagement in meaningful roles
- Psychosocial supports to enhance mastery and resilience
- Adoption and maintenance of health-promoting habits and routines

Importantly, advocacy for universally accessible environments and tolerance for diversity are vital for promoting social participation and quality of life for people living with HIV.

CASE STUDY

Patient Information

Nancy is a 54-year-old African American who identifies as a cisgender heterosexual woman and uses the pronoun “she.” She has been living with HIV for the past 25 years and, for the past 10 years, has responded positively to HAART medication. Nancy lives alone on the second floor of a walk-up apartment building and works as a receptionist in a small manufacturing plant. Her daughter and two young grandchildren live nearby. Nancy occasionally looks after her grandchildren in the evening and weekends.

Reason for Occupational Therapy Referral

Nancy was referred to outpatient occupational therapy by her physician as a result of concerns about her reports of occasional falls, thermal injuries when cooking, and worries about her ability to manage at home and work. Nancy was struggling to find ways to cope.

Assessment Process and Results

The initial occupational therapy assessment was conducted at an outpatient clinic. The therapist interviewed Nancy to understand more about her specific concerns, the contextual factors that were influencing her occupational functioning, and Nancy’s goals and priorities for valued activities and roles. The therapist administered several standardized tests for balance, sensation, cognition, pain, and fatigue. The therapist also completed a home visit to observe how Nancy was managing her home environment and constructed a profile of Nancy’s priority concerns, valued roles, and hopes for the future.

Results of the assessment identified that fatigue was negatively affecting Nancy’s ability to function at home and work. Fatigue is a common symptom of people aging with HIV, but may also have been exacerbated by Nancy’s grief from the loss of her partner. Assessment results also confirmed that Nancy was experiencing mild cognitive impairment, balance difficulty, and paresthesia that are common sequelae of HIV/AIDS and its treatments. Nancy reported that she

had engaged in excessive alcohol consumption and partying after the death of her partner that occurred 6 months earlier, but recently made a commitment to change these habits because they were exacerbating difficulties with her job and relationships with her daughter and grandchildren. Nancy was struggling to find new ways to cope using more positive habits and routines to help maintain valued roles. Despite the tensions that Nancy and her daughter were experiencing, her daughter remained supportive.

Occupational Therapy Problem List

- Chronic fatigue, making some ADLs and instrumental activities of daily living (IADLs) difficult
- Mild memory impairment and confusion, causing her to make frequent mistakes at work
- Intermittent loss of balance, impacting mobility
- Paresthesia, affecting the execution of fine motor tasks
- Grief from the death of her long-term partner who died of AIDS-related complications a year ago
- Uncertainty about her ability to maintain her valued roles

Nancy identified her primary goals as maintaining her job and being a good support and role model for her grandchildren.

Occupational Therapy Goal List

In collaboration with Nancy, the following specific goals were established:

- Nancy will implement self-management, lifestyle strategies, and routines that facilitate her participation in ADLs and IADLs identified as most important to her health and well-being while maintaining good nutrition and sleep hygiene.
- Nancy will learn and implement home safety strategies relying on cue cards posted, where most needed, and use home and mobility equipment.
- Nancy will identify the workplace accommodations needed to maintain her health and speak to her employer about these.
- Nancy will implement strategies to address the mild cognitive issues she is experiencing at work through the use of notes, reminders, and organizational tools.
- Nancy will identify two interests that will lead to safe and productive time use.

Intervention

A home-based program was initiated two times per week for 4 weeks initially and one time per week for the next 2 months, after which a reassessment would determine the need for further intervention. Appointments were scheduled in the late afternoon to accommodate Nancy's work.

The therapist implemented the following intervention strategies:

- Home modifications and equipment were recommended to increase safe mobility and transfers.
- Precautions and compensatory strategies were identified and demonstrated to address sensory and cognitive issues.
- Self-management education and lifestyle counseling were implemented to (1) promote self-care, including medication adherence, energy conservation, nutrition, and sleep hygiene and to (2) establish the balance necessary to continue her valued roles of working and being a role model for her children and grandchildren.
- Workplace accommodations and compensatory strategies were identified to support Nancy's work function and ensure that she has the necessary time off to attend medical and health-related appointments.
- Support was provided to help Nancy identify and pursue interests.
- A referral was made for intensive grief counseling.

As the intervention progressed, Nancy stated that she did not need the safety procedures most of the time. With her daughter's support, however, Nancy began to accept that it was safer to be cautious than to have an unnecessary injury. Thus, she started to use a walker when outside and began using safer bath transfers with the provided equipment. Nancy also began

relying on safety reminders in the kitchen and implemented many of the self-management recommendations, including scheduled rest periods. Nancy continued to be reluctant to talk to her work supervisor about her need for accommodation. She indicated that she had not told anyone at work about having HIV for fear of being ostracized or fired. The occupational therapist helped Nancy understand that she was not required to disclose her HIV status, but could instead inform her employer that she has a medical condition confirmed by her doctor. Nancy identified that one of her favorite activities was singing in church. With encouragement from her daughter and the occupational therapist, Nancy joined the choir, which gave her the opportunity to make new friends who were very supportive.

At the time of reassessment, Nancy appeared much healthier. She was enthusiastic about her participation in the church choir and mentioned that several choir members had even begun to visit her at home, which Nancy reported had helped to reduce the loneliness she felt since her partner's death. Because Nancy had a tendency to do too much, she needed to be reminded to add activities into her schedule gradually. Despite all that she had experienced, Nancy stated that she was no longer bitter and seemed to have accepted her diagnosis and its implications in her life. Nancy now demonstrated awareness of the importance of eating well, resting, and taking her medication. She reported that she has incorporated these self-management strategies into her routines most of the time. Additionally, Nancy stated that she has developed good rapport with her physician and has continued to attend appointments with her grief counselor.

Evidence Table for Occupational Therapy HIV/AIDS Intervention Studies

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Four-phase vocational program: (1) 8 weeks of self-assessment and preparation for work, (2) effort to reacquire productive roles through experiences, (3) support successful employment, and (4) support sustained employment ⁵²	Model of Human Occupation (MOHO)-based program customized to individual needs to explore, develop skills, and seek employment	Convenience sample of 129 men and women with HIV/AIDS (106 males, 21 females, and 2 transgendered persons; mean age = 41 years); 30% attrition rate (39 of 129 participants)	Phase 1: 8 weeks, group session one time a week plus individual sessions; length of subsequent phases varied by individual.	Qualitative and participatory action research to examine and improve the program as it unfolded Level NA	Fifty participants achieved employment, two returned to school, and eight participated in volunteer or internship programs from 6 to 24 months after the program. Persons with a history of mental illness were more likely to benefit.	Ninety participants completed program; 67% of those achieved successful outcome (achieved employment, returned to school, or started volunteering); effect size not reported.

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
A program designed to increase productive participation; implemented in supported living environments ⁵³	Experimental treatment based on MOHO and the Social Model of Disability: Enabling Self-Determination (ESD) aimed at achieving productive participation (employment, school or training, volunteering), consisted of group sessions focused on empowerment and the employment process, use of peer mentors; individual meetings with therapists on request. Control: Standard care: education related to employment and productivity, written materials on community resources, option of individual meetings with therapists.	Sixty-five recruited; 38 (31 men; 7 women) received ESD and 27 (21 men; 6 women) received control treatment. Seventy percent African American. No significant differences between groups before or after attrition; 29.3% attrition	Both conditions overseen by occupational therapists. ESD: 2-hour initial evaluation session, eight 1-hour weekly group sessions, optional individual sessions for client-driven consultation, and peer mentoring. Control: 1-hour peer week for 8 weeks, group sessions, monthly presentations on employment and productivity for 9 months, written materials, and optional meetings with therapist. Evaluation at 3, 6, and 9 months	Nonrandomized two-group design Level II	The ESD group achieved higher levels of participation than the control group at each study interval.	Intention-to-treat analysis indicated significantly more ESD participants were engaged productively: 3 months: $\chi^2_{(df=1)} = 6.08$ ($p = 0.015$), odds ratio (OR) = 3.89; 6 months: $\chi^2_{(df=1)} = 8.88$ ($p = 0.004$), OR = 5.44; 9 months: $\chi^2_{(df=1)} = 5.75$ ($p = 0.018$), OR = 3.96. The ORs indicate large effects for the ESD program, with those participants twice as likely to be productively engaged at all three time points.

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
A 2-year pilot program to improve balancing health, work, and daily life that combined job skills training with chronic disease self-management ⁵⁴	The job skills training program entailed daily participation to which 6-biweekly sessions were added to address disease self-management, health, vocational performance, and quality of life.	Six groups of adults ($n = 53$) participated in the program over a 2-year period, 28 females and 25 males diagnosed with HIV 4+ years. Forty-two participants contacted 3–5 months postintervention. Twenty-one percent lost to follow-up.	For 6–7 weeks, 6 hours per day. Six 1.5-hour self-management focused sessions were integrated into an existing job skills training program to facilitate transition to work. Topics included balancing work and daily life, energy conservation, and nutrition.	Nonrandomized groups (6) received the same intervention over a 2-year period with pre- and post-examination of up to 42 individuals on key outcomes as measured by 11 scales, including the Canadian Occupational Performance Measure. Level III	Fifty-two percent of retained participants were working successfully, with another 41% actively seeking employment.	Outcome was determined using paired t tests and effect sizes. Three of the 11 scales indicated moderate-to-large effect sizes upon follow-up: perceived ability to balance health, work, and daily life ($r = 0.46$); health management and work ($r = 0.61$); and perceived ability to work ($r = 0.72$). However, only perceived ability to work showed significant ($p = 0.00$) improvement after treatment, which indicated that the outcome was probably not owing to chance.
Case studies of occupational therapy interventions with three people living with HIV who had diverse comorbidities and impairments ⁵⁵	Interventions were tailored to each of the clients' goals and assessment results. Interventions primarily occurred within clients homes and included promotion of ADLs and IADLs, environmental modification for home safety, recommendations for equipment, community navigation, priority setting, problem-solving, energy conservation, planning for stable housing, and home exercise program.	Client 1 was a 57-year-old single white male who was HIV positive for 28 years. Client 2 was a 50-year-old single black male who was HIV positive for 12 years. Client 3 was a 28-year-old single black female who was HIV positive for 8 years.	Client 1 had seven home sessions and three follow-up phone calls. Client had 12 home sessions and on home follow-up appointment. Client 3 had six home sessions and one follow-up phone call.	Descriptive case reports Level NA	Client 1 had little positive change and declined in some areas. Clients 2 and 3 showed positive changes in several areas.	No statistical analysis

Chapter 51

Sleep Disorders Secondary to Orthopedic and Neurological Disorders

Sharon A. Gutman

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Identify and evaluate possible sleep disorders in patients receiving occupational therapy services.
2. Understand the physiology underlying sleep disorders that patients commonly experience.
3. Understand how sleep disorders can impact daily occupational activities and performance in therapy sessions.
4. Modify patient environments to promote sleep onset and maintenance.
5. Help patients establish new and modify existing routines and habits to promote sleep onset and maintenance.
6. Help patients modify daytime activity levels to promote sleep onset and maintenance.
7. Bring a nonpharmacological treatment approach to the treatment team to address patient sleep disorders.

CHAPTER OUTLINE

Sleep Disorders: Definition, Prevalence, and Background
The Physiology of Sleep
The Impact of Sleep Disorders on Daily Occupation
Occupational Therapy Evaluation and Intervention of Sleep Disorders
Case Study

TERMINOLOGY

- Chronic insomnia:** a sleep disorder characterized by an inability to obtain sufficient quantity and quality of sleep per night that persists overtime and leads to ongoing sleep deprivation.
- Circadian rhythm modulation:** a 24-hour biological clock that regulates sleep, arousal, body temperature, muscle tone, blood pressure, and hormonal secretion; is located in the hypothalamus; and responds to cues of light and darkness.
- Nighttime awakenings:** the experience of waking during the night for a length of time often resulting from the need to void, feeling too warm, anxiety and depression, and disordered neurochemical and neurohormonal sleep regulators.
- Sleep deprivation:** the experience of insufficient sleep that persists overtime and leads to chronic daytime drowsiness and fatigue, poor concentration and memory, poor school and work performance, and interpersonal relationship problems.
- Sleep latency onset:** the amount of time required to fall asleep (also referred to as sleep initiation or induction).
- Sleep maintenance:** the ability to remain asleep and return to sleep if awakened, during a 7- to 8-hour time period.

