This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Dedication

We dedicate this book to Dr. Jim Hinojosa and Dr. Anne Mosey—two of the foremost influential scholars in the profession of occupational therapy. We were fortunate to have both as mentors in our pursuit to become scholars in the profession. We are eternally grateful for their scholarship, knowledge, and insight that helped shape our thinking, guided the occupational therapy program at New York University, and provided pioneering and innovative direction for the profession as a whole.

Preface

The eighth edition of *Occupational Therapy for Physical Dysfunction* integrates the foundational concepts developed by Dr. Catherine A. Trombly Latham and the work of Dr. Mary Vining Radomski with new evidence in the profession to guide occupational therapy practice for adults with physical disabilities. The intention of this text is to provide comprehensive and detailed instruction in best practice for occupational therapy assessment and intervention with this population.

Organization

The eighth edition of *Occupational Therapy for Physical Dysfunction* has six sections that guide the reader in the conceptual foundations of the profession, assessment and treatment of commonly presenting problems, the use of technology and frames of reference, and the treatment of specific diagnoses in physical rehabilitation as follows:

- **Section 1: Occupational Function** provides the reader with the basis of the profession of occupational therapy including the foundational concepts, philosophy, clinical reasoning, art of practice, and documentation guidance.
- **Section 2: Assessment and Intervention** provides the reader with detailed steps and evidence to support the assessment and treatment process of deficits with which adults with physical disabilities may present. This section covers 11 specific areas of function including vision, visual perception, cognition, sensation, motor function, motor control, balance, communication, swallowing and eating, cranial nerve function, and environmental modification.
- **Section 3: Rehabilitation Technology** guides the reader in the use and fabrication of orthoses and in the selection and use of physical agent modalities, wheelchairs, and assistive technology.
- **Section 4: Restoration of Independent and Community Living Roles** presents information about how to improve

participation in activities of daily living, roles (family, parenting, social, home, community, work, and recreational), functional mobility, driving, and community mobility.

- **Section 5: Frames of Reference for Physical Disability Rehabilitation** provides the theoretical bases, function/dysfunction continua, indicators of function and dysfunction, and postulates regarding change for the Biomechanical, Rehabilitation, and Motor Learning and Task-Oriented Approaches. In addition, the functional uses of various neurological approaches including Brunnstrom, Neurodevelopmental Treatment (NDT), Rood, and Proprioceptive Neuromuscular Facilitation (PNF) frames of reference are discussed.
- **Section 6: Guidelines for Physical Dysfunction Diagnostic Categories** provides the reader with specific evaluations and interventions for 15 of the most common physical disability diagnoses with which adults present in occupational therapy practice. In addition, sleep disorders that may accompany these diagnoses and psychosocial adaptation to these physical disabilities are discussed to help guide occupational therapy assessment and intervention in these areas.

Features and Ancillaries

Many of the features of the seventh edition have been streamlined and integrated into the text in the eighth edition. Bulleted lists within the text provide information that had been provided in boxes, such as Procedures for Practice, in the previous edition. This edition includes several features to enhance learning and support occupational therapy practice with adults with physical dysfunction including assessment tables, evidence tables, and case studies. The assessment tables detail the description, administration time, validity, reliability, sensitivity, and strengths and weaknesses of the most commonly used measures. The evidence tables provide the most recent, best evidence to support intervention. These tables include a description of the intervention, participants, dosage, research design, level of evidence, and results of each

study. The case studies assist the reader in understanding application of chapter content to a typical individual who may be treated by an occupational therapist using that particular intervention in an adult physical dysfunction setting. Each case study includes patient information, occupational therapy recommendations, summary of short-term goals, intervention, and progress.

There are also ancillaries for this edition including an instructor test bank for each chapter and audiovisual content. The test bank includes 10 to 20 multiple choice questions written by chapter contributors. The audiovisual content, which is available to students, can be accessed at thepoint.lww.com. This content includes audiovisual examples of how to conduct assessments and treatments for various problems with which adults present in physical dysfunction settings.

Terminology

In this edition, the term **occupational therapist** is used as an inclusive term and not as an exclusive term. Occupational therapists include those who have been educated in the use of occupation as a means of intervention to achieve occupational participation as the desired treatment outcome. This term includes all who participate in practice, education, or research in the occupational therapy profession. There has been a push in the profession of occupational therapy to use the term **occupational therapy practitioner**, but the term becomes cumbersome and exclusive in its use. To be concise and inclusive, the term **occupational therapist** is preferred by the authors.

The reader will also note the use of both of the terms **patient** and **client** to indicate the person who is participating in occupational therapy services. The term used in each chapter was chosen by the individual chapter authors to reflect the term that is most often used in that practice setting. For example, in Chapter 48, Burn Injuries, by Dr. Rebecca Ozelie, the term *patient* is used because the person participating in occupational therapy services is most often treated in a primary, acute care, or inpatient setting in which the

participants are referred to as patients. In Chapter 31, *Restoring Driving and Community Mobility* by Dr. Sherrilene Classen and Dr. Beth Pfeiffer, however, the term *client* is used to reflect the outpatient or community-based setting in which the person is most often treated and in which participants are referred to as clients.

Throughout the text, terminologies from both the *Occupational Therapy Practice Framework: Domain and Process* (third edition) and the International Classification of Functioning from the World Health Organization are used based on congruence with common professional and interprofessional language in the practice settings addressed. The use of various terms and frameworks reflects the diverse ways occupational therapists communicate about our profession to various consumers, coworkers, and researchers. Just as with the use of the terms **patient** and **client**, the use of general terminology will often reflect the practice area. Individual chapter contributors were encouraged to use the terms that best reflected the terminology used in their practice areas.

Contributors

In this edition, we have 52 chapters authored by a total of 72 contributors with expertise as clinicians, researchers, and educators in the respective treatment areas discussed in each chapter. Each contributor provided a perspective that has a great depth of experience, but that is also clear, concise, and accessible to all readers including occupational therapy students who are learning the information for the first time, new occupational therapists who need detailed direction in their practice area, and experienced occupational therapists who desire information regarding the latest, evidence-based interventions. Each of the outstanding chapter authors has contributed to building this comprehensive resource that will help guide and shape occupational therapy practice for adults with physical dysfunction.

Diane Powers Durette

Sharon A. Gutman

Acknowledgments

A textbook of this magnitude is compiled by the efforts of multiple professionals who are dedicated to the profession's advancement of knowledge and continued growth. Foremost, we thank Dr. Catherine A. Trombly Latham, who developed this seminal textbook in 1977 and edited editions 1 to 7, and Dr. Mary Vining Radomski who, along with Dr. Trombly Latham, edited editions 5 to 7. Their collective work on this book has both advanced the education of thousands of occupational therapists and promoted the science underlying assessment and intervention techniques. We are prodigiously grateful for their expert consultation on the eighth edition.

If not for the many expert chapter authors, who generously shared their high level of knowledge and skill in the compilation of the eighth edition, this textbook would not have reached the highest standard of knowledge dissemination. The chapter authors helped to create a textbook that is accessible, easy to understand, and replete with the latest evidence-based knowledge regarding occupational therapy practice for adults with physical dysfunction. We are exceedingly grateful for their willingness to share their expertise and mastery (see the list of current contributing authors). The eighth edition was constructed on the solid foundation of the many editions before it, and we are also immensely grateful for and acknowledge the scholarship of the contributing authors of all past editions (see the list of past contributing authors).

Working behind the scenes, but whose efforts were paramount in the development of this eighth edition are the following professionals, who although not occupational therapists have demonstrated dedication to the profession's continued advancement through their sustained work on this textbook: Laura Horowitz (managing editor), Matt Hauber (acquisitions editor), Amy Millholen (senior development editor), Jennifer Clements (art director), and Tim Rinehart (editorial coordinator). Because of their commitment and aptitude, the eighth edition exceeded the standards we hoped

to attain. We are exceptionally grateful for these individuals' high level of skill and proficiency.

Lastly, we thank the many people whose assistance in the development of this textbook has gone without formal acknowledgment: those who served as photographic and video models; patients who allowed their images and stories to be presented in this edition; and colleagues, family, friends, and pets who provided support for and finessed the many details of this eighth edition. We are enormously grateful for the unseen but critically important contributions made by these individuals as well.

User's Guide

Framework

The eighth edition uses the framework established by Catherine A. Trombly Latham, who also wrote the first two chapters. This new edition is clear, concise, and streamlined with the inclusion of the essential information for occupational therapists in the physical dysfunction setting.

Learning Objectives, Chapter Outline, and Terminology

Each chapter begins with Learning Objectives that provide an overview of the content to follow. Chapter Outlines offer an overview of each chapter's content. Key terms and definitions for each chapter are presented in the Terminology list.

Occupation: Philosophy and Concepts

Catherine A. Trombly Latham

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Define occupation.
2. Discuss the importance of occupation in people's lives.
3. Discuss the concept of occupational balance.
4. Discuss occupation as a therapeutic medium.
5. Characterize occupation-as-end and occupation-as-means.
6. Discuss the therapeutic qualities of occupation: purposefulness and meaningfulness.
7. Cite evidence that supports the use of occupation as therapy.
8. Describe how therapeutic occupation is implemented in practice.

CHAPTER OUTLINE

Occupation Defined, p. 18

Importance of Occupation in People's Lives, p. 18

Occupation as Therapy, p. 19

Effectiveness of Therapeutic Occupation, p. 22

Implementation of Therapeutic Occupation

in Practice, p. 24

Case Study, p. 26

TERMINOLOGY

Activity analysis: a process by which properties of a given activity are identified for their ability to elicit targeted responses or enable a person to successfully accomplish the activity.

Constraints: limitations imposed on completion of an occupation. Extrinsic constraints include physical and sociocultural contexts, and environments and task demands. Intrinsic constraints include personal factors such as movement abilities, vision, sensation, cognition-perception, and cardiorespiratory capacity.

Habit: a behavior pattern acquired by frequent repetition that shows itself in regularity or increased facility of performance.¹

Occupation-as-end: the combined set of activities that, together, support desired occupational roles and purposeful end goals identified as meaningful to the individual.

Occupation-as-means: the array of activities that support the completion of tasks needed in daily life, but, by themselves, may not hold significant meaning to the individual.

Task demands: the specific features of an activity that influence the type and amount of effort required to perform the activity. Demands include the shape, size, texture, number of objects; the visual, auditory, physical, or emotional impact of surroundings; the meaning of ritual associated with the activity; the size, shape, weight, configuration of tools; and the colors, textures, weight, familiarity, etc., of materials. Also known as *activity demands*.

Velocity profile: a graph of time versus speed of movement from which the organization of movement can be determined.

All New Full-Color Art Program

For the first time, *Occupational Therapy for Physical Dysfunction* is in full color. The text contains hundreds of photos showing occupational therapists and patients in action, including assessments, interventions, equipment, orthoses, assistive technology, restoration of function, and disease-specific conditions.

Case Study

Each chapter ends with a Case Study that addresses Patient Information, Assessment Process and Results, Occupational Therapy Problem List, Occupational Therapy Goal List, and Intervention.

CASE STUDY

Patient Information

Gordon is a 78-year-old retired high school teacher, director of a high school vocational program, and carpenter who experienced a stroke related to carotid artery angioplasty with stenting. The stroke resulted in hemiparesis of his right, dominant side that affected balance, weight shift, and right UE strength and coordination. The emergency room doctor conducted the Mini-Mental State Examination (MMSE) where Gordon scored 20/30, which indicated mild cognitive impairment. He was in the hospital for 3 days and then returned home to independent living with his wife. While still in the hospital, Gordon lost his balance and fell in the bathroom while bending and rotating. He stated, "This stroke caused my right arm and hand to be a dish rag."

Assessment Process and Results

The occupational therapist met with Gordon for evaluation and intervention. One of the first things he told the occupational therapist was that he could not drive because he could not turn the key in the ignition or hold the steering wheel with his right hand. The occupational therapist used multiple tools for the assessment process, including patient interview, Activity Card Sort, the MMSE, biomechanical assessments (9-Hole Peg Test, power of grasp, tensiometer, ROM), and the Mini-Balance Evaluation Systems Test (Mini-BEST).

Results indicated that Gordon was also having difficulty brushing his teeth, buttoning his sleeve cuffs, and holding a spoon to scoop grapefruit pieces, which he reported eating daily to lower his cholesterol. He periodically verbalized concern about his inability to manipulate grapefruit pieces, suggesting that this was an important goal to target. Gordon was independent in all other self-care tasks. He additionally desired to complete his own home maintenance, such as lawn mowing. Gordon's occupational interests included carpentry, such as remodeling his daughter's basement, which required the ability to use tools such as a drill, trowel, and hammer; model airplane building and flying; and playing music with piano, guitar, and harmonica.

Since his initial hospitalization, Gordon's MMSE score improved to 28/30, indicating no cognitive impairment. Scores on the 9-Hole Peg Test were 50 seconds right and 30 seconds left UE. Scores for power of grasp were 10 lb on the right and 60 lb on the left. Scores for lateral grasp were 3 lb on the right and 20 lb on the left. ROM was within normal limits throughout both UEs but a slight movement delay was present in the right UE. Score for the Mini-BEST was 24/28 because of limitations in reactive postural control.

Occupational Therapy Problem List

- Difficulty feeding self with utensils, especially when scooping grapefruit because of right hand weakness and limited coordination
- Difficulty brushing teeth because of right hand weakness and limited coordination and postural instability

- Difficulty with home maintenance, such as lawn mowing, because of balance impairment and weak grasp to pull the mower starter cord
- Difficulty driving because of right hand weakness and limited coordination

Occupational Therapy Goal List

During selection of occupation-as-end activities, the therapist asked Gordon which activities were the most immediately important to him. He prioritized the following goals:

- Gordon will demonstrate modified independence in feeding himself with utensils, especially scooping grapefruit, with 10 lb lateral grasp, 15 lb power of grasp, and normal coordination within 2 weeks.
- Gordon will demonstrate independence in brushing teeth with 15 lb power of grasp, normal fine motor coordination, and intact reactive postural control with transitional movements to set up items needed within 1 month.
- Gordon will be able to start his lawn mower and mow his lawn with intact balance and weight shift within 1 month.
- Gordon will demonstrate independence in driving as evidenced by 10 lb of lateral grasp in order to turn the key in the car ignition within 1 month.

Intervention

To enhance performance of each occupation, it was important to target hand and finger strength, fine motor coordination, and balance with transitional movements. During the second visit, the therapist developed a bank of intervention activities that Gordon could perform within his natural environment including carpentry tasks, lawn mowing, brushing teeth, playing piano and guitar, and feeding himself grapefruit. The therapist used a neurodevelopmental treatment (NDT) frame of reference, while also integrating task-specific motor learning in which specific activity aspects were analyzed and modified to promote repetition, duration, specificity, and intensity.

The therapist initiated patient education during simulations of several meaningful activities that Gordon identified. For example, the therapist found a drill, screws, and wood from the maintenance department to show Gordon how to incorporate weight bearing on his affected, extended right UE. The drill handle was large, which facilitated Gordon's ability to grasp it. His grip strength, however, was too weak to hold the drill upright against gravity, as would be required to push screws into a wall. To grade the task to a lower challenge level, the therapist instructed Gordon to hold the drill downward so that gravity could assist when pushing the screw into the wood. With practice, Gordon gained the ability to activate the power switch with his right index finger. He used his left hand to precisely hold the screw when initially drilling it into the wood, followed by a two-handed method (both hands on the drill) to finish drilling the screw into the wood.

Evidence Tables

Many chapters include an Evidence table at the end that collects the best evidence for interventions in the topic area.

Evidence Table of Studies Involving Occupational Therapy Selection, Gradation, and Adaptation of Occupation						
Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Comparative effectiveness of (1) combined therapeutic exercise and occupation-based activities and (2) therapeutic exercise alone ¹⁸	Group #1: Picking up small everyday objects, typing on a keyboard, washing and wiping dishes in addition to therapeutic exercises in both hand therapy sessions and home program Group #2: Therapeutic exercises in both hand therapy sessions and home program	46 patients with UE injuries treated in outpatient hand occupational therapy clinic	10 weeks of therapy: supervised hand therapy 1-hour sessions, 2 times/week, and home exercise program 10 minutes, once a week	Randomized controlled trial, Level I	Combined intervention had better outcomes, including reduced pain, improved AAROM in fingers, subjective functional status, and subjective performance and satisfaction of performance	Combined intervention showed statistically significant improvement in outcome measures compared to therapeutic exercise group: DASH score ($p < 0.02$), total active motion ($p < 0.01$), neuropathic pain ($p < 0.02$), COPM performance ($p < 0.001$), COPM satisfaction ($p < 0.001$) Effect size not reported
Comparative effectiveness of occupation-based intervention and rote exercise ⁹	Group #1: Immobilization of healthy hand using therapeutic occupations for intervention Group #2: Immobilization of healthy hand during rote exercise of affected hand Control Group #3: No immobilization of healthy hand while practicing different movements and activities	36 outpatients (22–55 years old)	Groups #1 and 2 received intervention 3 hours each day, 3 days/week, over 4 weeks	Randomized controlled trial, Level I	Compared to rote exercise, occupation-based group had better performance in objective and subjective measures, motivation, satisfaction with and perception of performance, and continued improvement at follow-up	Post hoc analyses revealed significant difference among all three groups with most increased mean change for occupation-based group ($p < 0.01$) Effect size not reported
Comparative effectiveness between combined (1) resistive exercises, functional exercises, and ADLs, and (2) resistive exercises ²⁷	Group #1: Combination of resistance exercise, functional exercise, and ADL exercise Group #2: Resistance exercise	52 older adults, mean age = 73 years	Measured at baseline, postintervention, and 6-months follow-up	Randomized controlled trial, Level I	Postintervention improvement was found within groups but not between groups. At 6-month follow-up, a decline in resistance exercise group was found. Combined exercise group continued to show improvement. More adverse events (soreness, pain) for resistance exercise group	Combined intervention group (mean change = 0.29, $p < 0.02$); resistance exercise group (mean change = 0.24, $p < 0.13$). At 6 months postintervention, combined intervention group showed within-group mean change of 0.37 ($p < 0.01$)
Comparative effectiveness between occupation-based intervention and repetitive task practice ¹⁹	Group #1: Focused on performance of occupations with facilitation methods Group #2: Focused on 10–50 repetitions of each task	16 (21–69 years old) in chronic phase of stroke recovery	Measured at baseline and postintervention. Interventions were 55-minute sessions, 2 times/week for 4 weeks for both groups	Pilot randomized controlled trial comparative study with parallel group block design, Level I	Improvements in occupational performance and motor performance in both groups were similar. Authors suggested engagement greater and demand greater in occupation-based group because of meaningfulness and multijoint activities	Although within-group changes after intervention were found for both groups ($p < 0.0001$), no between-group differences were found. Effect size not reported

ADLs, activities of daily living; UE, upper extremity.

Assessment Tables

The chapters focused on assessment include an Assessment table that collects the most commonly used standardized assessments for the topic area.

Most Commonly Used Standardized Assessments						
Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Baking Tray Task ^{26,28}	Used to assess for unilateral spatial neglect	<10 minutes	Found to detect more cases of neglect than the three-item Behavioral Inattention Test and is even more accurate when used in combination with the Line Bisection Test	Test-retest 0.87	Increased through combination with other tests; more sensitive than the three-item Behavioral Inattention Test	Easy to administer. Most sensitive single test to detect spatial neglect. Easy and cost-effective to create your own with the measurements provided. Not a lot of depth to the test or scoring. Assumed cognitive impairment if spatial neglect is not present.
Line Bisection Test ²¹	Used to detect unilateral spatial neglect	<5 minutes	Convergent validity with Baking Tray Task: $r = -0.66$	Test-retest reliability 0.97 Internal consistency: no evidence	Detects spatial neglect with 76.4% accuracy	Many versions; however, the procedures are rarely standardized.
Trail Making A and B ^{19,29}	Used to assess visual conceptual and visuomotor tracking conditions	5–10 minutes	Construct validity for rapid visual search and visual sequencing. Trails A: Visual perceptual abilities Trails B: working memory and task switching	Test-retest reliability: Test A: $r = 0.83$ Test B: $r = 0.90$	Functional MRI studies demonstrate activation of the ventral and dorsal visual processing streams	Public domain assessment is easy to administer and obtain. Some versions have therapist correct mistakes along the way.
Bell's Test ^{15,37}	Quick screen for visual neglect in the near extrapersonal space	<5 minutes	Criterion Validity: more likely to evidence left neglect than Albert's Test, Star Cancellation Test, Line Bisection Test, and Line Crossing Test	No evidence	No evidence	The Bell's Test requires no specialized training to administer and only minimal equipment is required (a pencil, a stopwatch, the test paper, and scoring sheet). The test is simple to score and interpret.
Motor-Free Visual Perception Test (MVPT-3) ^{19,23}	Widely used standardized test of visual perception, assessing visual perception independent of motor ability	20–30 minutes	Criterion related: 0.78 with the DTVP-2 and 0.73 with the DTVP	Internal consistency: 0.86–0.90 Test-retest: 0.92	General measure for motor-free visual perceptual components	Does not provide norms for separate subtests. Short and simple measure that is tolerated well by most clients.

Section 1 Occupational Function

Conceptual Foundations for Practice

Catherine A. Trombly Latham

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the *Occupational Functioning Model* (OFM).
2. Relate the American Occupational Therapy Association's *Occupational Therapy Practice Framework* (OTPF) to the OFM.
3. Use the language of the *OFM* and the American Occupational Therapy Association's *OTPF* interchangeably.
4. Organize assessment and treatment planning according to the *OFM*.

CHAPTER OUTLINE

Introduction

The Occupational Functioning Model

The Process of Occupational Therapy for Persons with Physical Dysfunction

Summary

Case Study

TERMINOLOGY

Ability: a general trait an individual brings to learning a new task.¹

Activity (activities): in the *Occupational Functioning Model* (OFM), activities are considered small units of goal-directed behavior that make up tasks. The *Occupational Therapy Practice Framework* defines activity as a class of human actions that are goal directed; the term *occupation* encompasses activity.²

Activity analysis: the basic process used by occupational therapists to identify the properties inherent in a given occupation, task, or activity, as well as the skills, abilities, and capacities required to complete it.

Activity analysis is used to analyze performance; to select occupations to remediate deficient capacities and abilities, or, knowing the person's skills, abilities, and capacities; to modify an activity or environment to ensure successful completion of the activity.

Adaptive therapy: an intervention that promotes a balance among a person's goals, capabilities, and environmental demands by use of assistive technology, adaptation of the environment or methods of accomplishing an activity, and/or redefinition of goals.

Augmented maturation: the therapeutic techniques that challenge further development of first-level capacities or developed capacities. Such techniques include controlled sensory stimulation and activities that promote responses in developmental postures or patterns.

Capacities: potential attributes that, once developed into abilities and skills, will contribute to occupational functioning. Capacities are the basis of performance.

Context: the interrelated conditions in which something exists or occurs.³ Context is the personal, social, cultural, physical, temporal, and situational dimensions in which occupation occurs and may be fully understood.

Environment: the tangible objects, structures, or conditions by which one is surrounded and in which one's daily occupations occur. In the OFM, environment is considered the encompassing surround in which the person accomplishes the activities and tasks of his or her life.

Impairment: any significant deviation or loss of body structure or physiological or psychological function.

Occupation-as-end: occupation that is the functional goal (activity, task) to be learned or accomplished. Through repeated carrying out of an occupation (“task-specific training”), the patient will relearn the actions and routine of an activity, or through adaptation, the activity will be made possible for the person, given his or her current capacities and abilities.

Occupation-as-means: the therapeutic change agent to remediate impaired abilities or capacities.

Occupational balance: the distribution of occupations within a person’s life. When the occupations are balanced, the person perceives him- or herself to be healthy or stress free; too much or too little of an occupation or type of occupation is unhealthy. The dimension through which satisfactory balance may be achieved differs for different people and at different times in a person’s life. Dimensions identified to date are time (hours spent in self-care, play, work, and rest, for example), degree of difficulty (challenging occupation vs. relaxing occupation), and degree of self-focus (occupation is meaningful for the person vs. being meaningful for others; care of one’s self vs. care of others).^{4,5}

Occupational dysfunction: the inability to accomplish a necessary or desired occupational goal because of either impairment of abilities and skills or environmental barriers. Occupational dysfunction is the focus of occupational therapy.⁴

Occupational Functioning Model: a conceptual model that guides occupational therapy evaluation and treatment of persons with occupational dysfunction secondary to physical dysfunction. The particulars of the model are as follows: (1) To engage satisfactorily in a life role, a person must be able to do the tasks that, in his or her opinion, make up that role. (2) Tasks are composed of activities, which are smaller units of behavior. (3) To be able to do a given activity, one must have certain sensorimotor, cognitive, perceptual, emotional, and

social abilities. (4) Abilities are developed from capacities that the person has gained through learning or maturation. (5) Developed capacities depend on first-level capacities that derive from a person's genetic endowment or spared organic substrate.^{6,7}

Self-efficacy: the perceived capability to perform a behavior. It is the belief in personal competence.⁸

Skill: competence in doing.³

Introduction

Students may wonder how occupational therapists know what to do when a person with **occupational dysfunction** secondary to a disease or injury that results in physical **impairment** is referred to them. First, therapists have *specific knowledge* about what the diagnosis means in terms of limitations of bodily structure or function and subsequent probable limitation of occupational performance and they know the effectiveness of interventions available—the evidence base of practice. Second, they have *specific skills* for assessing and treating persons with occupational dysfunction secondary to physical impairment. Third, they know *how therapy is organized*—the conceptual foundation for practice. The organization or process of occupational therapy is found in various conceptual models of practice. An occupational therapy model of practice describes the interrelatedness of personal characteristics, environment, and occupational goals to guide assessment and intervention.

The American Occupational Therapy Association's (AOTA) *Occupational Therapy Practice Framework* (OTPF) is meant to be used in conjunction with conceptual models of practice. That framework describes the domain and process of the entire practice of occupational therapy.² The framework aims to standardize the language of the domain and process of occupational therapy. Because the framework is not a conceptual model, it is expected that occupational therapists will apply pertinent aspects of the framework through the particular conceptual model they choose to guide their practice. Therapists may choose from among many different

conceptual models of practice in order to put the framework into practice. This textbook has chosen the **Occupational Functioning Model (OFM)** to conceptualize the process of occupational therapy for persons with physical dysfunction. How, then, do the *OTPF* and the OFM relate? What are their similarities and differences? The language and process of the two are comparable (Tables 1-1 and 1-2). They share some commonalities and differ on others (Table 1-3).

Table 1-1. The Domains of the Occupational Functioning Model and the Occupational Therapy Practice Framework

OCCUPATIONAL FUNCTIONING MODEL	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK ²
<p>Competence and Satisfaction with Life Roles and Competence in the Performance of Tasks of Life Roles</p>	<p>Occupations</p>
<p>Life roles and the tasks that comprise them are defined by the patient or client. Generally, roles fall into one of the following three categories:</p> <p><i>Self-maintenance roles</i>—These roles maintain self, family, pets, and home, including all BADLs and IADLs associated with self-care; all IADLs associated with care of family; and all IADLs associated with care of home, and other possessions</p>	<p><i>BADLs</i>—Care of one’s body including bathing and showering, bowel and bladder management, dressing, swallowing, eating, self-feeding, functional mobility, personal device care, personal hygiene and grooming, sexual activity, and toilet hygiene <i>IADLs</i>—Activities to support daily life in the home and community including care of others, child rearing, care of pets, communication management, community mobility, financial management, health management and maintenance, home establishment and management, meal preparation and cleanup, religious observance, safety and emergency maintenance, and shopping <i>Rest and sleep</i>—Rest, sleep, sleep preparation, and sleep participation</p>
<p><i>Self-advancement roles</i>—These roles add to the person’s skills, possessions, or other betterment</p>	<p><i>Education</i>—Participation in formal or informal education; exploration of informal educational needs or interests <i>Work</i>—Employment interests and pursuits, employment seeking and acquisition, job performance, retirement preparation and adjustment, and volunteer exploration and participation</p>

OCCUPATIONAL FUNCTIONING MODEL	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK²
<p><i>Self-enhancement roles</i>—These roles contribute to personal accomplishment and enjoyment or sense of well-being and happiness</p>	<p><i>Play</i>—Play exploration and participation <i>Leisure</i>—Leisure exploration and participation <i>Social participation</i>—Engaging in activities that result in successful interaction at the community, family, or peer/friend levels</p>
<p>Competence in the Performance of Activities and Habits of the Tasks of Life Roles</p>	<p>Performance Patterns</p>
<p><i>Activities</i>—Smaller units of goal-directed behavior that comprise tasks <i>Habits</i>—Chains of action sequences acquired by frequent repetition that can be carried out with minimal attention. Therapy aims to sustain useful habits, release useless habits, and develop new habits</p>	<p><i>Habits</i>—Automatic, consistent behavior carried out in familiar situations or environments. Habits can be useful, dominating, or impoverished and either support or interfere with performance in areas of occupation <i>Routines</i>—Patterns of behavior that provide structure for daily life <i>Rituals</i>—Symbolic actions that contribute to the client’s identity and reinforce values and beliefs <i>Roles</i>—A set of behaviors expected by society, shaped by culture, and defined by the client</p>
<p>Abilities and Skills</p>	<p>Performance Skills</p>

OCCUPATIONAL FUNCTIONING MODEL	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK²
<p>Abilities and skills that are basic to interaction with objects and physical and social environments including:</p> <p><i>Motor</i>—Adequate strength, coordination, range of motion, dexterity, and muscular endurance</p> <p><i>Sensory</i>—Abilities to adequately receive and interpret sensory stimuli to enable occupational performance</p> <p><i>Cardiorespiratory</i>—Adequate cardiac and pulmonary function to sustain performance</p> <p><i>Visual-perception</i>—Adequate visual acuity and ability to perceive and interpret sensory stimuli and to perceive self and objects in space to enable occupational performance</p> <p><i>Cognitive</i>—Abilities and skills that are basic to interaction with the environment, to organizing life tasks, and to solving occupational problems; abilities include attention, memory, problem solving</p> <p><i>Socioemotional</i>—Abilities and skills that enable occupational performance in a social context or environment</p>	<p>Observable elements of action having an implicit functional purpose</p> <p><i>Motor skills</i>—Actions or behaviors used to move and physically interact with tasks, objects, contexts, and environments; includes reaches, bends, lifts, and manipulates.</p> <p><i>Process skills</i>—Skills observed as a person utilizes tools and materials; carries out actions; modifies performance when problems are encountered. Includes attends, chooses, uses, and sequences.</p> <p><i>Social interaction skills</i>—Skills observed during social exchanges. Includes approaches/starts, concludes/disengages, and empathizes.</p>
Developed Capacities	Client Factors
Voluntary responses that have developed from first-level capacities	<i>Body functions</i> —Includes mental functions; sensory functions; neuromusculoskeletal and movement-related functions.
First-Level Capacities	Client Factors
The reflexive subroutines of voluntary movement and behavior. These functional foundations for movement and behavior include sensorimotor, cognitive-perceptual, and socioemotional capacities	(as above)

OCCUPATIONAL FUNCTIONING MODEL	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK ²
Organic Substrate	Client Factors—Body Structures
Structural and physiological foundation for movement, cognition, perception, and emotions. The substrate includes central nervous system organization and the integrity of skeleton, muscles, peripheral nerves, heart, lungs, and skin	Those anatomical parts of the body that correspond to the functions mentioned earlier
Environment and Context	Context and Environment
<p><i>Physical</i>—Including the natural and built environments, objects and utensils, and the requirements that tools and utensils pose for use</p> <p><i>Personal</i>—Including age, gender, activity history, sense of competency, and spirituality</p> <p><i>Cultural</i>—Including norms, values, beliefs, and routines or rituals of the family, ethnic group, community, or religious group</p> <p><i>Social</i>—Including therapeutic interaction and relationships with family members, peers and friends, and community</p> <p><i>Temporal</i>—Including temporal demands of role tasks, activities, and habits; balance of activity types; and balance of activity and rest</p> <p><i>Situational</i>—Including circumstances related to the setting or surroundings at a given moment</p>	<p><i>Context</i></p> <p><i>Cultural</i>—Including ethnicity, beliefs, activity patterns, and behavior standards</p> <p><i>Personal</i>—Including age, gender, socioeconomic status, and educational status</p> <p><i>Temporal</i>—Including stage of life, time of year or day, duration, rhythm of activity, and history</p> <p><i>Virtual</i>—Defined as the communication that occurs via airwaves or computers with an absence of physical contact</p> <p><i>Environment</i></p> <p><i>Physical</i>—Including built and natural nonhuman environments and objects in them</p> <p><i>Social</i>—Including relationships with individuals, groups, organizations, and systems</p>

BADLs, basic activities of daily living; IADLs, instrumental activities of daily living.

Table 1-2. The Process of Occupational Therapy

PROCESS	OCCUPATIONAL FUNCTIONING MODEL	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK ²

PROCESS	OCCUPATIONAL FUNCTIONING MODEL	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK ²
Goal of therapy	Satisfactorily engage in self-identified, important life roles through which the person gains a sense of self-efficacy and self-esteem	Support health and participation in life through engagement in occupation
Evaluate to identify the problem(s)	<ul style="list-style-type: none"> • Identify roles, tasks, and activities the person wants to do or needs to do • Measure perceptions of self-efficacy regarding the tasks of identified goals • Assess occupational balance • Observe and analyze the person's performance, preferably within usual context • Identify inadequate performance • Identify impaired abilities or capacities that contribute to inadequate performance and assess level of impairment using valid, reliable assessment tools administered according to the standardized protocol • Identify environmental or contextual enablers or hindrances • Interpret assessment data to the patient and family and document in the patient's record 	<ul style="list-style-type: none"> • <i>Occupational profile</i>—To understand the client's occupational history, patterns of daily living, occupational balance, interests, values, needs, problems with performance, and priorities • Analysis of occupational performance by observation within personally relevant context to specifically identify client's assets and problems that affect performance skills • Assess environment and context; activity and occupation demands; client factors; performance skills and patterns • Interpret assessment data to identify facilitators and barriers to performance • Develop hypotheses about what strengths and weaknesses the client brings to occupation

PROCESS	OCCUPATIONAL FUNCTIONING MODEL	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK ²
Plan intervention	<ul style="list-style-type: none"> • Plan in collaboration with the person or family, after presenting the current evidence, to determine whether the person wants to engage in either remediation of impaired abilities or capacities to enhance overall performance or restoration of occupational performance through relearning and/or adaptation of method or environment • With the patient, establish short-term goals that directly relate to the long-term goal of successful role functioning identified by the patient and that can be objectively and reliably measured • Select interventions that have evidence for effectiveness for the immediate goal 	<ul style="list-style-type: none"> • With the client, develop a plan with objective, measurable goals and a time frame to guide action • Plan occupational therapy intervention based on theory and evidence • Select outcome measures • Consider discharge needs and plan • Refer to other professionals as needed
Implement the intervention	<p>Use therapeutic mechanisms, as appropriate:</p> <p><i>Occupation</i></p> <ul style="list-style-type: none"> • Occupation-as-end to restore occupational functioning • Occupation-as-means to optimize abilities or capacities <p><i>Therapeutic rapport</i></p> <p><i>Education</i>—Learning or relearning</p> <p><i>Adjunctive therapies</i>—Therapies such as orthoses, technological aids, physical agent modalities, mobility aids used to facilitate performance</p> <p><i>Contextual and environmental modification</i>—To facilitate performance</p>	<p><i>Determine occupational therapy interventions to be used and carry them out, such as</i></p> <ul style="list-style-type: none"> • Therapeutic occupations and activities • Preparatory methods • Education and training • Advocacy • Group interventions <p>Monitor and document client's response</p>

PROCESS	OCCUPATIONAL FUNCTIONING MODEL	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK²
Evaluate the result	Assess patient outcomes <ul style="list-style-type: none"> • Determine whether the short-term goals were achieved • Determine whether achievement of the short-term goals resulted in desired occupational performance • If not, reevaluate and modify the plan relative to achieving targeted outcomes • If yes, determine whether the person was satisfied with his or her achievement • Plan for the next level of therapy or plan for discharge and referral as appropriate 	<i>Intervention review</i> <ul style="list-style-type: none"> • Determine success or progress toward achieving targeted outcomes • Modify the plan as needed • Determine need for continuation, discontinuation, or referral
Types of outcomes	<ul style="list-style-type: none"> • Satisfactory occupational performance to allow expected discharge success • Voiced, or otherwise indicated, sense of self-efficacy and self-esteem • Prevention of further disability through education and follow-up, if necessary 	Occupational performance outcomes congruent with client goals

Table 1-3. The Similarities and Differences between the AOTA Occupational Therapy Practice Framework and the Occupational Functioning Model

	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK²	OCCUPATIONAL FUNCTIONING MODEL
Central focus	Achieving health, well-being, and participation through engagement in occupation	Self-fulfillment through role competence
A conceptual model	No	Yes

	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK²	OCCUPATIONAL FUNCTIONING MODEL
Describes the relationships (dynamic interaction) among the terms and categories in the classification system	No ⁵⁷	Yes
Domain	Incorporates all aspects of occupational therapy practice	Limited to practice for those with physical dysfunction
Hierarchical	No ⁵⁸	Yes; successful performance of higher occupations depends on lower abilities, skills, and capacities
Clients include person, organization, society	Yes	No; limited to practice with individuals
End goal	Support health and participation in life through engagement in occupation	Satisfactorily engage in self-identified, important life roles through which the person gains a sense of self-efficacy and self-esteem
Process	Evaluation, planning, intervention, outcome monitoring	Evaluation, planning, treatment, reevaluation
Evaluation	Occupational profile and analysis of occupational performance, including factors that influence performance	Determination of client goals; assessment of role, task, and activity performance; measurement of skills, abilities, developed capacities, first-level capacities, and determination of organic substrate, as needed. Assessment of environmental and contextual influences on performance
Top-down evaluation process	Yes	Yes

	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK²	OCCUPATIONAL FUNCTIONING MODEL
Process of evaluating, planning, treating, and monitoring outcome is iterative, not sequenced	Yes	Yes
Process is collaborative, that is, client centered	Yes ⁵⁹	Yes
Key skill of occupational therapist	Analysis of occupational performance: observe, analyze, and interpret performance and detect the client, contextual, or environmental factors that enable successful performance or that impede that performance	Activity analysis: observe, analyze, and interpret performance and detect the clinically relevant impairment and/or the contextual-environmental enablers or barriers to performance
Interventions	Therapeutic use of occupation and purposeful activities Preparatory methods Education and training Advocacy Group interventions	Therapeutic rapport Therapeutic use of occupation as occupation-as-means and/or occupation-as-end Learning (education) Therapeutic technologies
Occupational therapy intervention approaches	Create, promote (health promotion) Establish, restore (remediation, restoration) Maintain Modify (compensation, adaptation) Prevent (disability prevention)	Collaborate Remediate skills and abilities by therapeutic use of occupation-as-means Restore activities, tasks, and role performance by relearning or adaptation or environmental or contextual modification
Evidential support	None offered ⁵⁸	Tangential supporting evidence, i.e., incidental evidence of the various assumptions, but not direct evidence for the model

	OCCUPATIONAL THERAPY PRACTICE FRAMEWORK ²	OCCUPATIONAL FUNCTIONING MODEL
Practical usefulness (usable and clinically relevant; use of everyday language)	No ^{57,59}	Yes

AOTA, American Occupational Therapy Association.

The Occupational Functioning Model

The OFM guides assessment and treatment of persons with physical dysfunction, leading to competence in occupational performance and subsequent feelings of self-empowerment. The OFM was derived from clinical practice with persons with physical impairments. The primary belief is that people who are competent in their life roles experience a sense of **self-efficacy**, self-esteem, and life satisfaction. Research indirectly supports the idea that competency is related to satisfaction or a positive quality of life.⁹ Successful performance strengthens personal efficacy beliefs.^{8,10,11} The goal of treatment, according to the OFM, is to enable competent engagement in valued roles whether by restored self-performance (personal agency) or by directing others (proxy agency).¹¹

Another assumption of the OFM is that the **ability** to carry out one's roles, tasks, and activities of life depends on basic abilities and **capacities** (e.g., strength, perception, ability to sequence information). As with other systems, this hierarchical organization assumes that lower level capacities and abilities are related to higher level performance of everyday tasks and activities. This organization has been tangentially supported by research.¹²⁻¹⁵ However, the relationship between impairments and performance is multifactorial.¹³ Only part of the variance associated with performance is accounted for by any one ability or combination of abilities. For example, Rudhe and van Hedel¹⁶ found a moderately strong ($r_s = 0.84$) relationship between scores of the self-care category of the SCIM III (Spinal Cord Independence Measure III)¹⁷ and the scores of manual muscle testing and a moderate relationship

($r_s = 0.81$) between hand capacity tests and self-care scores. This outcome does indicate that sensorimotor control of the upper extremities is related to self-care, but because the variance (r^2) is only approximately 65% to 70% (0.81^2 or 0.84^2), other unidentified variables must account for the remaining approximately 35% variance associated with activities of daily living (ADLs). This makes sense because, in addition to upper extremity function, ADL independence requires such skills as sitting and standing balance, perception of positions of objects in space, ability to sequence steps of a procedure, environmental support, and so forth.

It appears that the relationship between two adjacent levels of performance (e.g., capacities and abilities) is stronger than between two nonadjacent levels (e.g., capacities and roles).^{12,14,18,19} The relationship between levels is strong both at the low end of the model^{14,20} and at the high end.^{12,17} Pendlebury et al. found a strong ($r = 0.90$; $r^2 = 81\%$) relationship between deficits in organic substrate and deficits of motor capacities and abilities.²⁰ In a large sample of persons with spinal cord injury, Dijkers found a moderate relationship ($r = 0.24$ – 0.42) between life satisfaction and roles related to social integration and occupation (work) but not between impairments and life satisfaction ($r = 0.04$ – 0.07).¹² He concluded that “these relationships suggest a causal chain [i.e., one link leading to the next]. . . . The impact of impairment on quality of life is almost entirely through its impact on disability, and the effect of disability is largely through its impact on handicap” (p. 874).¹² This research suggests that the relationship between low-level capacities and abilities and higher level tasks and roles is not direct. That is, having a particular ability, such as strength, does not ensure that a person can accomplish a given **activity** or task.²¹ Likewise, the ability to accomplish a single activity does not account for role performance. Many capacities contribute to the development of one ability, and many abilities are needed to engage successfully in an activity. When one capacity or ability is impaired, occupational dysfunction does not automatically occur. A person may adaptively use other capacities and abilities to allow accomplishment of the activity.²²

Another assumption of the OFM is that satisfactory occupational functioning occurs only within enabling **environments** and **contexts** particular to the individual.²³ True occupational functioning does not occur in a vacuum or in a controlled situation such as the clinic; occupational functioning is the successful interaction of the person with the objects, situations, and surroundings of his or her home, family, and community. Although the contexts of particular actions and occupations used to regain lost abilities and capacities may be controlled at first, therapy is not complete until generalization to the person's particular environment has occurred.²⁴

Achievement of occupational functioning after injury or disease is accomplished through occupation as well as adjunctive therapies described in this textbook. In the OFM, occupation has two natures: **occupation-as-end** and **occupation-as-means**.⁷ Occupation-as-end equates to the higher levels of the OFM, at which the person tries to accomplish a functional goal (an activity or task) by using whatever skills, abilities, habits, and capacities he or she has. Occupation-as-means, on the other hand, is *the therapy* used to bring about changes in impaired capacities and skills. Occupation-as-means is therapeutic because the goal presents challenges to impaired capacities and abilities, and the successful achievement of that goal results in improved organic or behavioral impairments.

The constructs of the OFM are described next.

Sense of Self-Efficacy and Self-Esteem

The goal of occupational therapy is the development of competence in the activities and tasks of one's cherished roles, which promotes a sense of self-efficacy and self-esteem. *Competence* is the effective interaction with the physical and social environments (Fig. 1-1). To be competent means to have the skills that are sufficient or adequate to meet the demands of a situation or task.^{25,26} It does not equate to excellence, normality, or the ability to do everything, and it recognizes that there are degrees of sufficiency and adequacy in people.^{25,27}

Figure 1-1 Competency of self-advancement role of musician.

Competence develops by enabling a person to engage in graduated, goal-directed activity that is accomplishable by that person and that produces a feeling of satisfaction.²⁶ Occupational therapists help people achieve competence through graded engagement in occupation, vicarious engagement in occupation (watching others), virtual engagement in occupation, developmental and instrumental learning with immediate and precise feedback, and therapeutic interaction with the therapist.^{9,28}

When people feel competent, they have a sense of self-efficacy. The most powerful source of personal efficacy expectations is past accomplishments in similar situations. They have perceived their capability to perform a behavior. Self-efficacy is concerned not with the skills one possesses but with the judgments of what one can do with those skills. Perceived self-efficacy is influenced through an ongoing evaluation of success and failure with each task people participate in over the course of their lives.²⁹ Feelings of self-efficacy are likely to lead people to esteem themselves.³⁰

Satisfaction with Life Roles [Occupations]*

Being in control of one's life means being able to engage satisfyingly in one's life roles or to voluntarily reassign a role to another. Role performance is a vital component of productive, independent living and life satisfaction.³¹ Various occupational therapy scholars have proposed taxonomies of roles. The OFM sorts roles into three domains related to aspects of self-definition: self-maintenance, self-advancement, and self-enhancement,^{4,6,7} but recognizes that the assignment of roles to a particular category is not absolute. Some roles may be classified in one domain by one person but in another domain by another person, depending on the motivation or context (Fig. 1-2). For example, volunteering may be classified by one person as a self-advancement role because volunteering promotes skills that will be useful in a worker role. Another person may classify volunteering as self-enhancement because it promotes a sense of satisfaction without expectation of gain. The individuality of motivation underscores the importance of assessing each person from his or her own point of view, letting each define his or her roles and their meaning.³¹ Assessment of individuality is a major aspect of client-centered therapy.

Figure 1-2 For this accomplished artist, painting a picture is a task of one of her self-advancement roles (worker). For another person for whom painting is a hobby, it would be classified as a task of self-enhancement role (hobbyist).

Self-Maintenance Roles [Activities of Daily Living, Instrumental Activities of Daily Living, and Rest and Sleep]

Self-maintenance roles are associated with care of the self, family, pets, and home. Examples of roles in this domain are independent person, grandparent, parent, son, daughter, homemaker (Fig. 1-3), home maintainer (Fig. 1-4), exerciser, cat owner, and caregiver.

Figure 1-3 Self-maintenance role: homemaker; task: meal preparation; activity: making pancakes.

Figure 1-4 Self-maintenance role: home maintainer; task: gardening; activity: flower arrangement.

*The comparable *Occupational Therapy Practice Framework* language is added in brackets to assist the student in using the language interchangeably.

Self-Advancement Roles [Work and Education]

Self-advancement roles are those that draw the person into productive activities that add to the person's skills, possessions, or other betterment. Examples of roles in the self-advancement role domain include worker (Figs. 1-1 and 1-5), student, intern, commuter, shopper, investor, manager, and voter.

Figure 1-5 Self-advancement role: contractor; task: tatami mat construction; activity: stapling.

Self-Enhancement Roles [Play, Leisure, Social Participation]

Self-enhancement roles contribute to the person's sense of accomplishment and enjoyment or sense of well-being and happiness (Figs. 1-2 and 1-6). Examples of roles in this domain include hobbyist, friend, club member, religious participant, vacationer, golfer, moviegoer, and violinist.

Figure 1-6 Self-enhancement role: pet owner; task: exercise dog; activity: walking.

Competency in Tasks of Life Roles [Occupations]

Roles consist of constellations of tasks. For example, the role of homemaker may include the tasks of food preparation (Fig. 1-3) and service, housecleaning, laundry, and decorating (Fig. 1-4). The tasks identified for the same role by different people may be different.^{6,7} The value ascribed to tasks varies among people of similar situations and may vary from what therapists consider important for patients. Because people have different values, each person must define his or her role by identifying the tasks that he or she believes are crucial to satisfactory

engagement in that particular role. The therapist cannot assume that particular tasks are or are not important to a person's interpretation of a role.

Tasks consist of constellations of related activities and are therapeutically developed using occupation-as-end, which is practicing the activities constituting the task in normal temporal order and environmental demand, with or without assistive technology as required.

Activities and Habits [Occupations and Performance Patterns]

Activities, in the OFM, are smaller units of goal-directed behavior that, taken together, comprise tasks. Activities bring together abilities and skills within a functional context. For example, one task of the gardener is pest control. Activities that make up this task may include hanging lures, spreading granular insect killer, mixing and spraying liquids, and picking insects off plants. Furthermore, each of these activities consists of even smaller units of behavior, such as opening the package and pouring granular insect killer into a garden spreader. Some activities, such as picking insects off plants, require full attention. Others, called habits, do not. Habits are chains of action sequences that are so well learned that the person does not have to pay attention to do them under ordinary circumstances and in familiar contexts. Physical dysfunction disrupts habits, requiring attention to be paid to the simplest of ADLs. This adds to the fatigue experienced by many persons.³² Using the OFM, occupational therapists seek to help the person sustain or relearn adaptive habits, let go of habits that are no longer adaptive, and develop new habits given the person's changed abilities and capacities.

Activities and habits are learned using occupation-as-end, that is, "task-specific training." In task-specific training, functional and meaningful activities are practiced over and over using assistive technology, adaptive methods, or adapted environment to enable performance, if necessary. See Chapter 2 for a discussion of the therapeutic use of occupation-as-end.

Abilities and Skills [Performance Skills]

Activities depend on more basic abilities.^{1,33} A person with a great number of highly developed abilities can become proficient at a greater variety of activities. An ability is a general trait, such as muscle strength or memory, that individuals bring with them to a new task.¹ In the OFM, abilities are seen as a combination of endowed talents and acquired skills. A **skill** is the ability to use one's knowledge to effectively and readily execute performance.³ Skill enables goal achievement under a wide variety of conditions with a degree of consistency and economy. Abilities and skills develop from one or more developed capacities. They are more voluntary and organized and evidence smoother execution than do developed capacities. The OFM identifies six categories of abilities and skills: motor, sensory, cognitive, perceptual, socioemotional, and cardiorespiratory.

To accomplish the activity of hanging lures in the previous example of the gardener, the person needs certain abilities, such as coordination, dexterity, and ability to follow directions. The person also needs to be able to translate these endowed talents into the skilled actions required to hang the lures. Carefully analyzed occupation-as-means is used to develop deficient abilities and skills. In the process of repeatedly accomplishing occupations that demand greater levels of the deficient ability or skill in varying contexts, the patient gains greater levels of that ability or skill. By varying the context, the therapist encourages more robust learning. See Chapter 2 for a more complete discussion of the therapeutic use of occupation-as-means.

Developed Capacities [Client Factors]

Developed capacities reflect the organization of first-level capacities into more mature, less reflexive, and more voluntary responses. For example, to support dexterity, an ability, a person needs independent use of fingers, graded release and pinch, which are developed capacities that derive from reflexive grasp and automatic release (first-level capacities). This organization is normally acquired through maturation. In therapy, occupation-as-means is used to develop these capacities. Therapeutic demands for gradually more mature

and varied responses are made through repeated opportunities to engage in selected occupations.

First-Level Capacities [Client Factors—Body Functions]

First-level capacities are the functional foundation for movement, cognition, perception, and emotional life based on the integrity of the organic substrate. In the motor domain, first-level capacities are reflex-based motor responses that reflect the organization of primary visual, sensory, and motor systems. Examples include reflexive grasp, reflexive release, primitive reaching, kicking, and stepping. They are the subroutines that Bruner³⁴ described as underlying the development of all voluntary movement. The ability to recognize a connection between an instrumental, nonreflexive response given consistently within a particular perceptual situation is a first-level capacity of cognition and perception. The fascination of babies with human faces is a first-level capacity of the socioemotional domain.

Organic Substrate [Client Factors—Body Structure]

Organic substrate is the structural and physiological foundation for movement, cognition, perception, and emotions, including the primitive central nervous system (CNS) organization in the neonate; the CNS organization that is spared or recovers spontaneously after injury or illness; and the integrity of the brain, skeleton, muscles, sensory and motor nerves, heart, lungs, and skin. If the organic substrate is not present, therapy cannot generate it. If it exists at all, therapy attempts to develop it into first-level capacities through techniques classified as **augmented maturation** (see Chapter 34).

Environment and Context [Context and Environment]

The words *environment* and *context* are often used interchangeably. In current health care literature, the term *context* is used to encompass all that influences any aspect of human functioning, including physical, social, personal, temporal, and situational influences, as well as familial and

cultural beliefs and practices that influence the life of an individual. Context is the interpretive dimension of the circumstances surrounding occupational engagement. Seemingly similar circumstances may result in different occupational behavior depending on the person's interpretation of the circumstances. It is this interpretive dimension of context that is important to the occupational therapist.

Environment is defined as the complex of external factors, circumstances, objects, structures, and social surround that inhibit or facilitate occupational functioning. Research has shown that familiarity of the environment positively affects daily functioning.^{23,24}

Context in the OTPF refers to cultural, physical, social, personal, temporal, and virtual aspects of living. Similar to the OTPF, the OFM assumes that context and environment surround and permeate all levels of the occupational functioning hierarchy. However, the OFM distinguishes between the greater influence of context and environment at the higher levels of the hierarchy and the lesser influence at the lower levels. At the lower levels, the immediate physical and personal context and environment influence the actions. For example, organization of a reaching movement was shown to differ when actual, natural objects and utensils were used versus when simulated objects were used.^{35,36} Cultural and social contexts pertain less to this level. At the higher levels of activities, tasks, and roles, however, all aspects of context and environment—personal, social, cultural, temporal, situational, and physical—interact with the person's abilities to yield occupational functioning for the particular person.

When the challenges of the environment exceed the capabilities of a person, that person is said to be disabled.³⁷ A person with impaired abilities and capacities, however, may be able to accomplish activities and tasks of his or her roles if the environment is adapted to enable that.²³ Therefore, occupational therapy treatment may focus on changing the environment or context rather than on remediating the person's impaired abilities or capacities.

The Process of Occupational Therapy for Persons with Physical Dysfunction

The process of occupational therapy follows the universal plan for problem solving: identify the problem, determine possible solutions, intervene, and evaluate the result. The occupational therapist, however, focuses only on problems related to the person's occupational life, including **occupational balance**. What a person needs to do, wants to do, and can do are identified. Discrepancy between what the person needs or wants to do and what he or she can do identifies the problem. The occupational therapist then uses various occupational, adaptive, and adjunctive therapies to intervene. Or the occupational therapist may detect dissatisfaction or stress caused by an occupational imbalance and intervene using educational therapies. The processes of the OFM and the OTPF are similar (Table 1-2). A discussion of the OFM process follows.

Assessment [Evaluation]

The hierarchical organization of the OFM indicates that higher level occupational functioning is established on a foundation of abilities and capacities. Assessment *always* follows a top-down approach. That is, the therapist determines what roles and tasks the person was responsible for in life before the accident or disease and what the person is expected to be, and wants to be, responsible for in postrehabilitation life, including the context and environment in which the person typically engaged in these valued roles and tasks.^{6,7} The *AOTA Occupational Profile* guides discussion of clients' occupational history, goals, context, and environment; its use is a requirement of the CPT evaluation codes.² Other examples of assessments the therapist may use to gather more in-depth information are *The Role Checklist*,^{38,39} the *Canadian Occupational Performance Measure (COPM)*,⁴⁰ and the *Client-Oriented Role Evaluation*.⁴¹

The therapist may also measure the patient's sense of self-efficacy concerning the ability to do the tasks required to fulfill particular roles by having the patient assign a number on a visual analog scale that ranges from 0 (not at all confident)

to 10 (absolutely certain) for each major task that defines a specific role. For example, “on a scale from 0 to 10, how confident are you that you can prepare your own lunch without help?” Other assessments of self-efficacy are the *Self-Efficacy for Functional Activities Scale*⁴² and the *Self-Efficacy Gauge* designed especially for occupational therapists to measure the patient’s current level of perceived self-efficacy and the change in perceived self-efficacy over time.²⁵

Occupational balance, a person’s perception of whether his or her life activities are in balance, can be assessed through careful interviewing or the use of an assessment such as the *Life Balance Inventory* that evaluates perceived balance between desired and actual time usage.⁴³

When evaluating a patient’s competence to accomplish the roles identified as important, the therapist observes the patient attempting to do the tasks and activities that the patient identifies as key to those roles in the most familiar context. The *Assessment of Motor and Process Skills* (AMPS),⁴⁴ the *Klein-Bell ADL Scale*,⁴⁵ the *Barthel Index*,^{46,47} and the *Performance Assessment of Self-Care Skills* (PASS)⁴⁸ are examples of standardized observational assessments of tasks and activities. Using an assessment that structures observation of performance and having knowledge of the probabilities established by the diagnosis and age of the person, the therapist detects which of the myriad abilities and capacities assumed to be related to accomplishment of these activities are impaired (the process of **activity analysis** applied to assessment; see Chapter 3 for client-centered activity analysis procedure and example). The therapist then assesses these abilities and capacities more directly using assessments that have been validated and found reliable for the type of patient being evaluated. For example, if the patient’s goal is to shave with an electric razor, but he appears to lack the grasp strength and endurance to do so, strength and endurance are assessed. A person whose abilities and capacities are found deficient may be treated to optimize them, allowing not only shaving but also other occupations.

Some therapists prefer to use a bottom-up evaluation procedure in which capacities, abilities, and skills are assessed

before occupational performance.⁴⁹ This practice, however, often results in emphasizing these lower level factors without translation of the regained abilities to occupational performance. Furthermore, when this approach is used, the patient often fails to see the connection between therapy to optimize skills and abilities and achievement of his or her occupational goals.

The environment in which the patient will live, work, or play is assessed to determine whether it enables or hinders occupational functioning. Assessments of the home environment have been developed (e.g., *Safety Assessment of Function and the Environment for Rehabilitation* [SAFER]⁵⁰ and *Home Occupational-Environmental Assessment*⁵¹), but assessments of other environments have not yet been developed. To assess the effects on occupational performance of other physical and social environments typical for the patient, the occupational therapist needs to observe performance under those conditions, using the process of client-environment fit activity analysis (see Chapter 3). In practice, this assessment usually occurs immediately before or after discharge from an inpatient rehabilitation setting.

Treatment [Intervention]

Treatment may focus on changing the environment,²⁴ changing the impaired skills and abilities of the person,⁵² teaching specific tasks or activities using goal-directed training,⁵³ or teaching compensatory ways to accomplish activities and tasks. Treatment to improve occupational functioning, then, may start toward the bottom of the OFM hierarchy, focusing on optimizing abilities and capacities; or it may start higher, at the activity level of the hierarchy, focusing on restoring competence in doing the activities and tasks of valued roles that the patient has identified as concerns; or it may start peripheral to the person, focusing on modifying the context or environment. The starting point should acknowledge the problem that the patient has identified as an immediate concern, although treatment may not actually start there. For example, if the patient identified resuming fishing as the goal, the therapist may choose to teach adaptive methods to enable that. If, however, the evidence and the experience of the

therapist indicated that it would be more effective to start treatment by regaining finger dexterity to enable various activities related to fishing (e.g., baiting the hook and removing the fish from the line), the therapist *must help the patient understand* how treatment of this lower level ability addresses the stated concern at the task level. In addition, the therapist *must ensure carryover* of any gained dexterity to the fishing task.

Optimizing impaired abilities and capacities is accomplished through remedial therapy in which a change in physiological structure, function, or organization is sought through occupation-as-means. If remediation of deficit abilities or capacities does not restore occupational functioning, if economic constraints prevent such thorough treatment, or if the patient is not committed to the extensive work required to recover abilities and capacities, a degree of competence can be restored using goal-specific training and/or adaptive therapy. **Adaptive therapy** seeks to find and promote a balance among the person's goals and environmental demands and his or her current capacities and abilities. In this type of therapy, the method of doing an activity may be modified, assistive technology may be used to enable completion of the activity, and/or the physical or social environments may be modified. The person may be counseled to reassess the need to accomplish a particularly difficult or time-consuming activity alone and opt to employ another to do it.

Optimizing Abilities and Capacities [Intervention]

As in the typical development of capacities and abilities, therapy engages the patient in circumscribed encounters with the environment using occupation-as-means. Occupation-as-means, that is, activities that provide stretch of soft tissues, active or passive movement to preserve and restore full range of motion, resistance and other stress to strengthen weak muscles, or graduated, increasing levels of aerobic exercise or time of engagement to improve endurance, is used to optimize motor abilities and capacities. Using the example of the man who wanted to shave, the therapist might start treatment by providing a cuff to hold the razor to eliminate the need for

grasp (adaptive therapy) and let the patient shave as much as he could. Then the occupational therapist would finish the activity. Day by day, the patient's endurance for shaving would increase, and he would do more of the task on his own (occupation used as a means of remediation). Concurrently, the therapist would engage the patient in other activities that require increasingly greater grasp strength until the patient was able to hold the razor.

When impairment of the CNS results in the inability to move voluntarily to effect a desired change in the environment, a therapist may use occupation-as-means in conjunction with controlled sensory input and ontogenetic or recovery-based developmental postures or patterns (**augmented maturation**) to facilitate change in first-level and developed capacities of sensorimotor organization. Whereas some therapists have anecdotally reported success using controlled sensory stimulation and developmental movements or postures to develop motor control, there is little to no evidence in the literature to support these approaches. However, because some therapists do find aspects of these approaches clinically helpful, especially when there is a need to optimize first-level capacities, a chapter describing these approaches has been included in this textbook (see Chapter 34), while recognizing that the approaches lack an evidence base.

Alternatively, because of the preponderance of research that documents that neural reorganization occurs secondary to practice of goal-directed movements, the therapist may use motor learning principles in conjunction with occupation-as-end to bring about change in voluntary movement behavior.⁵³ This approach uses functional tasks to improve task performance, heeding the research findings on the effect of context on the organization of movement, which indicates that practicing a skill under simplified, non-context-specific conditions is different from practicing with an actual object in a context-specific situation.^{36,54,55} The therapist arranges practice schedules and provides appropriate feedback to facilitate the learning process.

Restoring Competence [Intervention]

When activity, task, and role levels of the OFM are dysfunctional, treatment may aim at restoring occupational functioning in spite of any residual impairment. Competence in tasks and activities is synthesized through successful engagement with the environment. Occupational therapists are skilled in developing graduated encounters with objects and the surrounding physical and social environments to promote successful performance. They are also experts in teaching methods to compensate by reorganizing activity patterns or adapting techniques, equipment, or the environment. Some therapists use this compensatory approach exclusively; others believe that first optimizing the impaired abilities and capacities requires less compensation and produces more versatility of performance. There is no research to support one point of view over the other.

The goal is independence in activities and tasks of valued roles. People are considered independent when they perform tasks for themselves using assistive equipment, alternative methods, or adapted environments, as required, or when they appropriately oversee completion of activities by others on their own behalf. The therapist teaches the patient or caregiver the principles and concepts of adaptation so that the patient or caregiver can become an independent problem solver. Therapeutic mechanisms of change include occupation-as-end, teaching-learning, therapeutic rapport, and environmental and/or process modification.

Summary

This chapter describes one model, the OFM, to guide the process of occupational therapy for persons with occupational dysfunction secondary to physical impairments and relates that model to the *OTPF*, which is an official document of the AOTA concerning domain and process of the entire practice of occupational therapy. The framework needs an organizational model to guide assessment and intervention. That model can be the OFM, *the Model for Human Occupation* (MOHO),³³ the *Occupational Adaptation Model*,⁵⁶ or any number of other models that complement your way of thinking and analyzing problems and that facilitate your clinical reasoning.

CASE STUDY

Patient Information

- **Diagnosis.** Mr. J has a fracture/dislocation of C6–7 vertebrae secondary to a diving accident. He is status post cervical laminectomy and fusion; medically stable; exhibits C6 functional level (see Chapter 38).
- **Occupational Profile (abbreviated).** Mr. J is a 24-year-old college graduate who lives with his parents in a second-floor apartment. His four older brothers live away. He was employed as a computer programmer and identifies keyboarding as a crucial task of this role. The company is holding his job for him. He has many friends and plays sports. The family is supportive but expects him to be independent in self-care and to resume work.

Assessment Process and Results

- **Observation:** He is unable to move his lower extremities and has poor sitting balance. Dependent in all basic activities of daily living (BADLs) and instrumental activities of daily living (IADLs).
- **Measurement:** Manual muscle testing revealed that Mr. J's proximal upper extremity musculature rated 4 to 5, with the exception of the triceps, which graded 2 (see Chapter 13, which describes muscle strength grading). Wrist extensors graded 3+ on the left and 4– on the right; wrist flexors and finger and thumb muscles graded 0 bilaterally.

Occupational Therapy Problem List

1. Paralyzed lower extremities; unable to walk or relieve ischial pressure
2. Weak upper extremities
3. Unable to grasp
4. Poor sitting balance
5. Dependent in tasks and activities of valued roles (independent person, computer programmer, sports)

Occupational Therapy Goal List

1. Develop beginning independence in basic self-care
2. Develop beginning wheelchair skills
3. Improve upper extremity strength
4. Develop tenodesis grasp
5. Develop habit of relieving pressure on skin to prevent decubiti
6. Explore adapted methods of computer use

Intervention

1. Collaborate with the physical therapist to order wheelchair
2. Engage in occupation-as-end to relearn basic ADL skills, learn to use wheelchair, learn to relieve ischial pressure to prevent decubiti, learn to solve problems by adapting methods or equipment to enable performance of tasks
3. Use occupation-as-means to increase strength of upper extremities
4. Group educational sessions for social, emotional, and practical problem solving with other persons with similar activity limitations

Outcome

1. Able to wheel 50 feet on flat carpeting
2. Proximal upper extremity musculature recovered to normal strength
3. Learned adaptive methods for relieving pressure to maintain skin integrity
4. Wrist extensor strength improved to 4+ bilaterally, which allowed a functional tenodesis grasp. This enabled showering, dressing, and bowel and bladder management.
5. He keyboards using universal cuffs with typing sticks tipped with rubber ends. He learned to adapt his computer to allow one-key depression for all operations and other adaptations.

6. He learned about the local wheelchair basketball team from the group that he plans to join.

Referrals

1. Outpatient occupational therapy to continue improving his strength, improving his IADLs, and have environmental evaluations at home and work executed
2. Occupational therapy driving specialist
3. Social worker to arrange for visiting nurse to supervise bowel and bladder care and ischial pressure relief until these becomes habitual; to arrange for handicapped accessible housing; to hire an in-home helper to help him achieve occupational balance
4. Organizer of the wheelchair basketball team

Chapter 2

Occupation: Philosophy and Concepts

Catherine A. Trombly Latham

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Define occupation.
2. Discuss the importance of occupation in people's lives.
3. Discuss the concept of occupational balance.
4. Discuss occupation as a therapeutic medium.
5. Characterize occupation-as-end and occupation-as-means.
6. Discuss the therapeutic qualities of occupation: purposefulness and meaningfulness.
7. Cite evidence that supports the use of occupation as therapy.
8. Describe how therapeutic occupation is implemented in practice.

CHAPTER OUTLINE

Occupation Defined
Importance of Occupation in People's Lives
Occupation as Therapy
Effectiveness of Therapeutic Occupation
Implementation of Therapeutic Occupation in Practice
Case Study

TERMINOLOGY

Activity analysis: a process by which properties of a given activity are identified for their ability to elicit targeted responses or enable a person to successfully accomplish the activity.

Constraints: limitations imposed on completion of an occupation. Extrinsic constraints include physical and sociocultural contexts, and environments and task demands. Intrinsic constraints include personal factors such as movement abilities, vision, sensation, cognition-perception, and cardiorespiratory capacity.

Habit: a behavior pattern acquired by frequent repetition that shows itself in regularity or increased facility of performance.¹

Occupation-as-end: the combined set of activities that, together, support desired occupational roles and purposeful end goals identified as meaningful to the individual.

Occupation-as-means: the array of activities that support the completion of tasks needed in daily life, but, by themselves, may not hold significant meaning to the individual.

Task demands: the specific features of an activity that influence the type and amount of effort required to perform the activity. Demands include the shape, size, texture, number of objects; the visual, auditory, physical, or emotional impact of surroundings; the meaning of ritual associated with the activity; the size, shape, weight, configuration of tools; and the colors, textures, weight, familiarity, etc., of materials. Also known as *activity demands*.

Velocity profile: a graph of time versus speed of movement from which the organization of movement can be determined.

Occupation Defined

Occupation is both the center of human experience and the core of our profession.² Occupation is the unique therapeutic medium of occupational therapy³ as well as outcome.⁴ Occupation is “everything people do to occupy themselves, including looking after themselves, enjoying life, and contributing to the social and economic fabric of their communities.”

Although the terms *occupation* and *purposeful activity* have been used interchangeably, they are distinct in meaning. The key difference is that occupations are central to a person’s identity and influence how one spends time and makes decisions, whereas purposeful activity is a class of human actions that are goal directed and allow a person to develop skills that enhance occupational engagement but do not assume a place of central importance or meaning to a person’s life. Each occupation is composed of several purposeful activities.⁵ Purposeful activity is circumscribed, demands specific responses within particular contexts, and is used therapeutically to facilitate change in impairments and functional limitations. In this text, **occupation-as-end** is equated to occupation, and **occupation-as-means** is equated to purposeful activity.

Importance of Occupation in People’s Lives

Occupational engagement contributes to the experience of a life worth living.^{6,7} Engagement in positive occupations (e.g., care of self, others, property, and creative or productive endeavors), for which a person has both the capability and desire, regulates the rhythm of personal and community life. Such occupations absorb attention and evoke creativity, promote feelings of satisfaction with achievement, and contribute to a sense of self-esteem and self-efficacy (Fig. 2-1). These occupations are potentially therapeutic. In the absence of social and productive occupation (as occurs, e.g., early in retirement, in the acute stage of motor disability, or immediately after a profound loss⁸), a person may experience a sense of disorganization, depression, and lost sense of self-worth.

Figure 2-1 Occupation-as-end. Baking again under new circumstances after stroke.

Not all occupation is beneficial. Attempts to engage in occupations beyond one’s capabilities can lead to frustration, anxiety, and depression.⁹ Engagement in negative occupation (e.g., crime and destruction) disrupts personal and community life. Doing the same activity repetitively beyond the requirements of the task, as seen in obsessive-compulsive disorder (OCD), reinforces pathology. Imposition of unsuitable, negatively meaningful activities (e.g., children’s games used as therapy for elderly patients) fails to build a sense of self-esteem and satisfaction. These types of occupation are not therapeutic. Therapeutic occupation, a special type of occupation, is defined as the use of

positive, relevant, meaningful, and purposive activities to improve a person's ability to participate in life, or to improve abilities and capacities to enable improved occupational functioning.

Occupational Balance

Occupational therapy subscribes to the belief that the balance of engagement in life occupations, including rest, is basic to health and wellness.^{10,11} The ideal configuration of this balance is individually defined, consisting of occupations that are meaningful to a particular person and that promote wellness.^{12,13} As part of the occupational profile interview, therapists can ascertain whether patients feel that they are in occupational balance and on what basis each person defines that balance.

Balance may be defined on the basis of challenging versus relaxing occupations, activities meaningful to the individual versus those meaningful to society, or activities intended to care for oneself versus those intended to care for others.¹² Other gradients on which balance is established include allotment of time among physical, mental, social, and rest occupations, or mixing physically taxing occupations with light, relaxing occupations (also called pacing).

If balance is skewed toward one end of the gradient, then occupational dysfunction can occur. For example, if too much time is spent in self-enhancement activities (e.g., video gaming) to the detriment of other roles, then the person's work, social life, and/or self-care suffers, and he or she is occupationally "out of balance." If the person engages in mentally challenging occupations without balance with rest or lesser challenging occupations, then the person becomes stressed ("burned out"), unhealthy, and ineffective in other life areas. If the person engages in physically stressful occupations or movements without rest, damage occurs to involved body structures (e.g., cumulative trauma).¹⁴

Occupation as Therapy

Occupational therapists work with people who have experienced, or are in danger of experiencing, significant occupational dysfunction secondary to changes in their physical, cognitive, emotional, or social well-being, or to their environments. It is the role of the occupational therapist to help patients grieve losses and reconstruct acceptable occupational identities.¹⁵

Occupation is used to create or promote health, to remediate impairments or restore an ability or skill, to modify or adapt performance, to maintain performance capabilities, or to prevent disability.⁵ The appropriate occupation results in the participant's sense of mastery.¹⁶ Occupational intervention becomes therapeutic when it is guided by theory. In this text, the theoretical guideline is the Occupational Functioning Model (Chapter 1), but therapists may choose to use other guidelines or frames of reference.

What about occupation that maintains or restores health? That question is still debated, but one suggestion is that occupation is therapeutic when it has meaning for the patient, when it makes demands on the system needing improvement, and when it fulfills a purpose in the person's life.¹⁷ The notion that purpose is necessary for a therapeutic effect has persisted throughout the history of therapeutic occupation, whereas the idea that occupation should be meaningful was temporarily lost after World War II, during the biomechanical era of occupational therapy. At that time, occupational therapists, in an attempt to mirror the medical model, promoted exercise using the motions of an activity—thereby "preserving" meaningfulness—without true meaning (e.g., "weaving" on a floor loom for exercise without thread on the loom).¹⁶ Another aspect of therapeutic occupation is the just right challenge, the optimal fit between demands of the occupation and the skills of the person.^{2,9} An occupation is therapeutic when it requires effort for the patient but is possible to accomplish. By accomplishing the occupation, the patient

improves the impaired ability or capacity being challenged. By succeeding in the challenge, the patient is motivated to continue or repeat the experience.⁹ A successful therapeutic occupation results in feelings of self-efficacy, self-esteem, and self-satisfaction, as well as improved occupational functioning.

Occupational therapists help people achieve satisfying occupational competence in several ways. One way is to adapt methods of accomplishing activities; another is to adapt the environment or tools and teach the person how to use these contextual adaptations.¹⁸ In this case, occupation is both the treatment and the end goal (occupation-as-end). Occupation-as-end may remediate impairments, but this benefit is serendipitous, and the occupation is not chosen for that purpose. A second way is to remediate impaired capacities and abilities that prevent successful performance of activities and tasks required of a patient's roles.¹⁸ In this case, occupation is the means to remediate impairment (occupation-as-means) (Fig. 2-2). The occupation used may actually be the same, for instance, chopping apples to make a pie. If the goal is to relearn how to make an apple pie, then it is considered occupation-as-end. If the goal is to improve grasp strength to enable multiple other life occupations, then chopping apples is considered occupation-as-means.

Figure 2-2 Occupation-as-means. Folding towels to improve sitting balance after stroke.

The key skill of the occupational therapist is the ability to analyze activities in terms of the required skills, abilities, and capacities; what influence the social and physical environments have on the likelihood of successful occupational performance; and what abilities and capacities the person brings to the therapeutic encounter. Analysis allows selection, gradation, and adaptation of activities to promote a therapeutic outcome (as described in Chapter 3).¹⁹

Occupation-as-End

Occupation-as-end is the complex of activities and tasks that comprise roles (Fig. 2-3). It is a person's functional goal that he or she tries to accomplish in a given environment using the abilities and capacities he or she has, and any adaptations that may be necessary. The occupational therapist uses a person-environment-occupation focused analysis to evaluate and plan therapy. Successful intervention involves a match among the client's goals and abilities, the task itself, the client's perception of the task's challenges, the client's sense of self-efficacy regarding the task,²⁰ and the environment in which the task is to be carried out.

Figure 2-3 Occupation-as-end. Relearning to make bed after stroke.

Purposeful occupation-as-end organizes a person's behavior, day, and life. Occupation-as-end is purposeful by virtue of its focus on accomplishing valued activity goals. Occupation-as-end is not only purposeful but also meaningful because it is the performance of activities that a person perceives as important. Meaning is individual, and although the occupational therapist can speculate about what may be meaningful to the patient based on the person's life history, the therapist must verify with each patient that the particular occupation *is* meaningful to that person *now* and verify that the person perceives value in relearning it. What a person finds meaningful may not only relate to his or her occupational history but also be a function of the person's stage in the recovery trajectory. That is, even if someone has an occupational history of enjoying cooking, she may not be ready emotionally to assume cooking tasks after a devastating injury because engaging in that occupation would force her to confront her loss and therefore would not be positively meaningful to her. Using a client-centered approach, occupational therapists encourage patients to choose the occupational goals of most importance at the present time. Therapists cannot substitute their own estimation of occupational goals for patients. However, patients may need help to develop more general goals into SMART goals, that is, ones that are specific, *measureable*, *attainable*, *realistic*, and *time specified*.²¹ From such goals, both patients and therapists can estimate progress.

Meaningfulness is not only a psychological term but also a mechanism of change. It affects neurological functioning, as was seen in a positron emission tomography (PET) study by Decety et al.²² who discovered that brain activation differed with the meaning of an action regardless of subjects' strategies. Newman-Norlund et al.²³ also discovered, using functional magnetic resonance imaging (fMRI), that certain neurons in the brain distinguish between meaningful and meaningless actions.

Habits and Routines as Components of Occupation-as-End

Most self-maintenance and many self-advancement and self-enhancement roles depend on habits and routines. **Habits** are behavior patterns performed automatically. Routines are performance patterns that give life order.^{5,24} Both habits and routines are carried out without conscious thought until they are disrupted by change in the environment or to a person's capabilities, at which time they fail to accomplish a specified goal requiring the person to pay attention and modify actions. Injury, disease, environmental change, and significant life changes disrupt useful routines and habits that may cause occupational dysfunction.

Habits may be preserved after brain injury. If a patient with brain injury is placed in a familiar context that provides the cues needed to perform habitual actions, he or she may be able to engage in formerly important, albeit automatic, occupations, even when he or she may not be able to learn new methods. Therapists would be interested in determining whether such habits were preserved in patients with brain injury by setting the context to trigger habitual responses.

When habits or routines are disturbed, for example, as occurs when moving to a nursing home or after a sudden trauma, life suddenly becomes chaotic and confusing, unlike the orderliness of familiar routines that contributed to an efficient and goal-directed life prior to the change.²⁴ The therapist will acknowledge this loss with the patient and prepare to develop new habits and routines, given the new circumstances. Habits and routines are learned through repetition of an action under particular cue conditions that result in a reward (successful completion of an activity). In the beginning, the person must focus on the action, but with repetition and consistency of context, little to no attention is necessary.

In a study of Swedish adults who experienced stroke, Wallenbert and Jonsson²⁵ learned that although patients were frustrated in their daily occupations because of impairments, they resisted developing new habits because they feared that doing so would diminish possible gains they could make by struggling to regain lost skills. They perceived development of new habits as detrimental. Resistance to change should be explored with patients to better understand the benefits of learning new habits.

Some habits or routines are not health promoting and need to be changed, for example, sitting for prolonged periods without relieving pressure on compromised skin regions. In this case, therapists should attempt to interrupt the habitual aspect of the action by (1) changing the cues (environment/context) and/or (2) changing the reward, that is, ensuring that the habitual action does not accomplish the goal the person expected. For example, a switch could be installed beneath a wheelchair cushion that would turn a computer or TV off if skin pressure was not relieved after an allotted time period.

Occupation-as-Means

Occupation-as-means is the use of occupation as a treatment to improve a person's impaired capacities and abilities to enable eventual occupational functioning. Occupation-as-means refers to occupation acting as the therapeutic change agent. An occupational therapist uses a client-focused **activity analysis** (see Chapter 3) when prescribing therapeutic occupation. It is important to remember that although the linkage between occupation-as-means and the remedial goal is obvious to the therapist, it is likely not to the patient. Therefore, when using occupation-as-means, the therapist must *repeatedly* and clearly explain why a given activity is recommended or used in therapy. Various arts, crafts, games, sports, exercise routines (Figs. 2-4 and 2-5), and daily activities that are systematically selected and tailored to each individual are used as occupation-as-means.

Figure 2-4 Occupation-as-end. Relearning to vacuum after stroke.

Figure 2-5 Occupation-as-means. Playing cards using an adapted card tray to improve coordination.

Occupation-as-means is therapeutic when the activity has a purpose or goal that challenges the patient's capacities and abilities needing improvement, yet has a prospect for success ("just right challenge") and engages the person *repeatedly* in the action.²⁶ Because the central nervous system (CNS) is organized to accomplish goals,²⁷ the goal or purpose seems to organize the most efficient response, given the **constraints** of person

and context.²⁸ Furthermore, if an activity has meaning and relevance to the individual requiring change, it is more likely to motivate the patient's will to learn and improve.

Meaningfulness in the sense of occupation-as-means has an immediate aspect. Choosing to participate in an activity at the moment is based on immediate motivation that is guided by currently perceived needs, feelings, and desires that may or may not be related to life goals. The meaningful aspect of occupation-as-means may be the emotional value that an interesting and creative experience offers the patient.²⁹ Meaningfulness may also stem from familiarity with the occupation, its power to arouse positive associations, the likelihood that completion of it will elicit approval from others who are respected and admired, its value in learning a prized skill, or its potential to contribute to recovery. Thus, the therapeutic aspects of occupation used as a means to change impairments are purposefulness and meaningfulness.

Evidence that Occupation-as-Means Organizes Responses

Evidence of changes in organization of emotions, cognition, and perceptions secondary to engagement in occupation or activity having the therapeutic quality of purposefulness is not easily obtained. However, evidence concerning the organization of movement can be easily gained using kinematic instruments to track the spatial-temporal aspects of movement. Movement organization can be detected from the shape of the **velocity profile** (Fig. 2-6),³⁰ which is a graph of time versus speed of movement. Different velocity profiles, which indicate differences in movement organization and CNS control, emerge for particular goals or purposes.³¹ Examples of evidence that goal-directed or purposeful occupation-as-means organizes movement responses are reported here and in the Evidence table.

Figure 2-6 Velocity profiles of two reaches showing different movement organizations. The profile on the left is symmetrical and bell-shaped, which is commonly seen in preplanned, or programmed, reach. This organization may be seen in reaching to a stationary large target, to a familiar object, or to accomplish an automatic goal such as throwing the object. The peak of the velocity profile, which is the end of the acceleration phase of the reach, occurs roughly mid-reach. The profile on the right is left-shifted, which is commonly seen in guided reach to a small or imaginary target or to accomplish a precise goal such as putting a coin in a slot. The peak velocity occurs early in the reach and the deceleration phase is extended as the person guides the hand to the target.

In 1987, Marteniuk et al.³² demonstrated for the first time the effect of goal on the organization of movement as detected from velocity profiles. They found that five university students organized movement differently when they reached for the same object for different purposes. One goal was to pick up a 4-cm disk and *place it* into a slot. The other goal was to pick up the disk and *throw it* into a basket. They measured the reach *to* the disk, not the placing or throwing motion. The distance and biomechanical demands were exactly the same under both conditions. Only the intent after reach was different. The two goals produced different velocity profiles for reaching for the disk, indicating different movement organizations.

Goal or purpose is generated from the patient's own intention, from the therapist's directions,^{33,34} or from the context, including which objects are available, the relevance of the objects, and what the objects afford the person in terms of action. We are familiar with generation of goals by the person or by the therapist, but contextual indication of

goals may be unfamiliar. High object affordance (e.g., presence of real functional objects as opposed to imagined, absent, or substitute objects) promotes optimal motor performance according to a systematic review of 35 studies by Héту and Mercier³⁵; this finding implies that the goal, as defined by the object, organizes movement. Filippi et al.³⁶ mapped gray matter volume changes associated with motor learning of goal-directed motor sequences and nonpurposeful motor actions in 31 healthy subjects. The researchers concluded that motor learning results in structural brain changes, with specific areas affected depending on whether learning involves a goal. In terms of motor responses, then, purposiveness, as transmitted by instruction or context, appears to organize behavior and may affect brain structure and function. Further study is required to verify these ideas and confirm them to be true for other performance skills.

Evidence that Occupation-as-Means Motivates Participation

Although the meaningfulness of occupation to a person must be determined by interview and discussion with that person, for research purposes, *meaningfulness* has been operationalized in four ways: to (1) provide enjoyment^{37,38}; (2) offer choice³⁹; (3) offer an end product that can be kept⁴⁰; and (4) enhance or make the context more applicable to the person's life.⁴¹ The response, *motivation*, is operationally defined as the number of repetitions or length of time engaged in the occupation or the amount of effort expended.^{42,43} Examination of the studies cited here as well as others leads to the conclusion that meaningfulness appears to motivate continued performance, although further research is needed.

Effectiveness of Therapeutic Occupation

Based on personal experience and observation, occupational therapists have historically believed, before evidence was established, that occupation maintained or restored mental health and gave meaning and quality to one's life through its organizational and attention-demanding aspects.^{3,16} Later, on the basis of deductive reasoning and anecdotal accounts, that belief was extended to include restoration of physical function through the biomechanical aspects of engagement in occupation. Occupational therapy began as a philosophically based profession and is now becoming a scientific, evidence-based profession.^{16,44} The research efforts of occupational therapists and other scientists have begun to establish a solid basis for the health-regaining action of occupation. For example, advances in technology have enabled examination of brain function of humans engaged in occupations. Such research has resulted in remarkable advances in knowledge demonstrating that the cortex is functionally and structurally plastic throughout life and that engaging—or not engaging—in occupation modifies the brain's topography and physiology.⁴⁵ There is, however, an urgent need to experimentally verify the effects of occupation to cause particular changes⁴⁶ and to determine the key therapeutic mechanisms underlying *how* occupational interventions cause therapeutic change.⁴⁷

Evidence that Occupation Restores a Sense of Self-Efficacy or Self-Esteem

Very few studies address the association between self-efficacy and self-esteem. A qualitative study by Rebeiro and Cook⁴⁸ provides some evidence that engagement in occupation restores one's sense of efficacy and self-worth. The participants were eight long-time members of an outpatient women's group at a mental health facility who engaged in a cooperative occupational project—making a quilt. On interview after 25 weeks of participation, the participants reported that engagement in the occupation gave them a sense of self-confidence and competency because of their accomplishment, which they did not have before the introduction of occupation to the group. Another is a pretest–posttest, three-group design by Landa-Gonzalez and Molnar⁴⁹ who evaluated the effectiveness of occupation-based intervention (10–15 minutes of preparatory activities followed by 30 minutes of occupation-based activities 2 times/week for 4 weeks) versus enabling/preparatory intervention (30 minutes of preparatory activities followed by 10–

15 minutes of occupation-based activities for the same frequency and duration) versus no treatment (social visiting at same frequency and duration) on improving self-care skills, perceived performance, satisfaction, role function, and self-esteem/self-efficacy of 29 community-dwelling elders with osteoarthritis who were randomly assigned to the group. Both intervention groups scored significantly ($p = 0.012$) higher than the control group on measures of self-esteem/self-efficacy; however, there was no significant difference between intervention groups on these measures. Contamination of the independent variable (both groups received occupation-based activities in different amounts) may have influenced this outcome. Therefore, further research is needed to confirm that occupation restores a sense of self-efficacy or self-esteem.

Evidence that Occupation-as-End Restores Self-Maintenance, Self-Enhancement, and Self-Advancement Roles

Orellano et al.⁴⁶ reviewed 38 studies, of which 82% offered Level I evidence, to determine the effectiveness of occupation- and activity-based interventions on performance of instrumental activities of daily living (IADLs) basic to role engagement by community-dwelling elders. They concluded that the evidence was moderate to strong in support of these interventions. Another systematic analysis of 15 studies⁵⁰ determined that there was a 16% greater success rate for improved IADL and a 30% greater success rate for improved basic activities of daily living (BADLs; self-care) as a result of home-based, task-specific, occupation-based training than occurred due to control conditions. Wolf et al.⁵¹ reviewed 39 studies published between 2003 and 2012, of which 21 addressed activities of daily living (ADLs) performance of stroke patients. They found strong evidence to support the use of occupation-based interventions to improve BADL performance. However, they also found that too few studies addressed IADLs, leisure, or social participation to draw conclusions regarding these domains. Trombly et al.⁵² studied the achievement of valued IADL goals in persons with mild to moderate brain injury and found that goal-directed, occupation-based therapy resulted in achievement of 81% of all goals named by participants. A thorough systematic review and meta-analysis, with 14,593 possible studies narrowed down to 9 well-controlled randomized trials that met inclusion criteria, concluded that patients who received occupational therapy that focused on improving ADLs after stroke were significantly ($p = 0.01$) more independent in personal ADL as compared to control.⁵³ But not all patients benefited and the authors stated the need to define who are most likely to benefit.

Evidence that Occupation-as-Means Remediate Impairments

Studies of the effects of occupation-as-means on persons with particular physical impairments are few and scattered. One systematic review of 29 studies on the effects of occupational therapy on psychosocial, cognitive-perceptual, and sensorimotor impairments poststroke concluded that engaging in homemaking tasks resulted in greater improvement in cognitive ability than paper-and-pencil drills and that practice of movement to achieve a specific action goal had small to moderate positive effects ($r = 0.27$) compared with control conditions.⁵⁴ Another review of 149 studies conducted to determine the effectiveness of interventions to improve occupational performance in people with motor impairments after stroke found that there are a variety of effective occupation-as-means-type interventions. The commonalities among the effective ones were goal-directed (purposeful), individualized (meaningful) activities that promoted *high repetition* of task-specific movements.²⁶ Clearly, much more research is needed.

Implementation of Therapeutic Occupation in Practice

Occupation-as-end is implemented by teaching the activity or task directly, using whatever abilities the patient has and/or by providing whatever adaptations are necessary to enable performance. Because occupation occurs within a person-task-environment interaction, change in any one of these variables may result in successful performance.

Implementation of occupation-as-end focuses on changing the **task demands** and/or the environment, whereas occupation-as-means focuses on changing the person. Therapeutic principles for application of occupation-as-end derive from cognitive information processing and learning theories. Such therapeutic principles are referred to as the rehabilitative approach. In this approach, occupations are analyzed to ensure that they are within the capabilities of the patient, but are not used to bring about change in these capabilities per se. The patient learns the skill with the help of the therapist as teacher and adaptor of task demands and context. In the therapeutic encounter, the therapist:

- determines the patient's occupational goals
- analyzes the task and environment to determine whether the task is within the person's capabilities in that environment
- organizes or modifies the environment or task demands to facilitate success
- organizes the subtasks to be learned so the person will succeed
- provides clear instructions
- provides feedback to promote successful outcome
- structures the practice to ensure continued improvement

To implement occupation-as-means, occupations of interest are analyzed to determine that they demand particular responses from the person and that the responses demanded are slightly more challenging than what the person can easily produce. The therapist provides the opportunity to engage in the potentially therapeutic occupation repeatedly, and as the person makes the effort and succeeds, the particular impairment—which the occupation-as-means was chosen to remediate—is reduced. In the therapeutic encounter, the therapist:

- ascertains the patient's interests
- selects occupations that reflect those interests
- analyzes the occupations to determine which would provide the correct challenge to impaired abilities
- lets the patient choose from among several offered occupations
- explains to the person how engaging in this activity should improve his or her ability and how that relates to achieving the person's overall goal
- instructs the patient in the correct procedure for doing the activity to derive the most therapeutic benefit
- grades the occupation to increase the challenge as the patient improves

Lyons et al.⁵⁵ described ways they organized one clinic to efficiently use occupation therapeutically. The treatment areas in the clinic were rearranged to resemble a homelike environment (e.g., bedroom, living room, and nursery). The therapists prepared "occupation kits," which were large plastic boxes containing all the props necessary to engage in an occupation. Occupation kits were made for gardening, letter writing, pet care, fishing, scrapbooking, and car care, which were the most commonly named activities by their clients. Furthermore, therapists in this clinic were encouraged to work with patients in the various areas of the hospital campus and surrounding environment, the larger community, and the client's own community (e.g., barbershop, market, or place of worship) to provide meaningful occupation-based interventions in natural contexts.

The processes involved in using occupation therapeutically are activity analysis, selection and gradation, and adaptation. Guidelines for these processes are presented in Chapter 3.

CASE STUDY

Patient Information

Chesa is a 65-year-old, right-handed woman who sustained a left cerebral vascular accident (LCVA) resulting in hemiparesis of her dominant side. She is depressed because she fears the loss of important roles and occupations. She was originally from the Philippines, where she worked as a schoolteacher. Now she is retired, living in the United States with one of her daughters.

Assessment Process and Results

Using the *Occupational Profile*, a description of a typical day in chronological sequence revealed that her routine consisted of cooking breakfast for her granddaughters, participating in housework, playing with her grandchildren, going to church in the evening, and sending text messages to her friends in the Philippines.

Evaluation of impairments included assessments of muscle tone and strength, voluntary control of movement, sensation of the affected upper extremity (UE), and standing balance. The speech pathologist reported recovering motor aphasia. The results were (1) decreased motor control and strength but development of volitional movement in her right arm, (2) impaired sensation, (3) slight spasticity in the right side of her body, (4) ability to stand for short periods of time, and (5) impaired but improving expressive language.

Occupational Therapy Problem List

- Inability to carry out BADLs independently
- Inability to prepare light meals
- Inability to participate in home management tasks such as laundry and vacuuming
- Loss of habitual computer skills
- Impaired proprioceptive sensation of the affected UE
- Weakness in affected UE
- Impaired motor control of the affected UE
- Impaired standing balance
- Depression

Occupational Therapy Goal List

Goal setting was accomplished using the COPM (Canadian Occupational Performance Measure⁵⁶). Chesa's goals included the following most valued occupations:

- care for own BADLs
- prepare light meals
- engage in play with grandchildren
- send e-mails to friends
- participate in church

Intervention

Therapy included occupation-as-end and occupation-as-means. Occupation-as-means to improve strength and motor control involved incorporating Chesa's right arm into activity completion. While standing, she used the light meal preparation occupation kit to practice handling implements and packaging, which promoted motor skills and standing balance as well as prepared her for light meal preparation. Occupation-as-end involved daily morning practice of dressing and grooming skills using familiar clothing and utensils in her room. Other intervention sessions were held in the kitchen to learn safe and adapted methods of making sandwiches, soup, and cookies, and in a simulated living room where her daughter and two children visited. At first, the granddaughters did not know how to play with Chesa as they had before. But Chesa used her teaching skills to explain her new participation level and started a therapist-suggested game to play with her grandchildren. Occupation-based treatment involved

developing Chesa’s new view of herself as someone who could now continue to participate in her roles, which lightened her depression.

Outcome

At discharge from inpatient rehabilitation, Chesa’s status was as follows:

- Affected UE strength and motor control recovered enough to permit independence in BADL, light kitchen work, use of the computer, and handling of prayer books.
- Standing balance recovered to allow working in her kitchen, walking into the church, and participation in the women’s group.
- Confidence in her abilities allowed her to adopt a creative approach to playing with her grandchildren.

Examples of Evidence Regarding Effectiveness of Therapeutic Occupation

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Occupation-as-end: Goal-specific training to achieve valued occupational goals ⁵⁷	Valued ADLs goals were worked toward via a series of written contracts that specified interim and short-term goals. Carried out in homes, day centers, and workplace. Control: Booklet that listed resources with those particular to what the participant highlighted	110 (75.5% male) community-dwelling persons with moderate to severe TBI aged 16–65 years, in acute to chronic stages of recovery. Randomized to group. 94 (85%) available at 2-year follow-up, but only 75 (68%) available for analysis of BICRO-39 ^a	2–6 hours/week for a mean of 27 weeks for experimental group; one visit for control group. The independent variable was compromised because some of the patients in the control group received up to 1 month of experimental treatment before randomization.	Randomized controlled trial. Level I	Practice of valued goal activities in a community setting yielded benefits to persons with severe TBI that outlived the active treatment period by at least 18 months.	35% of experimental group vs. 20% of control group improved significantly ($p < 0.05$) from baseline to follow-up on the Barthel Index. The experimental group scored significantly ($p < 0.05$) better at posttest than the control on the total BICRO-39 score and self-organization and psychological well-being subscales. Effect sizes could not be calculated from data provided.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Occupation-as-end: Group-based and individual task-specific dressing retraining ⁵⁸	Group-based retraining for outer garment dressing supervised by two occupational therapists and individual training for underclothing and particular dressing problems. Multiple repetitions were encouraged.	Consecutive cohort of 119 patients; ~2 weeks poststroke, medically stable	Group: 1 hour twice weekly Mean = 4.0, 1-hour group sessions. No record of number of individual treatments	Pretest–posttest design; retrospective analysis of data. Level III	Yes. Task-specific practice of dressing made a clinically important difference to dressing performance.	Three subgroups: upper body dressing, lower body dressing, and both upper and lower body dressing. All groups improved significantly ($p = 0.0001$) on the questions relating to dressing on the FIM. The effect size was estimated to be small ($r = 0.34$).
Occupation-as-means: Hand Dance Pro gaming system to reduce UE impairment and improve function ⁵⁹	High repetitions ($M = 1,118$ per session) of unilateral and bilateral reaching to targets coordinated to music and visual prompts with immediate feedback. The target buttons aligned with affected shoulder and placed to encourage maximum elbow extension. Trunk restrained to prevent substitution.	Nine persons poststroke, categorized by FMA UE subtest to mild ($>50/66$; $n = 3$), moderate ($26–50/66$; $n = 5$), or severe ($<26/66$; $n = 1$). All able to actively raise the involved arm from side (0°) to 45° in any plane ^b	Fifteen 2-minute songs per session with at least 1-minute rest between songs; 18 sessions over 6 weeks	Single-group cohort pretest–posttest design. Level III	The gaming intervention improved UE movement kinematics, but not clinical measures in this group. The subjects enjoyed playing the game and were motivated to improve scores. Carryover of kinematic improvements to functional tasks may require concurrent practice of those tasks.	Significant ($p < 0.05$) improvements and medium to large effect sizes in kinematic measures of movement duration ($d = 0.67$), ^c velocity ($d = 0.97$), and elbow excursion ($d = 0.45$). Some subjects improved in performance time, grip strength, and hand function, but not scores of Wolf Motor Function Test ($d = 0.04–0.17$) or Stroke Impact Scale ($d = 0.08–0.34$).

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Occupation-as-means: Activities in a modified C-IMT ⁶⁰	Practice of purposeful activities at high repetitions in clinic and at home while wearing a mitt constraint on unaffected hand. Resisted exercise, stretching, and weight bearing were used in preparation.	52-year-old female violinist 4 years after ischemic stroke affecting right side of body with returning voluntary movement of right UE	3 hours/day, 5 days/week, for 4 weeks plus 5–6 hours/day outside of therapy for 4 weeks	Case report. Level V	She improved in gross and fine motor coordination, UE strength, and spontaneous use of the UE. Able to play her violin to her satisfaction and rejoin the community symphony orchestra, as was her goal.	NA

^a BICRO-39 is the Brain Injury Community Rehabilitation Outcome-39, a self-report that measures level of activity, participation, and psychological aspects of functioning in the community.

^b Some voluntary movement at the outset is a prerequisite for regaining voluntary control through therapy.

^c *d*, Cohen's *d* effect size; small, 0.20, medium, 0.50, and large, 0.80.

ADLs, activities of daily living; C-IMT, constraint-induced movement therapy; FIM, functional independence measure; FMA, Fugl-Meyer assessment; TBI, traumatic brain injury; UE, upper extremity.

Chapter 3

Occupational Selection, Analysis, Gradation, and Adaptation

Julie L. Grabanski and Scilinda L. Janssen

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Select occupations based on patient self-reported meaning, desired participation, and ability to promote client-centered therapeutic outcomes.
2. Analyze occupations by examining how the activity, patient abilities and limitations, and environmental characteristics affect occupational participation.
3. Analyze occupations to determine whether they are within patient capabilities and identify specific impediments to participation.
4. Grade occupations to challenge the patient's abilities and improve occupational performance.
5. Adapt occupations to enhance the patient's participation in desired roles.

CHAPTER OUTLINE

Introduction
Activity Selection
Activity Analysis
Gradation
Adaptation
Case Study

TERMINOLOGY

Activity analysis: a systematic process through which occupations are analyzed to understand their component parts, their meaning to patients, and their therapeutic potential.¹

Activity demands (also called task demands): the specific physical, cognitive, and psychosocial skills required to carry out and complete desired occupations.

Learning: a change in behavior (including knowledge, attitudes, and skills) that can be observed or measured, and that occurs as a result of exposure to internal and external environmental stimuli.²

Occupation-as-end: the activities that collectively support the roles of a given individual.^{3,4}

Occupation-as-means: the client-centered activities that therapists select to remediate specific skill deficits and impairments.^{3,4}

Task analysis: a similar process to activity analysis that is primarily used in relation to work assessment (ergonomics) and refers to an analysis of the dynamic relationship among a patient, an occupation, and the environment.⁵

Therapeutic grading: the modification of activity demands to reduce or increase the activity's challenge level.

Introduction

Participation in desired occupations is central to an individual's identity, self-efficacy, and life meaning.⁶ As described in Chapter 2, occupation is the therapeutic medium of occupational therapy and should be used to facilitate patient health and life participation.⁶ Therapists must select appropriate occupations that will help to remediate specific patient skill deficits (occupation-as-means) and facilitate the performance of patient-valued occupational roles

(occupation-as-end).³ To select appropriate occupations, therapists must be able to perform activity analysis. To improve decreased abilities, selected occupations must appropriately challenge impaired abilities and be continually adjusted as the patient's performance changes. Therapists control the challenge level of all occupations by grading activities along a therapeutic continuum and by adapting occupations to match the patient's abilities. When the patient's impairments and limitations prevent usual engagement in an occupation, therapists adapt activity demands, activity properties, and environmental contexts to enable performance of desired occupations. This chapter describes how to select, analyze, grade, and adapt occupations.