Sleep Disorders: Definition, Prevalence, and Background

An estimated 50 million adults in the United States have diagnoses of **chronic insomnia** that exist independently of or occur secondary to a comorbid medical condition.¹ Approximately 70% of primary care patients² and 35% of assisted living residents³ have been treated for chronic insomnia or disrupted sleep. Chronic insomnia is a sleep disorder characterized by an inability to obtain sufficient quantity and quality of sleep per night that continues overtime and leads to ongoing **sleep deprivation**.¹ Chronic insomnia can take the form of poor sleep initiation and maintenance, persistence **nighttime awakenings**, early morning awakenings, and an inability to return to sleep once awakened. Chronic insomnia that exists independently of a comorbid clinical condition is believed to result largely from neurochemical and hormonal mechanism impairment that disrupts **circadian rhythm modulation** and the regulation of sleep–wake cycles. Sleep disorders that occur secondary to medical conditions (e.g., sleep apnea, traumatic brain injury [TBI], chronic pain) may begin as secondary consequences of a physiological problem, but if left untreated, become chronic and result in circadian rhythm dysregulation.⁴

Patients with ongoing and undiagnosed sleep deprivation experience daytime drowsiness and fatigue, poor concentration and memory, irritability leading to problems in interpersonal relationships, and poor work and school performance.⁴ There is substantial evidence that chronic insomnia increases the risk of hypertension, cardiopulmonary disease, diabetes, depression, anxiety, obesity, and hospital readmission.⁵

Typically, sleep disturbances are medically managed through sedative–hypnotic pharmaceuticals.⁶ Although medications such as benzodiazepines (e.g., temazepam [Restoril], triazolam [Halcion], flurazepam) and non-benzodiazepine receptor agonist hypnotics (e.g., zolpidem [Ambien], zaleplon [Sonata], eszopiclone [Lunesta]) have high efficacy and are widely available, they are associated with dependence and tolerance overtime, commonly leading to morning drowsiness and memory impairment, and have been reported to cause disorders such as somnambulism (i.e., sleep walking) and sleep amnesia (i.e., engaging in behaviors that cannot be recalled upon awakening).⁷ More alarmingly, the use of sedative–hypnotics in the elderly has been highly correlated with falls and resultant hip fractures.⁸ As a result of these negative side effects and drug use consequences, there is a growing movement among physicians and patients to increasingly use nonpharmacological interventions in the treatment of chronic sleep disorders.⁹

Occupational therapists provide nonpharmacological sleep interventions that target modification to (a) the environment, (b) routines and habits related to the daily sleep–wake cycle, and (c) daily activity levels impacting sleep initiation and maintenance.¹⁰ This focus contributes a unique perspective to the treatment team that, combined with medical management, can effectively ameliorate fragmented sleep commonly occurring in patients referred for occupational therapy services as a result of neurological or orthopedic conditions. This chapter describes the occupational therapy evaluation and intervention of sleep disorders resulting from disrupted circadian rhythm regulation secondary to environmental factors and/or comorbid medical conditions.

The Physiology of Sleep

Normal sleep is divided into two types, non-rapid eye movement (NREM) and rapid eye movement (REM) sleep that alternate throughout the sleep period. In the absence of sleep disorders, humans begin sleep through NREM stages 1 to 3. The first REM sleep period occurs approximately 90 minutes later and the two sleep types—REM and NREM—alternate in 90-minute periods, with each successive REM stage commonly increasing in length. NREM is divided into three distinct stages of progressive depth.¹¹

Each NREM stage has distinct brain wave patterns, eye movements, and muscle activity. The initial sleep stage, NREM stage 1, commonly occurs from 1 to 7 minutes and is characterized by alpha waves marking a wakeful relaxed state. NREM stage 2 follows and occurs for 10 to 25 minutes of the initial cycle but increases in length with each successive sleep cycle. NREM stage 2 sleep constitutes approximately one half of a total

sleep period and is characterized by low-voltage brain waves with sleep spindles and K-complexes that are believed to be important in learning and memory consolidation. NREM stage 3 follows and is characterized by delta brain waves consisting of slow, high-voltage waves lasting for about 20 to 40 minutes of the initial sleep cycle and constituting 10% to 15% of the total sleep period. REM stage is then entered and is characterized by low-voltage, mixed-frequency brain waves (theta and slow alpha), musculoskeletal paralysis or atonia, and REMs. REM stage sleep initially lasts for about 1 to 5 minutes but can increase to 30-minute periods as successive REM cycles occur. Dreaming commonly occurs within REM stage sleep.^{11,12}

The sleep–wake cycle is largely regulated by the circadian rhythm system, which is a 24-hour “biological clock” that regulates sleep, arousal, body temperature, muscle tone, blood pressure, and hormone secretion. This system is located in the suprachiasmatic nucleus of the hypothalamus and responds to cues of light and darkness. The suprachiasmatic nucleus receives messages from brightness detector cells located in the retina that serve to daily reset the clock.¹³ Researchers have suggested that the advent of industrialization, a 24-hour light availability, and access to technology with internal light sources (computers, smartphones, Kindles) have contributed to 20% of sleep disorders in Western societies.¹⁴ The suprachiasmatic nucleus also connects to a pathway that controls the secretion of melatonin, which is a sleep-inducing hormone produced by the pineal gland primarily in the evening before bedtime. Normal sleep–wake cycles are regulated by a homeostatic balance between a drive for sleep and a drive for wakefulness. Human sleep needs accumulate during the day and early evening, peak before bedtime, and diminish during the sleep period.¹⁵

Several neurotransmitters play key roles in the sleep–wake cycle, including dopamine, norepinephrine, serotonin, histamine, glutamate, acetylcholine, and orexin. Many of these neurotransmitters exhibit high activity during wakefulness, diminish during NREM sleep, and are at their lowest levels during REM sleep. For example, both serotonin and histamine promote wakefulness, increase the amount of time it takes to fall asleep, and can decrease REM stage sleep. Although orexin activation facilitates wakefulness, low levels of this neurotransmitter in the evening can serve to stimulate sleep. Conversely, orexin deficiency may result in fragmented sleep characterized by dysfunctional cycles of NREM and REM stages.¹⁶

The neurotransmitter and neuromodulator adenosine serves to inhibit wakefulness and induce sleep. Adenosine levels build throughout the day, and, during the night, after the body has experienced sufficient NREM restorative sleep, adenosine levels decline, allowing for wakefulness.¹⁷ Cytokines, which are small signaling protein molecules (including interleukin and interferon), contribute to this process. While cytokines are usually produced by the immune system in response to infection, they also have hypnogenic properties that induce drowsiness—perhaps to allow the body to conserve energy so that the immune system can optimally attack pathogens.¹⁸

As noted earlier, melatonin is a sleep hormone converted from serotonin in the pineal gland and increases in level before bedtime, causing drowsiness and lowered body temperature. Melatonin levels then increasingly rise to a normal level by the early morning. Synchronously, secretion of the stress hormone cortisol begins to increase toward the early morning in preparation for waking and is commonly capped by a 50% increase in production approximately 20 to 30 minutes after waking, referred to as the cortisol awakening response. Dysfunction in any of these neurotransmitter and neurohormonal systems, or in multiple systems, can result in sleep disorders.¹⁶

The Impact of Sleep Disorders on Daily Occupation

As noted earlier, chronic sleep disorders in the general population negatively impact daily participation in desired activities and result in daytime drowsiness; decreased attention, concentration, and memory; poor performance in work and school activities; and

irritability that affects social interactions.⁴ Chronic sleep deprivation has also been highly correlated with both auto vehicle and work-related accidents and injuries,¹⁹ and an increased risk of systemic disease, including hypertension, cardiopulmonary disease, and diabetes.⁵

The effects of chronic insomnia are doubly consequential when they occur in patients receiving hospital and assisted care services who, as a result of sleep disorders, are more likely to have poorer health outcomes, falls, and morbidity.²⁰ Patients receiving occupational therapy services, who have fragmented sleep as a result of hospitalization, are commonly unable to participate fully in rehabilitation activities, have difficulty concentrating and attending to therapy services, and may be more resistant to engage in therapy-related occupations. Sleep disorders are common in many neurological and orthopedic disorders and can exacerbate symptoms, reduce restorative sleep, and increase the risk of falls.²¹ In the elderly with dementia, sleep disorders adversely affect cognitive functions such as memory, increase agitation and wandering, and heighten the risk of falls with resultant fractures.²²

Patients with TBI commonly experience disruption of the circadian rhythm cycle as a result of injury and lose normal sleep–wake cycles. This loss of normal sleep patterns can result in chronic sleep deprivation that exacerbates the executive function impairments commonly accompanying TBI. Poor concentration, reduced executive control of cognitive functions, and greater disinhibition of thoughts and verbalizations can all become pronounced with the onset of a sleep disorder. Patients may be more lethargic than normal, or conversely, more rowdy and resistant to participate in therapy.²³ Relearning basic daily living skills lost as a result of injury (e.g., self-care, grooming, cold meal preparation) commonly becomes more inefficient when patients experience chronic sleep loss. Relearning or newly learning higher level life skills (e.g., money management, hot meal preparation, public transportation use) may become more challenging and seemingly unattainable when cognitive processes are negatively impacted by chronic sleep disruption.

Sleep disorders are also common after cerebrovascular accident (stroke), and an estimated 50% of patients with stroke experience chronically disrupted sleep resulting from circadian rhythm dysfunction and/or breathing difficulties secondary to stroke. Sleep apnea, in which the upper respiratory tract becomes obstructed repeatedly during sleep, is the most common breathing disorder resulting from stroke and increases the risk of a second stroke by 20% to 40%. Sleep disorders secondary to stroke may also result from circadian rhythm impairment in which the neurotransmitters and hormones responsible for sleep induction and awakening are not functioning appropriately. In both cases, sleep deprivation adversely inhibits neural recovery after stroke and heightens cognitive and motoric deficits.²⁴ Patients may arrive to therapy lethargic and disengaged, or conversely, may be agitated and resistant to participate in therapy activities. Cognitive deficits secondary to stroke are commonly exacerbated by sleep loss and may inhibit new learning or relearning of daily life skills.

It is estimated that 70% of patients with spinal cord injury (SCI) experience sleep disturbance as a result of one or more of the following: hypoventilation and obstructive sleep apnea, circadian rhythm dysfunction resulting from neurochemical–hormonal disruption and body temperature dysregulation, movement disorders such as restless leg syndrome, chronic pain and paresthesia syndromes (abnormal sensations such as burning or tingling), depression and anxiety, and voiding problems. As a result, patients with SCI may feel chronically sleep deprived, experience daytime drowsiness and fatigue, have memory and concentration problems, and may feel unmotivated to participate in therapy.²⁵ Adults with SCI and sleep loss commonly report a high percentage of napping during the day that interferes with daily activities such as maintaining a regular weight shift schedule to reduce skin breakdown and decubiti ulcers; regularly emptying urinal leg bags and voiding, which may otherwise result in urinary tract infections, kidney damage, and

autonomic dysreflexia (a life-threatening event resulting in uncontrolled hypertension); regularly inspecting skin integrity to reduce the occurrence of skin breakdown; and engaging in possible exercise and stretching to maintain available muscle strength and prevent contractures.²⁶

Chronic pain syndromes (e.g., rheumatoid and osteoarthritis, low back and neck pain, fibromyalgia) account for the most common reasons that patients experience sleep disturbance, and an estimated 20% of primary care patients report sleep disruption secondary to chronic pain.²⁷ In several studies, 60% to 70% of patients referred to pain management programs reported chronic sleep loss with longer periods needed to fall asleep, fewer total hours asleep, more frequent nighttime awakenings, and nighttime awakenings of longer duration than that of the average population.^{27,28} In another study, researchers found that pain tolerance decreased and pain perception increased as people experienced fewer hours of sleep.²⁹ Patients with pain were also found to experience fewer minutes in deep sleep stage 3 in which cell restoration and healing are believed to be most active.^{30,31} Patients with sleep disorders secondary to chronic pain syndromes commonly avoid daily occupations that may trigger pain, or they may feel too fatigued to participate in desired occupations. Activity avoidance commonly results in diminished muscular strength and endurance that exacerbates the pain syndrome. Activity avoidance also leads to diminished or insufficient daytime activity that compounds the sleep disorder in a bidirectional manner.³¹

Occupational Therapy Evaluation and Intervention of Sleep Disorders

As noted earlier, occupational therapists provide evaluation and intervention of sleep disorders that target modification to (a) the environment, (b) routines and habits related to the daily sleep–wake cycle, and (c) daily activity levels impacting sleep initiation and maintenance. When therapists detect patient sleep disorders, they should alert other members of the treatment team or, for community-dwelling patients, encourage patients to disclose sleep disorders to primary care physicians (PCP). While occupational therapists provide nonpharmacological sleep interventions, such services may be most effective when combined with medical management including continuous positive-airway pressure (also known as CPAP) ventilators and nonpharmacological sleep inducers such as melatonin (which can be obtained over-the-counter but should be discussed first with a PCP to determine its potential interaction with other medications).