Activity Selection

Using occupation as a means of therapy is the core of occupational therapy practice.⁶ Occupation is used to promote the functional performance of a person's roles and routines, thereby supporting self-esteem and meaning.³ The benefits of using occupation as therapy are well supported in the literature.⁷ Although rote exercise interventions are valuable for targeting specific skill limitations, the use of occupation as therapy has broader, long-term benefits for overall occupational functioning.⁸ Use of occupation as therapy fosters motivation toward performance by selecting interventions that are meaningful to the patient and that are able to remediate skill deficits. Occupation as therapy also promotes a broader range of improvement through the simultaneous recruitment of multiple and synchronized skills needed to perform an activity.

Selection of Occupation-as-End Activities

Occupation-as-end activities are those that support the patient's life roles and routines. The therapist and patient identify key occupations that enable him or her to engage in desired roles within particular environmental contexts. Through activity analysis, the therapist matches a patient's skills to the demand level of a specific occupation. Comparison between activity demands within the usual environmental context and the patient's skills determines whether the patient will be able to perform the activity independently, with adaptation, or not at all.^{7,8} Self-efficacy and mastery are fostered when patient skills match the situational challenges posed by the activity.

Selection of Occupation-as-Means Activities

The patient's occupational goals help to determine the activities that should be used in intervention to promote the restoration of impaired patient abilities, referred to as occupation-as-means. Activities used to restore impaired skills must not only be within the patient's capacity, but also challenge the patient's ability level so that improved performance can be facilitated through effort and practice. Some specific characteristics of the goals commonly addressed by occupational therapists who treat patients with physical disabilities include increased range of motion (ROM), strength, coordination, memory, and attention. When therapists select contrived methods of therapy—for example, using pegs and cones to increase strength and ROM—instead of the patient's self-identified, real-life, daily activities, the value of therapy is often diminished. Contrived methods also require the patient to focus directly on the process of activity, rather than the end goal, further undermining therapeutic value. An example of the appropriate selection of occupation for a musician whose end goal is to restore hand function after injury would involve intervention activities related to playing a patient-specific musical instrument, such as the piano or violin. Inappropriate examples of occupational selection would include the singular use of pegboards, putty, elastic bands, and weights.

Activity Analysis

Activity analysis, or **task analysis**, is a fundamental skill of occupational therapists. Occupational therapists analyze activities to determine (1) whether a patient with specific abilities can be expected to perform an activity and (2) how an activity can be adapted to facilitate improved occupational performance. Activity analysis enables therapists to understand an activity's components and skill requirements.⁶ Therapists begin activity analysis by identifying **activity demands**, that is, the essential skills required for participation. Activity

analysis also requires the identification of patient skill limitations that may impede performance. Some activity demands to be considered are the size and type of tools, the placement of selected tools and equipment in relation to the patient, the speed at which the activity is to be performed, the complexity of the activity, and the physical and/or social environment in which the activity will be carried out. Changes in any of these variables alter activity demands and may impact patient performance. The prerequisite abilities needed to accomplish an activity should be identified. If a patient is lacking these prerequisite abilities, and the goal is to participate in the activity to support a specific patient-desired role (occupation-as-end), the activity must then be modified to promote the patient's participation. Modification may involve the adaptation of one or more specific activity demands to reduce challenge level so that the patient can complete some components of the activity (occupation-as-means)—for example, practicing the maintenance of balance while sitting upright at a piano using a bench with an adapted backrest.

Although activities require particular performance skills and abilities, identification of these factors is a high-level skill that requires practice under supervision. Activity analysis involves three primary components: analysis of (1) the activity, (2) patient performance, and (3) environmental supports and barriers influencing activity participation.

Analysis of the Activity

Using an analytical approach, the therapist examines an occupation to determine its components and required skill level (see Table 3-1). Activity analysis can be used to select activities for remediation, match a patient's skills with the demands of the activity, or modify the activity to enhance patient participation. All analyses should occur within some conceptual framework to give them direction, coherence, and meaning.⁹ For example, planting a tulip bulb in a container can be analyzed using various frames of reference. The biomechanical approach prompts the therapist to examine the physical requirements of an activity such as grasp, coordination, and ROM, whereas the cognitive-perceptual approach is used to examine the activity according to its cognitive or perceptual demands, such as attention, problem solving, and spatial requirements.

Table 3-1. Activity Analysis

STEPS OF ANALYSIS	ACTIVITY (BANK OF IDEAS)	PATIENT (OCCUPATION-AS-MEANS)	ENVIRONMENT (OCCUPATION-AS-END)
1. Identify the activity, patient capabilities, and context	Describe activity	Identify primary goals that the activity is intended to enhance through patient performance.	Identify the environment(s) in which the patient wants or needs to perform a given activity.
2. Identify aspects to target	Activity demands, e.g.: <ul style="list-style-type: none"> • objects used • environmental demands • social demands • sequencing and timing • activity steps • prerequisite capabilities • safety precautions 	Identify the primary patient abilities the activity is intended to challenge, e.g.: <ul style="list-style-type: none"> • ROM • strength • motor performance • sensation • visual-perception • cognition • praxis 	Identify the environmental demands of the activity, e.g.: <ul style="list-style-type: none"> • space demands • equipment height • work space surface area • standing/sitting demands • floor surface demands • visual contrast of foreground/background • social demands • noise level • lighting • temperature
3. Identify therapeutic aspects and value as related to desired performance	Adapt activity demands to align with therapy goals.	Evaluate the activity's therapeutic value based on patient characteristics, e.g.: <ul style="list-style-type: none"> • meaningfulness • within patient's capabilities • repetitive • gradable 	Evaluate how environmental demands can be modified to meet/challenge the patient's performance level.

STEPS OF ANALYSIS	ACTIVITY (BANK OF IDEAS)	PATIENT (OCCUPATION-AS-MEANS)	ENVIRONMENT (OCCUPATION-AS-END)
4. Calibrate difficulty level to promote performance	Modify activity demands, e.g.: <ul style="list-style-type: none"> • objects used • space demands • social demands • contextual demands • sequencing and timing • activity steps • needed skills level • safety precautions 	Specify activity parameters for patient performance, e.g.: <ul style="list-style-type: none"> • instructional method • nature and level of cuing • social and environmental demands • required performance skills 	Implement environmental modifications to promote performance.
Example: Patient with CVA, right dominant hemiparesis; enjoys painting	<ol style="list-style-type: none"> 1. Activity: Brushing teeth, painting activities 2. Toothbrush, social demand of good hygiene, intact proximal stability and fine motor coordination 3. Built-up handle, sitting in wheelchair 4. Gradually decrease size of handle and progress toward standing 	<ol style="list-style-type: none"> 1. Patient will brush teeth independently while standing at sink 2. Patient challenge: stability and right hand fine motor coordination 3. Patient enjoys painting; skills transfer to patient goal of brushing teeth 4. Built-up handles to paint and brush teeth. Grade from sitting to supported standing. Decrease size of handles as patient skills emerge 	<ol style="list-style-type: none"> 1. Brush teeth independently at home 2. Evaluate bathroom at home 3. Narrow space that prevents use of wheelchair; stable bathroom vanity for proprioceptive input (e.g., resting hand on surface) 4. Decrease fall risks; remove clutter from vanity surface

CVA, cerebrovascular accident; ROM, range of motion.

The first step of an activity analysis is to compile a detailed description of activity demands, followed by the activity's therapeutic aspects, and finally the gradations to activity demands that can calibrate the level of difficulty or challenge. Activities selected to restore motor function must take into account the person's physical status, cognitive and visual-perceptual skills, emotional status, cultural background, and interests. An analysis of the cognitive functions required for an activity should include the number and complexity of the steps involved in performing the activity, the requirements for organizing and sequencing the steps, the amount of concentration and memory required, and the ability to follow verbal or written instructions. Visual-perceptual factors include whether the activity requires the patient to distinguish figure from ground, determine position in space, construct a two- or three-dimensional object, or interpret topographical orientation. Psychosocial aspects of an activity that may be important to patients include whether the activity must be done alone or in a group, requires verbal and/or nonverbal interaction, involves the sharing of materials with others, is likely to cause frustration, requires insight and emotional regulation, and offers the likelihood of producing a satisfying outcome.

Some therapists maintain files of activity analyses, which they can adapt to specific patients. Over the years, activity analyses have been published for general use by therapists including Hi-Q game,¹⁰ macramé,¹¹ planting a small garden,¹² and bilateral inclined sanding.¹³ An activity analysis form⁵ was published based on the American Occupational Therapy Association's Occupational Therapy Practice Framework.

Analysis of Patient Performance

When evaluating whether a patient possesses needed skills to perform a desired occupation, therapists should consider (1) the patient's sensory and motor, visual-perceptual, cognitive, and psychosocial functions; and (2) whether these underlying skills are at a level sufficient to support occupational participation. When deficits in these underlying skills impede desired occupational participation, therapists must select occupation-as-means activities to remediate skills, adapt activity demands to promote patient engagement, or use compensatory strategies and devices that substitute for a patient's deficient skills.

As a first step, the therapist should observe the patient's performance of role-related occupations to determine whether the patient can accomplish desired roles in accordance with self-identified needs and expectations.¹⁴ If not, the patient should identify the activities within the role that are not accomplished to his or her standards. Observing the patient's attempt to

perform an activity provides the therapist with clues about which abilities and capacities may need further evaluation and treatment.

The performance analysis proposed by Fisher and Bray Jones¹⁴ involves observational evaluation of the “transaction between the client and the environment as the client performs a task that is familiar, meaningful, purposeful, and relevant” (p. 517). To accomplish this, Fisher uses a standardized performance analysis, the Assessment of Motor and Process Skills (AMPS),¹⁴ although analysis can also be completed through informal observation. The quality of patient performance, rather than the patient’s underlying capacities, is graded, although patient capacities are considered when interpreting outcome and planning treatment.

Analysis of the Environment

When therapists analyze the environment in which an activity is performed, they analyze the person–environment fit—in other words, how well the environment supports or impedes a patient’s occupational participation. Environmental analysis is an essential component of activity analysis because any subtle change in environmental conditions can significantly affect a patient’s performance level. For example, a patient may easily be able to self-propel a wheelchair on a clinic tile floor, but may struggle to self-propel it at home on a carpeted floor. A patient’s dynamic balance may be sufficient for ambulation across the therapy gym, but may deteriorate on unlevel sidewalks in the community.

In addition to the physical environment, therapists must also address the patient’s social contexts and financial resources. For example, a practitioner may complete a home evaluation with recommendations for installation of shower grab bars and toilet handrails. Although such equipment would enhance a patient’s safe self-care performance and reduce possible falls, the patient may not have the financial resources to purchase the equipment or employ a contractor to install them. In such cases, the therapist must identify needed community resources such as organizations that provide used, restored durable medical equipment at low or no cost, and contractors who provide services to economically compromised groups for a minimal fee.

Similarly, a therapist may wish to provide a home therapy program to a patient who sustained a cerebrovascular accident (CVA). The home therapy program may incorporate the use of modified constraint-induced movement therapy (mCIMT) in which a restraining mitt is placed on the unaffected upper extremity (UE) to promote use of the affected extremity in daily activities. Although mCIMT has been shown to increase motor performance of the affected limb in patients with CVA, mCIMT requires the presence of a caregiver who can secure the mitt onto the patient’s affected extremity and monitor the patient’s use throughout the day. Patients who live alone or in facilities without this level of social support would not be able to benefit from home therapy programs incorporating mCIMT, and therapists would then be required to develop home programs with less demand from the patient’s social environment.

Gratation

Therapeutic grading is the modification of activity demands to reduce or increase the activity’s challenge level. Grading is used to change activity demands to promote psychomotor **learning**, leading to increased occupational performance. Multiple dimensions of an activity can be graded to increase or reduce challenge level. Some examples of commonly graded activity dimensions include ROM, weight, resistance, speed, position, surface height, texture, size, duration, repetition, complexity, number of steps, cognitive demand, and assistance level. When more than one dimension is identified for gradation, the therapist should be careful to grade one or two dimensions at a time so that change in each dimension can be assessed. The best activities for remediation are those that demand a specific response requiring skills targeted for improvement, and that allow incremental gradations beginning at the level at which the patient can be successful (see Table 3-2).

Table 3-2. Selecting and Grading Occupation-as-Means Activities

REMEDICATION GOAL	KEY DIMENSIONS OF THE ACTIVITY
To retrain sensory awareness and/or discrimination	Offer various textures, sizes, shapes. Grade from diverse to similar, coarse to smooth, large to small.

REMEDICATION GOAL	KEY DIMENSIONS OF THE ACTIVITY
To decrease hypersensitivity	Offer various textures and degrees of hardness or softness. Grade from acceptable to barely tolerable.
To relearn skilled voluntary movement	Require patient-desired, purposeful movement; allow feedback. Grade from simple to complex movements.
To increase coordination and dexterity	Require skilled motor actions that the patient can control. Grade from slow, gross movement involving limited number of joints to fast, precise movement involving a greater number of joints.
To increase active ROM	Require repeated movement to the limits of joint range. Grade to demand greater amounts of movement.
To increase passive ROM or elongate soft tissue contracture	Provide controlled stretch or traction. Grade from lesser to greater ROM.
To increase strength	Require movement or holding against resistance. Grade from lesser to greater resistance or from slow to fast movement.
To increase cardiopulmonary endurance	Use activities rated at the patient's current MET level. Grade by increasing duration, frequency, then intensity (METs).
To increase muscular endurance	Require repetitive movement or holding against 50% or less of maximal strength. Grade by increasing repetitions or duration.
To decrease edema	Allow use of the extremity in an elevated position and require isotonic contraction.
To improve perceptual impairments	Perform activities that require perceptual processing at the patient's highest current skill. Grade by complexity of stimuli.
To increase attention	Practice activities that are graded from less distracting to more distracting, and from less time demand to more time demand.
To increase memory	Practice activities that are graded from simple to complex in terms of demand on the patient's ability to remember.
To improve problem solving	Practice activities that are graded from simple (one step) to complex (multiple steps), concrete to abstract, and familiar to unfamiliar. Higher level activities should include unexpected challenge.

MET, metabolic equivalent; ROM, range of motion.

Adaptation

Activity adaptation is the process of modifying an activity of daily living to enable performance, prevent cumulative trauma injury, or accomplish a therapeutic goal. There are four reasons to adapt an activity in the treatment of patients with physical disabilities. One is to modify the activity to make it therapeutic when it would not be so otherwise. For example, while washing windows with a patient who has limited shoulder strength, the occupational therapist can add a weight to the patient's wrist to make the activity more therapeutic.

A second reason for adaptation is to grade the amount and type of exercise offered by an activity along a therapeutic continuum to accomplish goals. For example, to increase coordination, an activity should be graded along a continuum from gross-imprecise to fine-accurate movement. Checkers and other board games lend themselves easily to such gradations. For example, checker and cribbage boards, and their pieces can be changed in size so that the patient can engage in self-identified leisure activities while continuing to benefit therapeutically.

A third reason for adapting activities is to enable a person with physical impairments to perform an activity for which he or she would be otherwise unable. For example, after sustaining a CVA causing hemiparesis (weakness of one UE), a patient can learn one-handed dressing methods. Similarly, the environment in which a favorite activity is accomplished can be modified to allow engagement. For example, a gardener who undergoes bilateral lower extremity amputation secondary to diabetes can continue to garden from a wheelchair using raised planting beds.

A fourth reason for adapting activities, particularly work activities in which people participate for long periods, is to prevent cumulative trauma injury. Examples of such adaptation include changing table height to reduce back and UE strain, or performing the activity while seated to reduce lower back stress.

As with all therapeutic techniques, it is vital for the patient to understand the reason why an activity is adapted. For patients with cognitive impairment, it is important to determine their

cognitive capacity to process complex and abstract information, and explain the reason for activity participation using understandable language.¹⁵

Parameters Used to Adapt or Modify Activities

There are multiple characteristics of beneficial adaptations. First, adaptations should promote normal movements, body postures, and motor patterns. It is also essential that adaptations be safe. Adaptations should additionally demand a specific automatic response upon which the client does not have to concentrate. Finally, adaptations should support, rather than detract from the meaningfulness of the activity.

Activity Demand: Required Body Functions

This group of adaptations focus on specific body functions that support the actions used to perform activities (e.g., muscle strength and standing balance).

Positioning the Activity Relative to the Person

The position of the person relative to the activity to be accomplished dictates all required movements and the specific muscle groups that must be used. Poor positioning of activity equipment relative to the patient's size may result in musculoskeletal discomfort or repeated stress injuries.¹⁶ Adaptive positioning of the activity in relation to the patient refers to changes in work surface height and incline, work equipment location, and equipment item placement to require specific body movements.

Activities that are commonly performed on a flat surface, such as painting, board games, and sanding wood, can be made more or less resistive by changing the surface incline. For example, resistance is provided to shoulder extension and elbow flexion when the surface is inclined downward and away from the patient. Resistance is provided to shoulder flexion and elbow extension when the surface is inclined upward and toward the patient (Fig. 3-1).

Figure 3-1 A. Resistance is provided to shoulder extension and elbow flexion when the surface is inclined downward and away from the patient. B. Resistance is provided to shoulder flexion and elbow extension when the surface is inclined upward and toward the patient.

Similarly, the standard horizontal work surface can be raised or lowered to make demands on specific muscle groups or to alter the effect of gravity. For example, a table raised to axilla height allows flexion and extension of the elbow on a gravity-eliminated plane and may enable a person with grade 3+ muscles to eat independently. These positional changes serve to increase joint strength and ROM, and promote performance.

Placing items—such as nails, mosaic tiles, yarn, beads, darts, beanbags, and paintbrushes—in various locations changes the movements required to reach and retrieve them. Placement may be high to encourage shoulder flexion or abduction; lateral to encourage shoulder rotation, trunk rotation, or horizontal motion; or low to encourage trunk flexion or lateral trunk flexion. All of these placements would encourage improvement in dynamic balance.

Arranging Objects Relative to Each Other

To grade an activity for improving perceptual skill deficits (e.g., poor figure-ground discrimination, unilateral neglect), the arrangement of objects and the amount of page print can be graded from sparse to dense (e.g., fewer objects or words with space between vs. many objects or words with little or no space between). Placing game pieces on the right side of a game board encourages use of the right hand, whereas placement on the left encourages use of

the left hand. Arrangement of ingredients on a kitchen counter across the room from the mixing bowl encourages walking that would not occur if all supplies were placed together. On the other hand, placing all objects needed for an activity together reduces the energy required to perform the task.

Modifying Lever Arm Length

The amount of work that a muscle or muscle group expends depends on the resistance. Resistance is determined by the pull of gravity on a limb and the equipment used by the patient, which together act as the resistance lever arm. The effect of a given amount of resistance can be altered by lengthening or shortening the resistance arm. The longer the resistance arm, the greater the force required to counterbalance it. The resistance arm can be altered by shortening or lengthening the limb. For example, flexing the knee, which shortens the limb, offers less resistance to hip extension than if the knee was extended. Another example involves carrying an object close to the body, which requires less involvement of back muscles than if the object was carried at arm's length. On the other hand, increasing the length of the force lever arm decreases the muscle activity needed to accomplish a task (Fig. 3-2).

Figure 3-2 Patient sitting in a wheelchair using an extended brake handle to increase leverage.

Attention to lever arm length is important both to adapt an activity's required body movements to make the activity more therapeutic and to adapt object weight for patients with decreased strength. The adaptation of lever arm length guides workers in methods of lifting and handling to avoid musculoskeletal injuries on the jobsite.

Activity Demand: Required Actions and Performance Skills

This group of adaptations focuses on methods used to adapt the actions and skills required to carry out an activity.

Modifying Performance Method and Physical Context

Modifying the performance method is used both for **occupation-as-means** and **occupation-as-end** activities. Such compensatory adaptation allows the performance of an activity that would be impossible otherwise because of a patient's disability. Bowling, basketball, and many other sports can be accomplished while seated instead of standing. A change of rules adapts some sports, such as track and field events, to match the activity limitations of physical impairment. Sewing and needlework, typically bilateral activities, can be made unilateral by adaptations that hold the material steady for the working hand. Books, laptop computers, and other tools can be transported via a rolling backpack or rolling table instead of carrying them.

By altering the physical context, individuals are able to perform an activity more optimally.¹⁷ For example, if a patient cannot flex his shoulder against gravity, placing him in a side-lying position will minimize the effects of gravity, allowing the desired movement. Movement organization in a gravity-eliminated plane, however, differs from movement in an against-gravity context, requiring different muscle recruitment. Movement organization is also atypical in simulated contexts using contrived objects, as compared to movement patterns executed in natural contexts with real-life objects.^{8,18-20} Because movement organization is sensitive to contextual changes,¹⁷ some rehabilitation centers are now designed with manufactured "real" environments that allow patients to practice in realistic contexts to facilitate best performance and carryover to real-life contexts (Fig. 3-3).

Figure 3-3 A. Patient using a simulated grocery store in a clinical setting. B. Patient relearning to drive in a simulated clinic vehicle.

Modifying Level of Difficulty

Patterns for craft activities, game rules, number of steps, and creativity level can be downgraded to enable patient success or upgraded to demand higher performance level. Modifying an activity's difficulty level can entail changing the number of pieces and instructions that must be navigated, changing the problem-solving level from concrete to abstract reasoning, and changing the directions from specific to general. For example, a patient with traumatic brain injury may be unable to write a check if the desktop is cluttered with papers, but may be able to manage if one bill is presented on a cleared desk surface. A patient with low cardiopulmonary endurance may not be able to stand for long periods in the kitchen to prepare a simple meal, but could complete a kitchen activity while seated on a stool. As endurance increases, difficulty level can be increased to include standing positions during activity portions.

Activity Demand: Objects and Their Properties

This next group of adaptations focuses on the adaptation of the tools, materials, and equipment used to perform an activity.

Modifying Materials and Textures

To change an activity's level of resistance, gradation along the strengthening continuum may be accomplished through the selection of materials by type, texture, and density. For example, resistance can be changed by beginning a project requiring scissor cutting first with tissue paper and then progressing to heavier materials. Metal tooling can be graded for resistance by choosing materials in grades from thin aluminum to thick copper. Sandpaper is graded from extra fine to coarse, and resistance increases as the grade coarsens. Mixing ingredients can be graded along a continuum from making gelatin dessert, to scrambled eggs, and finally to biscuit batter. If materials are graded in the opposite direction—that is, from heavy to light—

the activity demands increased coordination from the patient. Weaving may begin using thicker material, such as rug roving yarn, and be graded toward fine linen threads as the patient progresses in coordination. Cutaneous stimulation changes with the amount of object and surface texture. By making balls from yarn or terrycloth toweling, carpeting the surfaces upon which a patient works, and padding handles with textured material, the therapist adapts the activity to increase sensory stimulation.

Modifying Tool and Utensil Handles

Padding the handles of utensils and tools with high-density foam or other firm but soft material reduces stress on painful finger joints and enhances use by patients with poor grip strength. For example, patients with rheumatoid arthritis often benefit from foam tubing placed on toothbrushes, pens, hairbrushes, and eating utensils to provide a larger grip area that reduces pain and promotes motor control (Fig. 3-4). Other modifications to tool handles include using weighted-handled eating utensils to decrease tremors for patients with Parkinson disease.

Figure 3-4 Patient using built-up handles to eat (A) and brush teeth (B).

Modifying Object Size and Shape

Therapists can adapt the size and shape of board game pieces to offer a therapeutic benefit that would not be possible with standard objects. For example, checkers, which are usually flat pieces approximately 2.5 cm in diameter, can be replaced by cylinders, squares, cubes, or spheres; can range in size from tiny to as large as a person's grasp permits; and can be adapted with handles for easier retrieval.

Reducing the size or changing the shape of an activity's objects and pieces facilitates the goals of increased dexterity and fine motor coordination. Therapists creatively change the size of craft materials (e.g., weaving thread, tiles, paint-by-number guidelines, and ceramic pieces) and recreational materials (e.g., puzzle pieces, chess pieces, and target games) to increase coordination. Tools and utensils can be adapted by changing the length, diameter, or shape of their handles, or by adding handles to tools that do not typically possess them. The actual size of a tool can be selected to offer greater or lesser resistance. For example, saws range in size from small coping saws and hacksaws to large cross-cut and rip saws. The resistance of saws can also be graded by the number of teeth per inch on a blade—the fewer the teeth, the greater the resistance. Woodworking planes vary in size, and the amount of exposed blade can be adjusted to provide resistance. The size of scissors, screwdrivers, stirring spoons, and other tools and utensils can also be varied.

Modifying Color Contrast between Objects

Figure-ground discrimination¹⁰ can be facilitated by changing background and foreground objects from similar to increasingly contrasting colors. For example, patients with visual-perceptual deficits may have difficulty distinguishing light-colored foods (e.g., mashed potatoes and sliced chicken) against white plates, and white bars of soap against white bathroom sinks. In such cases, it would be beneficial to place foods against plates with a distinctly contrasting color background. Similarly, the color of toothpaste brushes and tubes, lotions, and hairbrushes can be modified by adhering brightly colored tape to these items to provide contrast against a white bathroom countertop (Fig. 3-5).

Figure 3-5 The color of toothpaste tubes, soaps, and lotions can be modified by adhering brightly colored tape to these items to provide contrast against a white bathroom countertop.

Modifying or Using Supplemental Tools and Utensils

Using tools when none are typically used or modifying tools and utensils enables a patient to accomplish activities and tasks that he or she would not be able to perform otherwise. For example, toast can be retrieved from a toaster using a wooden, spring-hinged clothespin when sensory precautions are in effect. Angling the handles on carving knives allows a person with rheumatoid arthritis to cut meat or vegetables without placing deforming forces on the wrist and fingers. Changing keyboard or mouse designs can prevent carpal tunnel syndrome. Including the tool in a specially designed splint can reduce symptoms caused by prolonged holding. Although manufacturers offer tools and household utensils designed to enable patients with weak grasp or arthritic pain to use them comfortably, therapists must not assume that tools labeled “ergonomic” offer better positioning or less discomfort than nonadapted tools. Patients’ perceived comfort and ease of use must guide the selection of all tools and utensils.²¹

Adding Weights

The addition of weights adapts an activity to meet such goals as an increase of strength, promotion of muscular co-contraction, and an increase of passive ROM by stretch. Some nonresistive activities can be made resistive by adding weights directly to the apparatus or by using pulleys. Others may be made resistive by adding weights to the person using weighted cuffs. Tools also are weights that can be selected and adjusted to offer graded resistance (Fig. 3-6). For instance, hammers range from lightweight tack hammers to heavy claw hammers.

Figure 3-6 Tools are weights that can be selected and adjusted to offer graded resistance.

Adding Springs or Rubber Bands

Springs and rubber bands are a means of adapting activity to increase strength through resistance, to assist a weak muscle, or to stretch a muscle and other soft tissues to increase passive ROM. When offering resistance, the spring or rubber band is positioned so that its pull is opposite to the pull of motion of the target muscle group. If used for assistance, the spring or rubber band is set to pull in the same direction as the contracting muscle group. Springs and rubber bands applied for the purpose of stretching are placed so that the pull is against the tissue to be stretched. Springs of graduated tensions may be applied directly to larger pieces of equipment. Rubber bands can be added to smaller pieces of equipment and can be graded from thin with light tension to thick with heavy tension. For example, a rubber band can be wrapped around the pincer end of a spring-type clothespin to add resistance when it is used in games involving the retrieval of small pieces.

Activity Demand: Sequence and Timing

This final group of adaptations involves changing demands related to the steps involved in an activity including the sequence of steps and the time required to complete the steps.

Modifying Steps

An activity can be modified by increasing the number of steps to complete the activity. Grading the number of steps from one to two steps to multiple steps can be used to increase attention, concentration, and memory. For example, the activity of “brushing teeth” can be graded from two steps: (1) brush teeth and (2) rinse mouth; to five steps: (1) get supplies from cabinet, (2) put toothpaste on brush, (3) brush teeth, (4) rinse mouth, and (5) return supplies to cabinet.

To address memory deficits, an activity can be adapted to include a sequential checklist of the steps needed to perform the activity. Depending on the person’s cognitive ability, the

checklist can be written or pictorial. Using the same example above, a written checklist for the steps involved in brushing teeth could be posted on a mirror in the bathroom. Conversely, the patient may receive a singular instruction to complete a multistep task (such as prepare and clean up a light lunch within 30 minutes) to facilitate decision-making and problem-solving skills.

Modifying Time

Changing and monitoring the length of time needed to complete the individual steps of an activity, or the entire activity, can be used to enhance patient attention and concentration skills. For example, making a peanut butter and jelly sandwich can be graded by increasing the required time to make one or more sandwiches. Devices can be used to promote a therapeutic goal or enable performance such as the use of a kitchen timer or alarm clock.

CASE STUDY

Patient Information

Gordon is a 78-year-old retired high school teacher, director of a high school vocational program, and carpenter who experienced a stroke related to carotid artery angioplasty with stenting. The stroke resulted in hemiparesis of his right, dominant side that affected balance, weight shift, and right UE strength and coordination. The emergency room doctor conducted the Mini-Mental State Examination (MMSE) where Gordon scored 20/30, which indicated mild cognitive impairment. He was in the hospital for 3 days and then returned home to independent living with his wife. While still in the hospital, Gordon lost his balance and fell in the bathroom while bending and rotating. He stated, “This stroke caused my right arm and hand to be a dish rag.”

Assessment Process and Results

The occupational therapist met with Gordon for evaluation and intervention. One of the first things he told the occupational therapist was that he could not drive because he could not turn the key in the ignition or hold the steering wheel with his right hand. The occupational therapist used multiple tools for the assessment process, including patient interview, Activity Card Sort, the MMSE, biomechanical assessments (9-Hold Peg Test, power of grasp, tensiometer, ROM), and the Mini-Balance Evaluation Systems Test (Mini-BEST).

Results indicated that Gordon was also having difficulty brushing his teeth, buttoning his sleeve cuffs, and holding a spoon to scoop grapefruit pieces, which he reported eating daily to lower his cholesterol. He periodically verbalized concern about his inability to manipulate grapefruit pieces, suggesting that this was an important goal to target. Gordon was independent in all other self-care tasks. He additionally desired to complete his own home maintenance, such as lawn mowing. Gordon’s occupational interests included carpentry, such as remodeling his daughter’s basement, which required the ability to use tools such as a drill, trowel, and hammer; model airplane building and flying; and playing music with piano, guitar, and harmonica.

Since his initial hospitalization, Gordon’s MMSE score improved to 28/30, indicating no cognitive impairment. Scores on the 9-Hole Peg Test were 50 seconds right and 30 seconds left UE. Scores for power of grasp were 10 lb on the right and 60 lb on the left. Scores for lateral grasp were 3 lb on the right and 20 lb on the left. ROM was within normal limits throughout both UEs but a slight movement delay was present in the right UE. Score for the Mini-BEST was 24/28 because of limitations in reactive postural control.

Occupational Therapy Problem List

- Difficulty feeding self with utensils, especially when scooping grapefruit because of right hand weakness and limited coordination
- Difficulty brushing teeth because of right hand weakness and limited coordination and postural instability
- Difficulty with home maintenance, such as lawn mowing, because of balance impairment and weak grasp to pull the mower starter cord

- Difficulty driving because of right hand weakness and limited coordination

Occupational Therapy Goal List

During selection of occupation-as-end activities, the therapist asked Gordon which activities were the most immediately important to him. He prioritized the following goals:

- Gordon will demonstrate modified independence in feeding himself with utensils, especially scooping grapefruit, with 10 lb lateral grasp, 15 lb power of grasp, and normal coordination within 2 weeks.
- Gordon will demonstrate independence in brushing teeth with 15 lb power of grasp, normal fine motor coordination, and intact reactive postural control with transitional movements to set up items needed within 1 month.
- Gordon will be able to start his lawn mower and mow his lawn with intact balance and weight shift within 1 month.
- Gordon will demonstrate independence in driving as evidenced by 10 lb of lateral grasp in order to turn the key in the car ignition within 1 month.

Intervention

To enhance performance of each occupation, it was important to target hand and finger strength, fine motor coordination, and balance with transitional movements. During the second visit, the therapist developed a bank of intervention activities that Gordon could perform within his natural environment including carpentry tasks, lawn mowing, brushing teeth, playing piano and guitar, and feeding himself grapefruit. The therapist used a neurodevelopmental treatment (NDT) frame of reference, while also integrating task-specific motor learning in which specific activity aspects were analyzed and modified to promote repetition, duration, specificity, and intensity.

The therapist initiated patient education during simulations of several meaningful activities that Gordon identified. For example, the therapist found a drill, screws, and wood from the maintenance department to show Gordon how to incorporate weight bearing on his affected, extended right UE. The drill handle was large, which facilitated Gordon's ability to grasp it. His grip strength, however, was too weak to hold the drill upright against gravity, as would be required to push screws into a wall. To grade the task to a lower challenge level, the therapist instructed Gordon to hold the drill downward so that gravity could assist when pushing the screw into the wood. With practice, Gordon gained the ability to activate the power switch with his right index finger. He used his left hand to precisely hold the screw when initially drilling it into the wood, followed by a two-handed method (both hands on the drill) to finish drilling the screw into the wood.

Gordon and his therapist also addressed the difficulty he was experiencing scooping grapefruit with a spoon. He reported that it felt like "there was oil on my spoon handle." The therapist adapted his grapefruit spoon and toothbrush by placing 2-inch foam tubes onto both handles to make them larger and easier to grasp. She also gave Gordon 1-inch tubes to replace the 2-inch ones, as his hand strength and coordination progressively improved.

In his third visit, Gordon brought carpentry tools and a list of tasks he needed to complete to remodel his daughter's basement. The use of these tools was meaningful, within his capabilities, repetitive, and gradable in nature. The therapist and Gordon initially practiced each activity in a simulated manner, primarily using Gordon's right hand as a stabilizer with the intent to improve grip strength. Two-handed techniques were then used to improve coordination. Gordon and the therapist continued to grade the activity by gradually increasing key elements such as range, resistance, speed, and surface height. The therapist concurrently used restorative NDT with activity-specific techniques and precautions for balance. Demonstration and return demonstration were used as teaching and learning strategies.

The fourth visit took place in Gordon's home in order to observe his activity performance in his natural environment. Gordon pointed out the tall, uncut lawn grass and was highly motivated to mow the lawn. The therapist examined Gordon's ability to operate the lawn

mower (activity analysis), attend to uneven lawn surfaces (environmental analysis), and maintain his stability while pushing and turning the mower (analysis of patient abilities). Mowing stimulated bilateral hand use and repetitive, activity-specific movement patterns (stepping, crossing midline, turning, and weight shifting) over an extended duration of time. Gordon initially practiced with the mower off, but turned it on once his motions were safe. The handle of the mower served as a stabilizing element for his balance and he gradually, and safely, increased his speed.

Gordon said that he felt ready to start work on his daughter’s basement over the next month, including tasks such as pounding nails into and finishing sheetrock walls. These carpentry activities offered inherent gradation to further challenge strength, coordination, and balance. Gordon’s strength improved, enabling him to hold the drill upright against gravity to drill screws into walls.

During another session, the therapist and Gordon attempted piano playing to facilitate fine motor coordination. Although he improved within 15 minutes of playing, he acknowledged that it was still too frustrating for him and he did not wish to continue. This activity was not a good therapeutic selection because of the mismatch between the activity challenge level and Gordon’s personal abilities and standards.

Gordon spent the next month engaged in “his therapy,” as he described to friends and family, by remodeling his daughter’s basement and by participating in additional therapeutic exercises. After 2 months, he regained strength, balance, and most fine motor coordination, with limitations in his third, fourth, and fifth digits. Gordon demonstrated modified independence with dressing, using a buttonhook as an adaptation. He regained independence in driving, mowing his lawn, brushing his teeth, and eating with utensils, including scooping grapefruit. Finally, he regained sufficient fine motor coordination to build model airplanes and play the harmonica. Gordon reported being satisfied with his recovery from stroke because he was able to perform meaningful occupations that supported his roles as a father and carpenter. He now enjoys describing his therapy to others by stating that, “I did all of my therapy in my daughter’s basement.”

Evidence Table of Studies Involving Occupational Therapy Selection, Gradation, and Adaptation of Occupation

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Comparative effectiveness of (1) combined therapeutic exercise and occupation-based activities and (2) therapeutic exercise alone ¹⁹	Group #1: Picking up small everyday objects, typing on a keyboard, washing and wiping dishes in addition to therapeutic exercises in both hand therapy sessions and home program Group #2: Therapeutic exercises in both hand therapy sessions and home program	46 patients with UE injuries treated in outpatient hand occupational therapy clinic	10 weeks of therapy: supervised hand therapy 1-hour sessions, 2 times/week; and home exercise program 120 minutes, once a week	Randomized controlled trial. Level I	Combined intervention had better outcomes, including reduced pain, improved AAROM in fingers, subjective functional status, and subjective performance and satisfaction of performance.	Combined intervention showed statistically significant improvement in outcome measures compared to therapeutic exercise group: DASH score ($p < 0.02$), total active motion ($p < 0.01$), neuropathic pain ($p < 0.02$), COPM performance ($p < 0.001$), COPM satisfaction ($p < 0.001$) Effect size not reported.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Comparative effectiveness of occupation-based intervention and rote exercise ⁸	Group #1: Immobilization of healthy hand using therapeutic occupations for intervention Group #2: Immobilization of healthy hand during rote exercise of affected hand Control Group #3: No immobilization of healthy hand while practicing different movements and activities	36 outpatients (22–55 years old)	Groups #1 and 2 received intervention 3 hours each day, 3 days/week, over 4 weeks	Randomized controlled trial. Level I	Compared to rote exercise, occupation-based group had better performance in objective and subjective measures, motivation, satisfaction with and perception of performance, and continued improvement at follow-up.	Post hoc analyses revealed significant difference among all three groups with most increased mean change for occupation-based group ($p < 0.01$) Effect size not reported.
Comparative effectiveness between combined (1) resistive exercises, functional exercises, and ADLs, and (2) resistive exercises ²²	Group #1: Combination of resistance exercise, functional exercise, and ADL exercise Group #2: Resistance exercise	52 older adults, mean age = 73 years	Measured at baseline, postintervention, and 6-months follow-up	Randomized controlled trial. Level I	Postintervention improvement was found within groups but not between groups. At 6-month follow-up, a decline in resistance exercise group was found. Combined exercise group continued to show improvement. More adverse events (soreness, pain) for resistance exercise group.	Combined intervention group (mean change = 0.29, $p < 0.02$); resistance exercise group (mean change = 0.24, $p < 0.13$). At 6 months postintervention, combined intervention group showed within-group <i>mean change</i> of 0.37 ($p < 0.01$).
Comparative effectiveness between occupation-based intervention and repetitive task practice ²⁰	Group #1: Focused on performance of occupations with facilitation methods Group #2: Focused on 10–50 repetitions of each task	16 (21–69 years old) in chronic phase of stroke recovery	Measured at baseline and postintervention. Interventions were 55-minute sessions, 2 times/week for 4 weeks for both groups	Pilot randomized controlled trial comparative study with parallel group block design. Level I	Improvements in occupational performance and motor performance in both groups were similar. Authors suggested engagement greater and demand greater in occupation-based group because of meaningfulness and multijoint activities.	Although within-group changes after intervention were found for both groups ($p < 0.0001$), no between-group differences were found. Effect size not reported.

ADLs, activities of daily living; UE, upper extremity; AAROM, active assistive range of motion; DASH, disabilities of the arm, shoulder, and hand questionnaire; COPM, Canadian occupational performance measure.

Acknowledgments

We thank Devon Olson and Marilyn Klug for their assistance in chapter preparation. We also thank “Gordon” for sharing how occupation as therapy was used during his recovery from a

stroke.

Chapter 4

The Teaching and Learning Process

Lenin C. Grajo and Angela K. Boisselle

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the teaching and learning process within occupational therapy practice.
2. Define the stages of learning according to Dreyfus: acquisition, retention, transfer, and generalization.
3. Describe Meichenbaum's model of mastery: global learning strategies and metacognition mastery.
4. Assess the learning capacities of patients to optimize the therapeutic relationship.
5. Apply various teaching and learning principles during assessment and intervention.

CHAPTER OUTLINE

The Occupational Therapist as a Facilitator of Learning
Stages of Learning: Acquisition, Retention, Transfer, and Generalization
Applying Teaching and Learning Theories in Occupational Therapy
Assessing Patient Learning Capacities
Using Teaching-Learning Principles in the Therapy Process
Summary
Case Study

TERMINOLOGY

- Acquisition:** is a process of learning a new skill involving the development of strategies and skill completion.
- Domain-specific strategies:** are cognitive techniques that facilitate or improve performance that is task-, child-, or situation-specific.
- Functional literacy:** is the ability to interpret common written materials needed to effectively carry out basic daily life skills and participate in meaningful occupations and social roles.
- Generalization:** is the ability to take a newly learned skill and apply it to a real-life situation.
- Global strategies:** are methods that focus on increasing metacognitive awareness through training the patient to self-monitor and self-evaluate.
- Health literacy:** is the ability to obtain, process, and understand the basic health information and services that patients need to make appropriate health decisions.
- Metacognition:** is the awareness of one's cognitive level and ability to control one's thoughts.
- Occupational profile:** is a summary of gathered information about the patient's occupational participation and needs.
- Retention:** is a process of learning that involves storage of information for later use.
- Transfer of skills:** is the application of previously learned skills to a new task or activity.

The Occupational Therapist as a Facilitator of Learning

Facilitating teaching and learning is a continuous process embedded within occupational therapy evaluation and intervention. Occupational therapists work with patients who need to either acquire new skills or relearn lost skills secondary to illness, disability, or atypical human development. From the first encounter with patients, occupational therapists employ a variety of teaching and learning strategies in an array of therapeutic contexts. The methods through which occupational therapists employ teaching and learning approaches may facilitate or hinder successful therapeutic relationships. This chapter provides an overview of teaching and learning contexts, theories, and principles to help occupational therapists maximize the therapeutic context when supporting patients.

Contexts for Teaching and Learning within the Occupational Therapy Process

First, six different contexts for teaching and learning within the occupational therapy process are introduced. Later in this chapter, these contexts are applied as practical principles that can be employed in the therapeutic relationship.

Assessment as a Teaching and Learning Context

During the screening and/or formal evaluation of a patient, the occupational therapist both gathers information about the patients' occupational needs and uses this opportunity to educate the patient about the role of occupational therapy. Such education both supports the patient's understanding and helps to develop a mutually beneficial therapeutic relationship. A later section of this chapter describes how teaching and learning can be optimized when gathering data to produce a patient occupational profile.

Establishing a Therapeutic Relationship

Occupational therapists and the patients they work with all have varying teaching and learning styles. The right match between a therapists' teaching approach and a patient's learning style can significantly impact the therapeutic relationship. Some patients make greater therapeutic progress when paired with a more directive and hands-on occupational therapist, whereas other patients may require a more supportive and guiding therapist.

Skill Development, Strategy Generation, and Enhancing Occupational Participation

Appropriate teaching and learning processes not only influence the therapeutic relationship but also determine how well patient skills develop and strategies are generated, and occupational participation is enhanced. No one teaching-learning context is similar. Some teaching approaches may work for patients with specific learning styles and at distinct stages of readiness for change in the recovery process, whereas other approaches may not work. The teaching and learning process must be understood as an ongoing and continuously evolving process that is facilitated by the patient and shaped by the therapist's abilities. The teaching and learning process must also be viewed as mutually beneficial: both the patient and therapist facilitate each other's learning as they explore various strategies to best reach the patient's rehabilitation goals. Embedded within the teaching-learning process is problem identification, problem solving, and outcome assessment that unfolds as therapy progresses.

Modifying, Adapting, and Choosing Appropriate Environments

Teaching and learning is also employed as the occupational therapist and patient modify and adapt selected environments and contexts to support the patient's desired occupational participation. As much as possible, learning should occur in the natural environment. Although use of natural contexts may not always be possible in all practice settings, the occupational therapist should spend a reasonable amount of time creating realistic and occupation-based activities to help foster contextual learning.

Collaborative Relationship with Families, Caregivers, Interprofessional Team, and Social Networks

Teaching and learning approaches are used within a variety of therapeutic contexts with patients, family members, caregivers, and interprofessional team members. The occupational therapist must both teach others and learn from the perspectives of families, caregivers, and interprofessional team members about how to best apply patients' newly learned skills to enhance occupational participation in the home and community. Therapists must also collaboratively discuss challenges and opportunities for skill transfer and generalization within the patient's desired social networks. Oftentimes, this collaborative relationship requires education about the roles of the occupational therapist, identifying ways to embed the patient's typical daily routines while in the clinical setting, and strategizing methods to co-manage the patient's clinical condition. In certain cases, the occupational therapist may also need to collaborate with the patient's employers, school, and community infrastructures (e.g., neighborhood grocery store, spiritual organizations, community wellness facilities) to teach and learn ways to help the patient reintegrate into, resume, or newly assume desired occupational roles.

Health and Wellness Promotion and Disability Prevention

Occupational therapists must also use teaching and learning approaches not only when working with individual patients, but when working with patient groups and populations to teach health and wellness promotion and disability prevention strategies. Occupational therapists also engage in teaching and learning with patient stakeholders (e.g., insurers, community leaders, policy makers) that may directly or indirectly impact occupational therapy provision for specific patient groups. For example, if patients are denied therapy services by their health care insurers, therapists should take an active role in documenting the client's occupational performance and participation needs to justify the medical necessity of occupational therapy services. Therapists should also provide third-party payers with high-quality evidence supporting the effectiveness and value of occupational therapy interventions specific to the patient.

Stages of Learning: Acquisition, Retention, Transfer, and Generalization

Occupational therapists use a combination of cognitive and motor learning approaches when considering the manner through which patients learn. Both approaches are discussed in greater detail in Chapters 10, 11, 15, and 16. Educational philosopher John Dewey contended that learning is not merely a cognitive act of absorbing theoretical ideas; nor is it based simply on the physical act of doing.¹ In addition to cognitive and motor learning strategies, learning involves the value and meaning that patients place upon the activities in which they participate. To better understand learning from a cognitive and motor perspective, it is important to first explore stages of learning. Although there are several theories describing learning stages across various disciplines, the acquisition, retention, transfer, and generalization stages as they relate to occupational therapy practice are the focus of this chapter.

Acquisition

Acquisition occurs when patients learn new skills, develop strategies for learning (either consciously or unconsciously), and apply new learning in desired, natural contexts. Acquisition begins when information is stored in memory.² In the Dreyfus Model,³ one of the most recognizable learning theories related to skill acquisition, it is theorized that learning occurs on a continuum of five levels: novice, advanced beginner, competent, proficient, and expert. The novice learner requires specific and clearly defined directions. The advanced beginner learner possesses some acquired knowledge and can rudimentarily apply learning to real-life situations. The competent learner emerges as a person gains skill proficiency based on exposure to multiple experiences and begins to

build a repertoire of skills that can be used in problem identification and resolution. The proficient learner uses a solid foundation of previously learned concepts and can intuitively apply acquired knowledge to similar contexts. The master/expert has a vast storage of implicit and explicit knowledge and is intuitively able to engage in problem identification and resolution without a formal set of guidelines or instructions.⁴ Consider a patient with an above-elbow amputation of the dominant right arm who has been fitted with a myoelectric arm prosthesis. The patient is now learning to use the device in daily functional tasks. The novice learner begins by first learning to control electrodes within the device to flex and extend the elbow, wrist, and fingers. As the patient learns to use the prosthetic arm to perform tasks with more refined motor movements, such as grabbing and releasing an empty glass, the patient becomes an advanced beginner learner. With repetitive and varied practice in different contexts, the patient gains competency in prosthetic arm use. Proficiency develops as the patient learns to grab, lift, and transfer a water glass from table to mouth, and drink from the glass with minimal spillage. The patient may be considered an expert when he or she learns to use the prosthetic arm in more refined tasks such as using a fork to stabilize meat on a plate while the right hand slices pieces with a knife.

Overall, the learning of new skills initially requires greater attention and intention because of a lack of experience, but eventually becomes automatic, requiring less execution time. In the beginning stages of learning a new skill, the individual is focused on learning concrete steps (e.g., controlling the prosthetic device to flex and extend the elbow; using the prosthetic device to retrieve a coin from a desk), rather than on the contexts where learning transpires (e.g., using the prosthetic arm to complete computer tasks at work). Learning and relearning occur frequently for all patients throughout life as skill levels change and are impacted by aging, injury, and the progression of disability or disease. An example of the need to relearn previously acquired skills occurs when a patient fractures a dominant arm. The patient may need to relearn desired daily life activities such as writing, eating, buttoning clothing, and driving using different strategies and skills than those previously learned. Strategies for acquiring a new or modified skill may be intuitive, but in cases of difficulty require the skilled intervention of an occupational therapist. The therapist helps the patient focus on areas that are identified as meaningful and supports the development of strategic plans to problem solve and develop new methods to perform tasks.⁵

Retention

Retention of learning involves the storage of information for later use in familiar situations. To retain learning, retrieval practice is used to promote long-term retention of learned information. Retrieval or skill practice requires several processes⁶: monitoring of learning, cumulative learning, and strategy development and utilization. Monitoring of newly learned information is a repetitive process in which the patient identifies whether the desired performance skill is being enhanced. Cumulative learning is the solidification of knowledge by practicing new skills in familiar and novel situations. Strategy development and utilization involve the generation and application of tools and cues to enhance desired performance skills.

Transfer

Transfer of skills is the application of previously learned knowledge to a new task or activity.⁵ An example of skill transfer occurs when an older adult with memory problems attempts to learn use of a new microwave whose control panel is similar to an older model that no longer works. Because most of the new microwave panel functions are the same as those on her old microwave, she is able to transfer her previously learned skills more easily. Another example involves a young adult with traumatic brain injury who attempts to learn tablet and touch screen computer use. Because the patient has already learned the performance skills of pinching, swiping, and double tapping needed to use a

smartphone, he can transfer those skills when learning digital tablet and touchscreen computer use.

Generalization

Generalization refers to the ability to take a newly learned skill and apply it to a variety of real-life situations.⁷ One example of generalization occurs when a patient who experienced a spinal cord injury attempts to relearn driving using adaptive vehicle equipment. The patient often begins training in a clinical setting, perhaps with a virtual platform. Once motor skills required for adaptive driving are learned in the clinical setting, the patient must then apply these skills while behind the wheel of a real adapted automobile. The patient will typically begin to drive the adapted vehicle in a minimized setting such as a parking lot. Once preliminary skills are mastered, the patient then begins driving on roads with lesser traffic before attempting heavily trafficked roads. Similarly, a patient with a traumatic brain injury learning strategies for self-administration of medication may begin by sorting multiple medicines into a medication container, then progress to identifying and sorting her own medicine with supervision, and finally to sorting medications independently while at home. It is not sufficient for patients to learn segregated components of a task in contrived environments. Patients must practice and apply newly learned performance skills in real-life occupations and settings.

Applying Teaching and Learning Theories in Occupational Therapy

This section addresses the application of specific teaching-learning theories in greater depth and relates them to occupational therapy practice.

Model of Mastery

Using a constructivist approach, Meichenbaum, a cognitive psychologist, developed a model of mastery that has been widely used in cognitive behavioral training and theoretically influenced the development of the Cognitive Orientation to daily Occupational Performance⁸ (CO-OP) approach in occupational therapy. The model of mastery⁹ states that as part of human development, an individual must learn new skills and concepts, sets of strategies to apply the skills and concepts, and strategies to accomplish tasks independently. As a highest order in the model of mastery, Meichenbaum⁹ asserted that task learning involves:

1. Specification of the goal
2. Developing a plan of actions or procedures
3. Actual implementation of a task
4. Evaluation of the outcome's success

This four-step process of task performance was adapted as the Goal-Plan-Do-Check⁸ global problem-solving strategies in the CO-OP approach. This teaching-learning process involves a facilitative and iterative process of:

1. Specifying the goal (Goal)
2. Creating a plan of action (Plan)
3. Implementing the task (Do)
4. Evaluating the outcome (Check)

For example, using the four-step process, a therapist teaches a patient with right-sided arm weakness to relearn how to trim nails with a nail clipper (see Fig. 4-1). The therapist facilitates the patient to:

Figure 4-1 A therapist teaches a patient with right-sided arm weakness to relearn nail trimming with a clipper.

1. Identify the task-specific goal: “I will trim the nails of my left hand using my weak right hand.”
2. Create a plan to complete the task: “I will use the three strategies of (a) an adapted nail clipper that is stabilized on a counter; (b) positioning my right arm, forearm, and hand appropriately for the task; and (c) adjusting my left hand finger position as my nails are being trimmed.”
3. Perform the task following the plan: “I will now complete the task using all three strategies.”
4.
 - a. Evaluate the outcome: “I was able to clip the nails of my left hand in 25 minutes but feel extremely tired afterward,” and
 - b. Generate opportunities for learning task performance more efficiently: “I may need to choose a counter with a better height. I need to reposition the distance of the stabilized clipper so that it is closer to me. I need to learn a different right hand grip to help with clipping. I need to take a quick hand stretching break.”

According to the model of mastery, a skill has been mastered when the individual demonstrates the ability to perform the skills, incorporates the skills when planning and implementing new tasks, and solves problems that may arise in the course of using the skills in various tasks.

Teaching Thinking: Facilitating Metacognition

Within the teaching-learning process, it is important that patients become agents of change in the therapeutic context. Instead of merely becoming passive participants in the therapeutic process, patients should take an active role in treatment. Occupational therapists must use facilitative rather than instructive techniques to help patients problem solve and transfer learned skills to a variety of occupational participation contexts. To be able to assume the role of change agents, occupational therapists may need to facilitate **metacognition** in the patients and families they serve. Meichenbaum¹⁰ defined metacognition as the individual’s awareness of his or her own level of cognition—in other words, the conscious awareness of one’s thinking processes and the ability to relate to these processes in some way. Metacognition also involves the ability to control one’s cognitions—for example, planning cognitive tasks, developing strategies to learn cognitive tasks, and monitoring the quality of task performance. Meichenbaum developed guiding principles for teaching thinking skills, which are adapted below for use in the therapeutic context.¹⁰

Learning Is a Sustained, In-depth Process that Occurs Over Time and Requires Feedback

Learning new skills or relearning previously learned skills is an iterative process that requires time and ongoing feedback. Both the occupational therapist and the patient must appreciate progress in small increments and understand that certain skills require longer time for mastery. To ensure motivation and facilitate a sense of mastery and competence, the occupational therapist must use occupational analysis to break down tasks and skills into smaller components so that mastery is achieved.

The Patient Is a Collaborator in the Process of Change

The patient is a collaborator and the central agent of change in the therapeutic process. The occupational therapist must learn to master facilitation instead of directly teaching patients skills and concepts. The patient must learn to develop and modify strategies to master a skill and use both strategies and skills in a variety of contexts.

Learning of Strategies Must First Be General in Nature and Can Be Applied in Various Contexts

Begin the learning process with the use of **global strategies** that are more general, before using more **domain-specific strategies** that are specialized.⁸ Global strategies are an array of cognitive strategies that focus on facilitating or improving performance that is task-, patient-, or situation-specific.⁸ For example, when teaching a patient how to chop vegetables, the occupational therapist first facilitates global learning strategies such as identifying proper safety precautions, awareness of body positioning relative to materials and tools, and self-monitoring the speed needed for chopping (see Fig. 4-2). Once global strategies are comprehended, the therapist can then facilitate the learning of domain-specific strategies—for example, how to chop distinct types of vegetables, use various kinds of knives, and employ different styles of chopping.

Figure 4-2 A patient learns the use of global strategies such as proper and safe positioning when chopping vegetables.

Learning Is Facilitated through a Reflective Process

Meichenbaum suggests using a coping approach¹⁰ when teaching thinking, learning, and relearning skills. A coping approach involves the facilitation of a patient's awareness of perceived thoughts and feelings during task performance. In the therapeutic context, for example, the therapist can ask about the patient's perception of the task's difficulty level, the quality of task performance, how performance can be improved, what supports the patient's need to enhance performance, and the patient's performance satisfaction level.

Learning Must Be Integrated within the Patient's Recovery and/or Development Process

When learning complex skills and tasks, the occupational therapist must integrate the teaching-learning process within the patient's developmental process or recovery. For example, for a youth with developmental delays, it may be necessary to develop prerequisite in-hand manipulation and fine motor integration skills before he or she will be able to manage buttons and different fastener types during dressing tasks. For an adult who had multiple surgeries after a vehicular accident, using activities that may require several steps and complex cognitive skills may need to be delayed until postoperation disorientation and memory difficulties subside. Here, skills in occupational analysis and task gradation are required.

Use of Carefully Selected Tasks Should Be Graded with Increasing Levels of Complexity and Difficulty; Tasks Used in the Therapeutic Context Should Actively Involve the Patient and Facilitate Learning

Similar to the principle of integrating learning within the context of development and recovery, the patient and occupational therapist must carefully select activities with increasing levels of complexity to facilitate mastery and competence. Activity selection and gradation require an iterative problem-solving approach to determine the just-right challenge. Depending on patient needs, some situations might require slightly easier or slightly more difficult activities to keep the patient engaged and motivated to participate in the therapeutic context. The occupational therapist must also make sure that activities are not selected for the patient, but rather involve the patient in the selection and grading of activities. The occupational therapist can use facilitative prompts such as “You did that activity really well. What can you do to make that a little more challenging?”

Training Must Use Natural and Multiple Contexts

To facilitate transfer and generalization of learned skills and concepts, the occupational therapist must allow for practice of skills through the use of various activities, natural contexts, and multiple scenarios. Although it may be difficult to use natural contexts in certain practice settings such as acute care facilities and outpatient clinics, the occupational therapist must use similar or actual items used by the patient in daily life. For example, the occupational therapist can use the patient’s actual clothes for buttoning or managing fasteners; use the patient’s actual self-care products for grooming; and incorporate the patient’s family members and friends in social occupations (such as cooking or recreation). Allowing patients to use their own materials, tools, and social support members can facilitate better transfer and generalization of learning, than merely using simulated activities and contrived contexts.

Assessing Patient Learning Capacities

Because every patient is unique, it is critical to understand each patient’s distinct learning needs in order to successfully teach targeted skills in a therapeutic setting that enable occupational participation in real-life contexts. Occupational therapists formally and informally assess the learning capacities and needs of patients throughout the evaluation and treatment process. Therapeutic decisions are made through continuous appraisal of patients’ psychological engagement with the therapeutic activity and context.

When analyzing learning capacity, one must take into account daily human dynamics that influence learning. Moment-to-moment learning processes can be positively or negatively impacted by a myriad of factors such as biological, psychological, and situational.² For example, a patient with multiple sclerosis may experience an increase in muscular weakness because of illness, weather, or a new environment demanding changes in muscle recruitment and endurance. Performance during a treatment session may be impacted by things seemingly unrelated to the learning activities at hand. The therapist should, whenever possible, attempt to explore confounding factors when the execution of learning seems to be more challenging than expected.

Learning with Disability

Assessment of the learning abilities of patients with varying degrees of disability can be a complicated process. In some cases, the patient may have motor and/or communication limitations that make it difficult to assess whether the patient is learning the concepts taught in therapy. The occupational therapist must collaborate with the patient, family members, caregivers, and health care team members to determine the most appropriate ways to assess the manner in which the patient learns. Informal and formal assessment of learning during the treatment and evaluation processes may occur through a variety of methods including the artful practice of functional observation and occupational analysis, assessing performance during standardized tests, and using patient or caregiver interviews.

Functional Observation

The occupational therapist can assess patient learning capacities during functional observation in various tasks or occupations. The therapist can use familiar and novel tasks to evaluate the patient's capacity to problem solve; learn simple or complex skills; perform simple or multistep tasks; learn tasks in familiar or novel environments or using familiar or novel tools; and generate, use, or modify strategies to solve occupational performance challenges. The therapist should also take note of how the patient responds to the therapist's prompts, verbal and nonverbal language styles, the pace and tone when giving instructions, and the level of questions (simple vs. longer sentences) that the patient can process.

Performance in Standardized Assessments

Determining how the patient learns can be facilitated by carefully constructed questions and standardized instruments. Assessments such as the Canadian Occupational Performance Measure¹¹ (COPM) and Goal Attainment Scaling¹² (GAS) may help facilitate a conversation about learning styles. Some noted advantages of these types of instruments include their focus on occupation, patient-centered perspective and applicability to all levels of patient function.^{13,14}

The occupational therapist can also observe how the patient responds to the level and complexity of questions in standardized assessments. Because standardized instruments have been developed using uniform protocols and carefully studied sets of instructions, the manner by which the patient participates in these tests can provide information about the types of cues and prompts the patient needs to process information. This information can be very helpful in the teaching and learning process.

Patient, Family, and Caregiver Interview

The occupational therapist begins the teaching-learning assessment and process by understanding the patient's background, interests, and occupational needs. The occupational therapist generally begins by creating an occupational profile (see below). When it is not possible to gather information from the patient secondary to disability level, the occupational therapist may gather and use information from an immediate caregiver. It is important, however, to emphasize to the caregiver that in order for skills learned in occupational therapy to be generalized and transferred to the natural context, the patient must assume an active role in therapy.⁷ When gathering information from families and caregivers, the occupational therapist can inquire about the most and least effective ways to communicate with the patient, ways to motivate the patient, and contexts that are most conducive for teaching and learning (e.g., time of day, kinds of prompts, physical environments).

Using Teaching-Learning Principles in the Therapy Process

In this section, all concepts from the chapter are synthesized as six essential principles to be considered in the teaching and learning process within the therapeutic context.

Identification of Patient's Meaningful Occupational Goals

As stated earlier in this chapter, the first context for teaching and learning within the therapy process occurs during screening and formal evaluation. During this process, the occupational therapist and patient discuss occupational needs and goals by developing an occupational profile. An **occupational profile** is an initial step in the therapy process needed to gather information about the patient's activity participation and needs.¹⁵ The occupational profile is an important first step to determine what kinds of formal and nonstandardized assessments the therapist can use during the formal evaluation process.¹⁶ Creating an occupational profile is also an important first step in establishing a teaching and learning relationship with the patient. Table 4-1 provides a summary of questions to ask as part of the occupational profile and illustrates how this information can facilitate the teaching and learning process.

Table 4-1. The Occupational Profile and Teaching-Learning Process

QUESTIONS AS PART OF AN OCCUPATIONAL PROFILE¹⁵	OPPORTUNITIES FOR TEACHING AND LEARNING WITHIN THE THERAPEUTIC CONTEXT
Why is the patient seeking occupational therapy services? What are the patient's concerns regarding occupational participation?	Information gathered can facilitate discussion about the role and distinct value of occupational therapy and clarify misconceptions about what occupational therapists do. Information gathered can open conversation about the therapy process, which activities may be done during therapy, what to expect during sessions, and how the patient and important others are involved in the process.
What are strengths and barriers affecting occupational performance?	Information gathered can help the therapist understand patient skills and capacities for learning and guide the development of therapeutic instructional materials (e.g., home program instructions, activity logs, health-related monitoring/tracking sheets).
What are the patient's interests and values? What are the patient's routine, roles, habits, and patterns of occupational participation?	Information can help the therapist understand ways to facilitate patient interests and motivation during therapy, and development and selection of therapy materials and tools to help reestablish habits, roles, and routines.
How is occupational participation impacted by the patient's contexts and environments?	Information can help the therapist (1) facilitate the patient's contexts (e.g., social networks) and involve them in the teaching-learning process; (2) understand how physical environments and cultural, temporal, and virtual contexts can promote understanding about how to develop instructional materials (e.g., suggestions for home and tool modifications, time-management worksheets, how to simplify activities using apps and technologies).

Selection of Teaching-Learning Modes Compatible with Patients' Learning Capacities

Once the occupational therapist has assessed the patient's learning capacities, the therapist can then select appropriate teaching-learning modes within the therapeutic context. The following provides a summary of commonly used teaching-learning modes with examples.

Instructional Modes

Instructional modes refer to the types of media through which teaching can occur and includes visual (e.g., gestural cues, written and pictorial instructions), auditory (e.g., verbal instructions, alerting signals and alarms), tactile (e.g., cues delivered through touch, hand-over-hand guidance), and multimodal (e.g., combined verbal explanation and visual demonstration). The therapist must determine through which instructional modes patients learn best. It should be noted that a patient's preferred learning style may be compromised as a result of disability, prompting the need for alternative strategies.

Reinforcement

Reinforcement is the provision of reward or encouragement in response to patient performance and can be offered in a variety of forms including verbal (e.g., praise, redirection), visual (e.g., use of a checkmark system, smiling, positive physical gestures), and tactile or physical (e.g., pat on back, handshake). Therapists should continually reevaluate reinforcement types and frequencies that best facilitate learning for each patient.

Facilitative Prompts

Facilitative prompts are words, phrases, sentences, and questions that provide guidance when patients encounter difficulties or challenges. Such prompts are intended to promote awareness of the need to modify task performance. For example, to promote a patient's awareness of his or her need to modify grasp during an activity, therapists may use word prompts (e.g., "grip"), phrases (e.g., "check your grip"), and questions (e.g., "How well

are you holding your glass?”). Therapists should continually reevaluate the types of facilitative prompts to which patients best respond when experiencing task difficulties.

Self-Monitoring Aids

Self-monitoring aids are methods that can be used to facilitate the patient’s awareness of the need to regularly check the status of health and/or behavioral changes. Self-monitoring aids allow patients to assess health and behavioral change over time and are particularly useful for patients with memory problems. Examples include technology-based aids (e.g., using smartphone reminders to cue patients to perform blood sugar level tests or engage in periodic and scheduled movement to prevent physical complications) and activity logs (e.g., using a journal or chart to record the performance of needed activity such as self-administering medication). Therapists should continually reevaluate the types of self-monitoring materials that best facilitate carryover in clients’ natural contexts (i.e., home, school, work, community).

Guidance

Guidance refers to the provision of instruction intended to help patients modify activity performance to promote optimal function and includes modeling, verbal cues, and physical assistance. Modeling occurs when a therapist demonstrates how to perform a specific activity such as proper body mechanics when lifting boxes from the floor. Verbal cues involve the offering of short words to guide and shape behavior, such as verbally reminding the patient to bend his or her knees when lifting boxes. Physical assistance is the provision of physical cues to shape behavior, such as tapping the patient on the knees to remind him or her to bend them when lifting boxes. Therapists should continually reevaluate the types of guidance that best facilitate learning and task adaptation.

Motivational Cues

Motivational cues are prompts that the therapist offers to patients as encouragement during challenging tasks and are intended to promote perseverance: “You are doing so well, keep going!” “That seemed easy for you! Good work!” “You can do it, you’re almost there.” Therapists should continually reevaluate the kinds of motivational cues to which patients best respond when experiencing frustration or lack of interest during therapy sessions.

Therapist Support

Therapist support refers to the roles that therapists assume in the teaching and learning process. Two common roles are (1) supportive-facilitative in which the therapist avoids direct teaching and allows the patient to assume greater active control over the teaching-learning context and (2) directive-instructive in which the therapist uses an instructor approach to actively convey specific information designed to be received by the patient. When selecting supportive or directive roles, therapists should determine a patient’s readiness for change and receptivity to new information.

Addressing Patient’s Health and Reading Literacy

There are multiple accepted ideas regarding the defining, assessing, and addressing of health literacy.¹⁷ The U.S. Institute of Medicine defines **health literacy** as the degree to which individuals can obtain, process, and understand the basic health information and services needed to make appropriate health decisions. Health literacy is a process that depends on patient capacities, skills, preferences, and expectations of health information and care providers.¹⁸ Other researchers have expanded definitions of health literacy with a multidimensional component to include:

- **functional literacy** (i.e., basic reading, writing, and numeracy skills)
- knowing when to seek health information (i.e., self-identification of the necessity to seek health care services)

- knowing where to seek health information (i.e., navigating health systems)
- verbal communication skills (i.e., the ability to describe one’s health issues and understand information provided by health professionals)
- retaining and processing information skills (i.e., the ability to understand and make decisions based on health information)
- assertiveness (i.e., the ability to advocate for health needs and information)
- application skills (i.e., the ability to follow instructions and address health issues)¹⁹

Within the domain of occupational therapy, Grajo and Gutman have proposed a definition of functional literacy²⁰ that is rooted in the American Occupational Therapy Association definition of functional cognition (i.e., the thinking and processing skills needed to accomplish complex everyday activities such as home, financial, and medication management; work, school, and volunteer activities; and driving and community navigation).²¹ Functional literacy is the ability to interpret common written materials needed to effectively carry out basic daily life skills and participate in meaningful occupations and social roles.²⁰ Grajo and Gutman assert that functional literacy must be part of occupational therapy evaluation and intervention.

To optimize the teaching and learning process, occupational therapists must assess the patient’s functional and health literacy skills. Various quantitative and mixed-methods assessments are available for health care professionals to assess patient health literacy. A systematic review details different assessments including²²:

- Short Assessment of Health Literacy—Spanish and English (SAHL-SE)²³: a 32-item reading test in Spanish and English.
- All Aspects of Health Literacy Scale (AALS)²⁴: addresses four items on functional health literacy, three items on communicative health literacy, four items on critical health literacy, and three empowerment items.
- Medical Term Recognition Test (METER)²⁵: contains 40 medical words and 40 nonmedical words.
- Rapid Estimate of Adult Literacy²⁶: contains 125 medical terms taken from printed patient education materials; regarded as one of the most widely used health literacy assessments.
- Test of Functional Health Literacy in Adults (TOFHLA)²⁷: a 50-item reading comprehension and 17-item numerical ability test using actual hospital materials; regarded as one of the most widely used health literacy assessments.

Table 4-2 provides an overview of how occupational therapists can seize teaching and learning opportunities within the therapeutic context based on formal and informal assessments of patients’ functional and health literacy.

Table 4-2. Teaching and Learning Opportunities after Assessment of Patient Health and Functional Literacy

HEALTH AND FUNCTIONAL LITERACY COMPONENTS^{19,20}	IMPLICATIONS ON THE THERAPEUTIC TEACHING-LEARNING PROCESS
Functional literacy	The occupational therapist can support development of and teach functional literacy skills as they relate to basic and instrumental activities of daily living and community participation.
Knowing when to seek health information	Within the context of health promotion and disability prevention, the occupational therapist can teach the client, family, and caregivers about causes and symptoms of illness or disability and how to gather information using online and community health resources.
Knowing where to seek health information	The occupational therapist can teach the client, family, and caregivers about different roles of the health care team and what kinds of questions to ask their health care team related to one’s condition.

HEALTH AND FUNCTIONAL LITERACY COMPONENTS ^{19,20}	IMPLICATIONS ON THE THERAPEUTIC TEACHING-LEARNING PROCESS
Verbal communication skills, retaining and processing health information skills, assertiveness with health professionals	The occupational therapist can teach the patient assertiveness and self-advocacy skills to facilitate skills in navigating the health care system, knowing how to ask the right questions related to health and well-being, and how to seek more information about one's health.
Application skills	The occupational therapist can teach the patient how to follow health care instructions and learn to embed health care practices into one's habits and routines (e.g., learning to schedule regular doctor's appointments; learning to include a healthy balance of exercise, leisure, and rest within a work week).

Assessing Patient's Readiness for Behavioral and Lifestyle Change

Another important consideration in optimizing the teaching and learning process within the therapeutic relationship is assessing the patient's readiness for health behavior and lifestyle change. Motivation is a critical dimension in influencing patients to seek, comply with, and complete treatment.²⁸ Change, just like recovery, is a process. One model of change commonly used in rehabilitation is the Transtheoretical Model of Change.²⁹ Prochaska's model specifies four stages:

1. **Precontemplation:** the stage in which the individual is not intending to take action in the foreseeable future.
2. **Contemplation:** the stage in which people are intending to take action in the next 6 months; a stage marked by considerable ambivalence.
3. **Preparation:** the stage in which an individual intends to take action in the immediate future.
4. **Action:** the stage in which the individual has made specific, overt modifications in his or her behavior within the preceding 6 months.

Illness, disease, and disability are marked by life-altering changes that require adaptation.³⁰ Assessing the patient's readiness to change health behaviors is an iterative process that has direct implications for the ways through which therapists must use teaching and learning approaches. One evidence-based approach that can be integrated in the teaching-learning process is the use of motivational interviewing. Motivational interviewing is a client-centered counseling style designed to elicit behavioral change by assisting patients to explore and resolve ambivalence to desired change.³¹ A systematic review and meta-analysis found that motivational interviewing in clinical settings effectively helped patients change their behavior and outperformed traditional advice-giving in approximately 80% ($n = 72$) of studies.³² Essential components and principles of motivational interviewing include the following³¹:

- The patient's intrinsic values and goals should be identified to facilitate behavior change.
- Motivation to change should be elicited from the patient and must not be imposed.
- The patient should receive assistance to better understand the perceived benefits and costs of health behavior change by eliciting, clarifying, and resolving his or her ambivalence to change.
- Readiness to change is not a patient trait, but a fluctuating product of interpersonal interaction.
- Resistance and "denial" may signify the need to modify motivational and teaching strategies.
- Central in health behavior change is eliciting and reinforcing the patient's belief in his or her ability to succeed.
- The therapeutic relationship is a partnership based on respect for patient autonomy and must be patient centered.

Structuring the Environment to Facilitate Learning

The patient's physical and social environments, and various occupational performance contexts, may significantly influence the teaching and learning process. This process may involve the following aspects, among many others:

1. **Identification of sensory qualities needed to best facilitate occupational performance in specific environments** (e.g., the patient may work best in a room that is not too cold and has natural lighting and limited distraction)
2. **Use of social and temporal contexts** (e.g., the activity is best performed in the morning with the patient's significant other)
3. **Modifying and adapting features of the physical environment** (e.g., the patient's bathroom door entrance needs to be widened to accommodate the patient's permanent need for a wheelchair)

Feedback and Practice

Feedback and practice are essential components of teaching and learning in occupational therapy. Feedback provides patients with information needed to correct errors on subsequent practice trials. Therapists select specific feedback types and schedules when shaping a patient's learning experience. This section presents an overview of definitions and examples of feedback and practice using different paradigms. A more in-depth discussion of feedback and practice as it relates to motor learning is discussed in Chapters 15 and 16.

Feedback Based on Availability to Learner

- **Intrinsic feedback** is information that is available to the patient based on his or her own sensory systems. For example, the patient observes the position of her arm and hand while holding the spoon and bringing it to her mouth.³³
- **Extrinsic feedback** is information that is supplemental to intrinsic feedback. For example, the therapist verbally cues the patient to visually monitor her arm movement when using the spoon during feeding.³³
- **Knowledge of results** is a form of extrinsic feedback in which the outcome of the movement serves as feedback. For example, the patient observes the placement of the spoon relative to her mouth when her shoulder is abducted and internally rotated.³³

Feedback Based on Sensory Modes

- **Visual feedback** is information derived from the visual-perceptual senses.³⁴
- **Auditory feedback** is information derived from the auditory senses.³⁴
- **Haptic feedback** is information derived from a combination of physical assistance and guidance (tactile, proprioceptive, kinesthetic).³⁴
- **Multimodal feedback** is information derived from a combination of visual, auditory, and multimodal feedback.³⁴

Various Definitions of Practice

- **Massed versus distributed practice** refers to the differences in practice time and rest time. In massed practice, patient practice time during trials is greater than rest time. In distributed practice, rest time between practice trials is equal to or greater than the amount of time for the entire trial.³³
- **Constant versus variable practice** refers to practice in which training conditions (e.g., speed, number of repetitions) are either constant or variable.³³
- **Random versus blocked practice** refers to practice in which the order of tasks is constant and ordered (blocked), or occurs in irregular patterns (random).³³

- **Whole versus part training** refers to practice in which the activity is completed fully (whole) or is broken down into smaller steps (part).³³
- **Mental practice** is the performance of a skill using imagination with no action involved.³³

Summary

Teaching and learning are essential components of daily occupational therapy practice. The teaching-learning process is a collaborative process that is patient centered and involves the patient's important social networks and interprofessional health care team members. Teaching and learning approaches are driven by patient characteristics and needs, rather than assuming a one-size-fits-all approach. The teaching and learning process must integrate various information gathered throughout the therapeutic context such as the patient's occupational profile; health and functional literacy; patient, family, and caregiver learning modes; and feedback from the patient's occupational contexts and environments.

CASE STUDY

Patient Information

Dereque is a 22-year-old African American male with mixed quadriplegia (spasticity with dystonia) who participates in a day program at a community center for adults with cerebral palsy. The program houses an assistive technology center that is staffed by an occupational therapist and offers specialized training in assistive technology for greater home and community independence. Dereque's mother, Anelia, is his legal representative and provided medical information during the occupational therapy evaluation. Dereque uses a manual wheelchair pushed by a family member to access his home and community. Previous neuropsychological testing from high school revealed that Dereque has an IQ of 84, which is within the low-average range.

Assessment Process and Results

Dereque attended the initial evaluation while in his manual wheelchair, pushed by his mother. His occupational therapist began the assessment by developing an occupational profile. The therapist remained seated to maintain eye-level contact with Dereque. When his response was difficult to understand, Anelia answered for him. The therapist asked for Dereque's permission to obtain his medical history from his mother; Dereque nodded in agreement. Anelia explained that Dereque understands all spoken words, but has difficulty clearly forming words because of dysarthria. Anelia stated that as a result, people often do not wait for Dereque's answers and have habitually made decisions for him. This feedback signified to the therapist that she should facilitate learning situations during treatment in which Dereque would have the opportunity to direct the activities and select relevant goals.

Several assessment methods were used including range of motion (ROM) measurements, the Modified Ashworth Scale³⁶ (MAS) to measure upper extremity tone, the Modified Tardieu Scale³⁷ to measure velocity-dependent spasticity, and the COPM to aid in goal setting. Although Dereque responded well during testing, he demonstrated a startle reflex when touched for ROM without a verbal warning from the therapist. The therapist learned that she needed to provide prewarning prompts before touching him.

During information gathering for the occupational profile, the therapist learned of several factors that may hinder occupational engagement:

- **Physical:** Dereque was unable to independently access his home and community because of his current wheelchair.

- *Social*: Because he depends on his family for all activities of daily living (ADLs) and environmental access, participation in peer activities was limited.
- *Personal*: Dereque's opinion or preferences were often overlooked because of insufficient means to communicate. Peers often perceived him to have intellectual impairment because of dysarthria.

Occupational Therapy Goal List

Dereque and his mother developed goals using the COPM.¹¹ They discussed specifics about his daily routines and interests, including identifying his favorite activities of watching football and television with his siblings. Dereque stated that he also enjoys Friday dances at the community center with his girlfriend. Among other identified goals, Dereque's main priorities included (1) beginning classes at the local community college and (2) hosting a college football game watch party with his siblings and closest friends.

Interventions

Intervention 1

Anelia mentioned that Dereque was once independent with a power wheelchair, but it was now in disrepair and he had outgrown it 4 years ago. Dereque acknowledged that he missed his power wheelchair because it allowed him to access more places at home and in the community without help. In collaboration with his neurologist and durable medical equipment (DME) provider, all agreed that it was advantageous to pursue obtaining another power wheelchair.

When Dereque's power wheelchair was delivered, Anelia attended each session to understand how to grade the activity. Because Dereque was essentially relearning how to drive a power wheelchair, the occupational therapist broke the task into small parts during the learning acquisition phase. She used a multimodal instructional approach that included visual, auditory, and tactile feedback. Dereque first learned to propel forward and backward, and left and right using a head array drive system (i.e., drive controls operated by pressure sensors in the headrest). The learning approach was initially introduced as constant and blocked practice, and later modified with increasing complexity of varied wheelchair speeds with random directional commands from the therapist. Anelia was taught how to manage the different wheelchair drive controls and how to engage/disengage the batteries.

After approximately 2 weeks, the occupational therapist accompanied Dereque on community outings. This provided Dereque with the opportunity to transfer skills from the clinic to the community and included navigation of the college campus. The therapist also provided verbal and written instructions of practice activities for wheelchair use in the community and home.

Intervention 2

Dereque used a touch screen augmentative communication device (ACD) provided several years earlier by his high school. He had limited carryover at home because his family was not familiar with the steps needed to program the device, and many of the activities were related to high school coursework rather than daily activities. Additionally, Dereque often became frustrated with the device because he would miss the target picture needed to communicate a specific need. He also was not particularly interested in most of the items on the device (e.g., course subjects from high school), which further limited carryover at home. The occupational therapist and Dereque jointly problem solved to identify the best method to access the device by trialing a variety of methods. They discovered that touch using his fingers was not the best option. Integrating the device controls into his wheelchair head array was also

cumbersome because it was difficult for Dereque to process the multiple steps required to navigate between the wheelchair drive controls and the communication device controls. After several trial-and error periods, the occupational therapist and Dereque discovered that eye gaze (using his eyes to select the target picture) was the best option. Dereque initially appeared to be unclear about various steps needed to use eye gaze control. The therapist worked with Dereque to clarify ambiguous steps and discussed the importance of making more challenging steps with each session. She often asked for his feedback about how he perceived his level of satisfaction by asking questions such as “How do you think you did?” and “Was that easy for you?”

Additionally, the therapist and Dereque used COPM results to guide the selection of activity options for the device, such as music, television channels, and favorite restaurant choices. Dereque’s family members were also trained in the steps to add new choices as needed. A digital page was created in the device for Dereque’s medical needs, such as medication times and doctor appointments, so that Dereque could begin self-advocating his health care needs.

Although Dereque was discharged from occupational therapy services, he continued to go to the community center and often visited the assistive technology lab to participate in adaptive gaming with several friends. He was proud to show that his device was now programmed (by his father) to control Dereque’s television controls and bedroom and bathroom lights. Dereque was also consistently using the device and his power wheelchair to independently access his home and participate in community activities. He plans to begin college in the following fall semester.

Evidence Table for Interventions Using a Strategy Training Teaching-Learning Approach

Intervention	Intervention Description	Participants	Dosage	Research Design And Evidence Level	Benefit	Statistical Significance And Effect Size
Occupation-based strategy training to improve occupational performance of adults with traumatic brain injury ³⁸	Adapted intervention of the CO-OP	Thirteen adults with traumatic brain injury (7 = treatment group; 6 = control group)	Two 1-hour sessions for 10 weeks	Partially randomized controlled trial. Level I	Increased performance and satisfaction in identified occupational goals and transfer of learned skills in real-world environments	Treatment group reported increased performance on occupational goals ($t = 2.36$; $p = 0.04$); increased satisfaction with occupational performance ($t = 2.67$; $p = 0.03$).

Intervention	Intervention Description	Participants	Dosage	Research Design And Evidence Level	Benefit	Statistical Significance And Effect Size
Strategy training and behavioral intervention to improve occupational performance and reduce apathy in adults with stroke in inpatient rehabilitation ³⁹	Occupation-based training with use of the Goal-Plan-Do-Check strategy training approach	Thirty adults with stroke (15 = strategy training; 15 = reflective listening approach)	One session per day, five times a week in addition to regular inpatient rehabilitation	Secondary analysis of a randomized controlled trial. Level I	Decreased level of poststroke apathy for participants	A significant group time interaction ($F = 3.61, p = 0.040$) indicated that changes in apathy symptom levels differed between groups over time. The magnitude of group differences in change scores was large ($d = 0.99, t = 2.64, p = 0.013$) at month 3 and moderate to large ($d = 0.70, t = 1.86, p = 0.073$) at month 6.
Use of cognitive interventions to improve executive functions during daily task performance ⁴⁰	Two interventions were compared: use of strategy training using the CO-OP approach and computer-based executive function training	Nine adults with stroke (5 = CO-OP training; 4 = computer training)	Sixteen training sessions for 1 hour each	Randomized controlled trial. Level I	Increased performance and satisfaction in occupational performance with transfer of skills learned in real-world settings; increased self-efficacy was higher in CO-OP group	Both treatment groups showed large improvements in self and significant other rated performance and satisfaction with performance on their occupational goals immediately postintervention and at follow-up (CO-OP: ES = 1.6–3.5; COMPUTER: ES = 0.9–4.0), with statistically significant within-group differences in CO-OP ($p = 0.05$).
Cognitive strategy and task-specific training to improve cognitive flexibility, upper extremity use, and reduce stroke impact in adults with stroke ⁴¹	Use of the Goal-Plan-Do-Check strategy of the CO-OP approach during occupational performance	Twenty-six adults with stroke (14 = CO-OP training; 12 = usual care)	Varied; data monitored when participants were discharged or received 10 sessions	Exploratory single-blind randomized controlled trial. Level I	Improved performance, cognitive skills, and arm movement in participants who received CO-OP training over usual care	At time 3, there was a medium effect for SIS Hand Function ($d = 0.6$) and the D-KEFS Trail Making subtest ($d = 0.5$).

CO-OP, Cognitive Orientation to daily Occupational Performance; ES, effect size; SIS, stroke impact scale; D-KEFS, delis-Kaplan executive function system.

Chapter 5

Clinical Reasoning and the Art of Practice

Laura Van Puymbrouck

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Define and differentiate the reasoning processes used by occupational therapists.
2. Describe the historic rationale for why the American Occupational Therapy Association (AOTA) and the American Occupational Therapy Foundation (AOTF) implemented and supported the Clinical Reasoning Study.
3. Identify the reasoning styles that distinguish a novice from an expert therapist.
4. Describe the elements of occupational therapy approaches to evaluation and intervention that make practice an art.
5. Describe and differentiate between problem-based and experiential learning.
6. Understand how problem-based and experiential learning facilitate professional reasoning in occupational therapists.

CHAPTER OUTLINE

Introduction
History and Background of Clinical Reasoning in Occupational Therapy
Definitions and Descriptions of Clinical Reasoning in Occupational Therapy
Developing an Art of Practice through Clinical Reasoning
Areas for Future Study
Conclusion
Case Study

TERMINOLOGY

Clinical reasoning: the thinking processes used by occupational therapists when planning, conducting, and reflecting on their practice.¹

Decision making: the cognitive process by which one makes a choice among two or more alternatives.²

Judgment: the cognitive process by which a person appraises a situation and determines the best course of action to take.²

Problem solving: the cognitive process by which one sequentially identifies a problem, interprets aspects of the situation, and selects a method to alleviate the problem.²

Professional reasoning: the thinking process used by occupational therapists inclusive of occupational therapy practices that extend beyond traditional settings to include those based in nonclinical settings such as schools, workplaces, or community programs targeting occupational performance; highlighting the overarching occupational lens used in reasoning unique to the profession.³

Reasoning strategies: methods or approaches to reasoning or the selection of a structure or organization for one's reasoning process.²

Introduction

During therapeutic evaluation and intervention, a therapist must identify and frame problems and make immediate choices based on the client's needs and the specific context of the interaction.⁴ How does an occupational therapist analyze the person, the environment, and the task to make the many clinical decisions that will result in the best outcomes for clients? This question has been the basis of inquiry in the profession since Joan Rogers highlighted the concept of clinical reasoning in her Eleanor Clarke Slagle lecture in 1983.¹ In this lecture, Rogers emphasized the importance of understanding the artistic as well as the scientific and ethical dimensions of clinical reasoning that distinguish occupational therapy from other medical and allied health professionals.¹ This, plus seminal work from Schon⁴ examining the tacit knowing of therapists, ignited excitement and interest in the profession for research exploring these dimensions and ultimately drove the impetus for the Clinical Reasoning Study⁵ sponsored by the American Occupational Therapy Association (AOTA) and the American Occupational Therapy Foundation (AOTF). This effort resulted in a special issue in the *American Journal of Occupational Therapy* (AJOT) in 1991 that included articles describing the findings of the study. This special issue provided the basis for much of the profession's understanding of therapists' clinical reasoning and laid the groundwork for

subsequent research. This body of work recognized the symbiotic qualities from both science and art as they guide our professional ethos⁶ and have evolved to define and describe our commitment to client-centered and client-driven occupation-based evaluations and interventions. However, fully understanding how therapist reasoning impacts the development and maintenance of a client-centered therapeutic relationship that optimizes client outcomes continues to be an area of necessary research exploration.^{7,8,9}

History and Background of Clinical Reasoning in Occupational Therapy

What Is Clinical Reasoning?

Allied health professions' clinical reasoning research has traditionally been medically oriented with a focus on understanding the logic and cognitive processes of a therapist informed by scientific knowledge of diagnostic pathways and procedures with evidence base that align with the profession's purpose.¹⁰ The Occupational Therapy Practice Framework (OTPF)¹¹ defines the occupational therapy profession's **clinical reasoning** as "the process used by therapists to plan, direct, perform and reflect on care."¹² The framework further emphasizes clinical reasoning as a key component to developing and managing the therapeutic relationship as the therapist works to help clients process, make sense, and invest in the therapeutic experience.^{11,13} Clinical reasoning is described as a core element of practice that includes scientific knowledge, reflection, and intuition that links professional research with clinical practice¹⁴ and a necessary skill in order for an occupational therapist to be successful.¹⁵ However, the processes therapists use can be heavily informed by temporal and spatial influences of the current conditions in which the profession exists.¹⁶ Naming clinical reasoning as **professional reasoning** extends the reasoning that occupational therapists use to include those contexts outside the clinical environment such as community-based practices.¹⁷ Whatever the clinical context, the fundamental processes that occupational therapists move through during assessment, analysis of information from the client, problem identification, and selection of intervention design specific to the client are clinical and professional reasoning distinctive to occupational therapy.¹⁵ Understanding these distinct elements is vital to supporting their development for the individual therapist and more broadly for the profession as a whole.

Historically, occupational therapy has grappled with the challenges of weaving scientific biomedical evidence-based knowledge and

social, humanistic, clinically acquired knowledge that explains all aspects of a therapist's clinical reasoning.¹⁴ Efforts to embrace a professional identity that moves beyond biomedical and impairment-based **problem solving** to client-centered practice demand therapists use knowledge informed by more than a scientific medical model evidence base in their decision-making strategies. One of the primary purposes of the Clinical Reasoning Study was to identify and distinguish the unique processes of reasoning used by occupational therapists compared to health professions informed by more of a purely biomedical stance.²

Clinical Reasoning in Occupational Therapy

Rogers states in her seminal Slagle lecture, "The goal of clinical reasoning is to make treatment recommendations according to the best interests of a client."¹ Rogers further describes the process therapists move through as being grounded by their own conceptual frame of reference that guides how they perceive the client, the environment, and client occupations. Her description highlights how therapists' individualism informs their choice of tools for crafting their own therapeutic approach. This individuality allows for the personal background, culture, beliefs, and assumptions of the therapist to have a determinant effect on the outcomes of the clinical reasoning process.¹⁸ These influences can shape what the therapist identifies as important, affect the meaning they are given, and inform the decisions made for evaluations and interventions.¹⁷ Broader perspectives and past experiences clearly contribute to what the therapist brings to the reasoning process as well as extends appreciation for the influences of the therapist's theoretical stance and appreciation for ethical influences. So, what are the perspectives and experiences that contribute to developing a therapist's broader worldview that might promote expertise in clinical reasoning and optimize therapeutic outcomes?

On a daily basis, occupational therapists make clinical decisions regarding the clients' needs during therapy, the clients' outcome potential, and how to make recommendations to enhance occupation. Scientific reasoning is the foundation of many medical and health professional diagnostic and problem-based decision making. However, occupational therapy has a unique clinical or profession-based reasoning described by the findings of the Clinical Reasoning Study⁵ as relying on several sources of cognitive reasoning processes. These include: procedural, interactive, conditional⁵ and pragmatic¹⁹ modes of thinking used by a therapist when attending to client and contextual factors. Fleming² extended

clinical reasoning from these more cognitive-based processes to embrace a narrative story line that includes contextual factors therapists use to influence interactions with clients.

Research describes that procedural, interactive, and conditional modes of reasoning account for the majority of thinking processes used by therapists.²⁰ However, the focus of the therapist whether it be a more biomedical lens or psychosocial lens appears to inform the mode of reasoning.^{2,20} Occupational therapy scholars suggest different preferences for modes of thinking and clinical reasoning may be dependent on the exposure to different academic stances during the educational process as well as during clinical learning experiences.⁸ Seven different modes of thinking (scientific, procedural, interactive, conditional, narrative, pragmatic, and ethical) and their specific process characteristics are described in the following sections of this text and summarized in Table 5-1.

Table 5-1. Definitions of Reasoning Approaches

REASONING APPROACH	DEFINITION
Scientific Reasoning	A cognitive process of problem solving that involves critical thinking in relation to content, procedural, and epistemic knowledge. ²¹ Uses diagnosis, impairment, and evidence-based approaches to inform decision making.
Procedural	A process of reasoning informed by clinical pathways or routines traditionally used by a therapist to improve function. Procedural reasoning stems from the scientific knowledge and evidence-based practice patterns that provide generalizable approach strategies for a client with a specific diagnostic presentation.
Interactive	Recognizes the client as expert in their own lived experiences and as such produces a process of interactive reasoning to collect critical information on the contexts of their lives and occupations of importance.
Conditional	Multifaceted and multiperspective reasoning process used to understand clients' needs to address potential shifts in identity because of changes in functional capacity. ² Reasoning that incorporates flexibility in responding to the client's ever-changing upstream as well as downstream concerns.
Narrative	"Narrative thinking is the primary way of making sense of human experience." ⁶³ Reasoning informed by knowledge gathered through listening to, reflecting on, and empathizing with the client to paint the picture for developing a client-centered intervention plan.
Pragmatic	Decision making that works within the parameters of the clinical as well as the social restriction of the context, the client, and therapist that includes time, place, and availability of resources. Can create dilemmas in clinical reasoning that force "underground" practices. ⁵
Ethical	In the moment or bigger picture knowledge that creates a conundrum in reasoning among client-centered care, social justice, and administrative or structural barriers.

Definitions and Descriptions of Clinical Reasoning in Occupational Therapy

Scientific Reasoning

Scientific reasoning is a cognitive process of problem solving that involves “critical thinking in relation to content, procedural, and epistemic knowledge.”²¹ It is a fluid process embedded from the onset of an occupational therapy referral, throughout evaluation and intervention and during discharge planning. Because of the increasing emphasis on evidence-based practice in all disciplines of medicine and allied health professions, it is also described as an essential skill for a therapist to develop over the course of his or her professional education.² Scientific reasoning is typically only one part of a therapist’s reasoning process because it does not include factors that ultimately influence decisions such as client factors or therapist experience. This approach to clinical problem solving is associated with focusing strictly on the biomedical diagnosis of a client using a hypothetical-deductive model of reasoning.²² Scientific reasoning explores the context of a problem including the state of the identified issue of concern, the end goal, the means to the end, and the action steps required to move from the current state to the goal state.²³

Occupational therapists evaluate the many client factors that impact a given occupational role and use scientific reasoning to understand action steps necessary to achieve the identified goals. At times, the logic and evidence of scientific reasoning may suffice in directing clinical decision making, although more often than not occupational therapists take additional steps to understand more holistically how client factors define an occupational diagnosis.¹⁰ The research findings of the Clinical Reasoning Study highlighted that clinical reasoning processes of occupational therapy do indeed extend beyond the hypothetical-deductive lines of logic described in the scientific reasoning literature from other medical professions to incorporate a shift that attends to occupational engagement.¹⁶

Procedural Reasoning

Procedural reasoning stems from the scientific knowledge and evidence-based practice patterns that provide generalizable approach strategies in intervention design on what to do and when to do it with a client with a specific diagnostic presentation. This vein of reasoning is in fact closely linked to scientific reasoning processes.¹⁹ A therapist identifies a problem and considers what to do and how to

design or approach the intervention. It is often considered to be the reasoning approach novice therapists gravitate toward as procedural reasoning provides a more concrete strategy for analysis, synthesis, and decision making based on the disease or disability of the individual client.²⁴ However, in the early findings from the Clinical Reasoning Study, Fleming² describes how procedural reasoning is used as well by experienced therapists. This form of thinking is based on an “if this is the case, then this is what I need to do” scenario. As a result, the more experiences from which a therapist has to draw, the possibility of procedural reasoning may occur more frequently as well as automatically. Procedural reasoning was linked by Fleming² to be associated less with experience and more by concrete, tangible, or biomedical aspects of working with clients with similar diagnoses that can be woven into processes that also integrate more abstract, psychosocioemotional aspects that may require attention. Factors such as client habits, culture, and support systems as well as therapists’ experiences with the given context move the therapist from strict scientific processes that guide decisions in intervention to incorporate the intersections of scientific and experiential knowledge. For example, procedural reasoning can be more rote decision making of a therapist based on experience such as the decision of whether to use a gait belt during a client transfer. A novice therapist’s procedural reasoning for gait belt use may be to incorporate it with each client in every session. This procedural strategy for making this choice is grounded in the lack of experiential knowledge as well as documented procedural strategies for safety in client handling and mobility. The more experienced therapist may recognize client factors that inform a clinical decision that a gait belt may not be necessary (e.g., the client who is fully independent in all areas of functional mobility).

Interactive Reasoning

Prior to the Clinical Reasoning Study,⁵ the primary clinical reasoning discourse in occupational therapy aligned predominantly with the scientific, hypothetical-deductive model used by the medical professions. The rise and increased commitment to client-centered practice in occupational therapy that demands consideration of the psychosocioeconomic factors of a client led to an appreciation for those strategies in problem identification and resolution that were different. Interactive reasoning is a process the therapist uses to understand the dynamics of the context, the client, and the diagnosis in order to develop a therapeutic relationship unique to each client. This form of thinking occurs during face-to-face encounters and is

bolstered when the therapist works to create a collaborative and empathetic understanding of the client's experience. The strategies experienced therapists use in interactive reasoning processes include: (1) providing clients with choices; (2) individualizing treatment; (3) structuring the context to maximize success; (4) extending the therapeutic role to include "doing extra" for the client; (5) sharing personal experience with a client; and (6) collaborating on problem solving.²⁵ However, other researchers suggest that a highly complex process of varying strategies of interaction exists for successful interactive reasoning, potentially highly influenced by values and belief systems that might inform the process of thinking itself.² Reflective appreciation by therapists to understand how their own thinking informs their **judgments** and interactions in a therapeutic relationship has been suggested as a fundamental method for developing a refined interactive reasoning process.¹⁹

Developing efficacy for these strategies of interactive reasoning requires that occupational therapy students and novice therapists have the opportunity to practice engaging in collaborative and meaningful ways with clients to attend to the professional commitment to client-centered care. Skills of interactive reasoning depend on a therapist's basic skills of communication such as active listening and interpreting the body language of the client.¹⁵ Curricula that rely heavily on scientific and procedural reasoning, promoting a more reductionist approach to interactions with clients, may overlook clients' contexts and understanding the meaningfulness of their occupations.²⁶ Often, interactive reasoning opportunities present themselves for the first time to a student during fieldwork experiences, later in the second year of occupational therapy education,²⁴ and this is one potential explanation for why interactive reasoning is observed more often in therapists with increased experience.¹⁹

Narrative Reasoning

Interactive reasoning, while valuable and critical to establishing rapport with a client, still only considers the client's impairment in the here and now. When a therapist considers the clients' perspectives, including their culture, motives, beliefs, and values, of the meaning of the illness or disability experience, a narrative approach to understanding occurs. Narrative reasoning is described by Mattingly and Fleming as "fundamental to the thinking of occupational therapists."⁵ This narrative process is one of story-making that contextualizes the client's lived experience and offers the therapist an avenue to develop a phenomenological appreciation

of the impact of the impairment or illness. Phenomenology explores the meaning of an experience, informed by the manner a person interprets a given event, at a given time.²⁷ Narrative reasoning also involves a reciprocal process of the therapist making sense through narrative exploration of a client's scenario with other therapists. Finally, this process can include narrative meaning making of therapeutic stories cocreated with the client to evoke motivation and investment of the client in the therapeutic process. Digging deeper through narrative reasoning provides a tool for therapists to link the client diagnosis and clinical observation to the heart of what's most meaningful and motivating to a client.

Narrative reasoning is critical to understanding in two ways: (1) it helps the therapist explore the possible ways a client is making sense of the experiences of disability and of the therapy experience, foreign to the client but familiar to the therapist; and (2) it helps the therapist examine the contextual and personal factors of the client as they might relate to their past client experiences as well as from experiences of the team of therapists around them.⁵ Therapists using narrative reasoning take what they know of the general conditions of an illness or diagnosis but work to understand how this version of the experience translates to impact the people who are their clients. There is an essential synthesis of the scientific (e.g., diagnostic, prognostic) and procedural knowledge of a therapist from professional training and clinical experiences (including exposure to practice models or frames of references) with knowledge gathered by listening to, reflecting on, and empathizing with the client to paint the picture for developing a client-centered intervention plan. This, in essence, is the foundation for developing an art of practice as it blends with science to shape a clinical reasoning that is distinct to the profession of occupational therapy.

Conditional Reasoning

Conditional reasoning extends from narrative as the therapist moves beyond the person to explore the social, temporal, and material contexts of everyday life.²⁸ This is a higher level of expert reasoning identified as being employed by the therapists from the Clinical Reasoning Study. It is a multifaceted and multiperspective reasoning process that is used to understand clients' needs to address potential shifts in identity, priorities, and approaches to occupation, because of changes in functional capacity.² This might translate to understanding how changes in occupational performance because of life transitions or environmental (including social, attitudinal, informational) alterations challenge the participation strategies and

patterns to which a person is accustomed. This type of reasoning involves logical and nonlogical schemes of thinking¹⁹ by the therapist to conceive of the impact of the experience of disability and therapy on the client and how different treatment choices might shape outcomes of participation and function. Conditional reasoning in combination with narrative reasoning may push the assumptions and presumptions of the therapist if they attend to understanding the meaning and implications of impairment based on their “social context, personal priorities and resources.”²⁹ By upholding the professional commitment to client-centered care, this may dictate that the therapist redirects intervention to attend solely on assisting the person in achieving full participation versus on reducing impairment.³⁰

Fleming discussed how the term *conditional* is linked to three different meanings: the entirety of the client’s condition, the changeability of the person’s condition (physical, social, financial, etc.), and the conditional agreement that must be made for “by-in” and participation by the client of the chosen therapeutic approach.² The therapist is challenged to creatively or artfully imagine the outcome for the client when deliberating on an approach to care, bringing into the process everything the therapist can gather about the client’s physical and social world blended with the therapist’s “clinical experience and expertise.”³¹ Conditional reasoning occurs because with each iteration of therapy, the client’s worlds may have changed.