Evaluation and Intervention of the Environment

Hospital and assistive care environments have been shown to adversely affect the amount and quality of patient sleep as a result of nighttime noise, lights, patient and staff activity, and sleep interruptions because of medical tests and procedures. Additionally, hospital and assisted care environments frequently do not provide sufficient access to external cues of day and night, and as a result, patients' circadian rhythm systems desynchronize with normal day–night cycles. It is common for hospital patients to feel sleep deprivation as a result of frequent awakenings, fragmented sleep, and insufficient restorative sleep.³² Residents of long-term care facilities, who have been exposed to these sleep reducing factors overtime, commonly experience chronic sleep deprivation that severely interferes with participation in daily occupation. Moreover, many long-term care residences are characterized by nonstimulating environments that promote excessive daytime napping that further exacerbates sleep disorders.³³ Therapists working within inpatient settings should expect that patients will likely experience sleep disruptions that may impact alertness, cognitive skills, motor function, and fatigue levels.

A number of sleep assessments, having acceptable reliability and validity, exist that can be used to measure patient sleep disturbances (e.g., Pittsburgh Sleep Quality Index³⁴ and General Sleep Disturbance Scale³⁵); however, because these collect data about sleep in the past weeks or more, they may not be appropriate for hospitalized patients in an acute or

subacute setting. Such assessments would be appropriate for use with long-term care residents and outpatients. As a general assessment, patients should be queried about their sleep amount and quality, including the following:

1. How did you sleep last night (poor, fair, good)?
2. Was your sleep restful?
3. On a scale ranging from 1 to 5 (1 = not at all fatigued, 5 = very fatigued), how fatigued do you feel today?
4. What time did you go to bed?
5. Did you have difficulty falling asleep?
6. How long did it take you to fall asleep?
7. Did you wake during the night?
 - a. How many times do you remember waking up?
 - b. How long were you awake before you fell back to sleep?
 - c. What made you wake up during the night?
8. What time did you wake up in the morning?
9. How many hours did you sleep last night?

Although several studies have found strong evidence that daytime light therapy improves both the quality and quantity of patient sleep, most hospital and assisted care environments do not provide sufficient exposure to daylight as a result of insufficient windows, reliance on florescent lighting, and location in regions lacking adequate sunlight. Patient rooms, resident dayrooms, and eating areas should be supplemented with artificial lighting systems that serve as an external cue to appropriately reset the circadian rhythm clock. Although the dose of light varied among studies, effectiveness was observed when artificial light systems of 2,500 to 10,000 lux were administered for 30 minutes to several hours per day (a typical room with average daylight has approximately 250 lux). Such light systems are relatively inexpensive and safe (do not emit heat or ultraviolet [UV] rays), and small light boxes can be purchased for patient rooms; larger systems can be installed in common areas. Researchers found that daytime use of external light systems in the range of 2,500 to 10,000 lux in hospitalized patients increased total sleep time, reduced nighttime awakenings, reduced sleep onset latency, and reduced nighttime wandering in the elderly with dementia.³⁶⁻³⁹ Outpatients experiencing sleep disorders can also use light boxes each day, for a prescribed period, in their homes (see Fig. 51-1).

Figure 51-1 Client using light box.

To further provide external light cues by which patients can reset their circadian rhythm system, patient room lighting should be dimmed in preparation for sleep 2 hours before bedtime. Eye masks and blinds or blackout shades have been shown to enhance sleep and should be used along with a cessation of noise and activity 1 hour before sleep onset (e.g., TVs turned off, patients should be undisturbed with the exception of medical necessities). One study found that the use of patient eye masks and earplugs to reduce light and noise disturbances, the dimming of facility hallway lights, and the provision of a 7-hour undisturbed sleep period enhanced sleep amount and quality in hospitalized patients and long-term care residents.⁴⁰ Outpatients' bedrooms should be evaluated to determine whether similar modifications are needed to reduce nighttime light and noise levels. Although nighttime light should be reduced to enhance sleep, it should be noted that automatically lighting nightlights should be used to prevent falls when patients awake and rise to use the bathroom or commode. Upon awakening, window blinds should be raised to allow daylight and artificial light systems described earlier should be used early in the day to provide cues by which patient circadian rhythm clocks can be reset.

Occupational therapists should also perform an ergonomic evaluation of patient beds and pillows to determine that both do not cause pain or discomfort that interferes with sleep. For side sleepers, pillows should be no higher or lower than the width between the lateral shoulder and cervical area and should allow the head to rest comfortably within a shallow depression. Pillows should maintain the head and neck in a neutral position and should not push the head and neck into flexion, extension, or rotation (see Fig. 51-2). For patients who sleep on their back or who have been positioned on their back and are immobile, pillows should maintain the head and neck in a neutral position and should not push the head into forward flexion. Pillows, wedges, and bolsters may need to be

incorporated into the sleep area to accommodate patients requiring specific positioning of the spine and limbs.

Figure 51-2 A. Pillow that appropriately supports the head and neck in neutral position. B. Pillow that inappropriately pushes the head and neck into forward flexion.

Mattresses should also be evaluated to determine that they are sufficiently soft to prevent pressure on bony prominences while maintaining the spine in alignment. Conversely, mattresses that allow patient spines to settle into a flexed position will likely cause pain and discomfort that interfere with sleep. One study found a significant reduction in cervical, thoracic, and lumbar pain that enhanced patient reported sleep quality by replacing traditional hospital beds with medium soft mattresses.⁴¹ When the replacement of mattresses is cost-prohibitive, inexpensive mattress toppers—such as memory foam toppers—can be used to modify the sleep berth.

Therapists should also assess the patient’s desired room temperature at night. Because the human body experiences a 1- to 2-degree temperature reduction at night to induce sleep,¹³ it is important that patient rooms remain sufficiently cool, but not cold. Because body mass index and weight affect one’s temperature, patients should be individually assessed to determine appropriate nighttime room temperature. When facility thermostat settings cannot be reset, the amount and type of bedding materials should be adjusted to maintain a comfortable sleep environment temperature.

A number of studies have also demonstrated the effectiveness of aromatherapy in the promotion of sleep onset and maintenance with patients in hospital and long-term care facilities, particularly patients having coronary artery disease, dementia, and renal disease. Although all scents used demonstrated similar sleep-inducing effects, lavender oil was found to be most effective in increasing total time asleep, reducing the amount and length of nighttime awakenings, and reducing nighttime wandering, specifically in patients with dementia. Patients also reported a reduction in general anxiety. In these studies, aromatherapy was delivered through massage or dispensed from a cool mist diffuser (with an automatic safety shutoff valve) that began approximately 1 hour before bedtime and continued for a 2- to 5-hour period.^{42–45}

Evaluation and Intervention of Routines and Habits Related to the Sleep–Wake Cycle

Occupational therapists also evaluate the routines and habits that affect patients’ sleep–wake cycles, particularly for outpatients and long-term care residents. Sleep researchers have found a high correlation between the evening use of technology having an external light source (e.g., computers, laptops, smartphones, Kindles, televisions) and the presence

of sleep disorders.¹⁴ Such technologies impact the circadian rhythm clock by providing false cues of daylight that reduce evening melatonin production normally inducing drowsiness.⁴⁶ For this reason, the National Sleep Foundation recommends that the use of such technologies be ceased, at a minimum, 1 hour before bedtime.⁴⁷ Similarly, in hospital and assistive care facilities, televisions should be turned off 1 hour before bedtime.

It is also recommended that patients maintain consistent sleep and wake times each day and limit daytime napping to no more than 30 minutes. If patients experience sleep problems one night, they should be encouraged to maintain their normal activity level the next day and refrain from napping in an attempt to recapture lost sleep. Food intake should be restricted to 3 to 4 hours before bedtime, and foods that disrupt sleep or stimulate wakefulness—such as caffeine, spicy and hot foods, chocolate, and carbonated drinks—should be ingested no later than 6 hours before bedtime, if at all. Stimulants, such as nicotine, caffeine, and alcohol, reduce sleep induction and maintenance, and should be avoided in patients identified as having sleep disorders.⁴⁷

The National Sleep Foundation also recommends the consistent and regular participation in sleep routines that serve as neural cues of sleep readiness. For example, patients can be taught to develop sleep routines involving the participation in calming activities directly before bedtime, such as taking a warm bath or shower (which temporarily raises body temperature and is then followed by a temperature reduction that promotes drowsiness), listening to relaxing music, reading (avoid Kindle use), or drinking noncaffeinated herbal tea. These activities, when engaged in regularly, come to be associated with sleep onset and may trigger the neurochemical and hormonal cascade of events responsible for sleep induction. Similarly, it is suggested that the bedroom area be used only for sleep (and sleep-related activities) so that an association can be made between its use and sleep onset.⁴⁷ This means that patients who are accustomed to watching television in bed, working at a desk in the bedroom, making phone calls from bed, and exercising in the bedroom area must be informed that such activities promote sleep problems. Such patients should be encouraged to reconfigure their habits so that performance of these activities occurs outside the bedroom area.

Several studies have demonstrated the effectiveness of engaging in self-calming activities directly before bed—such as meditation, mindfulness practice, and relaxing training—to induce sleep.⁴⁸ Patients can be taught the use of these strategies and can then engage in them independently or with the assistance of guided CDs and phone apps (these can be programmed to turn off automatically when completed). A number of studies have demonstrated that self-relaxation techniques used by community-dwelling clients and patients in long-term care residences improved sleep quality, reduced nighttime awakenings, and increased total time asleep.^{49–51} Self-relaxation techniques were shown to be not only highly effective in sleep promotion but also decreased depression and anxiety levels that interfered with sleep. Several complementary health researchers have found that 20 to 30 minutes of meditation per day can actually reduce the need for sleep if the meditation can induce the brain wave patterns found in sleep stages 1 to 3.⁵² The self-calming strategies used in the previously described studies were implemented for 20 to 45 minutes per session, 1 hour before bedtime. Self-relaxation training is a highly effective, simple, and inexpensive method of improving sleep in outpatients and long-term care residents.

Therapists should also ask community-dwelling patients with sleep disorders to complete a 2-week sleep diary in which information about sleep patterns are recorded and analyzed to determine what environmental, dietary, and physical factors may adversely impact sleep. Patients use sleep diaries to record such information as length of time needed to fall asleep, number and length of nighttime awakenings, total time asleep, reason for nighttime awakenings (e.g., bathroom use, excessive worry, warm bedroom temperature), food and drinks ingested during the previous day and evening, occurrence and length of daytime naps, use of medications, daytime activity level, daytime stress level, pre-bedtime

routines, use of technology with external light sources, and amount of daylight exposure (see Fig. 51-3). Over a 2-week period, the recording of such information can reveal factors that may disrupt sleep and that can be modified through changes to the environment, routines and habits, and daily diet. Therapists should note that lifestyle changes, even positive ones that promote sleep, are difficult for patients to make and should be undertaken in steps that allow patients to make needed adjustments at their own pace—otherwise, needed modifications may be abandoned.