Pragmatic Reasoning

The therapist’s focus and efforts are directed at optimizing a clinical experience to achieve the greatest gains for a client in prioritized and meaningful occupations. However, the contextual factors of the clinical environment, as well as the personal factors of the therapist, to a lesser or greater degree play a role in the possible decisions that are made and therefore must factor into clinical reasoning. These influences were recognized and described by Schell and Cervero¹⁹ as the pragmatic considerations therapists attend to while processing clinical decisions. In later research, Unsworth²⁰ describes pragmatic reasoning such as reimbursement or the availability of community resources in a client’s discharge environment as being distinct from other reasoning processes therapists take into consideration. The demands of the administrative realities of therapy produce constraints and barriers that at times conflict with the tenets of client-centeredness and present conundrums that the therapists must include in their decision-making strategies. The organizational and

structural components of providing care are recognized as having a significant influence that challenge therapists' choices.^{32,33}

Pragmatic reasoning approaches consider how therapists think given their personal factors such as their values, beliefs, spirituality, and personality. These are understood to tint the worldview of a therapist by informing assumptions about clients and influencing the decisions a therapist makes regarding therapy. This worldview offers a foundation for the styles or modes a therapist may also prefer in developing a therapeutic relationship.²⁵ In fact, it has been suggested that clinical practice is largely informed by the individual preferences for approaches to care influenced by sociocultural factors.³² Unsworth²⁰ suggests that these preferences may be too implicit to understand how they shape a therapist's decisions, but critical to acknowledge in understanding professional reasoning processes. A therapist's worldview is overarching and sets the stage for how thinking, even thinking about thinking, occurs and shapes the content that is valid and reasonable for consideration in clinical decision making and how the processes of reasoning emerge, are validated, used, and reused in daily practice. Research by Unsworth²⁰ describes a subcategory of reasoning labeled "generalized reasoning" that is based on a therapist's experience and knowledge and informs or influences each of the other modes of reasoning. The knowledge and general experiences of a therapist create a reciprocal relationship between their worldview and how thinking occurs. See Figure 5-1 for a visual image of how the worldview of a therapist encompasses, influences, and is influenced by the various forms of clinical reasoning.

Figure 5-1 Clinical reasoning in client-centered occupational therapy by Unsworth. Note: Generalization reasoning (GR) is a subcategory of each type of reasoning in the model. (Reprinted with permission from Unsworth CA. Clinical reasoning: how do pragmatic reasoning, worldview and client-centeredness fit? *Br J Occup Ther.* 2004;67:17.)

Ethical Reasoning

Ethical reasoning is defined as “the frequently made decisions regarding moral, political and economic dilemmas that therapists regularly confront.”³⁴ Ethical reasoning may occur in the moment for

a therapist or emerge following a clinical experience when a therapist ponders the client's narrative story and potential futures. Ethical **decision making** in occupational therapy is grounded in professional commitments to client-centeredness, autonomy, beneficence and nonmaleficence,³⁵ and social justice.³⁶ Ethical reasoning can stem from knowledge that emerges through the narrative, interactive, and conditional processes as they intersect with scientific, procedural, and pragmatic reasoning to inform collaborative decision making. The professional commitment to client-centered care challenges therapists to attend to the broader contextual factors of clients' everyday environments and how they enable or disable participation, and as such stimulates ethical considerations of equity and justice.³⁷

Critiques such as those that occupational therapists are confined to make clinical decisions based on the client's insurance plan³⁸ expose an ethical dilemma that can present itself in climates in which productivity and quotas supplant clinical judgment of what's best for a client. AOTA recognized this and put forth a Consensus Statement on Clinical Judgment in Health Care Setting (retrieved at: <https://www.aota.org/Practice/Ethics/Consensus-Statement-AOTA-APTA-ASHA.aspx>) in conjunction with the American Physical Therapy Association and the American Speech and Hearing Association stating that therapists are "ethically obligated to deliver services that they believe are medically necessary and in the client/patient's best interest, based upon their independent clinical reasoning and judgment as well as objective data."¹¹ The need for a therapist to process decision making using ethical reasoning may appear to be an infrequent occurrence, yet this strong stance suggests those constraints that call for pragmatic reasoning might in fact be ethical dilemmas on how to stay true to our professional ethos.⁶

Developing an Art of Practice through Clinical Reasoning

Therapeutic encounters between a client and a therapist require professional reasoning that blends person-specific sensitivity and design coupled with knowledge of the science that validates the use of occupation-based interventions. It also demands that the therapist is keenly mindful of how the delivery of the intervention is ripe with meanings the client gives to the context. In Suzanne Peloquin's Slagle lecture she definitively states "effective practice is artistry and science."⁶ The art of clinical practice is dependent on understanding that moments in therapy are moments in the journey

of the client's life. The craft of this art is having the skill to blend the sciences behind occupational engagement that facilitate, educate, coach, empathize, encourage, and promote to empower and enable versus disable the client's self-determined desire to achieve identified goals. In defining an art of practice, Rogers claims "artistry involves the orchestration of broad strategies for grappling effectively with the uncertainties inherent in clinical practice."¹ This requires that the therapist not only be informed by but also look beyond the science of occupation-based interventions to embrace and embolden the spirit and the knowledge of the client. It also requires a therapist to move beyond scientific/diagnostic and procedural reasoning and incorporate narrative, conditional, pragmatic as well as ethical reasoning in their professional reasoning repertoire of practice.

Gary Kielhofner highlighted the challenges occupational therapists have as therapists in the scientific medicalized world of allied health professions by our commitment to combining scientific knowledge and judgment with artful approaches to intervention design.³⁹ He emphasized in his own model of practice, *The Model of Human Occupation*,⁴⁰ the inadequacies of a typical approach in medical models for supporting the foundation of what occupational therapy professes as its unique contribution to client care. In fact, this unique contribution has recently been identified as having a statistically significant association on maintaining health and wellness compared to other services provided in acute hospitalizations.⁴¹

How does this skillful blend of knowledge and creativity develop in a therapist? Understanding the art of practice provides a foundation for exploring the means of nurturing its development in oneself as well as in others. One of the founding theorists for clinical reasoning, Donald Schön, describes that the art of practice might be taught to all therapists if it were tangible and constant, but it is neither.⁴ Fleming³¹ describes expert therapists as they readily shift among procedural, interactive, and conditional thinking styles without losing site of the bigger perspective of the client scenario in a manner that invokes images of an artist mixing colors to achieve the image they and their client have conceived of in their minds. Unsworth and Baker's description is analogous to a dance as "professional reasoning involves all the thinking processes of the clinician as s/he moves into, through and out of the therapeutic relationship and therapy process with a client."³ This blending especially calls for the reasoning processes that allow therapists to

artistically and creatively work with clients to cultivate an image and then outcomes of participation in meaningful occupations. Intentional decisions that therapists make based on their understanding of the impact of their own verbal and nonverbal communication on achieving optimal client outcomes are skills necessary for this level of professional reasoning.

Therapeutic Use of Self in Clinical Reasoning Approaches

Deliberately responding to a client in a manner that will facilitate occupational participation and performance requires reflection by the therapist on how his or her own behaviors can be used to promote this change.²⁶ Deliberate or intentional selection of behaviors demands a thorough assessment of how the client may react in the therapeutic encounter and to the therapeutic relationship, as well as a grounded knowledge of therapists' characteristics and communication styles used during therapeutic exchanges. The Intentional Relationship Model (IRM)²⁵ is a conceptual practice model of strategies a therapist can use to enhance the client–therapist therapeutic relationship in order to optimize a client's occupational engagement. This model encourages therapists to explore predispositions to communication styles with suggestions for nurturing strengths and the development of less utilized interpersonal skills that facilitate an understanding of the intentional use of self as part of clinical reasoning.¹⁵ Developing this understanding hones and evolves a therapist toward mastering the artistry of the therapeutic relationship.

The IRM reinforces that therapists must purposely reason and make decisions on how they might respond appropriately to the client during interpersonal events in order to develop a positive relationship and foster a therapeutic experience with the client. This intentionality requires preparedness by the therapists to understand their clients' perspectives and select manners of relating to clients, or modes of interaction, informed by the contexts of the experiences. The IRM identifies six interpersonal modes therapists might consider when preparing to address the needs of a client: advocating, collaborating, empathizing, encouraging, instructing, and problem solving.²⁵ Part of the preparedness of the therapist draws upon merging clinical reasoning, based on factors from the client and context, with the knowledge on how different modes of interacting may result in different responses of the client while engaged in therapy. Therefore, therapeutic use of self crisscrosses with clinical reasoning while in preparation for therapeutic experiences but also is used flexibly in response to a client's reaction to the context of a

therapeutic event. This skillful, thoughtful, and flexible use of self is a method for weaving interpersonal **reasoning strategies** into the clinical decision making of an intervention to facilitate a client's occupational engagement.

Influence of Theories and Frames of Reference

The evidence-based approach to occupational therapy is grounded in the theories that support our profession,¹⁶ but artful clinical reasoning requires that therapists have the ability for reflection, imagination, and creativity as well as beliefs that value and respect client choice. The type of clinical reasoning that a therapist uses can be influenced by exposure in professional training to theoretical frameworks and models of practice.²⁴ Many theories that provide an organizing foundation to the professional framework of practice have common features that represent the profession's commitment to the need for an artful element in our interventions.⁴² The biomedical, restorative, or rehabilitative frames of reference may be necessary to understand the person–environment fit⁴³ and provide support to interventions to enhance functional performance, but often only require a therapist to use scientific or procedural reasoning.

Frameworks or models of practice emerging from dynamic systems theories, such as the Person-Environment-Occupation model,⁴⁴ Model of Human Occupation,⁴¹ and Person-Environment-Occupation-Performance⁴⁵ align with a more comprehensive biopsychosocial model approach to analysis and support reasoning strategies with more phenomenological modes of thinking and reflection on the client–therapist relationship. These models share in common the resolute need to look at the person, the environment, and the occupation during problem identification and decision making in interventions and because of this may stimulate the development of more advanced clinical reasoning. However, the leaders in exploring clinical reasoning recognize that having a theory, model, or frame of reference itself is insufficient to help a student learn how to judge the context and make decisions.⁴⁶

Developing and Advancing Professional Reasoning

Unsworth and Baker in a systematic review of occupational therapy literature on clinical reasoning describe that “it is only through examining the often tacit knowledge of specialists in the field that the skill and artistry of these experts can be identified, elucidated and, potentially learned and assimilated by others.”³³ The challenge for students and novice therapists is identifying methods for recognizing and translating a master clinician's knowledge in a

manner that fosters existing reasoning skills and strategies and funnel these toward the more complex models of reasoning used by skillful occupational therapists.

Research supports that clinical reasoning in occupational therapy moves through five stages: novice, advanced beginner, competent, proficient, and expert.⁴⁷In the past, it was expected that entry-level therapists would continue to develop competencies in the more advanced stages of reasoning and achieve expert reasoning with experience.⁴⁸However, there is a professional commitment¹¹ as well as probable expectations that therapists with clinical doctorate degrees enter the workforce with more fully developed strategies in advanced clinical reasoning skills and therefore a necessary focus for professional curricula.

Occupational therapy curricula are mandated by the Accreditation Council for Occupational Therapy Education (ACOTE) (available at: <https://acote.aota.org>) to focus on the development of students' clinical reasoning as part of the critical skill set necessary for good client-centered intervention design. Students learn to attend to the three levels as defined by Fleming³¹ by developing skills in: assessing impairment, understanding and empathizing with the client, and examining the client's environmental world.²⁰ Becoming a well-rounded therapist that can deftly move between and within different problem-solving and reasoning strategies requires exposure to the basic concepts of clinical reasoning as well as to the process components¹⁰ of professional reasoning. Much of the content knowledge will promote the development of scientific and procedural reasoning while process components demand that therapists use reflection, intuition, and awareness of self and others to develop the capacity for therapeutic use of self²⁵ in order to become experts in the art of professional reasoning.

One well-recognized approach that can be used to facilitating clinical reasoning is using a case-based method of real-life client scenarios with guided intervention assistance from an instructor.⁴⁹Different formats for delivering these cases include written, videotape, simulated or standardized patients, and clients who identify as having lived experiences of different disabilities.⁵⁰ Traditionally, students work to identify impairment or problems within the case and apply knowledge from the curriculum to develop strategies for intervention design. This mode of reasoning is grounded in biomedical, impairment concerns and initiates scientific and procedural reasoning strategies. Using case-based scenarios that include more than a medical model perspective of a client, such as

incorporating contexts from the client's social environment, client stories have been used to promote more client-centered and advanced clinical reasoning strategy development.⁴⁹ Researchers suggest that case scenarios with a more comprehensive format, including triggers that produce narrative or conditional thinking strategies, can be used successfully in the context of a traditional classroom setting.⁴⁹

Advancing Professional Reasoning

It is clear that a therapist's advanced repertoire for reasoning supports a mastery of the art of clinical practice. Case scenarios focusing on problem-based learning (PBL) strategies through experiential learning appear to be growing as a popular approach for advancing clinical reasoning in occupational therapy curricula.⁵¹ PBL is an adult learning approach that uses active participation and places learning responsibility on the student as a means for acquisition of new knowledge.⁵² Advanced clinical and professional reasoning strategy development has been shown to occur with the dedicated inclusion of PBL that focuses on synthesizing knowledge for practice and increasing exposure to direct client contact.²⁴

Hands-on experiential learning has long been embraced and identified as advancing clinical reasoning and critical thinking skills in students and novice therapists.⁵³ Professional training in occupational therapy has always incorporated a philosophical commitment to the necessity and importance of fieldwork education as a critical piece to developing advanced clinical reasoning skills in students.⁴⁶ This affords students an opportunity to learn from modeling master therapists with more advanced reasoning styles as they observe critical thinking in the moment and synthesize observations with guided reflection.

Schell has developed a model¹⁷ of contextual teaching for professional reasoning, describing the interaction between student and teacher or master therapist as they interact to co-construct knowledge and engage in critical reflection to understand the meaning and significance of new knowledge (see Fig. 5-2). This process can occur in a preclinical narrative or written assessment or within an authentic context of learning that may require in the moment reflection superimposed during a guided and supervised clinical encounter.

Figure 5-2 John Schell's model of contextual teaching for professional reasoning.

In order to consider the best practice options that may be used, the “reflective therapist”⁴ uses both in the moment contemplation to direct clinical decisions and critical thinking to examine assumptions leading to clinical decisions. Schön⁴ describes this process as reflection-in-action where the therapist “allows himself to experience surprise, puzzlement or confusion in a situation... and become a researcher in the practice context.” Reflection is another valuable tool recognized for advancing clinical reasoning in the student, working therapist, as well as professional education experiences.⁵⁴ Using reflection⁵⁵ and models such as the IRM²⁵ has been suggested by researchers as an area in need of further study in understanding advancing skills in clinical reasoning.³ These suggestions position the therapist to challenge themselves to explore why they know what they know, why they think what they think, as well as why they act the way they do in interactions with clients, assessing their own assumptions and clinical reasoning modes of thinking.

Recognizing Clinical Reasoning Strengths and Areas in Need of Development

There are measures and tools for students to use in recognizing their own skill sets and development in clinical reasoning. Although not a measure per se of clinical reasoning skills, the Dreyfus and Dreyfus Model of Skill Acquisition⁵⁶ provides a framework for the development of student and staff clinical reasoning that include stages of: novice, advanced beginner, competent, proficient, and expert. Research shows the model to be predictive and descriptive of

skills development from one stage to the next.⁵⁷ Developers of this model recommend that to transition from a more novice entry-level therapist to a more advanced one demands that therapists remain open to experiential learning opportunities as they occur in the clinical world. For example, exposure to real-world problems with real-world solutions provides a basis for therapists to extend their hypotheses for conditional reasoning as well as offer alternatives in pragmatic reasoning. This suggestion encourages and supports pathways for students and novice therapists to seek out mentors in order to learn those tacit skills and multiple layers of professional reasoning through observing and modeling behaviors.

The Self-Assessment of Clinical Reflection and Reasoning (SACRR) by Royeen et al.⁵⁸ is a tool developed to assess students' perceptions of their clinical reflection and reasoning⁵² as impacted by different methods of instruction. It consists of 26 self-report items related to student reflection and reasoning as measured by a 5-point Likert-type scale.⁵⁹ Although it was developed to assess students from all allied health professions, it has primarily been used in occupational therapy.^{52,58,60} According to Royeen et al.,⁵⁸ a limitation of this instrument is that it relies on the subject's self-perception of clinical reasoning skills and behaviors rather than an objective measure of clinical reasoning performance. However, this may have value if used by a student or therapist as a tool for self-reflection and personal development. It was recently used as one measure in a study exploring the effect of using a student-run free clinic on interprofessional attitudes and clinical reasoning skills.⁵⁹ In this study, the SACRR showed a statistically significant change in occupational therapy, physical therapy, physician's assistant, medical, and pharmacy student perceptions of clinical reasoning skills when exposed to an interprofessional service learning course and student-run free clinic.⁶⁰ The Watson-Glaser Critical Thinking Appraisal (WGCTA)⁶¹ was also used in this study. It is an objective tool that measures the critical thinking skills of attitudes of inquiry; inferences, abstractions, and generalizations; and skills in employing/applying these attitudes and knowledge.⁶¹ In this study the WGCTA found that OT students compared to PT students had statistically greater increases in critical reasoning, causing the researchers to conclude that this might be due to OT curricula incorporating more activities where critical thinking processes were identified.⁶¹

These measurement tools and reported studies have explored how clinical reasoning is impacted by problem-based or experiential

learning or specific points within the student learning process. Unsworth describes that, “Although many studies on clinical reasoning have been undertaken, most explore discrete areas of practice or types of reasoning.”²⁰ What we know is that more holistic reasoning styles such as conditional reasoning are used more often by experienced therapists and procedural modes by novice therapists.²⁴ Research also points to how vital fieldwork practicums are, as they are the major channel through which occupational therapy students integrate knowledge into practice and advance their clinical reasoning styles.²⁴

Areas for Future Study

Research from over a decade ago suggests that the profession consider alternatives for understanding the master therapist’s intuitive reasoning using methods informed by judgment analysis.⁶² This research recognized that clinical reasoning is influenced by what a therapist recognizes and prioritizes as the key factors that lead to occupational dysfunction. The prioritized factors become the lens that the therapist uses to design intervention. If the factors that lead to occupational dysfunction are physical impairment, the therapist’s clinical reasoning dictates remediation of impairment through various biomechanical frames of reference.

In the recently published systematic review of the occupational therapy literature, Unsworth and Baker’s findings show a dense amount of literature on understanding what “professional reasoning is” but a dearth on examining the differences between novice and expert therapist reasoning pathways, including a need for assessment tools.³ To develop therapists that can master the art of practice, occupational therapy research recommendations point to extending problem-based and experiential learning to include and at times prioritize the contextual environments that influence occupational engagement beyond the clinical contexts.

Conclusion

Understanding how a therapist becomes an expert in clinical reasoning and artful practice that result in high levels of satisfaction from the clients served is useful for informing professional education, mentoring novice therapists, and advancing mastery with experience. Understanding relevance to the client demands dialogue and engagement with the client in the therapy process. It also demands reflective assessment from the therapist on their inner beliefs and assumptions.⁷ A therapist must use science, ethics, and

artistry to guide their clinical reasoning and ultimately the clinical decisions they make.¹ Artistry is a process that results in a unique outcome because of the uniquely individual attributes that the artist contributes. The art of practicing occupational therapy lies in blending experience and knowledge and including therapeutic use of self²⁵ to optimize opportunities for clients to engage in the occupations that they identify as being at the core of expressing who they are through engaging and participating in them. Considering the client and engaging the client dialectically in assessing their performance, the effectiveness of the intervention, and including subjective feedback on how the clinical process is impacting satisfaction with occupational performance are vital to the reasoning process. Client engagement in the exchange of reasoning processes offers optimal client-centered care as well as client ownership of the therapy journey. This process targets outcomes that address priorities for participation in a manner and style crafted to the client's needs together in partnership. This partnership is a therapist–client team that works collaboratively, inductively, and recursively to establish and achieve the therapy goals.

Occupational therapy straddles the worlds of a client's biomedical and psychosocial environmental concerns. The intersections between these two worlds requires professional reasoning simultaneously grounded in scientific and procedural theory and evidence, as well as is phenomenologically reflective and imaginative.¹⁰ The heart of the art of practice is grounded in collaborative reflection to identify what is meaningful to a client and how occupation can be used as a means to evaluate and intervene in a way that addresses prioritized needs and promotes full participation and enablement in all of a society's culturally relevant occupations.

CASE STUDY

Scientific Reasoning

Adam works in an acute care hospital and has just received an order for an occupational therapy evaluation and treatment of Eve, a 49-year-old woman with a diagnosis of C7 spinal cord injury (SCI). Upon review of the medical records, he identifies that she acquired the SCI years ago when she was 23 and is currently in the acute hospital for bacterial pneumonia and general deconditioning. He immediately understands from scientific and diagnostic processes of reasoning what musculature would likely have been impacted as a result of central nervous system damage

and how this might translate into functional performance. He also considers how her new illness might influence her overall functioning and uses this reasoning as a baseline prior to beginning his occupational therapy evaluation.

Procedural Reasoning

Adam begins his evaluation of Eve using his knowledge on what musculature he would expect her to have functional use of because of her level of SCI. His approach strategy is also influenced by his overarching knowledge of adaptive strategies and equipment she is likely to incorporate into her activities of daily living (ADLs). During the evaluation, Adam notes that Eve does present with the motor and sensory functional impairments that align with a diagnosis of a complete C7 SCI, although all of her innervated upper extremity (UE) musculature is weaker than anticipated. She also reports that she is having more difficulty in performing the UE dressing and grooming tasks than she was prior to the acute hospitalization.

Interactive Reasoning

During the initial evaluation, Eve confirms that she has lost “tons of strength” in both her arms and hand function. During the occupational profile, Adam identifies that Eve lives in her own apartment with a personal assistant who works for Eve daily to provide assistance with ADLs and instrumental activities of daily living (IADLs). During the evaluation, Adam uses processes of interactive reasoning to explore with Eve what she prioritizes for her occupational therapy sessions. Adam understands that Eve is an expert in living and managing her SCI as she has managed and lived with the disability for almost 26 years. Adam identifies that a strength and conditioning approach is necessary to increase ADL and IADL concerns but instead of immediately establishing an intervention course focusing on Eve’s diagnosis targeting these client factors, he collaborates with Eve using interactive reasoning to identify her priorities for the sessions she will receive while in the acute hospital. Including Eve as an active partner to collaboratively identify her areas of concern is at the core of an occupational therapy client-centered approach to clinical reasoning in intervention design.

Narrative Reasoning

Adam is intrigued by the knowledge Eve has of how to manage her health and wellness, her organized manner of supervising and managing her personal assistant hours, and her adaptive

approaches to performing ADLs and IADLs. He discusses some of her strategies for managing her ADLs with colleagues and the conversation shifts to how well she has managed her health living with SCI for 26 years. He begins to question what factors led her to acquire the pneumonia and his expert judgment compels him to pose this question to her during a morning therapy session. Adam's narrative reasoning that emerged through conversations with his peers informed him that this question may be an important one from an occupational perspective for working with her to manage her health and wellness.

Conditional Reasoning

In narrative exploration, Eve explains her perspective of her recent health crisis. She explained to Adam that for years she has been fortunate to have physicians, dentists, pharmacists, and other wellness providers that had an understanding of the accommodation needs of people with disabilities. However, when her dentist retired she was at a loss of how to locate an accessible dental clinic. She had been referred to a dentist by a friend but the visit was a negative experience for her as she had her teeth cleaned while seated in her straight back wheelchair because of the inability for the clinic to offer her a transfer into an accessible dental examination chair. Eve illustrated what a painful experience this was both psychologically and physically, describing she "felt like a burden" to the staff at the clinic. She described how this experience influenced her decision not to get the routine dental care she had been so diligent about in the past. She developed tender gums and periodontal disease which she later learned increased her risk for lung infections, and she believes resulted in her recent health crisis. Adam began to understand how the environment and context of a provider office might negatively impact Eve's participation in her occupation of health management, one of her most vital ADLs. Despite knowledge and insights of strategies and approaches for managing her health and wellness, Eve's knowledge and strategies for how to self-advocate in primary care for accommodations were underdeveloped. He envisioned how this type of barrier would continue to supersede her self-management strategies and impact her health negatively. He made a clinical decision to discuss with Eve learning strategies and approaches for accessing community resources and services.

Pragmatic Reasoning

Adam and Eve are both invested in working to develop a “toolkit” for strategies in community resource seeking and utilization for her remaining occupational therapy sessions, as well as basic knowledge on her specific accommodation needs. Adam had earlier anticipated 5 more days of work with Eve; however, a change in her medical plan occurred and now she had only 2 days left in the acute hospital before a transfer to a subacute rehabilitation facility. Adam’s pragmatic reasoning allowed him to realize that the limited time with Eve constrained the ability to directly work on skill acquisition on resource seeking and utilization and demanded he provide resources for Eve directly. He reviewed with her the names and numbers of her local Center for Independent Living as well as a basic introduction to the Americans with Disabilities Act, reviewing her right to equitable health care services. Their discussion included basic methods for effectively communicating her needs when making a provider appointment. Adam understood that this approach failed to address Eve’s larger issue of developing skills for community resource seeking and placed this recommendation in her discharge evaluation, hopeful the next occupational therapist might address this need. With this clinical experience, Adam had developed a new worldview on how access barriers can directly impact meaningful and vital occupational participation.

Ethical Reasoning

Adam’s ethical reasoning that informed his clinical decision to work with Eve on strategies for accessing resources was grounded in his knowledge of occupational therapy’s scope of practice. He understood that at times therapists are in positions to work on self-advocacy strategies with clients as described in the OTPF: “By understanding and addressing the specific justice issues within a client’s discharge environment, occupational therapists promote therapy outcomes that address empowerment and self-advocacy.”¹¹ His dilemma spurred his ethical reasoning on steps he might take to advocate for clients, also a scope of practice outlined in the OTPF: “Occupational therapists can indirectly affect the lives of clients through advocacy. Common examples of advocacy include talking to legislators about improving transportation for older adults or improving services for people with mental or physical disabilities to support their living and working in the community of their choice.”¹¹ As a result, Adam joined a local disability advocacy group working on state health care policies impacting people with disabilities.

Chapter 6

Documentation of Occupational Therapy Services

Patricia A. Gentile

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Understand the importance of clinical documentation from a professional and legal standpoint.
2. Describe types and formats of documentation used in clinical settings.
3. Utilize accepted principles of documentation throughout the service delivery process.
4. Recognize the importance of documenting medically necessary and skilled occupational therapy services.
5. Be familiar with legal and ethical issues associated with clinical documentation.

CHAPTER OUTLINE

Introduction
Purpose of OT Documentation
Formats of Documentation
Types of Documentation
The Electronic Medical Record
General Principles of OT Documentation
Legal and Ethical Issues
Case Study

TERMINOLOGY

Authentication: the process of showing authorship and responsibility for something documented in the medical record.

Documentation: the recording of patient observations and the health care services provided, which is used to

track a patient's status and communicate the health care provider's actions and thoughts to other members of the care team.

Fraudulent billing: to purposely bill for services that were never given or to bill for a service that has a higher reimbursement than the service produced.

Health Insurance Portability and Accountability Act (HIPAA): a federal mandate for individual rights in health information that imposes restrictions on uses and disclosures of individually identifiable health information and provides for civil and criminal penalties for violations.

Medical record: the chronological written or electronic document that includes a written account of a patient's medical and health history and complaints, physical findings, tests, interventions, and treatment outcomes.

Medically necessary: services that are needed to treat an illness, injury, condition, disease, or its symptoms and that meet accepted standards of care.

Protected Patient Health Information: individually identifiable health data, including demographic information, that are created or received by a health care provider that relate to an individual's past, present, or future physical or mental health or conditions; the provision of health care to the individual; or the past, present, or future payment for the provision of health care to the individual.

Skilled services: services that, because of the patient's condition, require the skills, expertise, clinical reasoning, and judgment of a qualified therapist to ensure the effectiveness of the treatment goals and ensure medical safety.

State Practice Act: a state law that governs a profession.

Third-party payer: an entity (other than the patient or the health care provider) that reimburses and manages health care expenses. Third-party payers include

insurance companies, governmental agencies such as Medicare or Medicaid, and employers.

Introduction

*Observe, record, tabulate, communicate*¹

Documentation is an essential tool used in the delivery of health care services. It is the recording of patient observations and the services provided; it is used to track a patient's status and communicate a provider's actions and thoughts to other members of the care team.² Documentation provides a means to plan, evaluate, and communicate a patient's treatment. In occupational therapy (OT), documentation is an important part of daily clinical practice. It provides a record of the reason for referral, offers a summary of the patient's occupational history and evaluation, outlines patient and therapist treatment goals and plans, and records interventions and the patient's responses to those interventions.^{2,3} In addition, documentation serves to substantiate coding used for billing, demonstrate compliance with regulations, provide data for quality improvement activities and utilization review, facilitate research, and offer evidence in medical–legal matters, including those involving malpractice lawsuits and professional discipline complaints.^{2–4}

Documentation should be completed whenever professional services are provided to a patient.⁵ There is no one single method for documenting OT services. Methods of documentation can vary in their mechanism (e.g., paper vs. electronic), format (e.g., narrative vs. template), and frequency (e.g., daily vs. weekly). The method used is established by the individual practice setting and is designed to meet all regulatory, accrediting, and payer requirements.⁵ According to the American Occupational Therapy Association (AOTA) Standards of Practice for Occupational Therapy, occupational therapists are required to be knowledgeable of and comply with “the time frames, formats, and standards established by the practice settings, agencies, external accreditation programs, state and federal law, and other regulatory and payer requirements.”⁶ In settings that employ OT assistants, the occupational therapist is responsible for all aspects of OT

service delivery.⁷ Therefore, in these settings, it is the responsibility of the occupational therapist to review and verify all documentation completed by the OT assistant.

Purpose of OT Documentation

The major purpose of OT documentation is to provide chronological, timely, accurate, and complete information about all services provided.^{2,3,8} Documentation should include the occupational therapist's observations, assessment, and intervention, as well as the patient's response to these interventions.^{2,3,8} It should reflect the decision-making process used during the delivery of care.⁹ Effective documentation also allows occupational therapists to articulate the profession's distinct value.^{6,10,11}

Documentation in the **medical record** provides an important mechanism for the occupational therapist to communicate with other health care providers. This communication is essential to facilitate patient safety and continuity of care. This is especially true when a patient is treated jointly by an occupational therapist and OT assistant, or as a patient moves from one treatment setting to another.³

AOTA⁷ has outlined several purposes of OT documentation. These purposes are to:

- articulate the rationale for provision of OT services and the relationship of this service to the client's outcomes
- reflect the occupational therapist's clinical reasoning and professional judgment
- communicate information about the client from the OT perspective
- create a chronological record of client status, OT services provided to the client, and client outcomes

It is important to keep in mind that information documented in the medical record is also used for other purposes and read by a variety of audiences (Table 6-1). It should be noted that these audiences can include patients, who under the **Health Insurance Portability and Accountability Act (HIPAA)**, are allowed access to their medical records.¹² Occupational

therapists should keep all of these potential audiences in mind when recording their encounters.

Table 6-1. Purpose of Documentation and Potential Audiences

PURPOSE OF DOCUMENTATION	PRIMARY AUDIENCE
Patient care information	Health care providers, patients
Reimbursement	Third-party payers
Quality improvement and utilization review	Case managers, third-party payers
Regulatory	Federal, state, and local regulatory bodies (e.g., The Center for Medicare and Medicaid, state health departments)
Accreditation	Accrediting bodies, including The Joint Commission and Commission on Accreditation of Rehabilitation Facilities
Research	Researchers, students
Legal	Risk management officers, attorneys

Formats of Documentation

Formats for documentation differ and fall into three major categories: narrative, template, and acronym.^{13,14} The format selected by the occupational therapist may vary depending on the practice setting and institutional policy.

Narrative Format

Narrative notes describe the sequence of events that occurred in the therapy encounter. Narrative notes are written in a free text format and can be organized in a variety of ways, but should always be specific, concise, and clear. Narrative notes provide descriptive information that may not be captured when documenting via a form or when using a checklist.¹³ The major advantage of narrative documentation is that it allows the occupational therapist to “tell the story” of the patient and the therapy encounter. Major disadvantages are that writing narrative notes can be time-consuming, the notes themselves tend to be lengthy, and because of the lack of structure, there is a risk of inadvertently omitting important information.^{13,14} The use of an outline can address these issues by reminding the

writer of key areas not to be missed in the note-writing process.¹³ An additional disadvantage when using narrative formats is that it can be cumbersome to gather information for utilization review or when collecting data for research.

Template Format

Templates provide formats that outline all required and relevant information that should be recorded as part of an OT encounter. When using a template, the occupational therapist generally fills in empty data fields manually or, if using an electronic charting system, selects items from a drop-down menu.¹⁵ Templates are useful because they are efficient and provide for standardization.^{3,14} However, the use of templates alone may not provide a full picture of a patient's condition or performance.^{13,15} If using templates, it is recommended that there be a space built into the template for the occupational therapist to add comments and observations.

Acronym Format

Documentation using acronym formats is highly structured and requires that information be recorded in the order of the acronym's initials.^{8,13} The "SOAP" note is the most common example of acronym documentation.⁸ The SOAP note is an acronym for subjective, objective, assessment, and plan⁸ (see Box 6-1).

Box 6-1

SOAP Note Components

Subjective

Patient's view on his condition or treatment in his own words. May include the patient's chief complaint and goals for therapy

Example: Patient reports pain in right hand has decreased since last therapy session

Objective

The reason and purpose for therapy. Includes a summary of the interventions provided as well as a summary of the patient's response to treatment. Observations, tests, and assessment results should be recorded here

***Example:** Patients continues to attend OT twice a week for pain management and ROM following right carpal tunnel release. Pain decreased to 5 to 1 to 10 scale; AROM wrist flexion 0° to 20° and wrist extension 0° to 15°. BADL improved; patient able to hold hairbrush to style hair now*

Assessment

The interpretation and analysis of all subjective and objective information, including their impact on functional performance. A projection of patient's potential for improvement and progress toward goals should be made here

***Example:** Patient remains motivated and actively participates in therapy. She demonstrates improvements in AROM of right wrist; pain is decreased, and as a result, patient is using right hand more during grooming activities. Patient is progressing toward goals and is compliant with her home exercise program*

Plan

A summary of planned interventions and follow-up, including the provision of any home program and referrals to other providers

***Example:** Continue therapy twice a week as per MD order; begin gentle resistive activities next session. Home program was reviewed and updated to include grasp strengthening*

The SOAP note format is applicable for use across practice settings and can easily be incorporated into both paper and electronic documentation systems.⁸ SOAP notes can provide a helpful guide to structure narrative notes and documentation templates. They can also be used to set up all types of documentation reports, including evaluations, re-evaluations, progress notes, and discharge summaries.

Types of Documentation

Occupational therapists need to be familiar with and comply with all professional, institutional, accrediting, regulatory, and **third-party payer** requirements when documenting in a patient's medical record.^{2,3} The AOTA has provided Guidelines for Documentation,⁵ which outline and provide information about typical documentation reports in OT service provision. These reports are categorized divided into three phases of service delivery: evaluation phase, intervention phase, and discharge phase. A summary of the reports used throughout these phases can be found in Box 6-2. Although the specific types of documentation requirements and reports may vary depending on the practice settings,⁵ these AOTA guidelines can be helpful to all occupational therapists to document their services.⁵

Box 6-2

Types of Occupational Therapy Documentation Reports

Evaluation Phase

- **Screening:** Brief assessment to determine whether patient could benefit from full evaluation
- **Evaluation:** Data gathered through the assessment process. Should include an occupational profile, an analysis of occupational performance, and identification of patient's functional deficits and strengths. Treatment goal and plans should be recorded here
- **Reevaluation Report:** A summary of the findings from the reassessment process; should include modification of treatment goals and plans goals based on these findings

Intervention Phase

- **Intervention Plan:** Based on evaluation and revelation findings, the establishment of treatment goals, and

planned interventions to achieve patient goals. Should include documentation of any home program or instruction provided and any referrals to other providers

- **Contact Note:** A record of interaction between the patient and therapist, including the types of intervention provided and patient's response. May also be used to document telephone contacts, participation in team meetings and consultations with other health care providers
- **Progress Report/Note:** Summarizes the therapy process and notes patient's progress toward goals achievement. As needed, records new assessment information, and the modification and updates to treatment goals and plans. Offers support for continuation of therapy services or the need to discontinue/discharge
- **Transition Plan:** Provides information to the next provider as patient moves from one treatment setting to another; provides "hand-off" information to next provider

Discharge Phase

- **Discharge/Discontinuation Note:** Summarizes therapy services provided and the reason for discharge/discontinuation; indicates if outcomes were met

Adapted from American Occupational Therapy Association. Guidelines for documentation of occupational therapy. *Am J Occup Ther.* 2013;67(6 suppl):S32–S38. doi:10.5014/ajot.2013.67S32.

The Electronic Medical Record

The shift in health care from paper charts to electronic medical records (EMRs) (e.g., digital version of a medical record) is the result of the belief that the use of an EMR will improve patient care, enhance patient safety, increase quality of care, improve efficiency, and reduce costs.¹⁶ The proliferation of EMR use by health care providers is a direct result of the passage of the Health Information Technology for Economic and Clinical Health (HITECH) Act,¹⁷ which provided extensive funding to encourage adoption of EMR systems.

Occupational therapists working in hospitals in particular will find themselves using EMRs because it has been reported that that 99% of hospitals in the United States are using electronic documentation systems.¹⁸ It is important that any occupational therapist using an EMR ensure that the system use formats that have all the elements needed to accurately record all best practices.¹⁴

The use of good documentation practices extends to the EMR, especially in regard to the timeliness and accuracy of note writing. Unlike paper charts, when using an EMR, each entry is automatically time-stamped, indicating the date and time of the entry. Therefore, it is essential that documentation be completed during or shortly after the provision of services. EMR documentation shortcuts, such as reusing previous entries by “cutting and pasting” or using prepopulating fields, should be avoided as the information carried forward may not be accurate or up to date.¹⁹

Occupational therapists documenting in EMRs should be assigned a digital signature to link them to their documentation entries. A digital signature links the provider to a unique password or identification number and is used to authenticate the contents of electronic documents.²⁰

EMR documentation is often done at the “point of service” (i.e., at the time of the delivery of clinical care). Point-of-service documentation is believed to improve the efficiency and accuracy of note writing. However, it can divert the provider’s attention away from the patient, making the patient feel disconnected.^{14,21} To prevent this, it important to keep the focus on patient throughout the therapy session, even when entering information into the EMR.¹⁴ This can be accomplished by²¹⁻²³:

- Informing the patient at the beginning of the encounter that notes will be taken and entered into the EMR during the therapy session
- When reviewing patient’s history that was previously entered, reading that information out loud and asking the patient to verify

- Sharing the screen to show patient his or her progress during reevaluations (e.g., improvements in goniometric measurements)
- Using the screen to provide and reinforce patient education materials

General Principles of OT Documentation

Documentation can be written in a paper medical record or entered directly into an EMR. Regardless of the format of the medical record, the basic general principles of good OT documentation should be adhered to (i.e., entries should be timely, comprehensive, objective, and accurate).³ General guiding principles to help achieve these objectives include:

- Being objective and factual
- Being accurate and concise
- Using correct grammar and spelling
- Avoiding jargon and slang
- Using only approved abbreviations
- Writing legibly and clearly
- Recording entries promptly
- Being sure to date, time, and sign all entries
- Reflecting individualized, patient-centered care
- Being professional; avoid disparaging remarks or comments about patient or other health care providers
- Never erasing or removing entries from the record; if changes or corrections need to be made after an entry is made, follow institution's correction or addendum policy

Medicare, who is the largest payer for OT services,²⁴ requires that OT documentation reflects the provision of medically necessary and skilled services²⁵ and includes goals focused on the improvement of impairments or functional limitations.²⁶

Medically necessary services are those services that are “needed to treat an illness, injury, condition, disease, or its symptoms and meet accepted standards of care.”²⁵ To demonstrate medically necessary services, the occupational therapist should document the reason the patient is being

referred for services, include why the patient's diagnosis or condition warrants the need for therapy, and adequately assess the patient in order to identify his or her impairments and functional deficits.²⁶

Skilled services are those services that, "because of the patient's condition, require the skills, expertise, clinical reasoning and judgment of a qualified therapist to ensure the effectiveness of the treatment goals and ensure medical safety."²⁵ Treatment is regarded as "skilled" only if it is at a level of complexity and sophistication that requires the services of an occupational therapist or an OT assistant supervised by a therapist.^{25,26} To demonstrate skilled service, the OT notes must support the need for, or the continuation of, skilled services. This can be accomplished by²⁶:

- Providing clear descriptions of skilled treatment and avoiding any indication that the patient is simply performing repetitive tasks
- Specifying any changes or adaptations made to interventions that are based on ongoing assessment of the patient's function and status
- Revising the treatment plan based on the occupational therapist's clinical reasoning and judgment, to move the patient toward the next more complex level or a more difficult task

To illustrate, during a treatment session focusing on upper extremity (UE) dressing with a patient who has left-sided inattention, the occupational therapist provides tactile cuing to increase patient's awareness of left side and to promote the use of left UE in the activity. These interventions need to be documented to show skilled service was provided. Therefore, rather than documenting that the patient "practiced UE dressing with cuing" (non-skilled), the occupational therapist should document that "due to left sided inattention, the therapist provided tactical cues to promote bilateral integration while donning a front-closure garment" (skilled).

Because most other third-party payers follow Medicare guidelines, it is recommended that OT documentation follow

Medicare requirements for all payers.^{2,4}

To demonstrate and help other health care providers, reviewers, and third-party payers understand the unique focus and emphasis of the OT treatment process, OT documentation should reflect the distinct value of the profession.^{6,10,11,27, 28} One way to achieve this is by incorporating an occupational profile and an analysis of a patient's occupational performance into the documentation process.²⁹ Regarding the inclusion of an occupational profile, occupational therapists should be aware that its use may be required in order to use certain evaluation billing codes.³⁰

Because a client-centered approach is an essential principle of OT,²⁹ it is important that documentation reflects this.^{8,31} This will demonstrate a partnership with and involvement of patients receiving OT services.³¹ To do this, the occupational therapists should continually record patients' priorities for treatment and their active participation in the goal-setting and treatment planning process.

Legal and Ethical Issues

The Medical Record

The medical record is a legal document. Documentation contained within the medical record becomes part of this legal document.^{32,33} The medical record may be handwritten, typed, or electronic. Regardless of its format, what the occupational therapist documents in the medical record needs to be a complete, accurate, and current account of all services provided and the outcome of these services.³³

Medical records may be subpoenaed as evidence for a variety of purposes, including lawsuits, malpractice cases, and reimbursement claims review.^{14,33} Occupational therapists need to be familiar with all federal and state guidelines regarding ownership, privacy, and retention of medical records^{33,34} (see Box 6-3) and what constitutes **protected patient health information**³⁵ before releasing any medical record information.

Box 6-3

Legal Considerations Regarding the Medical Record

- **Ownership:** The facility or practice generating the patient's medical record is the owner; however, all information documented in the medical record belongs to both the patient and the health care provider
- **Privacy and Confidentiality:** HIPAA regulations protect the privacy and confidentiality of protected patient health information. Health care facilities or practices should develop and implement policies and procedures to ensure compliance with these regulations
- **Retention:** State laws regarding how long medical records should be retained vary. Health care facilities and providers need to be adhere to their individual state's requirements

Legal Considerations

Occupational therapists need to be familiar with their individual **state practice act** to ensure that what they are documenting is consistent with the legal definition of OT practice for that state.³² For example, if a particular state's OT practice act does not include the use of physical agent modalities and the occupational therapist documents the provision of these modalities, it would mean that he or she is providing services outside the scope of OT.

Documentation is regarded as an essential part of the health care process³⁶; in the legal process, a health care provider's failure to document properly can be considered a breach of the standard of care.³⁶ Documentation by the occupational therapist provides evidence of services provided as well as the reasoning behind the provision of these services.^{34,36} In the event of a lawsuit, what is (and is not) documented in the medical record will form the basis for the plaintiff's case and or the health care provider's or facility's defense.³⁴ This evidence may be used to defend against lawsuits, malpractice cases, or claims by third-party payers of **fraudulent billing**.¹³ Consequently, it is important that occupational therapists be

aware and comply with key legal aspects of documentation related to legibility, timeliness, completeness, accuracy, and **authentication**.^{13,33,34}

- **Legibility:** All handwritten notes must be legible. Notes that are illegible may be misread or misinterpreted.
- **Timeliness:** Documentation should be up to date and written during or on the day of the patient encounter. All notes should contain date and time. Documenting in advance is never acceptable nor is backdating a note. If, for some reason, a note cannot be written on the day service was provided, it should be entered as a late entry.
- **Completeness:** All information documented about the service provided should be complete (i.e., include what was done and how, justification for service provided, and the patient's responses).
- **Accurate:** All information should be documented and should be correct, truthful, and reflect the actual services provided.
- **Authentication:** Authentication refers to the process of showing authorship and responsibility for something documented in the medical record.^{33,34} All documentation should be signed by the provider who delivered the service and should include the provider's credentials. In cases where an EMR is being used, a digital signature can be used for authentication.^{33,34} By authenticating (e.g., signing) his or her note, the occupational therapist is verifying what was done and is taking responsibility for the entry.^{33,34}

Occupational therapists need to be aware that depending on the state practice act or their specific institutional policy, they may be required to co-sign any notes written by OT students and OT assistants.⁷ By co-signing these notes, the occupational therapist is verifying that supervision is being provided and is taking responsibility for what is written.² It is important that the occupational therapist reviews these notes carefully and clarifies any questions he or she may have before co-signing.

In the event of a lawsuit, what is (and is not) documented in the medical record will form the basis for the plaintiff's case and or the health care provider or facility's defense.^{33,34}

Therefore, it is essential that occupational therapists follow good documentation practices should they have to defend themselves in a lawsuit.

Ethical Considerations

Occupational therapists should follow standards of practice and ethical principles when documenting. The AOTA Occupational Therapy Code of Ethics³⁷ stresses the need for occupational therapists to be honest, accurate, and timely when documenting and to comply with all applicable regulations. Ethical challenges related to documentation often arise when occupational therapists are asked to document false or erroneous information in order to insure reimbursement.³⁸ Some examples of these ethical challenges might include:

- An administrator directs an occupational therapist to document that a patient is receiving 60 minutes of therapy, even though the patient is easily fatigued and can only tolerate 45 minutes.
- An occupational therapist is assigned to co-sign notes written by an OT assistant he or she is not supervising.
- A supervisor requests that an occupational therapist reword a treatment note so that a higher paying code can be assigned to a billing claim.

It is important that occupational therapists remember that documenting services that were not provided, using wrong billing codes, or co-signing notes without providing proper supervision are all serious infractions and could possibly result in legal and professional sanctions.^{4,32,38}

CASE STUDY

Case Scenario

Juana is a left-hand dominant, 75-year-old female. Two weeks ago, while running to catch the subway, Juana tripped and fell onto her left shoulder. Juana was seen in the emergency room immediately after her fall; radiographic studies revealed a left nondisplaced midshaft humeral fracture. A sling was applied to immobilize Juana's left

shoulder. She was seen in orthopedic care 1 week later, and at that time, the sling was removed. Juana was then referred to outpatient OT for twice a week (BIW) therapy for pain management, gentle active and active-assistive range of motion (AROM), and activities of daily living (ADLs) training.

Juana is a retired secretary who lives alone and was independent in all basic activities of daily living (BADLs) and instrumental activities of daily living (IADLs) prior to her fall. She is active in her community and was volunteering in her local church's food bank prior to her injury. Her goal is to return to independence and to resume her volunteer work. She has been attending OT for 2 weeks, is motivated, and appears compliant with her home exercise program.

Sample Treatment Contact Note: SOAP Format

- **S (subjective):** Patient reports continued stiffness in left shoulder and reports a “4” on the 1 to 10 pain scale. She states she continues to have difficulty washing her hair while in the shower and putting on a blouse but is using her left arm more during these activities.
- **O (objective):** Patient actively participated in the 30-minute OT session with focus on left shoulder AROM to increase ability to raise arm overhead to facilitate grooming and overhead dressing activities. Goniometric measurements taken of left shoulder at start of session: AROM: flexion 0° to 100° (increase 8°); extension 0° to 15° abduction 0° to 80° (increase 10°); external rotation 0° to 60° (increase 10°); and internal rotation 0° to 45° (increase 5°).

Patient performed multiple repetitions of left upper extremity (LUE) AROM forward and overhead reaching activities; she required occasional (<4) tactile cues to avoid trunk substitution when reaching above 90°. Trunk substitutions during reaching noted to increase as she fatigued. No complaint of increased pain reported; at end of activity, patient stated her shoulder “felt looser.” Following AROM, ADL training performed for UE

dressing; patient needed an initial verbal cue for correct placement of LUE into overhead garment. Patient was reeducated on home exercises program and was independent with return demonstration.

- **A (assessment):** Patient is demonstrating progress in UE AROM and functional use since last session. Reports of pain have decreased and improvements noted in AROM as per goniometric reevaluation. She is progressing toward goals. Patient can benefit from continued skilled OT to further improve ROM and functional use. Potential for return to independent function is good, and she is please with her progress.
- **P (plan):** Continue OT BIW for ROM, pain management and ADL training, and home program. As per telephone conversation with orthopedic surgeon, patient is cleared to begin gentle resistive exercise at the next visit.

Section 2 **Assessment and Intervention**

Chapter 7

Visual Function Assessment

Diane Powers Drette and Jennifer Fortuna

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Define the key terms related to visual function.
2. Determine the impact of visual deficits in populations as well as for individual clients.
3. Connect underlying neurological and physiological impairments to the resulting visual deficits.
4. Describe screening techniques for visual acuity, visual fields, and oculomotor control.
5. Identify commonly used standardized visual assessments and their value for use in assessing visual function.

CHAPTER OUTLINE

Visual Function and Impairment in Daily Occupation
Neurological and Physiological Basis of Visual Function
Impairments of Visual Function
Screening of Visual Skills
Case Study

TERMINOLOGY

Contrast sensitivity: the visual ability to distinguish the edges of objects against backgrounds of similar color or saturation.

Convergence: the oculomotor ability to move two eyes nasally simultaneously (the opposite is divergence).

Fixation: the oculomotor ability to maintain focus on an object in central vision.

Oculomotor: the ability to purposefully contract the muscles of the eyes to produce coordinated movement.

Saccades: the oculomotor ability to perform quick movements of the eyes from one target to another and focus the target in clear, central vision.

Scanning: the oculomotor ability of visually searching the environment.

Tracking/pursuits: the oculomotor ability to smoothly follow a slow moving target and keep it in the central vision.

Visual acuity: the level of clear central vision.

Visual fields: the span of vision that one sees while looking straight ahead. While the eyes are fixated straight ahead, the visual field is approximately 90° from center to the right and to the left sides, 70° inferiorly, and 60° superiorly.

Visual range of motion: the amount of movement of the eyes in all planes of movement vertically, horizontally, and diagonally.

Visual Function and Impairment in Daily Occupation

Visual function is the integrity of the visual system and includes visual acuity, oculomotor abilities, contrast sensitivity, pupillary function, and visual fields, which are all integral to the performance of daily occupations. Occupational performance problems can occur when a deficit arises in any of these components. Visual function is also the basis of many other client factors including visual perception, cognition, eye-hand coordination, balance, and mobility. Because vision underlies these other factors, a visual deficit can impact these factors that are also necessary for the performance of daily occupations. Visual deficits, therefore, can impact all aspects of a person's ability to perform activities of daily living (ADLs) and instrumental activities of daily living (IADLs).

Warren Model of Visual Functioning

Warren¹ described a visual perceptual hierarchy in adults (Fig. 7-1). This model suggests that higher level skills (such as visual attention and visual memory) are built on the foundations of **visual acuity**, **visual fields**, and **oculomotor control** (e.g. **fixation**, **saccades**, **visual range of motion**). The components in the hierarchy are as follows:

Figure 7-1 Hierarchy of visual perception. (Adapted from Warren M. A hierarchical model for evaluation for evaluation and treatment of visual perceptual dysfunction in adult acquired brain injury, Part 1. *Am J Occup Ther.* 1993;47:43. Copyright 1993 by the American Occupational Therapy Association, Inc. Reprinted with permission.)

1. Oculomotor control, visual fields, visual acuity
2. Visual attention and alertness
3. Visual scanning
4. Pattern recognition
5. Visual memory
6. Visual cognition
7. Adaptation through vision

Populations and Vision Impairments

Worldwide, an estimated 253 million people have vision impairments, with 36 million classified as blind and 217 million classified as moderately to severely visually impaired.² Table 7-1 shows the levels of visual impairment. Visual impairments are especially prevalent in the aging population, with 81% of people, aged 50 years and older, who are blind or have moderate or severe visual impairment.² Low vision is the third most common cause of impaired function among the elderly, and low vision disorders not only impair a person’s ability to function but also increase a person’s risk of depression, social isolation, falls, and a general decline in health.³ The most common low vision disorders include macular degeneration, diabetic retinopathy, glaucoma, and cataracts.⁴ Because of the aging of the global population, it is estimated that the number of people with visual impairment could triple by 2050 with 115 million people who are blind, up from 38.5 million in 2020.²

Table 7-1. Levels of Visual Impairment

LEVEL OF VISUAL IMPAIRMENT	DEFINITION
Moderate	Best-corrected visual acuity is less than 20/60.
Severe	Best-corrected visual acuity is less than 20/160, or visual field is 20° or less (legal blindness).
Profound	Best-corrected visual acuity is less than 20/400, or visual field is 10° or less (moderate blindness).
Near-total	Best-corrected visual acuity is less than 20/1,000, or visual field is 5° or less (severe blindness).
Total	No light perception (total blindness).

Beyond age-related vision loss and impairments, many clients experience vision problems because of neurologically based disability or illness. In a study of 328 patients who suffered a stroke, over 90% had visual problems in eye alignment, visual fields, and visual attention.⁵ Many service members with blast-related brain injuries also receive occupational therapy screening for vision problems.⁶⁻⁸

Neurological and Physiological Basis of Visual Function

Visual Acuity

Clear central vision begins with light entering the lens of the eye, passing through the pupil, and being processed by the photoreceptor cells of the retina⁹ (Fig. 7-2). The photoreceptor cells of the retina, the rod and cone cells, convert the light into neural signals.¹⁰ The rod cells specialize in low levels of light intensity, such as night vision, and the cone cells specialize in higher levels of light intensity, such as color vision.⁹ The cone cells are most highly concentrated in a small region of the retina, the fovea, where visual acuity is the greatest. Rod cells are evenly distributed in the retina, but are not present in the fovea.

Figure 7-2 Anatomy of the eye.

From the retina, the neural signals are conveyed via axons in the optic nerve (cranial nerve [CN] II) to the optic chiasm, to the optic tract and then to the lateral geniculate nucleus. From the lateral geniculate nucleus, the visual information is sent via optic radiations to the primary visual cortex in the occipital lobes.⁹

Oculomotor

Smooth, controlled eye movements are necessary for clear and accurate vision. Eye movements are controlled by the muscles of the eyes and the CNs that innervate them (Fig. 7-3). The muscles and the movements of the eyes that they control include the following¹⁰:

Figure 7-3 Muscles of the eye.

- Levator palpebrae superioris—Lifts the eyelid
- Superior rectus—Moves the eye upward
- Medial rectus—Moves the eye medially (nasally)
- Inferior oblique—Rotates the eye in and up
- Superior oblique—Rotates the eye down and out
- Lateral rectus—Moves the eye laterally (temporally)

CN II is responsible for transporting the image that comes in through the retina, but CNs III, IV, and VI are responsible for the movements of the eye (Fig. 7-4). CN III: Oculomotor innervates all of the muscles of the eye, except the superior oblique that is innervated by CN IV: Trochlear and the lateral rectus muscle that is innervated by CN VI: Abducens.

Figure 7-4 Innervation of the eye muscles. CN, cranial nerve.

Constriction and dilation of the pupil are also oculomotor functions of the eye. The muscles that control pupillary functions are the sphincter pupillae muscle and ciliary muscle, which are both innervated by CN III. Accommodation, an increase in the curvature of the lens to focus on near objects, is also controlled by the ciliary muscle.

Visual Fields

Although it would logically seem as if the right eye would perceive the right visual field and the left eye the left visual field, that is not how the visual system functions. Each visual field is perceived and processed by half of each eye⁹ (Fig. 7-5). For each eye, the optic nerve (CN II) is divided into half and wraps around the back of the eye. The left visual field is perceived by the nasal half of CN II in the left eye and the temporal half of CN II in the right eye. The right visual field is perceived by the temporal half of CN II in the left eye and the nasal half of CN II in the right eye. Visual information from the nasal halves of the retina crosses over at the optic chiasm and is transmitted

and processed on the contralateral half of the visual cortex. Visual information from the temporal halves of the retina, however, continues to the ipsilateral half and is processed on the same side of the visual cortex.¹⁰

Figure 7-5 Model of visual pathway.

Anterior to the lateral geniculate nucleus, some of the optic radiations carry visual information to the temporal lobes (Meyer's loop). Meyer's loop carries some of the visual information from the superior quadrant of the contralateral visual field. More medial parts of the optic radiations, which pass under the cortex of the parietal lobe, carry some visual information from the inferior quadrant of the contralateral visual field.¹¹

Impairments of Visual Function

Visual impairments may be caused by congenital or acquired disorders. Low vision disorders, infection, or trauma to the visual system or neurological systems that support vision can result in visual impairments. Low vision disorders, such as cataracts that cloud the lens; diabetic retinopathy and macular degeneration that deteriorate the center of the retina; and glaucoma that damages the optic nerve can all result in visual impairments.⁴ Damage, either due to infection or trauma, to any of the structures of the visual system can also result in visual impairments. These visual impairments can include visual acuity, oculomotor, and visual field dysfunction.

Visual Acuity

Refractive errors, in which the image is not accurately focused on the retina, include myopia (nearsightedness), hyperopia (farsightedness), and astigmatism (asymmetrical or distorted vision at any distance). In myopic vision, the image falls short of an exact focus on the eye because the eye is too long. The person can focus accurately on images that are near, but not on those that are far away. The opposite is true for hyperopia in which the image overshoots the retina. The person with hyperopia is farsighted, meaning that images that are far are clear, but those that are close are blurry. Astigmatism is caused by a curvature of the eye or the lens that then bends the light as it enters causing a distortion of the image on the retina.

As with the rest of the body, aging will impact the muscles and fluid of the eye and may cause presbyopia. Presbyopia is a loss of accommodation of the lens and a shortening of the eye caused by loss of aqueous fluid, resulting in the hyperopia in which the image overshoots the retina and the person becomes farsighted. This typically begins around 40 years of age.

Contrast sensitivity can also be impaired and typically declines with age. An inability to perceive contrast may be a combination of factors such as decreased acuity that result from refractive disorders, reduced pupillary function that regulates the input of light on the retina, and impaired accommodation of the lens.¹²

Visual scotomas, holes in visual acuity, can also occur. Scotomas can be caused by diseases or trauma that degenerate the macula or the retina, demyelinate or damage the optic nerve, or reduce the vasculature to the eye. They may also be caused by small lesions in the visual cortex.⁹

Oculomotor

Several oculomotor deficits may also be noted as follows:

- Strabismus: a misalignment of the eyes (e.g., esotropia: turned in, exotropia: turned out, hypertropia: one eye turned up)¹²
- Reduced ability to move one or both eyes through full range of motion
- An inability to smoothly and accurately track or pursue a target
- Nystagmus: small, involuntary, and repetitive movements of the eyes (sometimes elicited during attempts to perform saccadic eye movements)
- Convergence or divergence insufficiencies

Convergence and divergence are needed to bring objects into focus with both eyes. Binocular vision allows us to blend the two slightly different images from each eye into a singular image containing volume and depth (Fig. 7-6). Binocular vision depends on good eye alignment and the ability of the two eyes to work together. Binocular disparity is the visual difference in angles of the view of an object from two eyes when the eyes converge on an object. Binocular disparity is especially useful for perceiving depth and distance.

Figure 7-6 Binocular vision.

Visual Fields

Damage to the eye, optic nerves, or visual pathways may result in visual field losses (Fig. 7-7). Hemianopic visual field defects are loss of half of the visual field and are caused by damage to the visual pathways. Damage to the structures of the visual pathway posterior to the optic chiasm typically results in homonymous visual field deficits (loss of the same field in each eye). The visual field loss can be homonymous hemianopia, loss of the entire half of the visual field, or homonymous quadrantanopia, loss of one-quarter of each visual field. The loss is corresponding in each eye, which means that if the person loses the vision from the nasal half of the retina in the right eye, the vision from the temporal half of the retina in the left eye is lost. In this case, the visual loss would be a right homonymous hemianopia with a loss of vision for the right half of the visual field.

This could be due to damage to the optic tract, the lateral geniculate nucleus, the optic radiations, or the visual cortex on the left side of the visual pathway. Damage on the right side of the visual pathway posterior to the optic chiasm would result in left hemianopic deficits.

Figure 7-7 Visual fields deficits.

Homonymous quadrantanopia could also be caused by damage to parts of the temporal lobe (Meyer's loop), resulting in a superior homonymous quadrantanopia, or damage to the optic radiation underlying the parietal cortex, resulting in an inferior homonymous quadrantanopia.¹¹

Damage to the visual pathway posterior to the lateral geniculate nucleus may result in macular sparing.¹¹ Macular sparing is preserved input and processing of information from the fovea so that central, acute vision remains intact. The cause of this phenomenon is unknown.

Screening of Visual Skills

The occupational therapist should perform a screening of visual deficits with each client with whom he or she works. The screening can be completed in 5 to 15 minutes and should be completed before any testing of visual perception, cognition, and ADLs. Occupational therapists are not ophthalmologists or optometrists and, therefore, are not licensed to make diagnoses related to visual acuity, low vision disorders, or underlying neurological pathologies that may cause other visual deficits. The role of the occupational therapist is to screen visual function, make referrals as needed, and provide remediation, compensation, or adaptations to support function.

The occupational therapy assessment of vision includes a basic eye history; interviews with the client and/or family about subjective complaints (e.g., difficulty concentrating, double vision, eye strain, and bumping into objects on one side); and screening of visual acuity, oculomotor functions, and visual fields. If a deficit is noted during the screening, the therapist may elect to further assess the deficit using a standardized assessment. The Assessment table at the end of this chapter describes and summarizes the psychometric properties of various occupational therapy vision assessments.

Visual acuity, oculomotor control, and visual fields form the foundations for visual function. Although deficits in any of these visual functions can affect client performance, clients may not complain of any problems, or they may make complaints that appear unrelated to vision. Therefore, it is important to screen the foundations of visual function even if the client denies visual difficulties.

Setup and Procedure

Lighting

All testing should be done in a room with even, ambient lighting from overhead sources, windows, or lamps. Check for glare on testing surfaces and provide direct, task lighting if the ambient sources are not sufficient to illuminate testing materials.

Positioning and Process

Unless otherwise noted, conduct all testing sitting face-to-face with the client at the same height to directly observe the client's eyes. Confrontation testing, which is conducted to screen visual fields, should be completed as a two-person test with the therapist standing behind the client and an assistant in front to observe any eye movements.

Because functional vision and occupational performance are performed with both eyes, the screening should begin by assessing visual function with both eyes being used. If a problem is noted, one eye at a time should be occluded to determine the location of the problem, either in one eye or in both.¹²

A visual screening checklist can be used to guide the screening. See Figure 7-8 for an example visual screening form.

VISUAL SCREENING

Equipment

Screening of visual abilities can be completed with a simple set of equipment, most of which is readily available in settings in which occupational therapists practice (Fig. 7-9). The following is a recommended list.

Figure 7-9 Basic screening equipment.

- Reading materials such as a newspaper or magazine
- Ruler or dowel marked at 4 and 16 inches
- Contrast sensitivity chart
- Two pens, one with a red cap and one with a green or blue cap
- Penlight
- Scanning sheets
- Line bisection sheet
- Blank paper

Step 1: Visual History and Observation

Interview

Begin the screening by asking the client or the caregiver if the client is experiencing any difficulty with vision. Keep in mind that visual deficits may not be apparent to the client or caregiver or that the client may have reduced awareness of deficits as a result of an injury. Some specific complaints should be indicated to the therapist that a problem might exist. For example, a client may complain about sensitivity to bright lights, which may indicate a problem with pupillary function; about double vision, which may indicate misalignment or reduced convergence; or about difficulty focusing during eye movement, which may indicate impaired tracking or nystagmus. People with loss of central visual acuity commonly refer to their vision as being blurry or veiled; common complaints include reading difficulties and inability to distinguish facial features.

Next, ask the client about his or her current eyewear usage for near and distant vision. If the glasses are prescribed, ask how long it has been since the prescription has been renewed. All testing, except for confrontations, should be conducted using the most current eyewear. If glasses are not available, the client can view the visual acuity testing materials through a small pinhole punched into an index card.¹³ The pinhole method is a quick screen to determine whether visual acuity can be improved with eyeglasses or contact lenses, which can only be prescribed by an ophthalmologist or optometrist.

The therapist should also obtain a history of eye injury, deficits, and treatment. If available, a medical chart may contain some of this information, but ask the client or family member to confirm or add to any information about his or her visual history.

Observation

During the interview, the therapist observes the positioning of the client's body, head, and eyes. People typically hold their bodies in a neutral midline position and freely move their heads about as the environment is scanned or hold their heads directly facing objects or people on which they are focused. Deviations from midline with the head held to one side, tilted, pushed forward, or held facing slightly inferior or superior should be noted. For example, people with a left homonymous hemianopia may hold their heads slightly toward the left side to attempt to center the remaining visual field in front of their bodies.

During testing, the therapist should observe any attempts to compensate for visual loss. Clients may squint their eyes, move object closer or farther away, or turn materials sideways. They may also try to move their head instead of their eyes or blink excessively.

Eye Alignment

Observation of the resting position of the eyes should be noted before other oculomotor impairments are assessed (Fig. 7-10). Misalignment of the eyes may occur when there is an imbalance in the eye muscles or a fracture to the orbital socket. Note any inward, outward, upward, or downward deviations in one or both eyes.

Figure 7-10 Eye alignment.

Eye alignment is objectively measured by observation of the light reflected off of the corneas with both eyes at the same time. The client should wear glasses or corrective lenses if typically worn. The therapist asks the seated client to gaze at a target at least 20 feet away so that the eyes are in the position of primary gaze. The therapist holds a penlight centered approximately 16 inches away from the client's eyes. The therapist observes the light reflection in each eye; the reflection should be in the same position in both eyes (Fig. 7-10). Discrepancies in positions of the reflections are noted.¹⁴

Step 2: Visual Acuity Function

Distance Acuity

- Assure that the client is wearing prescribed eyewear.
- Point to three to five objects that are >10 feet away and ask the client to read or describe the image. Some examples can be wall clocks, paintings, or bulletin boards.
- Observe and record any difficulty with accuracy and observe any squinting or change in posture.

Near Acuity

- Assure that the client is wearing prescribed eyewear.
- Hold a newspaper or magazine 16 inches from the client's eyes (Fig. 7-11).

Figure 7-11 Visual acuity testing.

- Ask the client to read headline print, subheadings, and then fine print such as paragraph text.
- Observe and record any difficulties with accuracy at each of those levels and observe any squinting or change in posture or positioning of the text.

Step 3: Contrast Sensitivity

- Assure that there is sufficient lighting, but no glare.
- Have the client read the letters or numbers on a contrast sensitivity test, such as The Pelli-Robson contrast sensitivity chart, Vistech VCTS 6000 and 6500 Contrast Sensitivity Tests, or Hamilton-Veale Contrast Sensitivity Test (Fig. 7-12).

Figure 7-12 Contrast sensitivity testing.

- Note the level of contrast sensitivity and any deficits.

Step 4: Oculomotor

Fixation Testing

- Sit face-to-face with the client.

- Hold a target (pen or dowel tip) directly in front of and 16 inches away from the client's face (Fig. 7-13).

Figure 7-13 Fixation testing.

- Ask the client to focus on the object while the therapist counts for 5 seconds.
- Move the target horizontally 45° into the left visual field.
- Ask the client to look at the object, but to move only his or her eyes and not the head.
- Ask the client to maintain focus on the object while the therapist counts for 5 seconds.
- Repeat this in the right visual field.
- Note any difficulty maintaining fixation on the object.

Range of Motion

- Sit face-to-face with the client.
- Hold a target (pen or dowel tip) directly in front of and 16 inches away from the client's face (Fig. 7-14).

Figure 7-14 Range of motion and tracking/pursuits testing.

- Instruct client to hold his or her head still and move only the eyes.
- Move the target in a large capital H formation and an O formation while instructing the client to follow the target with his or her eyes.
- If the client is unable to follow the target (**Tracking/Pursuits**), ask the client to look in each of the following directions: up, down, right, left, diagonal up/right, diagonal down/left, diagonal up/left, and diagonal down/right.
- Note any difficulty moving in any of the directions.

Tracking/Pursuits

- While performing the aforementioned screening for range of motion, observe tracking/pursuits.
- Note the client's ability to maintain focus on the moving target while moving the eyes smoothly.
- Note any movement of the head or body that may be used to compensate for reduced range of motion or tracking/pursuits.

Convergence/Divergence

- Sit face-to-face with the client.
- Hold a target (pen or dowel tip) directly in front of and 16 inches away from the client's face.
- Instruct the client to focus on the target and to report when the target becomes blurry or double.
- Slowly move the target toward the client's nose and slowly back out to 16 inches (Fig. 7-15).

Figure 7-15 Convergence testing.

- Note the client's ability to bring two eyes together nasally and back apart.
- The client should report that the target becomes blurry at about 4 inches from the nose. Failure of the target to become blurry may be an indication of suppression of vision from one eye.
- Observe any drifting or deviations from the target in one or both eyes.

Saccades

- Sit face-to-face with the client.
- Hold a target (pen or dowel tip) in each hand. Each target should be of a different color (e.g., red and blue) and held approximately 16 inches away from the client's face and approximately 8 inches apart from each other.
- Instruct the client to hold his or her head still and look at one of the colored targets.
- Tell the client, "Look at the red target when I say red. Look at the blue target when I say blue, and remember to wait until I say to look."
- Instruct the client to look back and forth at the target for five to six times and then begin to move the targets farther apart. Instruct the client to keep shifting targets.
- When the targets are 12 to 14 inches apart, start to move them up and down and then cross them over each other and back three to four times while continuing to have the client switch focus on the targets.
- Observe the client's ability to maintain a focus on the target without over or undershooting it or moving the head or body. Also note any nystagmus that may be elicited during saccadic movements of the eyes (Fig. 7-16).

Figure 7-16 A. Saccades testing with shift to the right. B. Saccades testing with quick shift to the left.

Pupillary Function

- Sit face-to-face with the client.
- Hold a pen light or small flashlight on the temporal side of the client's head.
- Slowly move the light in front of the client's eye and then repeat on the other side (Fig. 7-17).

Figure 7-17 Pupillary function testing.

- Observe the constriction of the pupil in response to the light.
- Note any associated reactions (constriction of the contralateral pupil) because this is an indicator of intact communication between the cerebral hemispheres.
- If a pen light or flashlight is not available, the therapist can use an object such as a pen to elicit pupillary constriction that accompanies accommodation. The pen should be moved directly toward the pupil to elicit constriction.

Step 5: Visual Fields

Confrontations

- Stand behind the client with another therapist in front to watch for any eye movement.
- Hold a target (pen or dowel tip) in each hand.
- Instruct the client to look straight ahead and fixate on a target.
- Slowly move one target at a time into the client's visual field and back out (Fig. 7-18).

Figure 7-18 Visual field testing: confrontations.

- Instruct the client to point at each target when it comes into view.
- Repeat the movement of the targets into each quadrant of the visual fields.
- Note any delay in response in any of the quadrants or hemispheres.
- Lastly, perform a simultaneous presentation. Move both targets in at eye level at the same time. Note any delay in response on one side.

Scanning

- The client should be seated in front of a hard surface, such as a table or a desk. Give the client a pen.
- Place a scanning sheet at the client's midline squarely in front of the body. If the person attempts to move the paper to one side or turn the paper, tape the scanning sheet to the table in the correct position.
- Instruct the client to mark or cancel all of the targeted letters, numbers, or symbols on the sheet as quickly as possible (Fig. 7-19).

Figure 7-19 Sample of scanning sheet performance with right homonymous hemianopia.

- Observe the scanning pattern. Left to right and zigzag (left to right, then right to left) are the most common scanning patterns for people from Western societies in which they learn to read in a horizontal pattern. Other patterns are vertical or random. A vertical pattern may indicate reduced visual fields, and a random pattern may indicate deficits in attention.
- Measure the speed of scanning. Slowed speed may be used to compensate for deficits in scanning. Most scanning sheets can be completed in 1 to 2 minutes.
- Check the accuracy of the cancellations and note any patterns of errors. Missing targets in specific hemispheres or quadrants may indicate hemianopic visual field deficits.

Line Bisection

- The client should be seated in front of a hard surface, such as a table or a desk. Give the client a pen.
- Place a line bisection sheet at the client's midline squarely in front of the body. If the person attempts to move the paper to one side or turn the paper, tape the scanning sheet to the table in the correct position.
- Instruct the client to mark the middle or cut into half each line on the sheet (Fig. 7-20).

Figure 7-20 Line bisection sheet.

- Check the accuracy of the marks. If the line is marked toward one side on each line or if lines are missed on one side of the paper, it may indicate hemianopic visual field deficits. For example, a client who marks all of the lines toward the left side may be having difficulty seeing the right side of the lines, and therefore, the center is skewed.

Drawings

- The client should be seated in front of a hard surface, such as a table or a desk.
- Place a blank piece of paper in front of the client and give the client a pen.
- Instruct the client to draw a clock with the time at 9:15. You may also instruct the client to draw a person or draw a flower.
- If the person is having difficulty, this test can be graded by providing a line drawing to copy or a partially drawn figure.
- Note the accuracy of the figures and any lateralization, such as not drawing one side of the figure or drawing all of the parts of the figure on one half. These types of errors may indicate hemianopic visual field deficits (Fig. 7-21).

Figure 7-21 Example of figure drawing.

CASE STUDY

Patient Information

Quinn is a 43-year-old male who works full time as a project manager at a large technology firm. He was recently involved in a motor vehicle accident when driving home from work. As Quinn entered an intersection, another car ran a red light and struck his passenger side door at a high rate of speed. His car was totaled on impact. Quinn was sent to the hospital by ambulance for evaluation. He did not have any obvious head injuries and was discharged home the same evening. The next morning, Quinn's wife drove him to work. During the short 3-mile commute, Quinn experienced nausea and dizziness as a passenger in the car. While at the office, Quinn experienced headaches, dizziness, and sensitivity to light. He could not tolerate looking at his computer screen for more than a few minutes at a time. Quinn made an appointment with his primary care provider. He was diagnosed with a concussion, or mild traumatic brain injury (mTBI), and referred to occupational therapy for further evaluation. Prior to the accident, Quinn lived with his wife Sophie and two young daughters. He was independent in all ADLs and IADLs. Quinn maintained a very busy social life and active lifestyle.

Assessment Process

Prior to the initial evaluation, Quinn's OTR completed a chart review to create an occupational profile. During the client interview, the OTR asked open-ended questions to gain greater understanding of what a typical day is like for Quinn, what is important to him, and what he hopes to gain from occupational therapy intervention. The OTR summarized this information to create treatment goals with Quinn and Sophie. Next, the OTR administered the interviewer version of the National Eye Institute Visual Function Questionnaire-25 (NEI VFQ-25) to examine Quinn's vision-targeted health status. At the same time, Sophie completed the self-administered version of the assessment in the waiting room. Comparing the results of both assessments would provide insight into Quinn's current level of self-awareness, as well as the functional impact of visual impairment on his health-related quality of life.

The OTR completed a basic vision screening to assess Quinn's visual acuity, visual fields, oculomotor function (pursuits, saccades, convergence), and binocular vision. A standard vision chart was used to measure Quinn's visual acuity at near and far distances. A gross measurement of Quinn's visual fields was obtained through confrontation testing. Prior to screening Quinn's oculomotor function, the OTR assessed for misalignment of his eyes with a penlight. To assess smooth pursuits, the OTR instructed Quinn to follow a moving target in clockwise and counterclockwise motions, for two rotations in each direction. To assess saccadic eye movements, the OTR instructed Quinn to rapidly alternate his gaze between two stationary targets for five round trips, or a total of 10 fixations. To screen for deficits in convergence and divergence, the OTR instructed Quinn to fixate on a moving target as it moved slowly toward, and away from the

bridge of his nose. Should Quinn's vision screening indicate signs of visual impairment, the OTR would administer standardized assessments to gather additional information. Finally, functional task observations will be used to determine whether and how Quinn's visual impairment may be affecting his functional performance. The findings from Quinn's visual screening will assist the OTR when selecting adaptations and modifications to promote enhanced participation.

Assessment Results

Quinn's chart review revealed no significant medical history prior to the accident. During the client interview, Quinn's subjective complaints included headaches, dizziness, and sensitivity to light. He also reported blurred vision after brief periods of reading and difficulty keeping his place on the page. Sophie indicated increased irritability and fatigue because of disturbed sleep patterns. At baseline, Quinn had a love of books and was an avid reader. He enjoyed an active lifestyle as a mountain biking enthusiast and dedicated member of an amateur cycling team. Quinn also reported looking forward to coaching his daughter's soccer team next season.

Results from the NEI VFQ-25 identified role limitations, difficulty with near vision activities, and dependency on others because of vision. More specifically, Quinn reported extreme difficulty driving, reading ordinary print, and noticing objects off to the side when walking. He also reported accomplishing less at work and feeling limited in how long he can tolerate work because of his vision. Screening for specific visual deficits would help the OTR to explain these functional limitations.

During the interview, the OTR noted that although Quinn's body was in a neutral midline position, his head was held with a slight turn to the left. This posture was indicative of visual field loss. During confrontation testing, the OTR presented targets at the 2, 4, 6, 8, and 10 o'clock positions. Quinn had difficulty finding targets in the 8 and 10 o'clock positions (i.e., left peripheral visual field). Quinn's performance provided the OTR cause to "rule-in" the possibility of a visual field deficit.

Findings from Quinn's visual screening indicated oculomotor dysfunction; therefore, further examination with standardized assessments was warranted. The Northeastern State College of Optometry (NSUCO) Oculomotor Test was administered to evaluate Quinn's oculomotor function. As Quinn followed the target for smooth pursuits, he was observed to refixate four different times over four rotations. During the saccadic eye movement subtest, Quinn reported feeling nausea and dizziness after three round trips. The OTR observed moderate overshooting of targets on two occasions, as well as compensatory head movements >50% of the time. These results warrant a more comprehensive examination by a qualified eye care professional.

When assessing convergence and divergence, Quinn was unable to converge his eyes while fixating on a target positioned approximately 6 inches from the bridge of his nose. The OTR administered the convergence Insufficiency Symptom Survey (CISS) to quantify the severity of symptoms that may be associated with convergence insufficiency. Quinn's score of 30 on the CISS was indicative of convergence insufficiency. Functional observations confirmed that Quinn was having difficulty completing tasks at near point. Quinn was able to perform all ADLs and IADLs independently, except for driving, with minimal difficulty when given extra time. The results of Quinn's occupational therapy evaluation justified establishing a plan of care and making a referral to a neuro-optometrist for a more comprehensive evaluation.

Occupational Therapy Problem List

ADLs/IADLs:

- Client is dependent on his wife for community mobility due to visual impairment.
- Overall participation in daily activities has decreased due to irritability and fatigue.

Rest and Sleep:

- Sleep disturbances make falling and staying asleep difficult.

Work:

- Productivity at work is limited by constant headaches and fatigue.
- Sensitivity to light limits the client's ability to use a computer for extended periods of time.

Social Participation:

- Difficulty following moving objects hinders the client’s ability to fulfill his role as soccer coach.

Leisure:

- Decreased tolerance for visual motion limits the client’s ability to engage in physical activities such as mountain biking.
- Inability to converge the eyes at near point impacts the client’s ability to read.

Most Commonly Used Standardized Assessments

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Brain Injury Visual Assessment Battery for Adults (biVABA) ¹⁴	A battery of objective tests to evaluate visual processing skills following brain injury.	Individual subtests take between 3 and 5 minutes to administer. The entire test battery may take up to 60 minutes.	Not reported	Not reported	Not reported	<p>Strengths: Comprehensive includes detailed guidelines for administration and interpretation; can be used to evaluate clients with brain injury and low vision.</p> <p>Weaknesses: No psychometric data available. Only the visual search subtest has been empirically tested; however, most of the subtests have been accepted by ophthalmologists as valid and reliable assessment tools.</p>
Revised-Self-Report Assessment of Functional Visual Performance (R-SRAFP) ¹⁵	An objective assessment comprised of 33 vision-dependent ADL and IADL tasks that older adults with age-related eye disease most often report as being difficult due to vision loss.	Assessment takes approximately 20 minutes to administer.	Content Validity Index score of 0.9 demonstrates adequate evidence to evaluate the ability of older adults with vision impairment ^{16,17}	Internal consistency reliability coefficients for individual components (r range = 0.72–0.84); overall score (r = 0.92) (95% CI = 0.89–0.94) ^{16,17}	Not reported	<p>Strengths: Revised to reflect activities completed by older adults in the digital age; available online free of charge; provides detailed guidelines for administration and interpretation; toolkit spreadsheet automatically calculates composite score, percent disability, and C code level.</p> <p>Weaknesses: Requires copyright permissions from the authors.</p>

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
National Eye Institute Visual Function Questionnaire-25 (NEI VFQ-25) ¹⁸	A self-report survey of vision-targeted health status that measures the influence of visual impairment on health-related quality of life.	Administration of the interviewer format takes approximately 10 minutes.	Significant correlations between NEI VFQ-25 total score and SF-36 variables ($r = 0.06, p < 0.05$); best-corrected visual acuity (BCVA) for the better- and-worse seeing eyes ($r = 0.68, p < 0.0001$); contrast sensitivity (r range = 0.06–0.56, $p = 0.05$ –0.0001) ¹⁹	Internal consistency reliability coefficients for multi-item subscales (r range = 0.62–0.91); total score ($r = 0.96$) ¹⁹	Not reported	<i>Strengths:</i> Available online free of charge; interviewer administered or self-administered formats; a robust predictor of future health and mortality in population-based studies. <i>Weaknesses:</i> Scores do not translate to a specific level of visual acuity or visual field impairment.
Catherine Bergego Scale (CBS) ²⁰	A standardized checklist that detects the presence and degree of unilateral behavioral neglect and self-awareness of neglect (anosognosia) during self-care activities.	Administration may take approximately 15–45 minutes, depending on severity.	Significant correlation between CBS total score and performance on five conventional paper-and-pencil tests (r range = 0.49–0.77, $p < 0.0001$). Anosognosia correlated significantly with neglect severity ($r = 0.82, p = 0.0001$). ^{21,22} Significant correlation with line bisection subtest on the BIT ($r = 0.54, p < 0.05$). ²³	Good inter-rater reliability (r range = 0.59–0.99). Internal consistency reliability coefficients between individual question scores and CBS total score (r range = 0.58–0.88). ²² No studies have reported the test–retest reliability of the CBS.	The CBS was more sensitive to detecting the presence of spatial neglect than conventional paper-and-pencil tests. ²²	<i>Strengths:</i> Involves direct observation of performance during self-care activities; provides client insight into disabilities; clinician administered checklist and patient administered questionnaire formats. Normative data for adults. ²⁴ <i>Weaknesses:</i> No manual: for instructions on administration and scoring, see the Kessler Foundation Neglect Assessment Process (KF-NAP). ²⁵ May not be appropriate for some clients as test items require upper and lower limb movements in various testing positions.

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Behavioral Inattention Test (BIT) ²⁶	A standardized assessment battery that detects the presence and extent of visual neglect. Versions include the Conventional (BITC) and Behavioral (BITB).	Administration takes approximately 30–40 minutes.	Significant correlations between BIT scores and Occupational Therapy Checklist ($r = -0.65$), the Rivermead Activities of Daily Living Assessment ($r = 0.55$), ²⁷ and the Barthel Index ($r = 0.65$). ²⁸	Excellent test–retest reliability ($r = 0.89$ BITC; $r = 0.97$ BITB). Inter-rater reliability ($r = 0.99$ BITC; $r = 0.99$ BITB). ²⁷	The BITB was the single best predictor of poor functional outcomes at 3, 6, and 12-month follow-ups after stroke. ²⁹	Strengths: Involves observation during everyday tasks. Detects different forms of visual neglect. Normative data for adults. ²⁷ Weaknesses: Measures neglect in peripersonal space only. Unable to distinguish between sensory and motor neglect. Should not be used with client who have difficulty communicating (e.g., apraxia or aphasia).
Convergence Insufficiency Symptom Survey (CISS) ³⁰	A standardized self-report survey designed to quantify the severity of symptoms associated with convergence insufficiency.	Administration takes approximately 10 minutes.	Significant correlations between the responses of adults (0.88) and children (0.77). ³¹	The mean difference in CISS scores between the first and second administration (0.68 points, SD = 4.2) indicates minimum bias. ³¹	The CISS demonstrates excellent discrimination (sensitivity = 97.8%, and specificity = 87%). ³¹	Strengths: Available online free of charge; clinician administered or self-administered formats; Normative data available for children aged 9–18 ³⁰ and adults aged 19–30. ³¹
Mars Letter Contrast Sensitivity Chart ³²	An objective screening to determine the lowest contrast level that can be detected.	Administration takes approximately 1 minute on average.	Mean contrast sensitivity scores on the Mars test and the Pelli-Robson test did not differ significantly for the group as a whole, for subgroups, or between age groups. ³³	The Mars test shows good agreement with the Pelli-Robson test and similar test–retest repeatability. ³³	Not reported	Strengths: Hand-held, durable, and portable; easy to illuminate evenly, greater accuracy than wall charts due to finer contrast decrements and scoring procedure.
Useful Field of View (UFOV) Test ³⁴	A standardized assessment designed to estimate the spatial extent of the useful visual field of view.	Administration takes approximately 15 minutes.	Scores on the UFOV were highly correlated when using either a touch screen or mouse to respond ($r = 0.916$, $p = 0.001$). ³⁵	The UFOV has good test–retest reliability when using a mouse ($r = 0.88$) or touch screen ($r = 0.73$). ³⁵ Internal consistency reliability coefficients between three UFOV subtests (r range = 0.72–0.80) and composite score ($r = 0.88$). ³⁶	The UFOV showed better sensitivity and specificity as compared to standard perimetry testing and crash risk as compared to conventional neuropsychological measures. ^{37,38}	Strengths: Strong predictor of fitness to drive and motor vehicle crashes in older adults. Normative data for older adults aged 65–94. ³⁷ Weakness: The extent of usable field may not be constant across testing parameters and spatial range.

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Developmental Eye Movement (DEM) Test ³⁹	A standardized assessment of the quality, speed, and accuracy of saccadic eye movements.	Administration takes <5 minutes.	All DEM subtests except for ratio had significant negative correlations with the Wide Range Achievement Test (WRAT): vertical time ($r = -0.79, p < 0.001$); horizontal time ($r = -0.78, p < 0.001$), ³⁹	The DEM has good test-retest reliability for vertical time ($r = 0.89, p < 0.001$) and horizontal time ($r = 0.86, p < 0.001$). Medium test-retest reliability for ratio ($r = 0.57, p < 0.01$). Internal consistency reliability coefficients between all subtests were significant ($p < 0.001$), except vertical time and ratio score ($r = -0.5$). ³⁹	Not reported	Strengths: Useful for patients with poor attention and concentration. Normative data for children age 6–13 ³⁹ and youth and adult aged 14–68. ⁴⁰ Weaknesses: The visual-verbal format requires reading numbers; therefore, it is not useful with nonverbal individuals.
Northeastern State College of Optometry (NSUCO) Oculomotor Test ⁴¹	A standardized assessment that uses direct observation to assess visual saccades and pursuits.	Administration time is <5 minutes.	Significant correlations between the oculomotor behavior of above average and below average readers on a standardized reading assessment ($p < 0.05$). ⁴²	Good test-retest reliability ($r = 0.87, p < 0.05$). ⁴³ Inter-rater reliability pursuits ($r = 0.73$); saccades ($r = 0.75$). ⁴¹ Internal consistency has not been reported.	Not reported	Strengths: Requires limited verbal interaction. Examiner can make objective observations of performance to decide whether referral to a vision specialist is needed. Normative data for ages 5 to 14+. ⁴³ Weaknesses: Has not been formally tested on adults with acquired brain injury.

ADL, activities of daily living; IADL, instrumental activities of daily living; CI, confidence interval; SD, standard deviation.

Chapter 8

Visual Function Intervention

Christine P. Below and Kelly Lewis

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Identify and describe specific treatment strategies for low vision (LV) and visual deficits related to neurological conditions.
2. Identify and describe treatment approaches for visual field defects.
3. Describe the functional implications of LV diagnoses and visual deficits resulting from neurological injury.
4. Apply understanding of best intervention when providing treatment for clients with visual dysfunction.

CHAPTER OUTLINE

Introduction
Conceptual Foundation Underlying Interventions for Visual Impairment
LV Disorders
Neurological Vision Disorders
Specific Interventions for Visual Impairments
Remediation of Visual Deficits
Compensatory Strategies for Visual Deficits
Adaptations for Visual Deficits
Summary
Case Study

TERMINOLOGY

Anchor: a visual or tactile cue on the side of visual field deficit to indicate starting position and facilitate scanning.

Central vision: the portion of the visual field, which is the inner 30° of vision and central fixation.

Eccentric viewing (EV): a visual compensatory technique in which a person looks slightly away from the subject in order to view it peripherally with another area of the macula/retina.

Fresnel prism: a compensatory lens that is applied to glasses to shift an image from the nonseeing area into the intact visual field, typically used with individuals with homonymous hemianopsia.

Peripheral visual field: the portion of vision that is outside the center gaze, and it is the largest portion of the visual field.

Preferred retinal loci (PRL): a spot on the retina just outside the damaged area that allows a person to see using his or her best vision during EV.

Relative distance magnification: a nonoptical enlargement strategy achieved by decreasing the distance between the desired stimulus and the eye.

Relative size magnification: an enlargement strategy in which the actual size of the object is increased, thereby increasing the retinal image with either optical or nonoptical devices.

Vision therapy: an organized therapeutic regimen used to treat a number of neuromuscular, neurophysiological, and neurosensory conditions that interfere with visual function.

Visual efficiency: the visual system's ability to clearly, efficiently, and comfortably gather visual information at school, work, or play. The various component skills that are important in this process are called visual efficiency skills and include the subcategories of accommodation, binocular vision, and ocular motility.

Visual integrity: the visual system's ability to see clearly at all distances and have a healthy optical system and eye.

Introduction

Occupational therapists address visual impairments in adults following neurological injury and age-related eye conditions. Persons with visual impairments that have resulted from injuries or age-related eye diseases may experience decreased ability to use their vision to participate in daily occupations. Reading, writing, and driving are almost completely dependent on vision, and many other functional activities may be negatively impacted by a decline in vision. Occupational therapists need to understand how vision is related to activity demands, and the impact of vision loss on a person's occupational performance to provide effective treatment to maximize safety, independence, and confidence for completing daily functional activities. Occupational therapists need to also be aware of the various health care professionals that are involved in treatment of visual deficits. A preferred model of treatment for visual impairments whether related to low vision (LV) conditions or neurological conditions includes a team of practitioners who may include, but is not limited to, ophthalmology, optometry, vision rehabilitation therapists, orientation and mobility specialists, and occupational therapists.

Neurological causes of vision disorder include traumatic brain injury (TBI), stroke, and concussions; and diseases such as Parkinson, multiple sclerosis, and Alzheimer dementia.¹ According to Warren's hierarchy of visual perception, visual foundation skills, including acuity, visual fields (VFs), and oculomotor function, should be addressed before high-level perceptual skills.² While some visual impairments following neurological injury may be remediated, most LV conditions are progressive and will be addressed using compensatory and adaptive strategies. This chapter focuses on treatment of visual foundation skills of acuity, oculomotor, and visual field deficits (VFD).

Conceptual Foundation Underlying Interventions for Visual Impairment

A functional definition of LV is uncorrectable vision loss that interferes with daily activities. It is better defined in terms of function, rather than numerical test results.³ In other words, LV is not enough vision to do whatever it is you need to do, which can vary from person to person.

Many LV conditions cannot be corrected with surgery, leaving the individual with permanent vision loss. It is the occupational therapist's job to instruct and educate these individuals in techniques that will allow safe functioning at the highest level of independence possible in all activities of daily living (ADLs) and instrumental activities of daily living (IADLs).

An occupational therapist must use his or her best clinical judgment to choose treatments involving remediation, compensation, and/or adaptation. Each eye condition has its own set of symptoms, and each individual has a unique set of functional challenges relating to his or her eye condition. Therefore, it is important to know which strategies to use for the best functional outcome.

Remediation

Often, remediation is the preferred first treatment to address the underlying cause. Remediation, however, is only possible for some oculomotor conditions caused by muscle weakness or cranial nerve involvement. Each oculomotor issue has its own set of remediation strategies. Scanning and tracking exercises can be initiated to increase the strength of the eye muscles involved. Generally, scanning exercises start small and then advance to cover a larger area. For saccades, exercises are started at a greater distance, which requires less precision when changing focus from one object to another. As control is gained, near exercises are introduced, which require more precise control. For some oculomotor issues, a referral to an optometrist or ophthalmologist is advised because **vision therapy** may be indicated. This is true for binocular vision deficits.

In some cases, remediation has been shown to be not effective. For decreased acuity, remediation is not possible, so adaptation and compensation techniques are initiated to immediately impact safety and function, as well as a referral to an optometrist or ophthalmologist. Although controversy exists regarding the ability to remediate VFD, an occupational therapist will introduce compensation and adaptation strategies. In a situation when safety is at risk, compensation and adaptation strategies are introduced immediately to minimize safety risks during functional activities. Compensation and adaptation strategies may need to be implemented prior to remediation in this case.

Compensation

Compensation is the use of internal and/or external strategies to improve performance on a desired activity. This involves using a top-down approach to maximize safety and independence immediately. Examples of compensation include moving an object closer to the eye for better viewing, pacing techniques, organizational strategies, organized scanning patterns, line guides, and **anchors** to name a few.

Each condition requires its own set of compensatory strategies. For example, for poor oculomotor control that affects keeping one's place while reading, a line guide or using a finger to keep one's place may be taught. Having a bright-colored anchor at the left and/or right side of the page to encourage full scanning of the page may be helpful for those with decreased scanning abilities and/or VFD. Decreasing clutter in the environment may assist a person in finding an item when scanning ability is compromised. By teaching an individual about an organized scanning pattern, he or she is more likely to find an item when searching a busy cupboard or drawer. These strategies are taught to the individual with the goal of being used independently to maximize function and safety.

Adaptation

Adaptation is the process of using changes in the environment or changing the demands of a task to increase safety and function. Like compensation, adaptation is a top-down approach, and it can be used when treating all aspects of LV. The most common forms of adaptation for an individual with decreased vision are adjusting placement and intensity of lighting, increasing contrast between items, and adjusting print size to one that can be easily seen. Audible devices such as a talking thermometer and other sensory substitutions such as use of bump dots are common adaptation strategies.

Depending on the cause of decreased visual function, it may be appropriate to begin with remediation and then advance to compensation and adaptation if progress is not made following remediation efforts. Monitoring for progress and safety must be constant when deciding which type of treatment to use.

LV Disorders

Major causes of LV include cataracts, macular degeneration, glaucoma, and diabetic retinopathy (Fig. 8-1). In general, older adults with LV are approximately two times more likely to fall than those without vision loss.⁴ The underlying cause of each LV condition is different; however, the end goal of treatment is the same: to facilitate safe functional performance in ADLs and IADLs. Unfortunately, the underlying cause of many LV eye conditions cannot be remediated. An occupational therapist must look at each functional activity that is affected and determine the most appropriate treatment approach. There are many ways to adapt activities and compensatory strategies that can be taught and implemented to assist individuals with LV so that they can function at the highest level possible.

Figure 8-1 Simulated vision loss for most common low vision conditions.

Cataracts

- Functional Impact
 - Decreased visual acuity
 - Decreased contrast sensitivity
 - Difficulty with night driving
 - Diplopia
- Occupational therapy (OT) intervention
 - Color and contrast enhancement
 - Magnification
 - Management of lighting
 - Sensory substitution
 - Organizational strategies

Glaucoma

- Functional impact
 - Difficulty with night vision

- Difficulty with mobility because of limited peripheral vision
- End stage:
 - Difficulty with facial recognition
 - Difficulty with reading owing to central field involvement
- OT intervention
 - Education on VF impairment
 - Color and contrast enhancement
 - Glare control
 - Sensory substitution
 - Visual skills training
 - Organizational strategies
 - Magnification

Diabetic Retinopathy

- Functional impact
 - Can affect central and peripheral VFs
 - Development of scotomas
 - Decreased contrast and color discrimination
 - Decreased night vision
 - General visual fluctuations
- OT intervention
 - Color and contrast enhancement
 - Glare control
 - Magnification
 - Lighting enhancement
 - Visual skills training
 - Sensory substitution
 - Organizational strategies

Age-Related Macular Degeneration

- Functional impact
 - Decreased visual acuity, especially central vision
 - Creates scotomas (blind spots) in central vision, causing individual to miss pieces of the whole picture
 - Decreased contrast sensitivity
 - Difficulty with night driving and diplopia
- OT intervention
 - Color and contrast enhancement
 - Magnification
 - Management of lighting
 - Sensory substitution
 - Organizational strategies
 - Teach eccentric viewing (EV) strategies
 - Safety education

Psychosocial Aspects of LV

Individuals with LV can experience a variety of psychosocial challenges. It is estimated that between 10% and 30% of patients with macular degeneration develop clinically significant depression.⁵ Deemer et al. report that depression in those with macular degeneration is associated with “a decline in visual function and greater levels of disability, medical costs, and mortality rates.”⁵ More than one-third of individuals with LV report not getting as much social interaction as they would like, compared with one-fifth of those without vision impairment.⁶ Social relationships can be uncomfortable for the person with LV because of the difficulty interpreting visual social cues and decreased understanding by others.⁶ Anxiety can also impact a person challenged with LV. One study found that persons with visual impairment were more than twice as likely to be diagnosed with a major depressive and/or anxiety disorder than their normally sighted peers.⁷ By being aware of this correlation and making necessary referrals as needed, occupational therapists can help with these psychosocial aspects of vision loss. It is also important for the occupational therapist to

educate his or her client about the potential for depression and anxiety and encourage participation in activities that can combat social isolation, depression, and anxiety.

Neurological Vision Disorders

Clients who have experienced a neurological event, such as a cerebrovascular accident (CVA) or a TBI, may experience a variety of vision-related problems, including decreased acuity and refractive disorders, oculomotor dysfunction, and VFD. An injury to the brain may impact **visual integrity** (visual acuity, refraction, and eye health), **visual efficiency** skills (accommodation, binocular vision, and ocular motor dysfunction), and VFs (homonymous hemianopsia or homonymous quadrantanopsia).

In order to help clients regain complex functions, treatment of visual dysfunction should be started at the basic processing level and proceed through the hierarchy of skills according to Warren's visual perceptual hierarchy. It is crucial that the occupational therapist performs a vision screen, makes appropriate referrals to the eye care physician, and communicates the functional impact of vision deficits to other therapy team members in order to maximize the individual's rehabilitation potential.

When referring to an eye care physician, it is important that the eye care professional practices with a full appreciation of the complexity of vision and preferably has extensive experience in vision rehabilitation and functional vision care. If possible, it is beneficial to refer the client with neurological visual deficits to a physician associated with the College of Optometrists in Vision Development.

Specific Interventions for Visual Impairments

Decreased Acuity and Refractive Errors

Occupational therapists take on a supportive role when treating clients with decreased acuity and refractive errors. Individuals with LV experience acuity levels of 20/70 and worse.⁸ It is important to refer a client to his or her optometrist or ophthalmologist if refractive errors are suspected for correct diagnosis of potential problems and/or correction with prescription lenses if applicable. Decreased acuity can impact many aspects of ADLs and IADLs, including all self-care activities, reading and writing, home management, leisure and work activities, driving, and safety.

Accommodative Disorders

A client with accommodative insufficiency will have difficulty focusing on targets at various distances and may complain of blurred vision, headaches, eye strain, difficulty reading, fatigue, movement of print when reading, and difficulty with ADLs requiring sustained close work, or he or she may avoid close work altogether. Accommodative deficiencies occur in 20% to 30% of clients after TBI.⁹

One of the most effective tools for treatment of accommodative disorders is the use of lenses.¹⁰ Similar to adults over 40 years of age who have presbyopia, lenses can be used to compensate for impaired accommodation. The occupational therapist may take on a supportive role by facilitating optometric treatment recommendations and helping to ensure that the client follows the recommendations during therapy and during other functional activities. This may involve making sure that the patient wears the prescribed glasses or prisms in the appropriate manner.