Evaluation and Intervention of Daily Activity Levels Impacting Sleep Initiation and Maintenance

Multiple studies have been implemented to examine the impact of daily activity level on sleep quantity and quality in community-dwelling and long-term care clients. Although the results of this body of literature are mixed, about half found that higher daytime activity levels corresponded with greater sleep induction and maintenance.⁵³ Studies in which both physical and social activities were used to stimulate cognitive and motor functions—as opposed to exercise alone—had the greatest positive impact on sleep. Interventions were provided in the form of physical resistance strength training, walking, elastic band wheelchair exercises, and low-intensity Tai Chi, combined with engagement in socially stimulating activities (e.g., group discussions, games, creative arts) for 30 to 45 minutes, 3

to 5 days per week, over 7 weeks to 6 months. This body of research found that engagement in exercise alone was not sufficient to positively impact sleep behaviors, but when combined with socially stimulating activities, it significantly improved sleep induction and total sleep time and reduced nighttime awakenings.^{53–56} One study also found that when residents were prevented from daytime napping and instead engaged in an occupation-based intervention, they experienced greater total nighttime sleep.⁵⁷

When occupational therapists detect sleep disorders in community-dwelling and long-term care residents, they should evaluate the patient's daily activity level to determine whether it is sufficiently physically, cognitively, and socially stimulating. This can be achieved by having patients complete daily activity configurations or maintain daily activity logs and journals. Staff members and family can also be solicited to provide information about the patient's daily activity levels. Each patient's ability to tolerate and engage in activity will be unique, and therapists should tailor activity interventions for individual clients based on their specific abilities and impairments. Daytime napping and excessive engagement in passive activities (e.g., television viewing) should be prevented or significantly reduced and replaced with activity having a tolerable physical, cognitive, and social component. Engagement in activity should also be paced and spread throughout the day and early evening to prevent fatigue. Patients in long-term care residences should not be left to experience prolonged daytime periods (more than 1 hour) of inactivity; however, activity should be manageable and not fatiguing. Therapists should also assess sleep variables (e.g., sleep onset latency time, total sleep time, number and length of nighttime awakenings) after intervention has been provided for at least 2 weeks to determine intervention effectiveness and the need for modification. Because sleep needs tend to decrease with age, therapists should consider patients' perceived quality of sleep and reported daily fatigue level with greater importance in comparison to total sleep hours.

CASE STUDY

Patient Information

Angelina is an 84-year-old Philippine American woman who has returned to her assisted living residence after a 1-month rehabilitation hospitalization secondary to a fall and resultant right hip fracture. She has experienced memory loss in the past year and has been prescribed Aricept. Upon return to her long-term care residence, Angelina has been receiving both occupational and physical therapy to increase strength and endurance, but has not been making progress. She is often lethargic and cantankerous during therapy, and frequently refuses services. When she does attend therapy, she is often observed asleep in her wheelchair.

Reason for Occupational Therapy Referral

In addition to increasing strength and endurance, Angelina has been referred for occupational therapy services to increase independence in self-care and basic activities of daily living (ADLs).

Assessment Process and Results

The occupational therapist determined that Angelina's fall occurred in the middle of the night when she awoke to use the bathroom. Angelina reported that in the past year, she regularly experienced 2 to 3 awakenings per night for different reasons identified as needing to void, feeling too warm, hearing noises, and feeling pain from her fracture. She reported that she watches television until she can fall back to sleep. Because of her memory problems, her doctor decided that a sedative-hypnotic sleep medication would be contraindicated. She is presently taking Tylenol with Codeine to manage her fracture pain. Based on this information and observing Angelina fall asleep during therapy, the occupational therapist suspected a possible sleep disorder and administered the Pittsburgh Sleep Quality Index. This assessment revealed that Angelina had typically slept 4 to 5

hours per night in the last month, had a sleep onset latency time of 1 hour before she fell asleep, awoke three to four times each night, remained awake for 30+ minutes before falling back to sleep, and experienced a high level of daytime fatigue.

Further assessment of her daytime activity level revealed that Angelina watched television and napped most of the day. Her physical and occupational therapy sessions were scheduled back-to-back, and she reported feeling fatigued directly afterward. She stated that she remained in bed for most of the day because of pain, but noted that her mattress was not comfortable and often increased her pain level. This information prompted the therapist to evaluate Angelina's facility apartment, which is a small one-bedroom, one-bathroom unit with a kitchenette that is rarely used. Angelina reported that although she is usually a side-sleeper, she has been forced to sleep on her back after her fracture because of pain. The therapist noted that Angelina's pillow is too high and pushes her head into forward flexion. The apartment is north facing and has little sunlight. Noises from other residents and staff can readily be heard, and Angelina states that such noises keep her awake throughout the night. To reduce noise level and maintain some evening light in the apartment, Angelina reported that she keeps her bedroom television on throughout the night. No automatically lighting nightlights were observed. The apartment was noted to be warm, and Angelina stated that she liked a warm apartment because she often felt cold; however, she also reported that she sometimes woke during the night feeling too hot. The therapist additionally inquired about Angelina's dietary habits and found that she drank coffee at every meal and was reluctant to change this habit.

Occupational Therapy Problem List

- Decreased strength and endurance secondary to right hip fracture
- Decreased independence in self-care and basic ADLs
- Hip fracture pain that interferes with sleep
- Sleep disorder that may adversely impact therapy participation, memory, daytime alertness, and daytime activity level

Occupational Therapy Goal List

- Increase strength and endurance sufficient to participate in self-care and basic ADLs with minimum assistance by 2 weeks.
- Modify the bed and pillow to decrease pain interfering with sleep (from a self-reported pain level of 8 to 5 on a 10-point scale, 0 = low, 10 = high) by 1 week.
- Establish nighttime sleep routines that decrease sleep onset latency (from 1 hour to 30 minutes) and reduce nighttime awakenings (from 4 to 2) in 3 weeks.
- Establish daytime activity levels that increase total time asleep (from 5 to 7 hours) and decrease daytime fatigue levels (from a self-reported fatigue level of 8 to 5 on a 10-point scale, 0 = low, 10 = high).

Intervention

Angelina continued to receive occupational therapy services to increase strength and endurance needed to engage in bathing, grooming, and dressing with minimum assistance. She was observed to be more alert during therapy and was less resistant to participation. To make her bed more comfortable, a memory foam mattress topper was placed over her current mattress to provide greater cushioning and reduce pressure on her bony prominences, particularly at the fracture site. The pillow was also replaced with one that maintained her head and neck in a neutral position while lying supine on her back. These modifications now enabled Angelina to rest in bed with less reported pain. The therapist encouraged Angelina to use ear plugs while sleeping to reduce noise level; refrain from keeping the television on all night; and sleep with lighter, layered blankets to reduce the likelihood of waking from feeling too warm. An automatically

lighting nightlight was installed to provide illumination when awakening to use the commode. Angelina also agreed to try a cool mist aromatherapy diffuser (1 hour before bedtime and continuing for 5 hours), a 10,000-lux light box each morning for 30 minutes, and a relaxation CD 30 minutes before bed.

Although she was hesitant, Angelina agreed to replace her lunch and evening coffee with herbal decaffeinated tea. The recreational therapist and case manager also helped convince her to participate in several daytime activities (such as world events and creative arts groups) instead of watching television and napping. Her occupational and physical therapy sessions were rescheduled 1 hour apart to reduce fatigue level.

In 4 weeks, Angelina reported that she was able to maintain these changes and was sleeping better. A Pittsburgh Sleep Quality Index administered at 4 weeks revealed that her total sleep time increased from 5 to 6.5 hours, sleep onset latency was reduced from 1 hour to 30 minutes, total nighttime awakenings decreased from 4 to 2, and daytime fatigue level decreased from 8 to 4. Pain level at night was also reported to decrease from 8 to 5, and Angelina additionally stated that she felt more alert and experienced less memory problems.

Evidence Table of Intervention Studies for Sleep Disorders

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Reducing nighttime noise, light, and staff activity to increase sleep in hospital patients ⁵⁸	Nurse's nighttime care routines were changed to provide an uninterrupted period between 11:00 pm and 5:00 am. Noise level and activity were decreased, and light reduced to 40 lux.	Fifty-five surgical intensive care patients (28 = treatment group; 27 = control group)	Environmental changes occurred 7 days/week for 3 months from 11:00 pm to 5:00 am	Two group controlled study Level II	An undisturbed period from 11:00 am to 5:00 am and the control of nighttime noise, light, and care activities improved patients' perceived sleep quality.	Treatment group reported better perceived sleep ($t = -2.28, p = 0.027$) and sleep efficiency ($t = -2.03, p = 0.047$)

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Light therapy to reduce sleep problems in adults with sleep disorders ³⁶	Review of the effect of light therapy on sleep problems in adults with general sleep problems, circadian rhythm sleep disorders, insomnia, and sleep disorders related to dementia	Fifty-three studies with a total of 1,154 participants were included.	Light ranging from 2,500 to 10,000 lux delivered for a mean of 18.72 days (standard deviation [SD] = 18.49) and a mean of 1.81 hours/day (SD = 1.71)	Meta-analysis Level I	Light therapy was effective for sleep problems in general, particularly for circadian rhythm and insomnia disorders.	Hedges' <i>g</i> effect sizes were calculated. Light therapy was effective in the treatment of sleep problems in general ($g = 0.39, p < 0.01$) and for circadian rhythm sleep disorders ($g = 0.41, p < 0.01$), insomnia ($g = 0.47, p < 0.08$), and sleep problems related to dementia ($g = 0.30, p < 0.02$) specifically.
Comparison of (1) resistance strength training and walking (RST/W), (2) social activity (SA), (3) combined social activity and RST (RST/W + SA), and (4) usual care on sleep quality in long-term care residents ⁵³	RST/W received high-intensity physical resistance strength training and walking. SA group received social activity consisting of discussion, creative arts, music, and cooking groups. Control group received usual care.	One hundred sixty-five elderly residents of 13 long-term care facilities	RST/W group received intervention for 3 days/week for 45 minutes, over 7 weeks. SA group received intervention for 1 hour, 5 days/week, over 7 weeks. The combined RST/W + SA group received both interventions. Control group received usual care.	Randomized controlled trial Level I	Combined RST/W + SA significantly improved sleep in participants. The interventions by themselves had no significant effect on sleep.	Total sleep time was found to be significantly greater ($p < 0.01, d = 0.53$) in the combined RST/W + SA group compared to all other groups and increased 35.3 minutes. Sleep efficiency was also greater ($p < 0.05, d = 0.45$) in the combined RST/W + SA group compared to all other groups.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Aromatherapy to promote sleep quality in hospitalized and long-term care patients ⁴²	Aromatherapy was administered in the form of massage and inhalation.	Twelve studies were included in meta-analysis. Study participants ranged in number from 36 to 72 and consisted of hospitalized and elderly long-term care residents.	Seven studies administered aromatherapy before bedtime in the form of a massage; five studies provided inhalation aromatherapy 30 minutes before bedtime and continuing for 1–2 hours. Length of studies was not reported.	Meta-analysis Level I	Aromatherapy, used in the form of massage or inhalation, promoted sleep in hospitalized and long-term care patients.	Meta-analysis of the 12 studies using a random-effects model showed that aromatherapy effectively improved sleep quality (95% confidence interval [CI], 0.540–1.745; Z = 3.716). Subgroup analysis showed that inhalation aromatherapy (95% CI, 0.792–1.541; Z = 6.107) was more effective than massage therapy (95% CI, 0.128–2.166; Z = 2.205).
Mindfulness training to promote sleep quality in community-dwelling elderly with chronic insomnia ⁴⁸	Mindfulness training was provided in group sessions and practiced by participants independently. Control group received sleep hygiene education group.	Community-dwelling elderly with chronic insomnia were randomly assigned to mindfulness training group (n = 24) and sleep hygiene group (n = 25).	Both groups were delivered in 2-hour, weekly sessions over 6 weeks. Both groups were able to practice techniques independently on own.	Randomized controlled trial Level I	Mindfulness training group experienced improvements in sleep latency onset, sleep maintenance, and total sleep time compared to sleep hygiene group	At posttest, the mindfulness training group demonstrated a statistically significant improvement in sleep quality and efficiency compared to the sleep hygiene group (mean = 7.4 ± 1.9, p < 0.05, d = 0.89, 95% CI, 0.6–2.9).