Treatment for Visual Acuity/Refractive Disorders

Remediation

- Cannot be remediated by OT. Refer to eye care professional.

Compensation

- Move items closer
- Move items farther away
- Use tactile substitutions
- Organize personal spaces

Adaptation

- Increased lighting

- Increased contrast
- Wear corrective lenses prescribed by eye care professional
- Magnifiers
- Glare filters
- Increased size of print
- Audible and/or tactile substitution

Oculomotor Dysfunction

Individuals living with LV may experience difficulty with fixation, tracking/pursuits, and saccades all of which impact visual function. Without good fixation, an individual may not be able to input information about an object or a scene correctly and thoroughly. Tracking/pursuits and saccades involve following a moving object and switching back and forth between two objects, respectively. If an individual's vision is impaired, all three of these visual skills may be affected, therefore impacting the person's ability to read and complete ADLs/IADLs.

Oculomotor dysfunction, including decreased fixation, saccades, and tracking/pursuits, can also occur following a neurological injury and is commonly treated by occupational therapists. Ocular motility disorders affect a person's ability to perform functional tasks such as reading, writing, and driving. The therapist may observe excessive head movements, and the client may complain of frequently losing their place and/or skipping lines when reading. Impaired oculomotor skills can also reduce visual scanning ability, which may result in disruption of high-level visual cognitive skills.

A referral should be made to ensure best optical correction of refractive problems and accommodative and binocular vision disorders. Although the occupational therapist may take on a more supportive role when treating acuity and refractive disorders, they are able to address eye movement disorders without specialized training.

It is important to begin working within the capabilities of the patient to achieve some early success. The occupational therapist will emphasize accuracy first and then speed when treating saccadic or eye pursuit movements. For saccades, the therapist will start with gross (large) eye movements and progress to fine (small) eye movements. For pursuits, the sequence is opposite, from fine (small) to gross (large) eye movements. The therapist will want to eliminate head movements during both tracking/pursuit and saccadic eye movements that can be reasonably accomplished without head movement. As the client progresses, increase the complexity of the task to facilitate more reflexive, automated pursuits and saccades. Examples include adding a metronome, a balance board, or simple cognitive tasks during any ocular motility task.¹¹ There are also several computer programs and apps that address ocular motor skills. Vision therapy activities should be used by the occupational therapist in conjunction with functional activities that address tracking/pursuits and saccadic eye movements.

Binocular Vision Disorders

Binocular vision disorders are characterized as either strabismic or nonstrabismic, can occur after stroke, and are the most common vision problem following TBI.¹² Binocular vision disorders are often caused by damage to the cranial nerves 3, 4, or 6; midbrain injury; or injury to the oculomotor nuclei. With strabismus, the eyes are not aligned, and it is characterized by the eyes turning in (esotropia), out (exotropia), up (hypertropia), or down (hypotropia). A hallmark symptom of binocular vision is double vision or diplopia, which can greatly interfere with a client's ability to participate in functional tasks. Other visual symptoms may include blurred vision, headaches, eye strain, reading problems, avoidance of reading or other near tasks, and difficulty with ADLs that require stereopsis (driving, reaching for objects, pouring liquids).

Occupational therapists treating a client with binocular vision deficits should do so with guidance from an ophthalmologist or optometrist. If double vision is occurring, increasing the visual comfort of a client should be addressed first to increase his or her ability to participate in rehabilitation. Similar to accommodative disorders, occupational therapists in an inpatient rehabilitation setting may take on a supportive role when treating a client with binocular vision disorders. The therapist may implement the use of compensatory strategies or adaptations, such as using larger print and limiting time spent on tasks, which cause discomfort. The occupational therapist may also have the client perform ocular calisthenics to improve eye muscle function and prevent contractures of the involved muscles. An example of an activity involves the client looking all the way to the right, then all the way left, then up, and then down while holding each position for several seconds. This would

be repeated two to three times a day for a few minutes at a time.¹² An occupational therapist who specializes in vision therapy and often works under the direct supervision of an ophthalmologist or optometrist may use advanced vision therapy techniques including computer programs and use of virtual reality systems to target binocular vision disorders.

Convergence Insufficiency

Convergence insufficiency is a nonstrabismic binocular vision disorder in which a person's eyes have difficulty converging on a near object. A person with convergence insufficiency may experience difficulty with sustained near tasks, complain of headaches, and/or avoid close work. Impaired depth perception is often associated with convergence insufficiency. A referral to an optometrist is recommended if the occupational therapist suspects convergence impairments, as glasses and/or prisms may be necessary. Vision therapy procedures may also be used for convergence issues. The Brock string exercise (Fig. 8-2) involves a string either 6 or 12 feet long with different color beads. The client is asked to change his or her gaze from one bead to the next to practice convergence and divergence skills.

Figure 8-2 Brock string exercise.

Treatment for Oculomotor Dysfunction

Remediation

- Scanning exercises
- Tracking exercises
- Range of motion exercises
- Computer programs
- Dynavision
- Brock string exercises

Compensation

- Use visual anchors and line guides
- Use pacing strategies

- Increase awareness of deficit
- Head movements
- Teach systematic scanning

Adaptation

- Large print materials
- Prism glasses
- Increase lighting
- Increase contrast
- Eliminate visual clutter

Visual Fields

VFD associated with CVA or TBI include hemianopsia or quadrantanopia. This occurs due to a lesion along the visual pathways at some point from the optic nerve to the visual cortex. The right hemisphere of the brain carries information for the left half of the VF in both eyes, and the left hemisphere carries information from the right half of the VF in both eyes. VFD occur in 36% of people with right stroke and 25% of those with left stroke.⁹

An important aspect of VFD for occupational therapists to consider is perceptual completion. The visual system is automatic, and the brain tends to fill in any gaps caused by VFD. Because our brain can naturally and unconsciously complete a picture, patients with VFD will not necessarily recognize that they are missing part of the picture. Although a client with VFD may not recognize part of the picture is missing, he or she may complain of difficulty in mobility or ADLs. If visual inattention coexists with VFD, the rehabilitation process can be complicated by the client's difficulty implementing visual scanning strategies.

Education to create awareness and training for compensatory strategies is critical. Intact **peripheral VFs** play a large role in safety with ambulation and as our alerting system to make us aware of approaching danger. When the peripheral fields are affected, scanning strategies are an essential piece of the treatment plan. Peripheral VF loss may cause a person to not see drop-offs, obstacles, pets, or people because of a limited field of view.¹³ Safe ambulation is often impacted by decreased peripheral VF.

Visual scanning is the ability to efficiently, quickly, and actively look for information relevant to your environment.¹¹ It is important for individuals with VF loss to use their remaining vision efficiently by quickly scanning for obstacles in the environment when walking around their homes or in the community. Individuals with peripheral vision involvement need to use organized patterns for scanning to compensate for the missing areas of vision.¹³ A horizontal search pattern, vertical, or combined pattern can be used depending on situation. Field expansion devices such as prisms and telescopes used in reverse may be also beneficial.

Central VF Loss

Central field loss is a primary symptom of macular degeneration. Central field scotomas may interfere with reading, identifying objects, and clearly seeing a person's face. The scotoma may be relative or absolute in nature. Dense scotomas, or absolute scotomas, are insensitive to very bright objects, often making a black spot in the VF. Relative scotomas may create an effect of blur or fog over the image being looked at.¹⁴ Ring scotomas are circular VF defects centered on fixation. Central ring scotomas are most often found within the central 10°. ¹⁵ Individuals with central field scotomas may complain of things disappearing and then reappearing when they shift their point of fixation.

Treatment for VFD

Remediation

- VFD are not effectively remediated

Compensation

- Use of organized scanning strategies
- Use of line guides
- Use of anchors

- Turning head to affected side
- Increase awareness

Adaptation

- High-contrast visual anchors placed on affected side
- Prism glasses
- Increased contrast
- Place items on unaffected side
- Increased organization of client's environment

Remediation of Visual Deficits

Vision therapy may also be referred to as orthoptics, vision training, visual training, or eye training. It is an organized therapeutic regimen used to treat various vision disorders that interfere with visual functioning (Fig. 8-3). Most commonly binocular dysfunction, accommodative dysfunction, and oculomotor dysfunction can be treated with vision therapy. There are some optometrists and therapists who specialize in vision therapy, and an overlap can be seen between the role of an occupational therapist and vision therapist for clients with neurological injury. Because of an occupational therapist's role in a rehabilitation setting, he or she is well positioned to screen and determine the need for a referral to an eye physician. If vision therapy is recommended, the occupational therapist may be best suited to provide vision rehabilitation or a vision therapist may need to be consulted. Any vision therapy provided should be done so with direct supervision and guidance by the optometrist. The occupational therapist may perform daily therapy techniques prescribed by the optometrist and, most importantly, can help the patient generalize visual skills into ADLs as well as assist with integration of compensatory and adaptive techniques.¹⁶ The general guidelines for vision therapy from an optometric perspective are outlined in the subsequent section. These principles are in line with our framework as occupational therapists and demonstrate the similarities between the way occupational therapists and functional optometrists practice.

Figure 8-3 Examples of computerized tracking/pursuits (A) and saccadic vision therapy activities (B).

General Guidelines and Principles for Vision Therapy

- Determine a level at which the patient can perform easily
- Be aware of the patient's frustration level
- Use positive reinforcement
- Maintain an effective training level
- Make the patient aware of vision therapy
- Set realistic therapy objectives and maintain flexibility with these objectives or endpoints¹¹

Vision Therapy Activities

- Hart chart saccades
- Symbol tracking

- Letter tracking
- Visual tracing
- Rotator-type instruments
- Flashlight tag

Compensatory Strategies for Visual Deficits

Many individuals with visual deficits can be taught to use compensatory strategies that will help them independently function in their desired ADLs and IADLs. For visual deficits that cannot be remediated or for safety reasons, this may be the starting point of intervention for the occupational therapist.

Preferred Retinal Loci Training

To maximize vision when dealing with a central field scotoma, a person must learn to “move” the scotoma out of the way and use an alternative spot on the macula not affected by the degeneration. This strategy is called **eccentric viewing (EV)**, and the position on the macula is the **preferred retinal loci (PRL)**. Once learned, an individual can use his or her PRL to view close or distant objects. Some clients may have identified and be using a PRL without training. However, to make sure he or she is using the best and most efficient PRL, education with exercises should be initiated and practiced, making the use of the most effective PRL habitual for best results. Exercises to maintain oculomotor control, fixation stability, and skills to refixate on an object are necessary to maximize independence with reading and other functional tasks involving **central vision**.

Scanning Training

Visual scanning training is one of the most common interventions that occupational therapists use for VFD and oculomotor deficits. Scanning training may be remedial in nature when used for increased range of motion, accuracy, and/or speed of eye movements. When used for VFD, the goal of compensatory training is to establish an effective search strategy and to facilitate use of a systematic organized visual search of the environment (left to right, top to bottom). Warren¹⁷ outlines the following components of an effective search strategy:

- Initiation of wide head turn toward the blind field
- An increase in the number of head and eye movements toward the blind field
- Execution of an organized and efficient search pattern that begins on the blind side
- Attention to and detection of visual detail on the blind side
- Ability to quickly shift attention and search between the central VF and the peripheral VF on the blind side

The occupational therapist will have the client complete visual scanning activities in personal, peripersonal, and extrapersonal space to address various tasks that require efficient scanning. Training may include paper-and-pencil tasks, computer programs, scanning in a functional setting, and use of specialized equipment, such as the Dynavision. Although the initial focus of visual scanning training is accuracy, as the client progresses, the speed of scanning will be emphasized and integrating movement during scanning is used to improve visual motor integration. Addressing visual scanning during mobility will help maximize safety during functional mobility tasks. If a client demonstrates good awareness of his or her VFD, visual scanning training can often be completed quickly, with the client demonstrating immediate use of search strategies.

Clients with VFD often have difficulty with reading tasks. With right VFD, the client must look into their field impairment as they read across the line. They may lose their place reading along or have difficulty identifying the end of the line. They may also have errors in word identification, such as with compound words; they may read foot when the word is football. Individuals with left VFD may have difficulty finding the beginning of the reading materials. In order to compensate for his or her VFD, the client must be aware of the problem and how it is affecting functional abilities. The occupational therapist may provide various types of cueing to facilitate effective scanning to the impaired VF. Use of an anchor (supplying a cue on the impaired side to indicate starting position) can assist the client in focusing attention back to the side of VFD. An “L” shaped marker can be used as an anchor, or a ruler or straight edge can assist the client with maintaining his or her spot when reading. Figure 8-4 illustrates reorientation of the reading materials as an effective strategy for reading with VFD.¹⁸ It may be necessary to add adaptations to the environment such as contrasting color to objects such as door frames and furniture to help the client be able to locate them and to maximize safety.

Figure 8-4 Example of compensatory strategy for reading with right hemianopsia.

Organization

Being organized is one of the most important strategies for someone with visual deficits to adopt. Keeping an item in a consistent place allows the individual to find it with less difficulty. Organizing money, items in the pantry or refrigerator, toiletries, and clothing in a way that makes sense to each individual is very beneficial. This can decrease frustration and the potential for mistakes or injury. If the individual is unable to use this strategy independently, it is important to educate family members in maintaining organization for their loved one's success and safety.

Sensory Substitution

People who have LV rely more heavily on tactile and audible strategies. These strategies are often simple, cost-effective, and easy to incorporate into everyday activities. For example, many microwaves have flat control panels with poor contrast for numbers and other desired settings. By placing a high-contrast, tactile bump dot on a frequently used control, an individual can locate and press with improved accuracy and decreased frustration. By placing a rust-proof safety pin on the tag of black pants, an individual can identify black pants from pants of another color. Pouring salt into the palm of the hand and then adding a pinch is a tactile way to apply the desired amount.

Talking clocks, books, bathroom scales, timers, screen readers, thermostats, and other audible devices assist individuals in hearing information versus reading it when vision is impacted. The pitch, speed, and volume of talking devices can often be changed to accommodate for individual preference or need. As with any condition, it is important to look at the individual's abilities and limitations to best determine intervention strategies.

Adaptations for Visual Deficits

Environmental adaptations are often necessary to maximize independence and safety for those with visual deficits. Lighting, glare, and contrast can be controlled or modified for maximizing performance during ADL and IADL tasks.

Lighting

Changes to the number of photoreceptors (rods) in the retina, hardening of the lens of the eye, presence of floaters, decrease in the pupil size, and common eye diseases like cataracts and glaucoma can reduce the amount of light that the eye can use and increase how sensitive the eye is to glare.¹⁹ For some tasks, an individual aged 60 years may need 10 times the amount of light that a 20-year-old person would need.¹⁹ With the large variety of lighting sources available today, it is important to educate individuals on the options and the reason older adults, especially those with LV, need more light and what type can be most helpful. Task lighting is lighting that can be adjusted to shine directly on a person's work (Fig. 8-5). Many individuals report that the natural light from the outdoors is the most beneficial. Therefore, the daylight light-emitting diode (LED) bulbs are often preferred for simulating the natural light of outdoors most closely. Positioning of light is also important to consider when completing tabletop tasks.

Figure 8-5 Example of a task light with good contrast of book on dark placemat.

Lighting Strategies

- Task lighting: Adjustable lamp placed to shine directly on work area for near activities. Recommended: an opaque shade positioned below eye level, LED daylight bulb (800 Lumens)
 - When increasing brightness, be aware of glare. Use of filters to manage glare with increased lighting can provide increased comfort and function.
 - Use LED flashlights for “spot-lighting”
 - Use under cabinet LED lighting in kitchens to brighten workspaces
- Ambient lighting is important for safety. LED daylight bulbs can be used to simulate natural sunlight.
 - Use nightlights in hallways, bathrooms
- Strip lighting along the floor in hallways to use as guidance

Glare Management

When making lighting adjustments, it is important to consider how glare can affect the eye. Sensitivity to glare is associated with many visual deficits. When in the sun or even when a person is sitting in the shade, sun can reflect from surfaces producing uncomfortable glare. By wearing a special filter with a polarized lens, glare is decreased (Fig. 8-6). Less glare can result in increased clarity and visibility. Reduced glare also lessens eye fatigue.²⁰

Figure 8-6 Colored fit over glare filters in a variety of colors.

Colored glare filters can be worn to enhance contrast when viewing a computer screen or television. Each individual may have different preferences regarding tint of these glasses. It is, therefore, beneficial to try a variety of colors to determine which is most effective.

Contrast Enhancement

People with LV disorders and visual dysfunction due to neurological injury may experience decreased contrast sensitivity. Decreased contrast sensitivity can significantly impact a person's ability to function. Difficulty seeing where to plug in an electrical appliance into an outlet, seeing the level of dark coffee poured into a black cup, being able to see an unpainted curb, or safely navigate a flight of stairs are all examples of functional issues. Education can assist in helping the individual know the potential safety implications of decreased contrast sensitivity. By applying a high contrasting color with tape or paint to the object/situation that presents difficulty, an individual may regain some independence in function and safety. For example, applying bright orange tape around the holes of a white electrical outlet located on a white wall or applying a bright-colored strip of paint/tape on each step of a staircase, or just to the top and bottom step to create more contrast can impact the individual's safety.

Magnification

Adults with visual deficits often benefit from using magnification. There are two main types of magnification that an individual can use: relative distance magnification and relative size magnification. **Relative distance magnification** is decreasing the distance from the person to the item that he or she is trying to see. An example of this is moving closer to the TV screen or bringing a paper closer to read the writing. **Relative size magnification** is achieved using large print-written material or a magnifier. Many items are available in large print: books, magazines, bills, clocks/watches, telephones, and kitchen timers are just a few of the many large print items available. Computers are often equipped with accessibility features to enlarge print for websites and e-mail programs. An individual may need additional magnification from an optical device. There are many types of magnifiers: hands-free, stand- and handheld, electronic (both desktop and portable), spectacles, and telescopes (see Figs. 8-7 and 8-8). Each type of magnification has benefits and challenges. Regardless of which type of magnification that is used, it is critical to communicate with an optometrist or other eye care professional for recommendations and to then complete education and training for best use and success with the magnifier during functional activities.

Figure 8-7 Variety of handheld and stand magnifier good for spot reading.

Figure 8-8 Types of magnification. *Top left:* Monocular/telescope. *Top right:* Stand magnifier. *Bottom:* Two types of handheld electronic magnifiers.

Useful Information about Magnifiers

- Bigger is not always better!
- Greater magnification = smaller field of view.
- Educate on client on correct distance to hold magnifier from material (working distance).
- Use handheld and stand magnifiers for “spot reading” only—it is often fatiguing for continuous reading activities.
- Desktop electronic magnifiers are best for continuous reading activities and can be used for writing tasks, also.
- Hands-free magnifiers can be used for crafts, managing insulin pumps and other tasks that require two hands.

Prism Systems

Prisms are often prescribed by optometrists in the case of VFD when the client has good awareness of his or her deficits. The prism is used to shift an image from the impaired VF into the intact area. The optometrists will often use a temporary prism called a **Fresnel prism**, which can be cut to shape and adhered to the client’s glasses (Fig. 8-9). This prism is advantageous because it is inexpensive and temporary and can be easily adjusted and removed. The optometrist may also prescribe a permanent prism that is ground into the client’s prescription glasses.

Figure 8-9 Fresnel prism placement for hemianopia.

A prism system with significant research is the Eli Peli Visual Field Expansion System. Peli²¹ introduced his method of field expansion using Fresnel prisms. The prisms are initially placed in the superior VF, with the prism's base positioned toward the side of the VFD, in the peripheral field. It is placed along the entire length of the glasses so that the prism creates peripheral diplopia, while allowing for clear central vision. This diplopia acts as a cue to look to the side of the visual impairment. Recent studies have shown the Peli prism system can expand the VF by as much as 20° to 40° and allows the patient to be aware of potential obstacles in the periphery.^{21,22}

Occlusion

Occlusion can be used to eliminate the symptoms of double vision and can make ADLs and mobility tasks more comfortable and tolerable. There are different types of occlusion: total and partial; opaque and translucent. Total occlusion is done with a pirate's patch or a clip-on occluder. The prescription may be to alternate the patch between the two eyes, to cover the eye that has an extreme decrease in visual acuity, or to cover the better-sighted eye to increase the function of the more limited eye. The use of occlusion is somewhat controversial, and many eye care professionals specializing in the area of vision rehabilitation are no longer recommending total occlusion. The use of partial, translucent occlusion is typically recommended for elimination of double vision in an adult client. A small, central, circular patch using translucent tape is sometimes enough to help a patient avoid double vision.¹¹ This type of occlusion allows for peripheral input and does not impact depth perception as total occlusion would. Any type of occlusion should be used under the supervision of an ophthalmologist, optometrist, or physiatrist.

Technology

Many people with visual deficits are able to use cell phones, tablets, and computers successfully for a variety of activities. Most computers can adjust text size, contrast, and brightness and may have text-to-speech capabilities located in the accessibility features. Large button, high-contrast keyboards are available as well as screen reading software, screen magnification software, and dictation software, which can assist individuals in maintaining independence with computer use.

Apps for smartphones continue to advance, creating many opportunities for individuals with vision loss. Voice over technology can assist with all aspects of smartphone use. Smartphones apps, that are often free of charge, can now be used to identify objects, read labels, and connect with sighted people to get information regarding new surroundings, an expiration date on an item, to name a color, etc.²³

Virtual assistants, such as Alexa or Cortana, can assist clients with setting reminders, dialing a telephone number, reading the news headlines, and setting a timer. Some assistants can also be programmed to assist with setting thermostats and turning on appliances with only the spoken words of an individual. Because a large majority of people living with LV are older and may not be aware of these resources, education must be completed to the client and the family regarding how technology may be able to help.

Client/Family Education

Educating the family members on the client's vision condition, prognosis, potential for progression, and functional impact can lead to greater understanding and success in maintaining independence. Reviewing recommendations for environmental adaptations, psychological consequences, available community resources, and the need for ongoing support can ease adjustment to vision loss. Family

and caregiver support can make a significant difference in an individual's level of function and quality of life when new challenges arise.

Summary

As the number of clients with visual impairment grows, it is vitally important for occupational therapists to have the skills and knowledge to be able to provide appropriate, evidence-based interventions including remediation, compensations, and adaptations to address LV disorders and visual deficits associated with neurological conditions. Although there are numerous studies in the field of optometry and ophthalmology regarding vision rehabilitation, there is a need for occupational therapists to research the effectiveness of our role in vision rehabilitation to ensure the best standard of care for clients with visual deficits. The occupational therapist is often in the best position to observe functional vision problems and may be the first on the rehabilitation team to identify a possible visual impairment. Because of the complexity of vision disorders and the significant impact they can have on a person's ability to function, the occupational therapist must also possess a good understanding of other professionals who should be involved in the evaluation and treatment of clients with visual impairments. The occupational therapist should make appropriate referrals, which will facilitate establishment of vision treatment strategies using a multidisciplinary approach that will maximize the client's occupational performance and safety.

CASE STUDY

Client Information

Janet is a 57-year-old woman referred by her optometrist for outpatient OT. Janet had a stroke 2 months ago that resulted in a right homonymous hemianopsia. Janet had no other residual deficits from her stroke. Janet was also referred to an LV optometrist for prism evaluation, and the LV optometrist requested additional training be completed by the occupational therapist using the temporary Peli prism before the permanent prism is prescribed. Janet lives with her husband in a trilevel home, and prior to her stroke, she was completely independent and very active. Janet expressed concern that her husband doesn't understand her vision deficits and why she is having difficulty when moving around in unfamiliar environments.

Assessment Process and Results

A visual acuity assessment was completed using the LEA Numbers Low Vision Chart. The SK Read was utilized to assess functional reading skills. Client also engaged in scanning activity to assess speed and accuracy of scanning into impaired VF. Although client demonstrated functional near acuity using acuity chart, she experienced functional difficulty with reading, scanning, and mobility because of right VF loss. Client demonstrated good awareness of her deficit and was motivated to participate in therapy.

OT Problem List

Janet's chief complaint was her inability to drive. She also reported difficulty moving around in unfamiliar environments and had had instances of bumping into objects on her right side.

OT problems revealed during evaluation were as follows:

- Reading
- Writing
- Money management
- Use of technology
- Safety during mobility
- Community-level activities

OT Goal List

Based on Janet's motivation, intact cognitive skills, and awareness of her visual deficits, the occupational therapist recommended 6 weeks of therapy with a focus on providing home assessment/recommendations, training in compensatory strategies, and training for effective use of adaptive devices to maximize safety and independence in functional mobility during ADLs and community mobility. In collaboration with Janet, the occupational therapist established the following long-term goals:

1. In 6 weeks, the client will safely complete functional mobility activities in her home and in community settings at a modified independent level.
2. In 6 weeks, the client will demonstrate independent use of compensatory scanning strategies during ADLs.
3. Client will verbalize understanding of available community resources and appropriate resources will be put into place by time of discharge.
4. In 6 weeks, client will complete reading, medication management, and home management tasks at modified independent level with maximum safety.

The course of therapy would also include patient and caregiver education regarding the nature of homonymous hemianopsia and brain education to facilitate Janet’s husband’s understanding of her impairment. The OT recommendations also included a referral to a certified driver’s rehabilitation specialist for further evaluation for driving skills following training with compensatory prism and scanning strategies.

Intervention

Education was provided throughout the course of therapy regarding the nature of VF loss, functional impact of reduced field, and safety concerns. Facilitating full awareness of her visual deficit was completed using the prisms to demonstrate the impact on her field of view with and without prisms. The client’s husband was also educated on VF loss and how this impacted Janet’s safety during mobility.

During the OT sessions, client engaged in training for the use of adaptive aids such as task lighting, low-power magnification, large print items, and computer modifications to increase the contrast and size of print on the screen. Integration of these aids was completed during various ADLs to increase independence and facilitate independent use of aids. During evaluation, the client demonstrated effective scanning during reading tasks and tabletop activities. She demonstrated increased difficulty with large-scale scanning and scanning during mobility. Client engaged in both static and dynamic scanning activities focusing on accuracy first and then targeting speed.

Janet completed a community-level functional mobility activity to integrate the compensatory scanning strategies she learned during the previous sessions. A scavenger hunt-type activity was completed in several buildings and outside in a busy downtown area that Janet frequented.

Finally, education was provided regarding the importance of a driving assessment with a certified driver’s rehabilitation specialist. Client engaged in a computerized predriving screen during her OT sessions, which indicated she may benefit from driver’s rehabilitation. Client demonstrated a good understanding of safety concerns and was educated on alternative transportation options until she was able to be assessed for driving.

Janet demonstrated excellent progress during her course of OT. She has good motivation and was receptive to training with compensatory strategies. She was able to implement and use compensatory strategies independently by discharge to safely and independently complete functional mobility at home and in the community. She did follow through with a driving evaluation and eventually was able to return to driving using a temporary prism prescribed by the LV optometrist following training with the occupational therapist.

Best Evidence for Vision Interventions Used in Occupational Therapy

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistic Significance
--------------	-------------	--------------	--------	------------------------------------	---------	------------------------

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance
Functional Outcomes of the Low Vision Depression Prevention Trial in age-related macular degeneration (AMD). ⁵	Compare the efficacy of behavioral activation (BA) plus low vision rehabilitation (LVR) with an occupational therapist with supportive therapy on visual function in patients with AMD.	One hundred and eighty-eight patients aged >65 years; criteria included: bilateral AMD with best-corrected visual acuity <20/70; >5 anti-vascular endothelial growth factor injections if the better eye had neovascular disease, moderate difficulty performing a valued activity; and subthreshold depressive symptoms.	Six in-home 1-hour sessions over a period of 8 weeks with one of five study occupational therapists or six in-home 1-hour sessions with one of three study social workers/counselors over a period of 8 weeks.	Single-masked, attention-controlled, randomized clinical trial. Level II	BA + LVR with an occupational therapist services, provided by an occupational therapist in the patient's home following conventional low vision optometry services, are more effective than conventional optometric low vision services alone for those with mild visual impairment.	These results indicate that subjects who received the intervention had greater improvements in functional ability and a decrease in depression severity compared to those who did not receive the intervention.
Community-based trial of a peripheral prism visual field expansion device for hemianopia. ²¹	Examining the impact of 4-D prism on mobility activities after 6 weeks of wearing with a 1-year follow-up.	Forty-three participants with homonymous hemianopia; mean age = 63 years.	Participants were given verbal and written instructions about how to use the prism glasses and were encouraged to wear them as much as possible each day. They were instructed to remove glasses for driving or prolonged reading.	Pre-post design; participants recruited from 18 clinics across the United States. Nonparametric statistics were used for all between-group comparisons. Level VI	Participants reported significant benefits for obstacle avoidance during mobility situations.	Seventy-percent of participants were wearing prisms at 1 year. Long-term wearers reported the prisms were particularly helpful with shopping malls and stores and moving in crowded unfamiliar areas (17 participants [85%]). Eighty-on percent of participants reported a decrease in the device study period evidence the functional utility of the peripheral prism to patients with hemianopia with their general mobility.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance
Short-term persistence of oculomotor rehabilitative changes following oculomotor therapy (OMT). ²⁴	Examined the short-term persistence of previously obtained positive OMT findings at 3 and 6 months following completion of OMT.	Eight participants with mild traumatic brain injury who had completed OMT training (1 male, 7 females)	Thirteen clinical measures were evaluated at 3 and 6 months after oculomotor-based vision rehabilitation. Measures were evaluated over two separate sessions. Measures included: near point of convergence, accommodative amplitudes, reading rates, and a subjective rating using the Convergence Insufficiency Symptom Score.	Pilot study reassessing clinical oculomotor parameters at 3- and 6-month periods. Level IV	The improvement in near point of convergence break and recovery and monocular and binocular accommodative amplitudes after OMT persisted during follow-up. Reading rate improvements persisted during follow-up. The number of fixations per 100 words and grade-level efficiency significantly improved at the 6-month follow-up.	Statistical analyses compare clinical measure before OMT and after OMT at 3- and 6-months following completion of OMT for significant changes in clinical measure. More than 90% of the original abnormal baseline oculomotor parameters either significantly improved or were maintained at 9 hours of intense C

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance
The effect of visual training for patients with visual field defects due to brain damage: a systematic review. ²⁵	Studies were selected if they met the following entry criteria: (1) inclusion of only patients with HVFDs due to postchiasmatic lesions of the visual system after brain injury, documented by computed tomography/magnetic resonance imaging scans, and patients with left or right field defects ranging from homonymous quadrantanopia to complete homonymous hemianopia, with and without macular sparing; (2) applying the intervention of vision restoration therapy (VRT) or of compensatory saccadic eye movements and visual search strategies, that is, scanning compensatory therapy (SCT); (3) using the outcome measures of VF size, visual search field, reading time, and reading error, and subjective measures of questionnaires; (4) using the design of randomized controlled trial (RCT), controlled clinical trial, retrospective studies, or repeated measures design (RMD) studies;	Fourteen studies	Dosage of training varied in different studies.	Systematic review of 2 RCTs and 12 within-subject RMD. Level I	Five studies reported a significant effect of the VRT, whereas two studies reported no effect using scanning laser ophthalmoscopy or Goldmann perimetry as outcome measure. All authors of the studies on SCT found a significant effect of up to 30° visual search field, a significant increase in reading speed, or decrease in reading errors.	The effect of the restoration therapy needs to be further evaluated. Visual search therapy is recommended.
Technology learning and use among older adults with late-life vision impairments ²⁶	How do older adults who experience severe late-life vision impairments use technology to communicate and seek information? What challenges do these older adults face in learning and using accessible information and communication technologies (ICTs)?	Fifteen older adults (aged 60–99; $M = 76.71$, $SD = 12.51$; 6 females) who had an acquired, severe vision impairment (e.g., blindness, low vision).	Participants were encouraged to demonstrate how they used various devices (e.g., phones, desktop/laptop computers, tablet computers) and services (e.g., phone operator service, phone voicemail, screen readers, search engines, e-mail) as a way to help them.	In-depth interviews were conducted with older adults in their homes or in a private conference-type room within their residential community. Level VI	Training resources for older adults with late-life vision impairments should focus on one-on-one support while enabling ways of receiving support remotely.	Late-life impairments are not a static condition. Ongoing training and customized access to technology are needed.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistic Significa
Safety with visual field loss. Effects of acute peripheral/central visual field loss on standing balance. ²⁷	This study used a custom-made contact lens model to occlude the peripheral or central VFs in healthy adults compared with older adults with VF loss to improve our understanding of the etiology of balance impairments that may lead to an increased fall risk in patients with VF loss.	Nine young (aged 27.8 ± 2.1 years, 4 females) and 11 older adults (aged 72.2 ± 5.1 years, 7 females) were recruited.	Two visits were required to complete the study; the first visit consisted of screening procedures and the second included the experimental dynamic posturography session.	Within-subject approach. Level IV	Support to the functional sensitivity hypothesis that postulates central and peripheral VFs play different but necessary roles in postural control and stability/safety (especially in older adults).	VF occlu had a significant effect on center of pressure (COP) displacement but only older adults. This finding holds true when the is fixed ($p = 0.03$, $F = 3.39$, Table 3) sway-reference = 0.05, $F = 3.39$, Table 3) Postural control is most sensitive motion-re visual cu from the periphery—both central and peripheral visions are important to maintain balance, peripheral vision in particular may be more sensitive to motion.

HVFD, homonymous visual field defects.

<p>Psychosocial Functional Outcomes of the Low Vision Depression Prevention Trial in age-related macular degeneration.⁵</p>	<p>Compare the efficacy of behavioral activation (BA) plus low vision rehabilitation (LVR) with an occupational therapist with supportive therapy (ST) on visual function in patients with age-related macular degeneration (AMD).</p>	<p>One hundred and eighty-eight patients aged >65 years; criteria included: bilateral AMD with best-corrected visual acuity <20/70; >5 anti-vascular endothelial growth factor (VEGF) injections if the better eye had neovascular disease, moderate difficulty performing a valued activity; and subthreshold depressive symptoms.</p>	<p>Six in-home 1-hour sessions over a period of 8 weeks with one of five study occupational therapists or six in-home 1-hour sessions with one of three study social workers/counselors over a period of 8 weeks.</p>	<p>Single-masked, attention-controlled, randomized clinical trial. Level II</p>	<p>BA + LVR with an occupational therapist services, provided by an occupational therapist in the patient's home following conventional low vision optometry services, are more effective than conventional optometric low vision services alone for those with mild visual impairment.</p>	<p>These results indicate that subjects who improved in functional ability had a greater decrease in depression severity; intervention than those who did not improve functional ability.</p>
<p>Community-based trial of a peripheral prism visual field expansion device for hemianopia.²¹</p>	<p>Examining the impact of 4-D prism on mobility activities after 6 weeks of wearing with a 1-year follow-up.</p>	<p>Forty-three participants with homonymous hemianopia; mean age = 63 years.</p>	<p>Participants were given verbal and written instructions about how to use the prism glasses and were encouraged to wear them as much as possible each day. They were instructed to remove glasses for driving or prolonged reading.</p>	<p>Pre-post design; participants recruited from 18 clinics across the United States. Nonparametric statistics were used for all between-group comparisons. Level VI</p>	<p>Participants reported significant benefits for obstacle avoidance during mobility situations.</p>	<p>Seventy-percent of participants were wearing prisms at 1 year. Long-term wearers reported the prism was particularly helpful with shopping malls and stores and moving in crowded unfamiliar areas (17 participants [85%]). Eighty-on the participants reports a acceptance of the device and evidence of the functional utility of the peripheral prism to patients with hemianopia with their general mobility.</p>

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance
Short-term persistence of oculomotor rehabilitative changes following oculomotor therapy (OMT). ²⁴	Examined the short-term persistence of previously obtained positive OMT findings at 3 and 6 months following completion of OMT.	Eight participants with mild TBI that had completed OMT training (one male, seven females)	Thirteen clinical measures were evaluated at 3 and 6 months after oculomotor-based vision rehabilitation. Measures were evaluated over two separate sessions. Measures included: near point of convergence, accommodative amplitudes, reading rates, and a subjective rating using the Convergence insufficiency Symptom Score (CISS).	Pilot study reassessing clinical oculomotor parameters at 3- and 6-month periods. Level IV	The improvement in near point of convergence break and recovery and monocular and binocular accommodative amplitudes after OMT persisted during follow-up. Reading rate improvements persisted during follow-up. The number of fixations per 100 words and grade-level efficiency significantly improved at the 6-month follow-up.	Statistical analyses compare clinical measure before OMT and after OMT at 3- and 6-months following completion of OMT for significant changes in clinical measure. More than 90% of the original abnormal oculomotor parameters either significantly improved or were maintained after 9 hours of intense C

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance
The effect of visual training for patients with visual field defects due to brain damage: a systematic review. ²⁵	Studies were selected if they met the following entry criteria: (1) inclusion of only patients with HVFDs due to postchiasmatic lesions of the visual system after brain injury, documented by computed tomography/magnetic resonance imaging (CT/MRI) scans, and patients with left or right field defects ranging from homonymous quadrantanopia to complete homonymous hemianopia, with and without macular sparing; (2) applying the intervention of vision restoration therapy (VRT) or of compensatory saccadic eye movements and visual search strategies, that is, scanning compensatory therapy (SCT); (3) using the outcome measures of VF size, visual search field, reading time, and reading error, and subjective measures of questionnaires; (4) using the design of randomized controlled trial (RCT), controlled clinical trial (CCT), retrospective studies, or repeated-measures designs (RMD) studies;	Fourteen studies	Dosage of training varied in different studies.	Systematic review of 2 RCTs and 12 within-subject RMD. Level I	Five studies reported a significant effect of the VRT, whereas two studies reported no effect using scanning laser ophthalmoscopy or Goldmann perimetry as outcome measure. All authors of the studies on SCT found a significant effect of up to 30° visual search field, a significant increase in reading speed, or decrease in reading errors.	The effect of the restoration therapy needs to be further evaluated. Visual search therapy is recommended.
Technology Technology learning and use among older adults with late-life vision impairments ²⁶	How do older adults who experience severe late-life vision impairments use technology to communicate and seek information? What challenges do these older adults face in learning and using accessible information and communication technologies (ICTs)?	Fifteen older adults (aged 60–99; $M = 76.71$, $SD = 12.51$; 6 female) who had an acquired, severe vision impairment (e.g., blindness, low vision).	Participants were encouraged to demonstrate how they used various devices (e.g., phones, desktop/laptop computers, tablet computers), and services (e.g., phone operator service, phone voicemail, screen readers, search engines, e-mail) as a way to help them.	In-depth interviews were conducted with older adults in their homes or in a private conference-type room within their residential community. Level VI	Training resources for older adults with late-life vision impairments should focus on one-on-one support while enabling ways of receiving support remotely.	Late-life impairment is not a static condition; requires ongoing training and customized access technologies.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistic Significance
Safety with visual field loss Effects of acute peripheral/central visual field loss on standing balance. ²⁷	This study used a custom-made contact lens model to occlude the peripheral or central VFs in healthy adults compared with older adults with VF loss to improve our understanding of the etiology of balance impairments that may lead to an increased fall risk in patients with VF loss.	Nine young (aged 27.8 ± 2.1 years, 4 females) and 11 older adults (aged 72.2 ± 5.1 years, 7 females) were recruited.	Two visits were required to complete the study; the first visit consisted of screening procedures and the second included the experimental dynamic posturography session.	Within-subject approach. Level IV	Support to the functional sensitivity hypothesis that postulates central and peripheral VFs play different but necessary roles in postural control and stability/safety (especially in older adults).	VF occlusion had a significant effect on center of pressure (COP) displacement but only older adults. This finding holds true when the is fixed ($p = 0.03$, $F = 3.39$, $Tat = 3$). Postural control system is most sensitive motion-revisual cue from the periphery—both central and peripheral vision are important to maintain balance, peripheral vision in particular be more sensitive motion.

Chapter 9

Visual Perceptual Assessment and Intervention

Kara Christy and Natasha Huffine

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe various visual perceptual impairments and the impact on daily occupation and function.
2. Understand the neurological and physiological basis for visual perception.
3. Identify appropriate screening procedures and standardized evaluations for visual perceptual impairments.
4. Understand the conceptual foundation underlying interventions for visual perceptual impairment.
5. Describe the difference between a remediation approach, compensatory approach, and adaptations for treatment of visual perceptual impairments.
6. Identify specific interventions for visual perceptual impairments.

CHAPTER OUTLINE

Introduction
Visual Perceptual Function and Impairment in Daily Occupation
Neurological and Physiological Basis of Visual Perceptual Function
Screening of Visual Perceptual Skills
Conceptual Foundation Underlying Interventions for Visual Perceptual Impairment
Specific Interventions for Visual Perceptual Skill Dysfunction
Case Study

TERMINOLOGY

- Depth perception:** the visual ability to perceive relative distance of objects
- Figure ground perception:** the visual ability to distinguish foreground from background
- Form constancy:** the visual perceptual ability to identify objects despite their variation of size, color, shape, position, or texture
- Pattern recognition:** a perceptual process of matching incoming visual stimuli with stored visual memories
- Spatial orientation:** the visual ability to recognize the position of one's self or objects in relation to opposing positions, directions, movement, and environmental locations
- Unilateral inattention:** a phenomenon that causes one to experience an inability to orient and respond to one side of the environmental information
- Visual closure:** the ability to accurately identify objects that are partially covered or missing
- Visual memory:** the ability to take in a visual stimulus, retain its details, and store it for later retrieval
- Visual organization:** the ability to group objects on the basis of their identifying properties
- Visual perception:** the ability to interpret, understand, and define incoming visual information

Introduction

Visual perception is a dominant sense with which we gather information from our peripersonal (within arm's reach) and extrapersonal (beyond arm's reach) environments in order to use it for activities of daily living.¹ It is important that we are able to process this information accurately and efficiently for satisfactory engagement in daily occupations. The Occupational Therapy Practice Framework cites perception as a mental function under client factors, which influences

performance in occupations.² Thus, it should be at the forefront of occupational therapist's evaluation and intervention process in both objective and subjective information gathering.

Visual Perceptual Function and Impairment in Daily Occupation

Warren developed a hierarchy describing the different levels of visual processing and visuocognition in relation to function. Simply stated, the impact of vision at each skill level of this hierarchy influences the overall integration of the visual environment. As seen in Figure 9-1, the foundation includes oculomotor control, visual fields, and visual acuity. These are the basic visual skills required to perceive information accurately from our visual world. Without these basic-level skills, the ability to attend to the incoming information is impacted. Unilateral inattention is represented in this second level, and this deficit would complicate our ability to properly scan and attend to incoming visual information. Decreased visual scanning would present difficulties in pattern recognition, which includes (1) from constancy, (2) figure ground perception, (3) visual closure, (4) visual organization, and (5) spatial orientation. Moreover, the optimal functioning of pattern recognition skills is necessary for our ability to retain visual information, also known as **visual memory**. The highest skill level of this hierarchy is visuocognition, with which we are able to integrate visual perceptual information with other sensory input in order to complete executive functioning tasks, such as planning, problem solving, and decision making. Without knowledge of where a deficit is located along this hierarchy, it is difficult to develop appropriate evaluation and treatment protocols.³

Figure 9-1 Hierarchy of visual perceptual skill development. (Adapted from Warren M. A hierarchical model for evaluation for evaluation and treatment of visual perceptual dysfunction in adult acquired brain injury, part 1. *Am J Occup Ther.* 1993;47:43. Copyright 1993 by the American Occupational Therapy Association, Inc. Reprinted with permission.)

Dysfunction in these visual perceptual skill areas can severely compromise our ability to engage safely and independently in an array of performance components and activities of daily living associated with self-care, productivity, and play/leisure occupations.^{4,5} See Table 9-1 for examples of common diagnoses and associated functional implications to consider.

Table 9-1. Diagnoses, Areas of Deficit, and Impairments in Daily Occupation

DIAGNOSIS	AREA OF DEFICIT	IMPAIRMENT IN DAILY OCCUPATION
-----------	-----------------	--------------------------------

DIAGNOSIS	AREA OF DEFICIT	IMPAIRMENT IN DAILY OCCUPATION
Traumatic brain injury	<ul style="list-style-type: none"> • Binocularity • Ocular motility • Visual field deficits/neglect • Depth perception • Pattern recognition <ul style="list-style-type: none"> • Form constancy • Figure ground perception • Visual closure • Visual organization • Spatial orientation • Visual memory • Visuocognition 	<ul style="list-style-type: none"> • Negotiating stairs and busy environments • Pouring liquids/foods into containers • Packing medications • Safety with driving and ambulating in parking lots • Recognizing traffic signs • Sorting laundry • Locating items in the grocery store • Reading • Remembering the location of a locker or school desk
CVA/acquired brain injury	<ul style="list-style-type: none"> • Unilateral inattention/neglect • Visual agnosia • Visuocognition • Visual midline shift 	<ul style="list-style-type: none"> • Safety in self-care activities • Navigating personal environment • Recognizing utensils and measurements for cooking/baking • Locating offices for medical appointments • Floor and walls appear tilted, causing a lean in posture
Progressive neurological disorders: Parkinson disease/multiple sclerosis	<ul style="list-style-type: none"> • Ocular motility • Pattern recognition • Depth perception • Visual field deficits/neglect • Contrast/color sensitivity 	<ul style="list-style-type: none"> • Dressing • Home management • Navigation • Reading • Recognizing traffic signals • Navigating intersections while driving

Neurological and Physiological Basis of Visual Perceptual Function

Developmentally, vision is ever evolving in the brain from a neonatal state through adulthood. Vision and visual perception are processed globally throughout the brain. The right hemisphere is responsible for completing the initial processing of visual-spatial information. The left hemisphere is better at resolving detail of the visual-spatial array and carries out the fine processing needed to extract differences between objects. Both hemispheres are needed to ensure accurate identification of an object and deficits in visual cognition. More specifically, the parietal lobe is responsible for the localization of objects and their relationship to each other. The temporal lobe analyzes the visual information for details of color, form, and size. The occipital lobe is the primary visual cortex and analyzes visual information for position, movement, and orientation. The frontal lobe houses the prefrontal cortex in which we attend to and use the visual information for organization, planning, and sequencing of activities.³ Visual information coming from the occipital cortex to the prefrontal cortex can take either the dorsal stream or the ventral stream. The dorsal stream, known as the “where zone,” travels through the parietal cortex and is responsible for transforming information about location and size of objects, which facilitates actions. This stream is also responsible for distance and depth perception with the integration of these diverse cues. The ventral stream, known as the “what zone,” travels through the temporal cortex is responsible for identifying the object and its location by recognizing size, location, shape, and orientation in relation to other objects and surfaces, as well as past experiences using visual memory. Difficulties with processing visual perception occurs when there is an asymmetry between these tracts.^{1,6,7}

Screening of Visual Perceptual Skills

Before we can discuss formal evaluation of visual perceptual skills, it is imperative that we screen for the foundational visual skills outlined in the hierarchical model of visual perceptual dysfunction. Interpretation of higher level visual perceptual skills would not be accurate without first completing a thorough evaluation of these aforementioned foundational skills. Chapter 7 of this book can serve as a reference for specific details and instructions for screening measures. The advantage of applying a visual hierarchy framework to this process is that it provides a rationale for the selection of screening and evaluation tools that focus on the underlying causes of observed deficiencies.³

Visual perceptual deficits can often go unnoticed by clients and occupational therapists until they are evaluated directly. Diagnoses such as acquired brain injury, neurodegenerative diseases (multiple sclerosis, dementia, Alzheimer disease), autism, cerebrovascular accident, neuropsychiatric disorders (schizophrenia), and cerebral palsy are all commonly associated with visual perceptual changes.^{5,8-14} Clients may be able to compensate for visual perceptual deficits during basic activities of daily living (ADLs) and instrumental activities of daily living (IADLs) by drawing upon other strengths. Thus, it is essential to have reliable, valid, and sensitive evaluation tools that determine whether visual perceptual deficits exist.⁵ It is suggested that health care professionals recognize the importance of formally assessing visual perceptual abilities; however, this has been identified as one of the most difficult areas of evaluation.¹⁵ Assessments can range from brief tabletop screening tasks involving writing, copying, and matching items to behavioral observations during functional tasks, through to complex standardized batteries of tabletop evaluations. The limitations of nonstandardized screening approaches, observations of performance components, and occupational task performance include difficulty defining, documenting, and communicating results, changes, and outcomes. Using standardized evaluations implies uniform procedures for administration and scoring.¹⁶ In addition, standardized evaluations can be used to document current status, progress in therapy, and prioritize treatment goals.¹⁷

This process should begin with a clinical interview including a historical review of premorbid visual conditions as well as gathering the client and/or family complaints and symptoms. Following this, completion of clinical observation during functional activities and the use of screening tools can be a way for occupational therapists to quickly determine the presence of possible visual perceptual impairments. Clinical observation and screening can vary in depth depending on the facility and team members caring for the client. For example, in the school setting a therapist may need to rely solely on classroom observations due to limited communication with family members and eye care professionals. In contrast, an occupational therapist working in inpatient rehabilitation may be addressing an array of functional skills in

collaboration with an interdisciplinary team and onsite eye care professionals, giving ample opportunity for observation and clinical discussion of visual skills.

Visual Perceptual Screening Procedures

Form Constancy

Form constancy plays a primary role in visual perception, relying on distinguishing various types of forms by color, orientation, edge, motion, and shape cues. Difficulties with form constancy are thought to emerge from damage or underdevelopment of the parietal and temporal lobes; however, there is evidence to suggest this involves multiple visual areas of the brain along the ventral stream.^{6,10}

Screening Procedures

Form constancy can quickly be screened during various functional activities, determining if the client has difficulty with recognizing familiar items with various forms, such as kitchen utensils or food items at the grocery store. The following is an example of functional screening procedures:

- Have the client seated or standing in a well-lit area.
- Lay out various types and forms of kitchen utensils on a tabletop or countertop in a nonlinear array.
- Ask the client to identify the various kitchen utensils displayed.
- Observe for spatial neglect, perseveration, poor scanning patterns, and comprehension (see Fig. 9-2).

Figure 9-2 Example of functional screening with commonly used kitchen utensils for form constancy.

Assessing Impact on Daily Function

A client with decreased form constancy would likely experience difficulties with reading and writing, navigating and locating items in his or her personal environment, and recognizing various types of clothing for dressing. Subtle variations to form are difficult for a client to distinguish in recognition tasks, such as recognizing various pens and pencils as similar tools for writing. Various observations can be made in ADL and IADL tasks, such as experiencing difficulties with following directions with pictures on recipes or furniture instructions, problems with reading various types of handwriting or fonts, discriminating similar letters or words (b/d, was/saw), or difficulty recognizing people wearing different clothing or with a varied hair style.