Psychosocial Adaptation to Disability

Pat Precin

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Identify and evaluate possible psychosocial disorders in patients receiving occupational therapy services.
2. Understand the disability experience for the adult after experiencing disease or injury resulting in permanent disability.
3. Understand how psychosocial issues can impact daily performance and occupational activities during intervention.
4. Use different models of adjustment to disability to inform treatment.
5. Understand disability culture and the independent living movement.
6. Understand different methods that occupational therapists use to facilitate psychosocial adjustment.

CHAPTER OUTLINE

The Disability Experience
Adjustment to Disability
Disability Culture and the Independent Living Movement
How Occupational Therapists Facilitate Psychosocial Adjustment
Case Study

TERMINOLOGY

Adjustment to disability: a process by which individuals progressively acclimate to disability by passing through specific stages such as denial, anger, depression, and acceptance.

Cognitive-behavioral model: a psychosocial frame of reference often used to promote adjustment to disability.

Denial: a psychological defense mechanism used by certain individuals that involves not acknowledging certain aspects of reality (their disability) in order to tolerate anxiety.

Disability culture: a social movement initiated in the 1980s to recognize, understand, empower, and celebrate different lifestyles of people with disabilities.

Independent living movement: a worldwide philosophy and movement originating in the 1960s in which people with disabilities work together to advocate for decreasing barriers, equal opportunities, respect, peer support, self-respect, self-help, and self-determination.

Post-traumatic stress disorder: a psychiatric diagnosis originating from exposure to repetitive or an isolated psychological trauma and marked by persistent flashbacks of unprocessed trauma, hypervigilance, and a general feeling that the world is unsafe.

Psychodynamic model: a psychosocial frame of reference that helps patients increase participation in occupation by eliminating unconscious barriers.

Psychosocial adjustment: a process by which individuals are able to manage psychosocial issues following a disability in order to more fully participate in occupation.

Stage models: methods by which individuals can obtain psychosocial adjustment and adjustment to disability by passing through a series of linear stages predetermined by the model.

Transtheoretical change model: a model describing different stages that individuals pass through in order to make and maintain a change in their lives.

The Disability Experience

An estimated 1 billion adults or 15.3% of the adult global population have a disability.¹ Psychosocial issues are difficulties that pertain to both psychological and social areas.² Examples of

psychosocial issues often seen in physical rehabilitation are role loss, depression, **post-traumatic stress disorder** (PTSD), and substance abuse and are addressed in this chapter. Sleep disorders are also psychosocial issues that often occur secondary to neurological and orthopedic disorders and are addressed in Chapter 51.³ Psychosocial issues often co-occur with physical disabilities and have been shown to affect the disability experience and rehabilitation outcomes in patients with cardiac issues,⁴⁻⁶ stroke,⁷ spinal cord injuries,⁸ cancer,⁹ athletic injuries,¹⁰ and neurological diagnoses.¹¹

When an adult incurs a disease or injury in adulthood that results in permanent disability, he or she may experience a multitude of changes. These changes are not limited to the physical injury or disease process but can include psychosocial issues as well. Life roles, family position, work interactions, self-worth, and personal narrative can be affected. Disruption in any of these areas can hinder the process of adaptation. Yet, adjustments to these areas, if made in a thoughtful, careful, therapeutically guided manner, can not only aid in adapting to an illness but promote personal growth through having struggled with adversity. Occupational therapists are well equipped to assess and address issues related to these areas. Providing evidence-based interventions that foster adjustment to changes in roles, family position, work interactions, self-worth, and personal narratives can guide patients on their way to occupational, social, and community engagement.

Role loss frequently occurs in adults who have experienced disabilities as adults. After a disability, patients may no longer be able to fully participate in roles that were meaningful and necessary to them and their families. A mother may no longer be able to function in her role as the primary caretaker of her children. The loss of ability to function in previous roles can result in painful feelings, such as depression, confusion, loss of identity, and shame. These feelings can hinder adaptation by causing avoidance of taking steps to reengage in roles, especially if the steps bring awareness of limitations and difficult feelings. Therefore, the goal of trying to modify or resume roles can seem daunting to patients.

Role loss may affect the family and the patient's position in the family. A mother who can no longer assume her role as the caretaker of her children may have to relinquish this role to an in-law, changing her position in the family. Resulting feelings may include anger, helplessness, resentment, and fear that her children may grow up without experiencing her as their mother. These negative emotions can affect the mother's adaptation to disability and the family's ability to function as a healthy integrated unit. The role of the occupational therapist would be to (1) identify shifts in the patient's family position and possible areas of functional deficits that interfere with occupational engagement and (2) provide best practice interventions to the patient and family (in conjunction with the social worker if possible).

A patient who has incurred a disease in adulthood may also experience a change in work interaction. Work interaction can refer to job loss, job change, unemployment, altered work responsibilities, increased work pressure or stress, or a change in co-workers' or bosses' perceptions of the patient's new work abilities. There may also be a change in interaction with the work environment, such as requiring a different type of chair, desk, or light source. Even if a patient is able to return to work with a disability, the patient may experience new fatigue when attempting to perform job duties that were easy to perform in the past. The occupational therapist would assess the patient's work interaction and adjustment and then provide intervention that can help the patient make a smooth transition to his or her work or volunteer situation.

When a patient undergoes a disease process or injury that results in a permanent disability in adulthood followed by changes in roles, family position, and work interaction, self-worth is likely to be affected. Patients in this situation often experience a period of time when they feel distressed about themselves and their limitations. In addition, they may receive negative feedback from their social and physical environment. The physical environment is no longer as easy to negotiate. Patients are reminded of this on a daily basis. The social stigma of having a disability (being a person who is disabled, therefore not "normal") can be pervasive throughout work, social, and virtual environments¹² and is likely to affect a person's self-worth through internalization.

When patients experience a decrease in self-worth, their life narratives may also change. Life narratives are stories about how people view themselves in context.¹³ Each person's narrative is unique, fluctuates overtime, and is sensitive to experiences, emotions, and personal growth. Prior to injury, a patient's life narrative may include being a businessman, father of five children, loving husband, financial provider, and avid skier who feels confident in and proud of his roles and accomplishments at the age of 37. He may be looking forward to a long productive life with many grandchildren. His narrative did not include the fact that this all changed because of a car accident,

which resulted in an above the knee amputation. Four months after the accident, his narrative may sound more like this:

I hate this. I can't do this anymore. I'm in so much pain and everything takes so long to do. I can't believe that at age 37 I'm unemployed and my wife has to find a job to support us. I'm so stressed out that we may not make our mortgage payments. I feel so inadequate...like I let everyone down. I hate myself. I wish I could undo everything and go back to the way things were. Instead, I want it all to be over.

This is a sad but typical life narrative, given this patient's circumstance. His occupational therapist could help him begin to regain control and create a new life through narrative writing and cognitive-behavioral techniques in which he would create his (1) current life narrative, (2) projected future narrative, and (3) in-between narratives that would move him toward his projected future.¹⁴

Adjustment to Disability

Adjustment to disability is unique to each patient; however, there are different practice models that occupational therapists can use to help understand their patients' unique experience of disability and guide them through the **psychosocial adjustment** process while providing appropriate treatment. Some of these models include adaptation to disabilities, psychodynamic, cognitive-behavioral, and transtheoretical. **Stage models** are methods by which individuals can obtain adjustment to psychosocial and physical disability by passing through a series of linear stages predetermined by the model. An example of a stage model is the adaptation to disabilities model,¹⁵ where patients first experience, then pass through stages of **denial**, anger, depression, and acceptance in that order; the model is summarized in the subsequent sections.

Denial, Anger, Depression, and Acceptance

When patients first learn of their diagnosis or understand that they have an injury, they may use the defense mechanism of denial to ward off anxiety related to the reality of their situation. The process of rehabilitation allows patients to slowly become aware of their limitations through functional assessments and interventions directed toward improving deficits and maximizing strengths. This process helps patients move out of denial and into the second stage, anger.

Anger can be a healthy vehicle through which patients expel pent up energy and avoid initial depression (turning their anger onto themselves) and is an appropriate emotion to experience at this point in recovery. Some patients, however, never move past the anger stage, and prolonged anger can interfere with rehabilitation. An occupational therapist can help patients move out of the stage of anger by allowing them to verbally express their anger in the beginning of each session, then helping them to focus on the rehabilitation task. The patient's emotion is validated, and the patient is shown how to move through anger, or redirect the energy of the anger toward engagement in productive tasks. The patient may be better able to manage anger on his or her own after this experience. If anger is not validated, it may perpetuate and interfere with progress to the third stage, depression.

The stage of depression occurs as patients become exhausted from rehabilitation efforts, social supports and attention from visitors wanes, caregivers become emotionally and physically depleted and can no longer respond to the patient in the same supportive manner, disappointment from lack of swift progress is experienced by the patient and echoed throughout the family, and hope of return to previous functioning that may have been present in the beginning may be lost.

When a patient moves out of the depression stage, he or she moves toward acceptance. Those who achieve acceptance have come to terms with their limitations and are willing to use their strengths to accomplish new goals and roles in life. They are able to establish and engage in new occupations that hold meaning for their lives and enhance their social networks to include others who understand disability. Acceptance does not necessarily imply physical improvement. Instead, it is a lived attitude.

Psychodynamic Model, Cognitive-Behavioral Model, and Transtheoretical Change Model

The **psychodynamic model** focuses on how memories of past experiences and unconscious processes affect current behavior. The model values the symbolic nature of activities and mandates that they be selected for intrinsic meaning and relevance to the patient. This model is often used when conscious-based ego-focused interventions do not produce the desired result. For example, an occupational therapist observes that a patient in her money management group is not adhering to her

budget from week-to-week, despite having learned necessary money management skills. The occupational therapist reasons that there may be a psychodynamic component involved and asks what money means to the patient. The patient informs the group that her mother used to give her a small weekly allowance, but after her mother's death, her father said that she should be financially independent. The group empathetically inquired about the mother's death, and the patient replied that she was sad but secretly angry at her father for not replacing her mother's nurturance expressed through gifting the allowance. An interpretation was made that perhaps her repressed anger toward her father inhibited her budgetary follow-through. In the next group session, the patient had followed her budget, theoretically because she had become aware of how her repressed anger and desire for nurturance (both unconscious) had been affecting her current behavior.

Rather than reflecting on how the past and unconscious material affect current maladaptive behavior, the **cognitive-behavioral models** focus on how current unhealthy thought patterns can lead to unhealthy behavior. Interventions involve developing healthy patterns of thinking that lead to targeted behavioral changes. Cognitive-behavioral therapy (CBT) is an example of a cognitive-behavioral practice model whose effects have been found to generalize to real-world settings (home, community, work).¹⁶ Occupational therapists who use methods of CBT carefully observe, record, and examine patients' reactions to experiences and links between thinking and behaving. These therapists reward successively graded goals-shaping thoughts and behaviors that indicate successful adaptation. They point out patterns in patient narratives that suggest helplessness or negative projections about the future, helping to substitute more positive thoughts and self-statements. Treatment programs reinforce adherence and good self-care, such as wearing a splint or taking medication, and work to extinguish damaging habits, such as smoking, and socially isolating behaviors, such as aggressive outbursts. CBT treatment components may be designed for individual or group work directed toward specific symptoms, including pain, depression, or insomnia.¹⁷ Skills for self-regulation, including assertive communication and practicing the relaxation response (RR), may also be the components of CBT.¹⁸

The **transtheoretical change model** is based on the observation that people make changes by advancing through an ordered series of stages: precontemplation, contemplation, preparation, action, maintenance, and termination. Patients in precontemplation are not interested in making a change in the near future (6 months) and may not be aware that change is necessary. Occupational therapists can provide patients with psychoeducation about specific healthy and unhealthy behaviors related to their issues in order to help them become aware of their unhealthy habits and progress to the contemplation stage. During contemplation, patients use their new knowledge to intend to begin a healthy behavior within 6 months. Occupational therapists can help patients evaluate pros and cons and set goals because ambivalence around change can result in procrastination. During the preparation stage, patients are ready to begin their goal for change within the next month. Occupational therapists can help patients take short-term steps to help prepare for the change (e.g., informing friends and family that they would like to change their behavior) and create a plan for change. Occupational therapists can encourage patients to think, discuss, and write narratives about what their lives will be like once they have made the change, because fear of failure is the primary barrier to moving into the stage of action. Patients have made their change within the past 6 months during the action stage, so occupational therapists can help patients focus on their goal and resist temptation to return to unhealthy behaviors. Guiding patients through the processes of substituting positive behaviors for unhealthy ones; avoiding people, places, and things that may keep them from continuing their new behavior; spending time with supportive individuals; and rewarding themselves can enhance commitment to change. Patients are considered to be in the maintenance stage if they have completed 6 months or more of their new behavior. Occupational therapists can help patients identify and avoid triggers that may result in relapse (terminating the healthy behavior or engaging in the unhealthy behavior of the past), and identify and use healthy coping mechanisms (e.g., talking to friends) to handle stress and manage emotions instead of resorting to previous unhealthy behaviors. The final stage of termination is achieved after the patient's new behavior has become part of his or her routine/lifestyle and no energy is needed to successfully maintain it. Not all patients achieve this stage.¹⁹

Disability Culture and the Independent Living Movement

It is important to consider social context when attempting to understand the experience of disability in patients. The **independent living movement** is a worldwide philosophy and movement originating in the 1960s in which people with disabilities work together to advocate for decreasing barriers, equal opportunities, respect, peer support, self-respect, self-help, and self-determination.

This movement was successful in accomplishing some of these issues (e.g., through the Paralympics)²⁰ and led to what is now called **disability culture**. Disability culture is a social movement initiated in the 1980s to recognize, understand, empower, and celebrate different lifestyles of people with disabilities.¹⁵ The disability arts movement and the Disability Pride Parade are just a few examples of the many different movements and programs developed within disability culture that continue to flourish. As occupational therapists expand their rehabilitation framework to view themselves as professionals who use occupation to promote healthy living and well-being,²¹ they are better able to incorporate the independent living movement and disability culture into their interventions.

How Occupational Therapists Facilitate Psychosocial Adjustment

Occupational therapists provide evaluation of and intervention for psychosocial disorders such as role loss, depression, PTSD, and substance abuse that produce behaviors maladaptive to physical rehabilitation and the process of adaptation. When occupational therapists detect psychosocial disorders, they should notify the treatment team or persuade outpatient clients to make appointments with their primary care physicians because interdisciplinary treatment of psychosocial disorders may be the most effective type of treatment.^{9,22}

Occupational Therapy Evaluation and Intervention of Role Loss

The developmental tasks of adulthood include confirming career choice, finding a partner, and parenting children. When an adult at this point in the life cycle becomes disabled, plans and conceptions about the future, which may already have been the focus of substantial effort, require reorganizing. Ongoing life satisfaction and dignity, rather than level of self-care, are becoming recognized as the most valuable measures of rehabilitation success and may be most congruent with patient and family hopes and expectations.^{23,24} These measures should, therefore, be the basis of intervention concerning loss of and reassignment of roles.

The occupational therapist would begin treatment by identifying previous role functions and assessing the patient's ability, motivation, and support to resume them. The Role Checklist²⁵ is used to assess patients' past, current, and future roles and the amount of value patients place on each role. Occupational therapists can use this assessment to (1) identify barriers to current and future patient roles that are highly valued and (2) set goals for surmounting barriers, making accommodations within roles, and/or selecting new roles that hold value. If patients become overwhelmed with the process of redefining or selecting new roles, the Activity Card Sort²⁶ (see Fig. 52-1) can be administered to help patients gain insight into realistic activity preferences, which may then aid in role adjustment.

Figure 52-1 Administration of the Activity Card Sort.

Because patients may be striving to regain their roles by merging their old and new realities, occupational therapists can help them revise and reformulate expectations. The occupational therapy (OT) treatment plan integrates psychological demands and addresses them in concert with activities of daily living (ADLs), strengthening, endurance, mobility, and prevocational training. Adapting to disability occurring at this stage may require altering vocational course, finding different leisure activities, redesigning an intimate partnership, and rebalancing parenting roles. Occupational

therapists model problem-solving with realistic expectations—reconciling capacities, and working with patients’ strengths toward a sense of fulfillment²⁷—and helping patients reclaim personal continuity and create meaningful life narratives, which integrate their experiences of illness or injury.^{28,29} Occupational therapists can reinforce patients’ motivation to heal and nurture their well-being at critical turning points and in the face of what for some will be lasting physical compromise.³⁰

As an ADL, sexual activity merits an accepting, problem-solving focus. The occupational therapist explicitly helps the disabled person by encouraging him or her to reconceptualize sexuality and sexual activity more broadly and to explore new possibilities for sexual expression. When the disabled individual has a consistent sexual partner, the therapist may offer the opportunity to include him or her in teaching or treatment sessions. The disabled person and his or her sexual partner may learn to adapt to periods of fatigue, continence timing, or requirements for special positioning (see Chapter 27).

Families as well as patients may need help reorganizing. Family reorganization requires learning and concrete problem-solving, as well as transformation within the family unit, parallel to that of the disabled person. Occupational therapists can help partners and families forge new identities among themselves and within their communities.

Occupational Therapy Evaluation and Intervention of Depression

More than 300 million people currently experience depression according to the 2018 World Health Organization report.³¹ Depression may be more prevalent in patients receiving rehabilitation treatment or adapting to a disease process or injury than in individuals without disabilities.³² Depression is the most frequently experienced psychological result of stroke.³³ Up to half of stroke survivors develop depressive signs and symptoms³⁴; yet, depression is frequently underdiagnosed.³⁵ It is imperative that occupational therapists learn to identify symptoms, signs, and behaviors characteristic of depression in their patients during physical rehabilitation sessions.

Signs and symptoms of depression commonly observed in patients undergoing rehabilitation according to Precin³² are listed as follows. They are meant as a guide because the etiology of depression for each patient may differ: what may cause depressive signs/symptoms in one patient may not cause depression in another patient.

Mild Depression

- Poor concentration
- Sadness
- Irritability
- Neediness
- Anger
- Depressed mood
- Indecisiveness
- Lethargy
- Intrusive thoughts
- Loneliness
- Anxiety

Moderate Depression

- Despair
- Sensitivity
- Feeling overwhelmed
- Feeling inadequate
- Despondence
- Fearful
- Decreased self-esteem
- Anguish
- Excessive guilt

Severe Depression

- Change in weight

- Change in appetite
- Sleep disturbances (narcolepsy, insomnia)
- Decreased sexual drive
- Desperation
- Feeling hopeless
- Feeling helpless
- Feeling worthless
- Suicidal ideation

These symptoms and signs may manifest in different behaviors that can be recognized by occupational therapists. Some behaviors characteristic of mild, moderate, and severe depression that frequently occur in physical rehabilitation are listed as follows.³²

Behaviors Characteristic of Mild Depression

- Difficulty planning for the near future
- Obsessing about tasks
- Becoming frustrated easily
- Sitting alone

Behaviors Characteristic of Moderate Depression

- Reacting negatively to feedback
- Inability to make simple decisions
- Crying
- Making self-depreciating remarks
- Reporting psychosomatic symptoms
- Exhibiting overly dependent behavior
- Talking about the past, present, and/or future in a pessimistic manner
- Withdrawing socially
- Perseverating and/or ruminating on issues

Behaviors Characteristic of Severe Depression

- Staying in bed all day
- Poor hygiene
- Decreased interest in activities that used to elicit pleasure
- Suicide attempt

If occupational therapists identify any of the signs/symptoms/behaviors of depression mentioned previously, they could perform a more in-depth assessment using the following standardized, reliable, and valid instruments typically used to measure levels of depression, self-efficacy, and self-esteem: Beck Depression Inventory,³⁶ General Self-Efficacy Scale-6,³⁷ or the Rosenberg Self-Esteem Scale.³⁸ These are self-report assessments that can be completed in under 10 minutes. If the patient demonstrates signs, symptoms, or behaviors indicative of severe depression, the occupational therapist should make a referral to a psychiatrist and alert the treatment team. Additional referrals may be made to psychological services for chronic depression. The most important goal is patient safety.³⁹

If depression is not identified during physical rehabilitation, it may go untreated and worsen, resulting in the inability to make full use of rehabilitation. When depression is treated in rehabilitative settings, treatment usually consists of medication and psychotherapy, but the effectiveness of both is questionable and may produce harmful side effects, especially in the elderly.³⁵ Depression poststroke resulted in poor rehabilitation outcomes, increased caregivers' stress, cognitive and physical impairments, substance misuse, increased risk of suicide and patient death, increased utilization of medical resources, and poor treatment compliance.⁴⁰⁻⁴² Depression in cardiac rehabilitation predicted poorer outcomes⁶ and greater dropout rates⁵ when compared to cardiac rehabilitation patients without depression. Patients who developed depression during sports injury rehabilitation demonstrated poorer rehabilitation outcomes and less frequently returned to their sport¹⁰ when compared to sports rehabilitation patients without depression. Depression resulted in lower return-to-work rates in cancer survivors.⁹

Several studies have demonstrated the effectiveness of engaging patients in problem-solving activities in conjunction with antidepressants to decrease depression and promote overall psychosocial adaptation during physical rehabilitation.^{43,44} Occupational therapists can help patients identify several problems they are experiencing as barriers to rehabilitation and adaptation. The patient would be instructed to write a goal that would alleviate each problem and then identify three to four steps to take within a week to achieve each goal. The therapist would follow up with each of the patient's goals one-at-a-time until all steps had been taken and the goal accomplished. Problem-solving in this manner can help patients actively regain control over certain aspects of their daily life and empower them in the rehabilitation process.

Livneh and Martz⁴⁵ identified a combination of coping strategies that predicted psychosocial adaptation and decreased depression in patients with spinal cord injuries. These coping strategies were problem-solving, cognitive restructuring, planning, active acceptance, and seeking social support. Occupational therapists can engage patients in the act of cognitive restructuring (a component of CBT) by identifying patients' statements that indicate maladaptive thoughts, reality testing the validity of these thoughts during physical rehabilitation, and then readjusting thoughts to be more realistic and adaptive. An example of how to combine cognitive restructuring, problem-solving, planning, and seeking social support follows. A patient might express that he or she cannot do something (possible maladaptive thought). The occupational therapist would then perform reality test with the patient by saying, "I think you were able to do this yesterday, isn't that so?" The patient may respond, "yes." Then, the therapist might ask, "What is making it hard for you today?" (asking the patient to identify a barrier and challenging the belief that he or she cannot perform the task in question). The occupational therapist helps the patient problem solve around the barrier in order to alleviate the problem, which allows engagement in the activity that was previously thought to be impossible. This process dispels the patient's unrealistic and maladaptive thought and serves as an example of how the patient could then follow the same process on his or her own when future maladaptive thoughts arise. If the patient still requires assistance, the occupational therapist could help the patient reach out to family members (seeking social support) to help continue this process during family visits by training the family in this process (psychoeducation).

An evidence-based review of the effectiveness of interventions for adults with psychological impairment poststroke identified problem-solving, behavioral therapy, and motivational interviewing as effective interventions for the treatment of depression.⁴⁶ The four premises of motivational interviewing are empathy, identify discrepancies, promote self-efficacy, and accept patients' resistances.⁴⁷ When using motivational interviewing, occupational therapists would demonstrate consistent empathy while pointing out differences between patients' goals and current behavior and showing their belief that goals can be achieved.

A systematic review of OT and multidisciplinary approaches for the rehabilitation of patients with cancer revealed studies that supported the use of problem-solving, cognitive-behavioral therapy, psychoeducation, life review, and expressive writing approaches⁹ to decrease depression. Treatment for depression can also continue after discharge. A home leisure education program poststroke was found to be effective in the treatment of depression.⁴⁸ The goals of a leisure education program may be to (1) teach the patient the benefits of social participation and engagement in activities that lead to self-assertiveness, reengagement, and self-determination; and (2) then help them to identify and pursue new daily-life activities that are meaningful.³⁹

Occupational Therapy Evaluation and Intervention of Post-Traumatic Stress Disorder

PTSD is a psychiatric diagnosis originating from exposure to repetitive or an isolated psychological trauma and marked by persistent flashbacks to unprocessed trauma, hypervigilance, and a general feeling that the world is unsafe. Individuals injured or disabled through war, natural disaster, accident, abuse, or violent crime are at high risk. For some patients, the resulting disability may constitute lifelong physical evidence of the traumatic experience, serving as a proprioceptive cue or trigger for PTSD symptoms and continuing stress reactions. Symptoms observed during physical rehabilitation can include hyperarousal, nervousness, fearfulness, nightmares, flashbacks, ruminations, emotional numbing, and dissociation.⁴⁹ Individuals showing symptoms of PTSD usually require referral to be evaluated for specialized psychotherapy and possible medication. Coordination between caregivers is critical to a positive outcome for these patients, who need a safe, predictable environment in which they can make sense of their experiences. If the occupational therapist is not sure whether or not to make a referral, he or she can administer The Primary Care

PTSD Screen for DSM-5 (PC-PTSD-5),⁵⁰ a five-question screen for PTSD. If the score is 3 or greater, a referral should be made.

There are five defined stages of intervention for PTSD according to Herman,⁵¹ including:

1. Developing a healing relationship
2. Safety
3. Recalling past memories and mourning
4. Reconnecting
5. Commonality

Occupational therapists can help individuals during each stage. In order to develop a healing relationship, the occupational therapist can empower the patient by fostering trust, autonomy, initiative, competence, and identity formation. Patients with PTSD should be an active part of their recovery. Any intervention that takes power from patients has the potential to retraumatize patients by creating a “power-over” dynamic reminiscent of past trauma and may revictimize and trigger patients. Therefore, occupational therapists should counter the dynamic of dominance in the therapeutic relationship by increasing the range of treatment choices, respecting the patient’s autonomy by remaining emotionally neutral, validating feelings and narrative stories, providing psychoeducation on symptoms, using persuasion rather than coercion, using ideas rather than dogmatic interventions, and fostering mutuality rather than authoritarian control.

In stage 2, occupational therapists help patients regain safety over their minds, bodies, and environments. To regain safety over their minds, occupational therapists help patients name the problem by giving them language for the experience (diagnosis, signs, symptoms) and provide explanations for current difficulties, informing them that they are not alone, not crazy, and can expect to recover in the way others with PTSD have. Patients can be taught to keep daily logs to track their response to symptoms. Restoring ego functions includes helping the patient initiate, carry out plans, exercise independent judgment, and utilize self-soothing strategies. Control of the body includes basic health needs, regulation of bodily functions, sleep, eating, exercise, control of self-destructive behaviors, symptom management, and decreasing hyperarousal and intrusive symptoms. Control of the environment includes financial security, mobility, plans for self-protection, safe living environments, and family meetings.

During stage 3, occupational therapists help patients talk or write about their traumatic experience, helping them associate affect with factual statements of the experience while normalizing patients’ responses. Next, occupational therapists help patients construct new interpretations of the traumatic experience that are no longer about shame and humiliation, but affirm dignity and value. Listening to their narratives is a very important part of the first stage of their treatment but can be disturbing; strong team support and supervision become important for all involved, such as caregivers and occupational therapists.

Occupational therapists are well equipped to help patients at stage 4 reconnect with others and find new ways of living as survivors (social action and public truth-telling can be therapeutic). During the final stage of commonality, therapy groups can be used to create a sense of belonging because trauma isolates, bear witness and affirm because trauma stigmatizes and shames, restore humanity because trauma dehumanizes, provide a sense of universality, and provide treatment for different stages. Occupational therapists use groups at this stage to help members organize their daily-life structure and enhance their ability to feel safe while participating in meaningful roles and activities in the community.⁵²

Occupational Therapy Evaluation and Intervention of Substance Abuse

The use of drugs and alcohol has been associated with depression and anxiety after traumatic head injury⁵³ and may be prevalent in patients in vulnerable states as a result of other injuries or diseases. In response to the American Occupational Therapy Association’s Evidence-Based Literature Review Project,⁵⁴ Stoffel and Moyers⁵⁵ performed an interdisciplinary systematic review of effective treatment for individuals diagnosed with substance-use disorders and found four effective treatment approaches that could be used by occupational therapists: brief interventions, CBT, motivational strategies, and 12-step programs, and are summarized as follows.

Brief interventions occur in one session that can run from 5 minutes to an hour and focus on identifying a substance abuse problem and then motivating the patient to do something about it.⁵⁵ Substance abuse occurs frequently in people with disabilities, but patients in rehabilitation may be

reluctant to disclose their use even if it is problematic. Therefore, occupational therapists need to look for signs, symptoms, and behaviors of substance use that can be identified during a brief intervention. Pain medication can be very addictive, so it is important for the occupational therapist to understand patients' medication dose, frequency, and type. Signs, symptoms, and behaviors characteristic of patients who are abusing substances may include cognitive deficits, isolation, alcohol on breath, disinhibition, denial, belligerence, low frustration tolerance, inappropriate interpersonal behavior, paranoia, impaired judgment, poor boundaries, impulsivity, violence, emotional lability, thought disturbances, irritability, slurred speech, and intense emotions.³² If some of these characteristics are observed, occupational therapists can ask patients about substance use by taking an occupational history using the following questions:

- Is the patient functioning in work or school? Is the patient maintaining relationships?
- Are any family members likely to be helpful in describing the patient's history?
- Is there any evidence that substance abuse was a primary cause of the condition?
- Might the condition have provoked substance abuse?
- Are there predisposing factors such as depression, trauma, family history, or membership in a marginalized group?
- Does evidence support need for referral?

Sometimes, it is easier for patients to report their use if a standardized assessment is used (once removed from reporting directly to the therapist). The Substance Abuse Screening Test⁵⁶ is a short self-report questionnaire that an occupational therapist could administer to identify people who abuse substances and those at risk for abuse. Brief intervention could also include the distribution of psychoeducational material to the patient and his or her family that addresses the deleterious effects of use, benefits of harm reduction or abstinence, the fact that substance abuse is a chronic disease that involves relapse and not a result of victimhood or weak character, and information on available 12-step groups with a recommendation to participate.⁵⁵ Brief interventions work well when the treatment priority is physical rehabilitation due to the reason for referral, limited time, or lack of reimbursement for substance abuse services.

CBT can be used to develop healthy skills to avoid relapse by changing maladaptive thoughts and distorted thinking that trigger substance use. Maintaining and reviewing a substance-use diary documenting the nature of use (frequency of use, time of day, who they were with, what they were feeling and thinking, where they were, what they were doing, what drug they used, where they obtained the drug) can help patients identify maladaptive thoughts and cognitively restructure them. The diary can also be used to increase awareness of patterns of use that patients can use to predict and avoid future relapses. The more insight patients have about their addiction process, the greater the chance that they will be able to progress in the recovery process. This intervention does not take a lot of time because patients keep the diary on their own. They just require instructions about how to begin. Occupational therapists review diary entries as often as possible and provide positive feedback when appropriate.

The development of time and stress management, ADLs, and social skills are important to recovery because individuals who abuse substances may have deficits in each of these areas. Substance abuse can become an occupation that takes over all aspects of the patient's life. Once the abuse is no longer an occupation, patients often need help reorganizing their day-to-day activities and relearning to manage their emotions. There are workbooks¹³ with established effectiveness⁵⁷ that patients can use on their own to develop these skills. The occupational therapist can provide the patient with a workbook and then check the patients work in following sessions.

Occupational therapists can also use cognitive-behavioral methods to help patients achieve the following long-term goals:

- Improve health habits and self-care.
- Develop skills in self-regulation and impulse control.
- Develop substance-free leisure skills.
- Develop the ability to plan ahead to avoid relapse.
- Develop the ability to set realistic short-term goals related to sobriety.
- Experience group participation, learn to communicate needs, learn to give and receive support.
- Prepare for a constructive vocational role.
- Value a clean and sober identity.
- Connect with community resources such as Alcoholics Anonymous (AA) to maintain sobriety.

All of these skills promote patients' self-efficacy in their process of staying sober. It may also be helpful to guide patients in the process of comparing their lives before and after sobriety to reinforce their progress and the positive aspects of their lives so they keep moving in a forward direction.

Motivational strategies can be used to identify the patient's stage of change and then foster his or her motivation to change.⁵⁵ Motivational interviewing, as previously mentioned, is a patient-centered strategy that increases intrinsic motivation using nonconfrontational communication that reflects empathy and is an effective strategy to use when patients verbalize resistance to change.⁴⁷ Decision balancing helps patients weigh the pros and cons of using drugs so that the cons outweigh the pros. Motivational enhancement therapy can be used to keep patients involved in their change processes after initial changes have been made.⁵⁵

The 12-step treatment programs utilize the principles of 12-step support groups, such as AA and Narcotics Anonymous. Unlike 12-step support groups, 12-step treatment programs are often led by a professional, are nonconfrontational, accept harm reduction when full abstinence seems unattainable, and allow for the taking of prescribed medications. According to Stoffel and Moyers,⁵⁵ occupational therapists can use 12-step treatment programs to evaluate a patient's readiness for 12-step support groups, help patients develop external supports that promote sobriety, design interventions that incorporate 12-step principles, and promote continuation of healthy habits that replace unhealthy habits associated with substance use. They suggest the use of spirituality as a form of treatment to help patients identify their meaning of life and, in keeping with the 12-step tradition, to educate and reinforce that recovery from substance abuse is a lifelong commitment.

CASE STUDY

Patient Information

Leslie is a 66-year-old recently retired white female who has returned to independent living after a 5-day rehabilitation hospitalization secondary to a car accident and resultant complex fracture of the right wrist of her dominant hand. She has been prescribed oxycodone for pain. Leslie has been receiving outpatient OT at her community physical rehabilitation clinic for an exercise regime to decrease edema in her right upper extremity. However, it appears that she may not be performing her daily home exercise routine because she is unaware of how to do it in the clinic and appears lethargic and slurs her words.

Reason for Occupational Therapy Referral

In addition to decreasing edema, Leslie has been referred for OT services to increase independence in self-care and basic ADLs using her nondominant hand.

Assessment Process and Results

The occupational therapist inquired about Leslie's ability to follow through with her home exercise regime. Leslie reported being tired all the time and not being motivated to do much of anything. So, instead of conducting the OT treatment session planned for that day at the clinic, Leslie agreed to do a spontaneous home visit to determine her ability to function independently. Her home was in disarray. It was clear that she had not been doing dishes, laundry, or cleaning. She did not seem concerned about the status of her house and had no reservations about the occupational therapist noting its condition. Leslie was focused on taking her pain medication, stating that she did not want to start exercising until she had adequate pain relief. At this point, the occupational therapist suspected that Leslie may be taking too much pain medication and asked to see her medication vile. The remaining number of pills was too low for her dosage, indicating that she had taken too many. When the number of remaining pills was brought to her attention, Leslie responded that she was an alcoholic in recovery, had a high tolerance for pain medication, and needed more than an average person.

The occupational therapist administered the Substance Abuse Screening Test and took an occupational history regarding her substance use. Leslie had starting drinking in high school and continued until age 32 when her boss referred her to the Employment Opportunity Program for treatment or risk losing her job. Leslie followed through with substance abuse counseling and a 12-step program until she felt she no longer needed treatment for alcohol abuse at age 45. Prior to her retirement at age 65, Leslie had over 20 years of sobriety. After retirement, Leslie reported having nothing to do and feeling depressed and lonely because she never married, had children, and had not been in an intimate relationship for several years, stating that it was hard to find a lesbian partner at her age. To fill her time and loneliness, Leslie started drinking again. She

admitted that her current car accident could have been a result of her drinking before driving and, while crying, blamed herself for her current situation. Her occupational therapist empathetically added that her current pain medication is highly addictive and may be making it harder for her to function. Leslie replied that she wants to stop drinking now but continues to drink and isolate as a result of feeling unsafe in the world after the accident.

The occupational therapist administered the Beck Depression Inventory because of Leslie's self-blame and sadness. Results indicated that Leslie is depressed, but not suicidal, and has some hope for the future. The occupational therapist administered the PC-PTSD-5 because Leslie no longer feels that the world is a safe place after her accident and isolates herself inside her home. Leslie scored a 3 on the PC-PTSD-5, indicating the need for referral for full PTSD evaluation by a psychologist.

Occupational Therapy Problem List

- Inability to use dominant arm secondary to right wrist complex fracture
- Edema in the right upper extremity
- Co-occurring pain medication and alcohol misuse
- Currently experiencing depression
- Currently experiencing symptoms of PTSD
- Isolated in home most of the time
- Fatigue
- Poor ADL and self-care skills
- Social isolation
- Noncompliant with home exercises
- Few leisure pursuits
- Loss of the role of employee

Occupational Therapy Goal List

- Increase dexterity, strength, and endurance in the left upper extremity sufficiently to participate in basic ADLs and self-care by 2 weeks.
- Comply with daily exercise routine to decrease edema in the right upper extremity (using a written exercise log noting the amount of time spent exercising, whether or not the recommended routine was completed, and if not, what barriers prevented completion).
- Decrease oxycodone use until abstinent by 1 week upon recommendation by physician (from self-report) and decrease use of alcohol until abstinent by 2 months (by counting clean days).
- Decrease level of depression as noted on the Beck Depression Scale by 2 months.
- Decrease symptoms of PTSD by decreasing her score from 3 to 2 on the PC-PTSD-5 by 3 months.
- Increase the amount of time spent in purposeful activities (leisure and therapeutic) performed outside the home and with others from 2 to 7 hours per week by 3 weeks, using a self-report calendar.
- Decrease daytime fatigue levels from 9 to 6 on a 10-point scale (0 = low, 10 = high) in 2 weeks.

Intervention

Leslie continued to receive OT services to increase independence in self-care and basic ADLs using her nondominant hand and decrease edema in her dominant upper extremity. Her physician agreed to help her taper slowly off oxycodone and replace it with Tylenol 3 for pain management after which she was observed to be more alert and motivated during therapy sessions and no longer slurring her words. Leslie agreed to resume daily AA meetings at her local LGBTQ+ (lesbian gay bisexual transgender queer/questioning) community center because she was familiar with 12-step programs and found them helpful in the past. These meetings helped her make new friends with similar lifestyles. Her feelings of safety in these meetings extended to her larger world by helping Leslie realize that her accident resulted from her drinking and that she could become sober again. She met friends who shared common leisure interests and thus felt less lonely and isolated. Leslie became motivated to take care of her home in order to invite friends over.

Leslie received education from her occupational therapist about edema, which indicated that if severe enough could cause death. As a result, she completed her prescribed daily exercise routine

for her dominant upper extremity. She had more energy after decreasing her alcohol and oxycodone consumption and was thus able to complete all nondominant upper extremity exercises as per her daily exercise log.

After 3 months, Leslie reported that she was able to maintain these changes and was retested. Her Beck Depression Scale score improved. Her score on the PC-PTSD-5 improved from 3 to 2. Scores on the fatigue scale improved from 9 to 4. Leslie spent an average of 4 hours per day engaged in purposeful leisure, social, and therapeutic activities outside the home, as noted on her calendar. She was attending daily AA groups that she found very helpful and achieved her 30-day token for sobriety from alcohol and oxycodone. Through Leslie's work with her occupational therapist, she was able to redefine her role as retiree. In 3 months, she went from spending most of her time drinking to engaging in community leisure pursuits with newly acquired sober friends and participating in daily AA meetings.

Evidence Table of Intervention Studies for Psychosocial Adaptation to Disability

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit
Occupational therapy (OT) interventions to improve occupational performance for patients with psychological impairment poststroke ⁴⁶	Six interventions were identified to treat depression, mental health quality of life, or anxiety: 1. Exercise/movement therapy 2. Behavioral therapy and stroke education 3. Behavioral therapy only 4. Care support and coordination 5. Stroke education only 6. Community-based interventions	Thirty-eight studies were included in this evidence-based review. Thirty-seven studies were Level I, one study was Level II, and one study was Level III. Study participants consisted of stroke survivors in various settings and at various amounts of time poststroke.	Intensive interdisciplinary treatment in the community consisted of six or more home visits. No other lengths of interventions were given.	Evidence-based review Level I	Problem-solving, behavioral techniques, and motivational interviewing were effective in treating depression. Interdisciplinary home programs were effective in decreasing anxiety and depression and increasing health-related quality of life poststroke.
Psychosocial interventions for women diagnosed with substance abuse to improve: substance use, intrapersonal functioning, health education, skill development, parenting skills, trauma, mental health (depression, anxiety, PTSD), occupation/productivity, sexuality, mindfulness/meditation, housing, and body image ⁵⁸	Interventions included education, motivational interviewing, skills based, CBT, psychotherapy, therapeutic community, experimental, peer counseling, goal setting, mindfulness/meditation, and 12-step groups. Treatment was group based ($n = 18$), individual based ($n = 14$), and combined group and individual ($n = 10$).	Forty-two studies were included in this scoping review. Study participants consisted of women diagnosed with substance abuse in various settings (inpatient $n = 13$, outpatient $n = 22$, combined inpatient/outpatient $n = 7$).	All programs varied, no specific dosages were given.	Scoping review Level I	The majority of the programs used harm reduction ($n = 32$) and multiple interventions that addressed multiple goals for psychosocial rehabilitation related to substance abuse.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit
Interdisciplinary intervention and rehabilitation within OT scope of practice to maximize activity and participation in adult cancer survivors ¹⁰	There were four categories of intervention: multidisciplinary ($n = 5$), psychosocial ($n = 29$), return-to-work ($n = 3$), and sexuality ($n = 2$).	Fifty-two studies were included in this systematic review: 45 Level I, 3 Level II, and 3 Level III. Study participants consisted of adult cancer survivors in various settings and with various types and stages of cancer	Multidisciplinary treatment programs consisted of OT, physical therapy [PT], and other health care professional interventions. Psychosocial treatments included stress management, problem-solving, life review, expressive groups, CBT, and mindfulness. Return-to-work intervention included strengthening exercises. Sexuality interventions were psychoeducation, medical, and exercise.	Systematic review Level I	Psychosocial strategies reduced anxiety and depression and multidisciplinary rehabilitation improved function and participation in adult cancer survivors regardless of their type of cancer.
Interdisciplinary (OT, nursing, medicine, social work, psychology, public health, sociology) interventions for patients diagnosed with substance abuse ⁵⁵	Interventions were: brief interventions, motivational strategies, cognitive behavioral therapy (CBT), and 12-step programs	Twenty studies were included in this evidence-based review. Eight studies were Level I, five studies were Level II, one study was Level III, and six were Level V. Study participants consisted of patients diagnosed with substance abuse in various settings and at various amounts of time poststroke.	Brief intervention sessions: 5–60 minutes \times 3 sessions over time, CBT included teaching coping skills used for relapse prevention or harm reduction and cognitive reframing. Motivational strategies included decision balancing, motivational interviewing, motivational enhancement therapy, and FRAMES.	Evidence-based review Level I	Brief interventions, motivational strategies, CBT, and 12-step programs were effective in improving cognitive performance and health maintenance outcomes in patients diagnosed with substance abuse.
Psychosocial interventions for survivors of motor vehicle accidents diagnosed with PTSD ⁵⁹	Interventions were cognitive therapy, a self-help booklet based on CBT, or repeated assessments.	Ninety-seven survivors of motor vehicle accidents diagnosed with PTSD during the first 3 months postaccident at risk for a diagnosis of persistent PTSD	CBT delivered for a mean of 9-weekly 60-minute sessions and a mean of 2.4-monthly follow-up sessions. Self-help 64-page booklet. Repeated assessments were administered without intervention.	Randomized controlled trial Level 1	Cognitive therapy was effective in preventing chronic PTSD in patients diagnosed with recent-onset PTSD. A self-help booklet of CBT exercises was not effective.

PTSD, post-traumatic stress disorder.

visual impairments, 103–106

neurological and, 83

oculomotor, 83, 85

physiological basis of, 83

visual fields deficits, 86*f*

Visual history

eye alignment, 88–89, 89*f*

interview, 88

observation, 88

and observation, 88

screening equipment, 88*f*

Visual impairment interventions

adaptation, 102, 104

compensation, 101–102, 104

decreased acuity and refractive errors

- accommodative disorders, 103
- visual acuity/refractive disorders, 104
- oculomotor dysfunction, 104
- remediation, 101, 104
- Visual impairments, stroke and, 745
- Visual memory, 118
- Visual organization, 122
- Visual perception, 118
- Visual perceptual assessment and intervention
 - areas of deficit, impairments in daily occupation, 119*f*
 - case study, 133–134
 - conceptual foundation underlying, 125–127
 - daily occupation, 118
 - neurological and physiological basis of, 118–120
 - screening of, 120–125
 - skill development hierarchy, 118*f*
 - skill dysfunction, 127–132
- Visual perceptual function, 118
- Visual perceptual impairment
 - interventions for, 125
 - screening tools and observations for, 126–127*t*
- Visual perceptual skill dysfunction
 - cognitive loading examples, 129*t*
 - depth perception, 131
 - monocular depth cues, 131–132*t*
 - pattern recognition, 129
 - specific interventions for, 127
 - therapeutic activities related, 128*t*
 - unilateral inattention
 - audiovisual stimulation, 131
 - patching, 131
 - prisms, 129–130
 - scanning, 130–131
 - sustained attention training, 130
- Visual perceptual skills screening
 - assessing impact on daily function
 - figure ground perception, 121
 - clock drawing test, 124*f*

- depth perception, 124–125
- evaluation, 125
- form constancy
 - procedures, 120–121
- impact on daily function
 - visual closure, 121
- procedures, 120
- screening procedures, 121
- spatial orientation, 122–123
- stereo fly test, 125*f*
- unilateral inattention, 123–124
- visual organization, 122
- Visual skills screening
 - contrast sensitivity, 89
 - contrast sensitivity testing, 89*f*
 - fields
 - confrontations, 92, 92*f*
 - drawings, 92–93
 - line bisection, 92
 - scanning, 92
 - scanning sheet performance, 92*f*
 - fixation testing, 90*f*
 - oculomotor
 - convergence/divergence, 90–91, 90*f*
 - fixation testing, 89–90, 90*f*
 - pupillary function, 91–92, 91*f*
 - range of motion, 90
 - saccades, 91, 91*f*
 - tracking/pursuits, 90
 - setup and procedure
 - equipment, 88
 - lighting, 86
 - positioning and process, 86
 - visual acuity function
 - distance acuity, 89
 - near acuity, 89
 - visual acuity testing, 89*f*
 - visual history and observation

- eye alignment, 88–89
- interview, 88
- observation, 88

Vocal quality, 372

Volitional cough, 372

Volkman’s ischemia, 861

W

Wartenberg sign, 899

Weakness, activities of daily living and, 570–581

- bathing and showering, 572–574
- bed mobility, 570–572
- dressings, 576–579
- feeding, 579–580
- personal device care, 580–581
- personal hygiene and grooming, 575–576
- sexual activity, 581
- toileting and toilet hygiene, 574–575