Figure Ground Perception

Figure ground perception is the ability to distinguish a figure (foreground) from the background. The figure can be described as the primary focus of the individual at any given time. The separation of figure from background is established by differences in features such as color, depth, orientation, texture, and motion. There is contrasting evidence and theories determining if figure ground perception or object recognition occurs first developmentally, and this can incorporate both the dorsal and ventral streams through the visual loop.^{6,10}

Screening Procedures

Figure ground perception can quickly be screened during various functional activities, determining if the client has difficulty with identifying items from a background on the basis of

subtle or salient features. The following is an example of functional screening procedures:

- Ask the client to locate specific coins from various options placed in his or her hand.
- Ask the client to locate items in a pencil box (glue stick, colored pencil, and eraser) or silverware in a cluttered drawer.
- Ask the client to identify road signs while escorting on an outing through a busy city environment.
- Observe for poor acuity, spatial neglect, perseveration, poor scanning patterns, agnosia, and comprehension.

Assessing Impact on Daily Function

A client with decreased figure ground perception is going to have difficulties in everyday occupations and activities that require identifying or locating objects from a busy or similar background. This can create difficulties with basic self-care tasks with locating the buttons or sleeves of a solid colored shirt or locating the towel hanging on the white wall. This expands into accessing the community to difficulties in locating signs for directions or road rules, finding items in cluttered drawers or shelves, or navigating aisles in a grocery store.

Visual Closure

Visual closure is the ability to visualize a complete whole when provided with fragmented pictures or incomplete information. When lines or pieces are placed close together, such as partially incomplete written letters or numbers, the client should be able to visualize closure of these lines to complete the whole image. If there are portions of an object missing or covered up, or large gaps are present such as attempting to identify a road sign partially covered by a tree branch, visual closure and visual memory are required to identify the object.¹⁸ This is known to be a primary process of the ventral stream through the temporal lobe for object identification.⁶ Deficits with visual closure can be identified frequently in individuals through handwriting difficulties, when there are incomplete words or letters. Furthermore, handwriting difficulties are often perceived as a reflection of low intelligence when visual perceptual difficulties are overlooked.¹⁹ See Figure 9-3 for screening examples of handwriting before and after visual perceptual intervention.

Figure 9-3 Handwriting screening examples before and after visual perceptual intervention.

Screening Procedures

Visual closure can quickly be screened for during various functional activities, determining if he or she has difficulty with recognizing objects, drawings, or portions of an environment when partially occluded or with missing information. Following are examples of functional screening procedures:

- Ask the client to complete a partially drawn picture or stencil, or to identify the whole image from a partially drawn form.
- Have the client correctly identify 10 common objects from an array of 30 overlapping items.
- Write out a word or draw a simple image on a dry erase board, and erase a portion of this, asking the client to identify said word or image.

Assessing Impact on Daily Function

An individual with decreased visual closure skills will likely encounter difficulties with new learning tasks, handwriting skills, home management tasks, and community integration. If items are partially occluded due to clutter or due to overlapping within the visual field, accurate identification of objects is going to be difficult. For example, if a client is driving, and a stop sign is partially covered by another vehicle, the client would not be able to identify the sign accurately and make a safe decision. A face may become unrecognizable to the client with the eyes missing or covered. Providing opportunities for exposure to this deficit area, along with time for feedback, will aid in overall assessment of functional impact as well as additional chances for building awareness.

Visual Organization

Visual organization is a fundamental property of visual perception form discrimination. This visual perceptual skill is complex and requires dynamic integration of neural activity both within and between cortical areas of the visual loop. It requires the use of visual skills throughout the visual hierarchy and relies on notions of symmetry, continuity, and proximity for grouping visual information.^{20,21} Grouping principles include the following qualities: proximity, color, size, orientation, common fate, symmetry, parallelism, continuity, closure, and common region.¹³

Screening Procedures

In addition to functional task completion for observation, the Leuven Perceptual Organization Test (L-POST) can provide quick and valuable information for mid-level visual perceptual abilities. Several of these subtests are useful for identifying visual organization difficulties.¹⁴ The primary goal for this screening tool is to be a quick screen for possible mid-level visual perceptual deficits using digital technology.

- L-POST¹⁴
 - Visit L-POST testing site at www.gestaltrevision.be/tests.
 - Follow appropriate links to take the screening tool in your client's preferred language.
 - Complete the neglect pretest to rule out visual inattention for use of the computer screen. If inattention appears to be present, items will be presented vertically rather than horizontally.
 - Complete the 15 subtests, which takes a total of 15 to 20 minutes.
 - Scoring is completed electronically and automatically and saved under your account for comparison.
 - Norms are available for all subtests, along with image examples for comparison.
- Functional screening examples
 - Provide client with an array of similar and dissimilar items and ask him or her to sort into groups by various principals (color, size, texture, shape, etc.).
 - Provide client with two images and ask what is different and what is the same.
 - Provide client with visual images of a familiar task (e.g., cooking, grooming, playing a game) and ask him or her to put the images in sequential order.

Assessing Impact on Daily Function

Decreased visual organization creates difficulties in making sense of the extrapersonal and intrapersonal visual environments. Deficits in this area create increased difficulties with figure ground perception and visuoconstructional skills, where one would have to separate and group items in the foreground from the background, or organize visual pieces of information into a whole for two- and three-dimensional imagery.^{16,13} Uhlhaas also discusses how this type of impairment is highly correlated with facial recognition.²¹ If a client is unable to visually group and organize environmental information, increased difficulty is expected for visual memory and higher level visuo-cognitive and attention tasks such as sequencing.

Spatial Orientation

Spatial orientation includes both the ability to appreciate the location of objects in relation to each other and in respect to oneself. This is a function of the dorsal tract in the visual loop, known as the "where zone" through which information is directed from the occipital cortex to the parietal-temporal zone.^{3,6,7} Typically damage or underdevelopment of the parietal lobe, particularly the right side, is associated with deficits in spatial orientation. Information used to create a sense of relations and orientation is multisensory and includes visual, somatic,

proprioceptive, and auditory signals and is interpreted in relation to an ever-changing body scheme. This further requires intact attention skills, visual memory, and visual-motor for possible object manipulation.^{7,10}

Screening Procedures

Using a simple Cross Test can be a quick and easy screen for concerns with visual-spatial relations. The procedures are outlined below:¹⁰

- Provide the client with a card with various cross markings drawn or printed. Start with two crosses as a practice.
- Ask the client to draw the crosses on a blank card as exactly as possible. If he or she does not understand, demonstrate this practice for him or her.
- Provide feedback with a transparent guide to show any disparities in the spatial relations.
- Complete this with three additional cards with five to six crosses in various arrays.
- Scoring is nonstandardized, but can be measured in total number of centimeters of discrepancy between the model and client reproduction. If a cross is missing, this should be scored as half of the width of the card.
 - Intact: score of 0 to 300 cm
 - Impaired: score of 300 to 600 cm
 - Severely impaired: score of >600 cm

In addition to quick paper/pencil screens such as the Cross Test, observations can be made from functional activities as a screen for visual orientation deficits. Following are some examples:

- While in a therapy gym, classroom, or the client's home ask him or her to describe various orientations with visible objects in relation to other objects and in relation to the client. For example, ask "what is directly in front of the treadmill?" or "are the books to your right or to your left?"
- Complete a navigation activity: ask the client to follow a route either through a therapy/school environment or as the passenger of a car in an active passenger activity, and then have the client retrace his or her steps or follow a return route. Another variation is to provide a map and have the client provide verbal directions from point A to point B using spatial references.
- Have the client point to a particular target, such as a clock on the wall, and then have the client move to another part of the room or into the hallway and then point to where that target is. For more advanced screening including visual memory in spatial orientation, have the second location in a position where the initial target is no longer visible.
- Have the client reproduce an arrangement of objects, first in the same orientation and at the client's midline, and then rotated in a different direction and not in midline.

Assessing Impact on Daily Function

Deficits with visual-spatial orientation create functional difficulties in general awareness of oneself and of objects in the interpersonal and extrapersonal environments. This presents as difficulties with basic self-care, such as aligning buttons on a shirt or recognizing which side of a shirt is the front versus the back. Furthermore, more complex concerns include difficulties learning new routes in a rehabilitation facility, or following a navigation system while participating in driver rehabilitation.^{10,22}

Unilateral Inattention

Unilateral inattention is a decreased awareness of the body and spatial environment on the side contralateral to the brain lesion. It can occur in the peripersonal and extrapersonal environments⁹ and often occurs without a sensory deficit. In the most severe cases, it is as if that side of the environment or world does not exist to the person. This does not have to be a co-requisite of visual field loss, rather a neglect and possible midline shift of the environment. In a visual midline shift, the visual environment is perceived to be shifted away from the affected side, causing a feeling of a tilted environment.²³ Visual inattention is most commonly experienced following a right hemispheric lesion, where left-sided-body-specific inattention is seen with frontal lesions and left-sided environmental neglect is seen with parietal lesions. Recent research has explored the impact of sustained attention skills on patterns of unilateral inattention.⁷

Screening Procedures

There are several readily available and quick screens that can be used in a clinical setting to determine possible unilateral inattention. Unfortunately, according to Menon-Nair, standardized assessments or screens are not readily used at intake and discharge in inpatient rehabilitation settings in the United States, where 61% of positive cases of unilateral inattention had not been detected in admission assessments.⁹ The most commonly used screens in practice are the Bell's Test, Clock Drawing Test, Single Letter Cancellation Test, Star Cancellation Test, Comb and Razor Test, the Line Bisection Test, and the Rivermead Behavioral Inattention Test, among several other standardized evaluations. The screening procedures for the Clock Drawing Test and the Comb and Razor Test are outlined here. The procedures for the remaining screens are readily available online and are typically free assessment tools.

■ Clock Drawing Test

- Free Drawn: Provide the client with a blank sheet of paper and ask him or her to draw a clock set to a specific time (e.g., 10 after 11 o'clock). The 10-after-11-o'clock time setting requires visual attention to the left visual field, as well as cognitive skills such as transferring the 2 on the clock to 10 minutes.
- Predrawn: Provide the client with a sheet of paper with a circle predrawn, and ask him or her to draw the face of the clock and set to a specific time.
- There are several scoring guidelines available for the clock drawing test; with unilateral inattention, however, the therapist should screen for omitting numbers, missing hands on the clock, missing the left border of the clock or a presentation of an oblong clock face, or numbers crowding on one side of the clock (see, e.g., Fig. 9-4).

Figure 9-4 Example of a Clock Drawing Test following traumatic brain injury.

■ Comb and Razor Test

- For all clients, provide them with a comb and ask them to comb their hair. Time the client for 30 seconds and count number of right, left, and ambiguous strokes within the 30 seconds.
- For clients identifying as a male, provide the client with a razor with a shield and ask him to shave his face and continue until you say stop. Time this action for 30 seconds and count number of strokes on the right side, left side, and ambiguous strokes.
- For clients identifying as a female, provide the client with a powder compact and ask her to apply the powder until you ask her to stop. Time for 30 seconds and count the number of touches on the right side and left side as well as ambiguous touches.
- For the most updated scoring methods, apply the following calculation: $\% \text{ bias} = (\text{right} - \text{strokes}) / (\text{left} + \text{ambiguous} + \text{right strokes}) \times 100$. The % bias formula yields a score

between -1 (total left neglect) and +1 (total right neglect), with symmetrical performance at 0.²³

Assessing Impact on Daily Function

Depending on the severity of unilateral inattention, the functional implications can be vast and possibly hazardous. This could be as minimal as difficulties with reading and writing, or as concerning as missing information while operating a motor vehicle or navigating a grocery store parking lot. These are typically more concerning than with clients experiencing a visual field loss as there is not awareness that this visual perceptual change exists. Clinical observations may include experiences such as missing food on the left side of a plate, running into door jambs on the left side, missing items on the left side of a grocery aisle shelf, or washing only one side of the body or hair in the shower.

Depth Perception

Depth perception is a form of visual perception using coordination of both binocular cues and binocular disparity and the integration of monocular cues such as shading, texture, and linear perspective. When binocularity is intact, true depth perception is acquired through fusion of information from each eye on a horizontal plane, also known as stereopsis.¹⁰ Depth perception has been found to be processed in the inferior parietal regions of the brain for peripersonal space, and in the ventral premotor, middle frontal, and superior temporal areas of the brain for extrapersonal space.¹ Depth perception is a developmental skill that does not typically need to be taught. Deficits with depth perception can arise when there is a strabismus of one eye causing suppression of that eye, and in turn a lack of binocularity.

Screening Procedures

Two screens that are available to occupational therapists that are widely used to detect deficits in stereopsis are the Lang Stereo Test and the Titmus Test.²⁴ The Lang Stereo Test 1 is found to have the highest sensitivity for stereopsis at 89.9%, and it does not require any additional cross-polarized lenses. The Titmus Test is sensitive 83.3% of the time in detecting stereopsis difficulties for depth perception and requires the use of cross-polarized lenses. Both test plates are to be held at 16 inches by the evaluator, thus testing depth in the peripersonal space. See procedures below for both.²⁴ These stereopsis screens in addition to functional activity observations can be useful in detecting deficits in depth perception.

- Lang Stereo Test 1
 - Hold test plate at 16 inches (40 cm) from the client at 90°.
 - Ask the client to scan the card and identify what he or she may see. Observe eye movements. The client should report a cat, star, and a car.
 - Test failure is incorrectly naming or omitting objects.
- Titmus Test (see Fig. 9-5).
 - Have the client wear cross-polarized lenses. Hold the test plate at 16 inches (40 cm) from the client in a well-lit room.

Figure 9-5 Stereo Fly Test for depth perception screening.

- In rows A, B, and C, have the client identify which animals appear to have depth.
 - In areas 1 to 9, have the client identify which button appears raised (top, bottom, left, or right).
 - Answers are included on the back of the testing book. Test failure is inability to identify accurate animals for A, B, or C, as well as incorrectly identifying raised dots for items 5 to 9.
- Functional Screening Examples:
- Have the client seated at a table with glasses in various heights and at varying distance from the client. Ask the client to pour water from a pitcher into each of these glasses.
 - Ask the client to position his or her wheelchair in the safest location for a transfer into a chair or a bed. Determine if distance from the transfer surface is adequate and safe.
 - Place an object on the table in front of the client and ask him or her to pick it up. Move the object into various locations in space, within arm's reach, and ask the client to grab the object.

Assessing Impact on Daily Function

Assessing and using depth perception through binocular or monocular cues is imperative for safety in navigating our extrapersonal environment. Impacts on depth perception can create frustrating situations such as difficulties with putting on socks, putting toothpaste on a toothbrush, or putting on makeup. It can also create hazardous situations when the depth of curbs or steps cannot be detected accurately. Following a screen of foundational visual skills, it should be common practice to ask clients and their support systems if the client is experiencing situations such as tripping over uneven surfaces, bumping into things, stopping at unsafe distances while driving, or spilling during meal preparation to get a better idea of functional concerns. See Table 9-2 for screening tools and observations for visual perceptual deficits.

Table 9-2. Screening Tools and Observations for Visual Perceptual Deficits

DEFICIT AREA	CLIENT COMPLAINTS	CLINICAL OBSERVATION	SCREENING
Form constancy	Difficulty reading Can't find personal belongings Difficulty with dressing, cooking, bathing, grocery shopping	Difficulty following directions with pictures such as a recipe, building furniture, or learning a new board game. Problems recognizing unfamiliar handwriting or new fonts. Recognizing people wearing different clothing. Difficulty in mastering the alphabet and numbers	Occupational Therapy Adult Perceptual Screening Test (OT-APST) Functional Exercise: <ul style="list-style-type: none"> Locating various brands and sizes of items on a grocery store shelf Locating utensils and correct size bowls for baking tasks Reading directions to a game when words are in different fonts and colors
Figure ground perception	Trouble with laundry Unsafe driving Only plays with one toy	Unable to sort and match socks while folding laundry Difficulty locating clothing in drawers during ADLs Missing road signs or vehicles when driving Unable to locate toys in a toybox	Bells Test Occupational Therapy Adult Perceptual Screening Test (OT-APST) Star Cancellation Test Functional Exercise: <ul style="list-style-type: none"> Locating correct change during a money management activity Locating puzzle pieces during a jigsaw puzzle activity Locating classroom objects in a pencil box (i.e., Glue stick, eraser, blue crayon, paper clip, etc.)
Visual closure	Unsafe driving Trouble cooking Difficulty playing cards	Cannot identify traffic signs that are partially hidden behind a tree or other vehicle Difficulty locating items in the refrigerator that are partially covered	Functional exercise: <ul style="list-style-type: none"> Completing partially drawn pictures or stencils Identifying 10 common objects in an overlapping array of 30 items
Spatial orientation	Difficulty reading and writing	Letter and number reversals Difficulty with spacing and organization of written school work	Occupational Therapy Adult Perceptual Screening Test (OT-APST) Baking Tray Test
Unilateral inattention	Falling Misplacing items People honking their horns at me Floor appears tilted	Applying makeup or shaving only half of the face Walking into furniture, doorways, and other objects Eating food from half of the tray Leaning or weight bearing to the unaffected side	Occupational Therapy Adult Perceptual Screening Test (OT-APST) Clock Drawing Test Line Bisection Test Bell's Test Star Cancellation Test Albert's Test Comb and Razor Test Baking Tray Task Visual Midline Shift Test

DEFICIT AREA	CLIENT COMPLAINTS	CLINICAL OBSERVATION	SCREENING
Depth perception	Spilling Tripping/clumsy Running into objects Decreased abilities in sports	Misjudging distances while pouring liquids Fender-bender auto accidents, running stop signs Difficulty with grooming, putting in contacts, placement of makeup Difficulty with catching a ball	Titmus Fly Stereotest Randot Stereotest Cover/Uncover Test Functional exercise: <ul style="list-style-type: none"> • Navigating a therapy gym, hallway, or playground with obstacles • Estimating common distances (i.e., from person to a fixed-distance point, such as a car) • Pouring liquids into measuring cups
Visual memory	Difficulty spelling and reading Difficulty remembering routes Loses or misplaces items (keys, wallet, etc.)	Cannot remember sight words Often transposes common words Gets lost in familiar routes or newly learned routes Difficulty remembering faces or new people	Clock Drawing Test Scenery Picture Memory Test (SPMT) Spot the Difference for Cognitive Decline (SDCD) Functional Exercise: <ul style="list-style-type: none"> • Study a photograph for 30 seconds, and describe the photo and items included • Display an array of items or words, remove visual and report as many items as they can remember
Visual-motor integration	Clumsiness Different handwriting/signature Difficulty with typing	Difficulty with letter formation and handwriting Decreased participation in sports Decreased ability to complete a puzzle or construction of an object with pictorial instructions	Occupational Therapy Adult Perceptual Screening Test (OT-APST) Clock Drawing Test Trail Making A and B Functional exercise: <ul style="list-style-type: none"> • Write name or copy a sentence on paper • Copy simple line drawings • Scissor along various dotted lines
Visuocognition (planning and organization)	Disorganized Decreased reading comprehension	Difficulty sorting and organizing personal belongings Difficulty sequencing and planning for an activity or game Difficulty making sense of typed or written words and sequencing a story	Trail Making A and B Functional exercise: <ul style="list-style-type: none"> • Sequence a recipe on the basis of pictorial steps • Sequence a grooming task with displayed items (i.e., toothpaste, toothbrush, faucet, towel, cup)

ADLs, activities of daily livings.

Evaluation of Visual Perception

When further and more complex evaluation is warranted for visual perception, there are several factors that need to be considered before selecting your evaluation tool. Factors to consider include age, language abilities, education level, physical impairments, cognitive impairments, and environment. Based on goals and subjective information gathered, it should be determined whether testing should encompass motor reduced, visual-motor integration, or the combination of the two. Also to be considered is the validity, reliability, and temporal constructs of the evaluation tool.⁵ Typical visual perceptual assessments include multiple subtests to assess the following visual skills: visual discrimination, visual memory, visual-spatial relationships, form constancy, visual sequential relationships, figure ground, visual-motor integration, and visual closure.⁶ See the most commonly used standardized assessments at the end of the chapter.²⁵⁻³⁷

Conceptual Foundation Underlying Interventions for Visual Perceptual Impairment

Following screening and evaluation, proper treatment should consider both remedial and compensatory approaches. According to Warren, effective intervention should include three principals.³ First, remove or minimize sensory deficits of foundational skills. Second, provide consistent education to increase awareness of deficits; for accurate compensation to occur, clients must be aware that deficits exist and experience the decreased reliability of these senses. Last, incorporate consistent training to both remediate and develop compensation strategies for the deficit areas, promoting overlearning to ensure consistency. The more complex the task, the more the deficit must be practiced for adequate skill acquisition.³

A remediation approach uses activities that challenge current abilities with a therapist providing opportunities for practice using graded tasks in controlled therapeutic settings. This type of approach is based on theories of neuroplasticity. Neuroimaging studies have documented changes in brain activation and connectivity during visual-spatial, visual attention, and perceptual organization after completing training. Tasks should be initially rudimentary and become more complex following success with a strong emphasis on repeated practice, mastery of skills, and the reacquisition of confidence. A remediation approach may be considered when clients show a potential for improvement, awareness of current limitations, and the ability to receive feedback.³⁸ A bottom-up approach should be used for reacquisition of foundational skills before adding complexity into treatment.

Once the client has achieved maximal benefit from remediation approaches, the therapist’s next step could include practicing under a compensatory approach and using top-down treatment methods using strategies.¹⁶ This approach may teach strategies for functional skill completion, such as upper body dressing, and would not assess for and treat the underlying task components such as primary visual skills and perceptual abilities.

Remedial and compensatory approaches should be incorporated into a variety of contexts to ensure carryover and application with ADL and IADL abilities. A mastery of skills cannot be accomplished without the ability to transfer these abilities into functional settings. In addition, one may consider an adaptive approach, which places emphasis on changing the environment or activity to meet the needs of the client. This is typically introduced once remedial and compensatory approaches have reached maximal potential or for safety reasons.³⁸

Specific Interventions for Visual Perceptual Skill Dysfunction

There is evidence in the literature that supports the remediation of visual perceptual deficits, highlighting the importance of visual perceptual training occurring within functional context.³⁹ The theoretical approaches that should guide this treatment are both developmental and neurophysiological in nature. See the evidence table of intervention studies at the end of the chapter.⁴⁰⁻⁴⁴ Occupational therapists should consider using various types of therapeutic activities to improve visual perceptual functions (see Table 9-3).⁴¹ It is within an occupational therapists skillset to utilize activity analysis to identify appropriate treatment techniques and activities to remediate, compensate, and adapt for visual perceptual deficits.

Table 9-3. Commonly Used Therapeutic Activities Related to Visual Perceptual Performance Areas

Source: Menon-Nair A, Korner-Bitensky N, Ogourtsova T. Occupational therapists' identification, assessment, and treatment of unilateral spatial neglect during stroke rehabilitation in Canada. *Stroke*. 2007;38(9):2556–2562. doi:10.1161/STROKEAHA.107.484857; Christy K, Huffine N, Hannah T, DeLeon M. Outcomes after cognitive perceptual motor retraining (CPM) of patients with acquired brain injury (ABI). *Open J Occup Ther*. 2016;4(1). doi:10.15453/2168-6408.1076.

The remedial or developmental approach is typically initiated on the basis of the premise that the brain can acquire or reacquire function through environmental stimulation. Reacquisition of skills should follow the original path of development, a hierarchical approach to the remediation of perceptual deficits used in treatment. In Piaget's model of cognitive development, the lower level performance components are acquired before more advanced cognitive skills. Treatment activities should place initial emphasis on foundational skills, regardless of the individual's level of functioning, in order to ensure that the foundation is solid before advancing to higher level cognitive skills.^{39,45} Toglia emphasized the importance of practice drills and grading within treatment for direct remediation of observed deficits.⁴⁵ With that being said, repetition over a period of weeks should be implemented when using these various treatment approaches or modalities. Choosing activities that have multiple levels of difficulty and the ability to alter speed requirements and offer the opportunity to adjust levels of attention complexity are important to consider for grading activities up or down to foster meeting the client's goals while considering his or her just right challenge. Examples of grading activities up to maximize potential gains could include increasing environmental distractions by listening to music, podcasts, or news stations while participating in the visual perceptual activity. The therapist could also add time constraints, require recall of activity instructions, and implement categorization tasks or other cognitive loading activities while maintaining the expected accuracy and efficiency of the visual perceptual skill (see Table 9-4). To ensure continued appropriateness of a remediation approach, a therapist should complete periodic retesting for objective measures for comparison.

Table 9-4. Cognitive Loading Examples

Alternating between multiple tasks	Following a sequential key Self-timing transitions or following alarms Self-structure or structure the therapy hour activity

Compensation is a treatment approach that aims to maximize existing visual function by providing strategies to enhance the client's ability to assimilate visual information efficiently. A compensatory approach should also place emphasis on understanding underlying difficulties in visual perception in order to learn when to initiate the use of strategies to overcome limitations. Rather than focusing on one task-specific skill, the client should gain the ability to use the learned

strategies in various situations.⁴⁵ Warren supports the use of practicing strategies for visual perceptual deficits within context to ensure carryover of application to ADLs.³

Pattern Recognition

Pattern recognition is the perceptual process of matching incoming visual stimuli with stored visual memories. Although research is limited on the effectiveness of the use of computers, tablets, gaming systems, and tabletop exercises for the remediation of pattern recognition skills; it is common practice to utilize these modalities in treatment. Following this approach, compensation and adaptation for pattern recognition then requires personal and environmental alterations for deficits in the following skills: form constancy, figure ground perception, visual closure, visual organization, and spatial orientation. In general, these can include reducing visual stimulation and overlapping of objects, changing spatial arrangements into categorized or linear arrays, slowing down processing times for accuracy, forming proper scanning patterns, and incorporating multisensory techniques for visual perceptual input.⁴⁵ These strategies and adaptations can be used in both therapeutic activities and functional tasks. For example, during a laundry sorting task one could form piles of clothing to create categories by type to compensate for visual figure ground and form constancy. The clothing could also be sorted by color, and it could be unfolded to show its full form as a strategy for form constancy. While searching for a particular piece of clothing, one could start scanning in the top left portion of the pile moving to the right and then top to bottom to practice accurate and efficient scanning patterns. The person could then verbalize what is seen for further processing purposes, too.

Unilateral Inattention

When treatment planning for unilateral inattention, the therapist must consider the personal context that the client is impacted in. This can include impairments and inattention within personal, peripersonal, and extrapersonal space. Typically someone with unilateral inattention will also present with disrupted scanning patterns and poor awareness of the decreased visual input. According to Tham et al., unilateral inattention typically presents as disorientation to objects in the left half of a client's extrapersonal space, and clients typically are unable to wash or dress the left half of their bodies.⁴⁶ This can be compensated for by using prisms, attention training, scrolling text, audiovisual stimulation, video feedback training, learning new scanning patterns with anchors and guides, and lighthouse scanning to the affected side to enhance awareness of the visual field.^{9,47,48} In order to master compensatory strategies, one should practice these in a variety of settings within the office, home, and community. An occupational therapist should also be sure to practice these strategies in all ADL and IADL contexts to ensure automaticity and habit formation, as well as to build awareness of this deficit.

Prisms

Those with unilateral inattention oftentimes develop poor habits with visual scanning and motor movements. Optometrists, occupational therapists, and physical therapists can work collaboratively to stimulate neuroplasticity through prism adjustments, feedback, and gross motor integration. Multisensory approaches teach new visual patterns through the integration of proprioception, vestibular skills, and peripheral vision. While the use of prisms sometimes is automatically integrated, other clients will need guidance from the therapist to attend to visual information and improve posture. Prisms are easily integrated into functional tasks and therefore make them an ideal therapy tool.⁴⁹ However, the research on this can be controversial for self-care.⁵⁰

An optometrist will fit the client with the optimal size and type of prism through the use of objective balance and movement measures. The base end of the prism will be positioned on the same direction as the paretic side and visual inattention if there is a visual midline shift. Prisms yoked in this fashion have an effect of countering the expansion and compression of space, with the apex expanding space and the base compressing space.²³ An occupational therapist will use this tool during therapeutic scanning and functional activities (see Fig. 9-6). The therapist can first work with a client in the controlled environment to scan for signs, people, or objects on the affected side. To grade the task, the client will work up to busy environments and uneven walking surfaces in the community.⁵¹

Figure 9-6 Therapist and client working on a visual scanning and pattern recognition task with yoked prisms.

Sustained Attention Training

It has been theorized that unilateral inattention could be due to decreased cognitive attention, and improving overall sustained attention and awareness can improve this deficit area. Facilitating activation of the sustained attention system is a strategy that has been discussed to decrease unilateral spatial inattention.⁵² This is based on the premise that in the sustained attention system, one needs to anticipate a response in the absence of external stimuli.⁵³ A study integrated sustained attention training during a sorting task, first starting with an unpredictable auditory reminder with knocking and a verbal cue to “attend!” This was then graded to patient-driven auditory commands, and then to internal mental reminders, with encouragement to utilize this strategy in other daily tasks. The study concluded that this type of treatment program improved the patients’ ability to sustain attention and reduced the effects of unilateral inattention.⁵³ This is further supported by the development of an awareness training program as described by Tham et al., upon the assumption that having an increased awareness of a deficit is a prerequisite to be able to learn and effectively use compensatory strategies.⁴⁶ They found that with training in awareness of a unilateral inattention deficit paired with sustained attention training, improvements were seen in overall occupational performance and a reduction in unilateral spatial neglect.

Scanning

Visual scanning training is a frequently used therapeutic approach for compensating for unilateral spatial inattention. This can include paper-and-pencil tasks, computer and tablet activities, and functional tasks such as scanning for items at a grocery store. Another modality that can be used for scanning training would be the use of a Vision Coach, Dynavision, or Wayne Saccadic Fixator (see Fig. 9-7). This type of training has been shown to be effective; however, it is typically not generalized beyond that situation.⁵² For example, visual scanning training for a cooking task should be practiced in a kitchen environment, and developing scanning strategies for reading should be practiced with paper/pencil or tabletop activities. With that being said, a combination of

scanning training, sensory awareness, and spatial organizational training has been found to be effective for treatment for patients with right hemisphere damage.⁵³

Figure 9-7 Use of the Vision Coach for a visual scanning activity with balance compromised.

Quintana discusses both lighthouse scanning techniques, or imagining oneself as a lighthouse and using the eyes to sweep the environment, and using visual anchors to help bring attention back to the neglected side as effective strategies for unilateral inattention.⁵² This type of approach can further be graded by the therapist by increasing or decreasing the complexity of the array of information to be scanned, reducing or increasing the location and type of visual anchor, and providing additional cueing as needed to ensure thorough scanning of the visual environment. Again, these strategies should be practiced in a variety of tasks and settings so the client is not task-specific learning, and so that the strategy can be carried over for functional use.

Patching

Patching can be a quick, effective, and inexpensive therapeutic tool for decreasing unilateral inattention that can be used across disciplines. There is research to support the use of patching for unilateral spatial inattention in that in individuals without disruption to the nervous system, retinal input is strongest to the contralateral superior colliculus.⁵³ Visual stimulation to one side (right) of the superior colliculus generates saccadic movements to the contralateral side (leftward). There is an assumption that by patching an entire eye, visual stimulation follows the stronger pathway and would facilitate attention and visual saccades to the contralateral side. A study by Butter and Kirsch found that patching an entire eye demonstrated improvements in a standard battery for inattention; however, the results did not translate to function once the patch was removed.⁵⁴ Furthermore, an additional study found no difference between a test group and control group with monocular eye patching.⁵⁵ In fact, patching a monocular side is considered a contraindication for clients following brain injury and can worsen spatial judgments with left neglect.⁵⁶ Best practice in utilizing patching is seen with research in using hemifield patching as compared with a control group without patching and when compared with monocular patching. Patients who donned right hemifield patches demonstrated improvements in functional

independence measure scoring, pencil-and-paper tasks, and right eye movements in the left field.^{52,53}

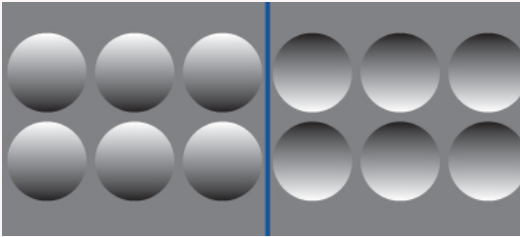

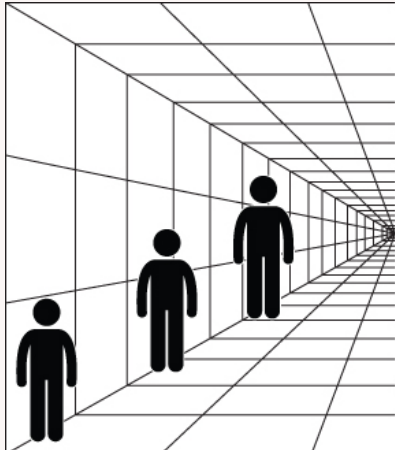

Audiovisual Stimulation

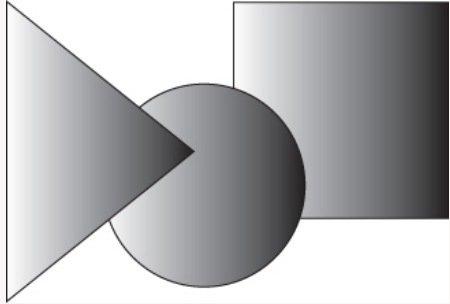

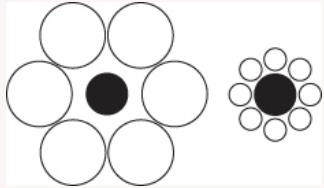

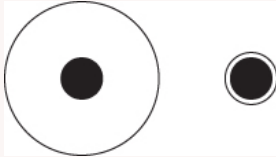

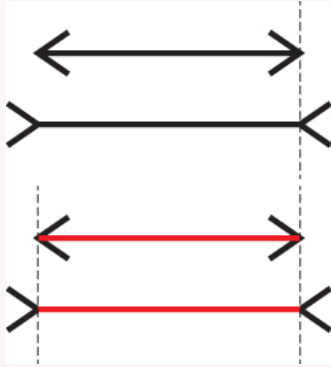

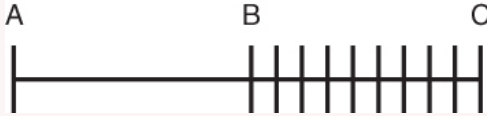

Multisensory treatment techniques have been shown to be an effective method for retraining visual perceptual function. Audiovisual stimulation provides opportunities for task grading with three types of stimulation integrating the audio and visual systems. As discussed in Tinelli et al.⁵⁷ and Frassinetti et al.,⁵⁸ these conditions include a unimodal visual condition with presentation of only visual stimuli, a unimodal acoustic condition with stimuli presented as only an acoustic cue, and a bimodal audiovisual condition, with audio and visual stimuli together. These can either be congruent or incongruent by location. The patients are cued to focus on a central focal point and shift their gaze (without head movements) to the visual target when detected, while pressing a response button. This type of treatment is shown to be effective through Telehealth services in facilitating the recovery of visual orientation skills.⁵⁷ Although research is limited on functional carryover of skills, bimodal multisensory integration with stimulation presented on the relative side improved awareness into the neglected visual region.⁵⁸

Depth Perception

When depth perception cannot be remediated due to decreased binocularity and eye teaming, or with a malalignment of the eyes allowing for reacquisition of stereo depth perception, environmental contextual cues can be used. Typically, our visual system performs size estimations efficiently and effortlessly. When this is not the case, learning to interpret visual illusions and monocular cues can be taught as a compensatory strategy. Understanding shadowing and texture gradation, line of parallax or size cues, and recognizing superimposition of objects can be learned strategies for depth.⁵⁹ For examples of these environmental cues, see Table 9-5.

Table 9-5. Monocular Depth Cues

ENVIRONMENTAL CUE	EXPLANATION	IMAGE
Shadowing	Highlights and shadows can provide information about an object's dimensions and depth. Our visual system assumes light comes from above	
Line of parallax	Has to do with angles along line of sight. Nearby objects have a larger parallax than more distant objects	

ENVIRONMENTAL CUE	EXPLANATION	IMAGE
Superimposition	When there are two overlapping objects, the overlapped object is considered further away	
Size illusions	Ebbinghaus illusion	
	Delboeuf illusion	
	Mueller-Lyer illusion	
	Oppel-Kundt illusion	

CASE STUDY

Patient Information

Jaden is a 17-year-old high school senior who prefers not to use gender-based pronouns and was involved in a motor vehicle accident. Jaden received inpatient rehabilitation immediately following the accident and was recently discharged to outpatient therapy. Jaden was employed as a restaurant host and busboy before their injury. They currently live at home with their parents and two brothers and have a strong network of friends, all of whom are supportive of Jaden's recovery process. Jaden is highly motivated to return to driving and normal life at school. However, they demonstrate limited acceptance and awareness of their brain injury and related changes and therefore does not understand the purpose of therapy in enabling them to return to these meaningful activities. Jaden is often disrespectful to therapists and distracted during sessions.

Assessment Process and Results

Upon admission to outpatient rehabilitation, Jaden participated in a full physical and cognitive occupational therapy evaluation. Their muscle tone, gross sensation and perception, range of motion, and strength was found to be within functional limits. Jaden's orientation and time management skills were also found to be intact, and psychosocial skills were appropriate for the environment. Jaden's visual screen indicated diplopia and deficits with ocular range of motion, saccadic movement, and pursuits. Jaden's visual deficits combined with difficulty with memory and slowed information processing speed led the occupational therapist to suspect that Jaden's visual perceptual skills had been affected in the accident. The occupational therapist administered the Developmental Test of Visual Perception–Adult Version. Jaden ranked in the fourth percentile for the Motor Reduced Visual Perceptual subtests with a *z*-score indicating mild impairment in this skill area. Within this skillset, figure ground perception and visual closure were most difficult for Jaden. Jaden's performance on the visual-motor integration earned them a percentile rank of less than one and a *z*-score representing borderline severe impairment in this skill area. Jaden especially struggled with the Visual Motor Search And Copying subtests, indicating difficulties with motor planning, visuoconstructional skills, and motor speed in response to visual input (see Fig. 9-8 for the Copying subtest). The occupational therapist also administered Trailmaking A and B to determine if visual cognitive skills were impaired, in which they scored within the severe impairment range. Jaden's performance on the variety of evaluations administered by the occupational therapist indicated deficits with visual perceptual skills.

Figure 9-8 Copying subtest of the DTVP-A before and after Cognitive Perceptual Motor Remediation intervention.

Occupational Therapy Problem List

Based on the skill deficits revealed by Jaden's performance on the perceptual evaluations along with observations of functional tasks, the occupational therapist compiled a list of visual perceptual deficits to address with Jaden during their sessions.

- Difficulty identifying objects in a busy background, such as road signs or pedestrians within a city or town.

- Trouble identifying objects that may be partially covered or missing, such as the remote control sitting partially underneath a throw pillow.
- Difficulty alternating between two or more tasks efficiently and accurately, which is required for homework, driving, meal preparation, etc.
- Trouble managing controls in a motor vehicle while driving, difficulties typing or handwriting at an efficient speed, and/or difficulties with everyday tasks such as preparing food and playing sports.
- Difficulties with independent use of the hands without visual assistance, such as using a blinker while driving, taking notes from a projector screen, or typing on a computer.
- Challenges comprehending new information in school or a productive employment setting secondary to decreased information processing speeds.

Occupational Therapy Goal List

Short-Term Goals:

- Jaden will improve visual scanning, visual anchoring, figure ground perception, eye/hand coordination, visual-motor integration, and visual information processing speeds to within-average ranges through participation in therapeutic activities.
- Jaden will improve visual perceptual skills to within-average ranges while participating in therapeutic activities with cognitive loading including focused/shifting visual attention, selective visual attention, sequencing, organization, and divided attention.
- Jaden will demonstrate independence in IADLs through the use of compensatory strategies for visual figure ground perception, visual scanning, visual anchoring, visual-motor integration, and visual information processing speeds.

Long-Term Goals:

- Improve visual-spatial, visual-motor, and executive functions to within-average ranges ($Z = -0.4$ to 0.4) on standardized testing measures to maximize safety, independence, and efficiency in the home, workplace, and community.
- Implement compensatory strategies 90% to 100% of the time independently to improve accuracy and efficiency in all IADLs.

Intervention

Based on findings from the evaluation, the occupational therapist determined that Jaden's significant visual and cognitive perceptual difficulties would best be addressed through a treatment method referred to as Cognitive Perceptual Motor Remediation (CPM). This therapy utilizes client-centered activities that require divided attention skills, quick information processing speeds, and visual perceptual skills such as form constancy and visual-motor integration. Jaden's typical sessions included many iPad application activities because these activities could be easily graded to their current level and increased in difficulty as skills progressed. Use of the iPad applications also allowed the occupational therapist to obtain quantifiable data on Jaden's performance to quickly assess skill progression. In early sessions, these applications required Jaden to interpret visual information and quickly respond with a motor output, as well as solve visual information problems and recognize the foreground versus the background. The activities also drew on Jaden's alternating and divided attention skills, which are necessary prerequisites for driving. The occupational therapist's short-term goals for each application accounted for Jaden's baseline performance and where it was determined Jaden's skills could be at discharge. After 3 months of therapy focusing on these applications with grading as necessary, Jaden had met four activity objectives with noted improvement on visual sequencing, visual-motor speed, and information processing speed.

With progress noted, Jaden was soon engaging in activities requiring increased visual memory skills, as well as increased eye-hand coordination and independent use of each hand. The occupational therapist graded her own level of co-participation in these activities to challenge Jaden, yet still provide them with a sense of achievement. For example, the occupational therapist would engage in an activity at 75% capacity when it was first introduced to Jaden to avoid causing them to feel frustrated and discouraged when comparing their skills with those of the occupational therapist.

By March, 6 months after beginning therapy, Jaden had met all their visual perception goals. The occupational therapist readministered the assessments initially used to evaluate Jaden's skills. Their scores improved to the mild impairment to average ranges. As an example of progress, Jaden's improvement on the Copying subtest of the DVTP-A is illustrated in Figure 9-8. Occupational therapy services continued, but the focus on visual perceptual skills shifted to task-specific training sessions. Jaden was pleased with the progress they had made despite the frequent frustrations throughout the months of intervention.

Most Commonly Used Standardized Assessments

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Baking Tray Task ^{25,26}	Used to assess for unilateral spatial neglect	<10 minutes	Found to detect more cases of neglect than the three-item Behavioral Inattention Test and is even more accurate when used in combination with the Line Bisection Test	Test-retest 0.87	Increased through combination with other tests; more sensitive than the three-item Behavioral Inattention Test	Easy to administer. Most sensitive single test to detect spatial neglect. Easy and cost-effective to create your own with the measurements provided. Not a lot of depth to the test or scoring. Assumed cognitive impairment if spatial neglect is not present.
Line Bisection Test ²⁷	Used to detect unilateral spatial neglect	<5 minutes	Convergent validity with Baking Tray Task: $r = -0.66$	Test-retest reliability: 0.97 Internal consistency: no evidence	Detects spatial neglect with 76.4% accuracy	Many versions; however, the procedures are rarely standardized.
Trail Making A and B ²⁸⁻³⁰	Used to assess visual conceptual and visuomotor tracking conditions	5-10 minutes	Construct validity for rapid visual search and visual sequencing. Trails A: Visual perceptual abilities Trails B: working memory and task switching	Test-retest reliability: Test A: $r = 0.83$ Test B: $r = 0.90$	Functional MRI studies demonstrate activation of the ventral and dorsal visual processing streams	Public domain assessment is easy to administer and obtain. Some versions have therapist correct mistakes along the way.
Bell's Test ^{31,32}	Quick screen for visual neglect in the near extrapersonal space	<5 minutes	Criterion Validity: more likely to evidence left neglect than Albert's Test, Star Cancellation Test, Line Bisection Test, and Line Crossing Test	No evidence	No evidence	The Bell's Test requires no specialized training to administer and only minimal equipment is required (a pencil, a stopwatch, the test paper, and scoring sheet). The test is simple to score and interpret.

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Motor-Free Visual Perception Test (MVPT-3) ^{10,33}	Widely used standardized test of visual perception, assessing visual perception independent of motor ability	20–30 minutes	Criterion related: 0.78 with the DTVP-2 and 0.73 with the DTVP	Internal consistency: 0.86–0.90 Test–retest: 0.92	General measure for motor-free visual perceptual components	Does not provide norms for separate subtests. Short and simple measure that is tolerated well by most clients.
Test of Visual Perceptual Skills (TVPS-4) ^{4–6,17}	Visual Perception Test to use with children	25 minutes	Discriminative validity is significant for testing participants with and without neurological impairments for all subtests ($p < 0.001$).	Reliability was found in testing outlined skills within subtests using Spearman Rho Correlations. Significant Correlation with figure ground perception (0.306), spatial relations (0.193), and form constancy (0.465) between the DTVP-2 and TVPS-R.	Not established for most recent fourth edition	Simple to administer, able to use with students/clients with motor impairments. Test designs are bold, and verbal responses are not required.
Developmental Test of Visual Perception Adolescent and Adult (DTVP-A) (DTVP-2) ^{4,5,10}	Comprehensive assessment with subtests for motor reduced visual perception and visual-motor integration	20–30 minutes	Discriminative validity is significant for testing participants with and without neurological impairments for motor-free subtests ($p < 0.001$). Motor portions of the DTVP-2 were valid with subtests of the TVPS-4.	Interrater: 0.94–0.99 Test–retest: 0.70–0.84	The DTVP-A measures potential visual perceptual deficits for adults with diagnosed neurological impairment.	Able to standardize scores on the basis of age for all subtests and to separate out visual-motor integration and motor reduced visual perception. Ceilings for all subtests.
The Occupational Therapy Adult Perceptual Screening Test (OT-APST) ^{16,34–36}	Designed as a quick screening tool of 25 items for occupational therapists to assess for presence of visual perceptual impairment in the main constructs of visual perception and apraxia	20–25 minutes	Concurrent Criterion Validity for neglect: $p = 0.006$ (moderate correlation) Concurrent Criterion Validity for agnosia: $p \leq 0.001$ (moderate correlation)	Interrater reliability ranged from 0.66 to 1.0 for all subtests. Intrarater reliability ranged from 0.64 to 1.0 for all subtests. Test–retest reliability ranged from 0.76 to 1.0.	In comparison with the LOTCA sensitivity for agnosia is 85.7% and neglect is 69.2%.	Quick and easy-to-administer screening tool for visual perception and apraxia, paired with functional observations. Required to screen for primary visual functions before completing the OT-APST.

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Rivermead Perceptual Assessment Battery (RPAB) ^{16,37}	Tests for 16 performance areas in visual perceptual skills	60–120 minutes	Reported content criterion and construct validity	Reported Interrater and test–retest reliability	RPAB is a significant predictor of functional outcomes in stroke patients.	Simple instructions to administer, including demonstrations. Longer assessment to administer, however, is designed to help with treatment planning.
Loewenstein Occupational Therapy Cognitive Assessment (LOTCA) ¹⁰	Assessment in six different areas for orientation, visual perception, spatial perception, praxis, visuomotor organization, and thinking operations	45 minutes	Overlapping Figures Subtest: Administration of entire LOTCA is recommended versus administering subtests.	Interrater reliability: 0.82 to 0.97 for all subtests Internal consistency of Visual Identification of Objects: 0.87	No evidence	Lengthy assessment, however, can be completed over multiple sessions. Can be used to set therapeutic goals and to monitor cognitive status over time.

Evidence Table of Intervention Studies

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Cognitive Perceptual Motor Remediation (CPM) ⁴⁰	A remedial approach for deficits in cognitive, perceptual motor, and sensory-motor functioning following a brain injury. It is hierarchical in nature, using a bottom-up approach and repetition. This approach uses computerized activities, paper/pencil tasks, manipulation of objects, and other tabletop activities, beginning with sensory-motor and perceptual tasks that precede cognition.	This study reviewed records of a total of 53 clients in which 30 identified as male and 23 identified as female. The mean age was 35.8 years. 43% were classified as severe traumatic brain injury, 19% as moderate brain injury, and 38% as mild.	CPM is typically prescribed 3 hours/week for therapy sessions. Additional home exercise programs can be recommended. In this study duration included 4 participants 12 weeks or less, 19 participants at 13–24 weeks, 18 participants for 25–36 weeks, 11 participants at 37–52 weeks, and 1 participant at more than 1 year.	This was a retrospective study, reviewing records from 1998 to 2009. The main outcome measures were objective changes in evaluation test scores. The tests of visual-spatial perception included Figure Ground Subtest of the Southern California Visual Perception Test, Cancellation of <i>H</i> , Alternating dot to dot, and Minnesota Spatial Relations Test. This was an evidence level of III.	Improvements in CPM-enabled clients to participate in more challenging therapies, such as vocational rehabilitation, and at discharge more than half of the participants were engaged in productive activity. Also, more than half of the participants returned to living at home independently or with initial supervision levels.	$p \leq 0.000$ for all four subtests. r (effect size) Figure ground = 0.431 Cancellation of <i>H</i> = 0.335 Alternating Dot to Dot = 0.471 Minnesota Spatial Relations Test = 0.557

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Computer-Aided Cognitive Rehabilitation (CACR) ⁴²	CACR uses standardized and structured training tasks that allow users to grade tasks on the basis of cognitive levels, focusing on visual reaction, visual scanning, attention, information processing speed, memory, and problem-solving abilities. It is objective and provides immediate feedback to clients. The tasks focus on ADLs such as driving, functional math, remembering names and faces, and other functional tasks.	Subjects were 30 individuals between the ages of 65 and 80 years in Korea. They were randomly and equally distributed to either a training group or a balance group.	CACR was used three times per week, 15 minutes each, for a total of 6 weeks.	This was a randomized control trial, evidence level I study. Pre- and posttest scores were reviewed using the Motor-Free Visual Perception Test (MVPT).	There were benefits in visual perceptual skills in both the CACR and the balance groups.	$p \leq 0.05$ for MVPT scores, but no statistical significance between the test group and balance group postintervention. MVPT t -value test group: $t = -2.46$ Balance group: $t = -4.253$
Visual Feedback Training (VFT) ⁴²	VFT training using a force plate based on a computer game was used to allow clients to check their positions and posture for center of gravity in real time. For this study VFT was used in sitting to see effects on sitting balance and visual perception.	Participants included 26 individuals with chronic stroke from Korea. They were included if they could sit independently for 30 minutes, had no other orthopedic injuries, had a score >21 on the Korean Mini-Mental State Exam, and had not participated in any other balance training programs in the last 6 months. They were randomly assigned to either an experimental group or control group. Four total participants withdrew due to discharge.	Participants in the control group participated in standard physical therapy 5 days a week for 4 weeks, 60-minute sessions. Participants in the experimental group participated in the standard PT in addition to VFT sessions for 30-minute sessions, 5 days per week for 4 weeks.	This was a randomized control trial, evidence level I study. Pre- and posttest scores were reviewed using the MVPT.	This study, in addition to previous studies, shows improvements in visual perception, as well as static and dynamic sitting balance, in patients with chronic stroke using VFT methods.	Improvements were significant from pre- to posttesting using the MVPT between the two groups ($p < 0.05$).

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Virtual Reality–based Rehabilitation ⁴³	The Interactive Rehabilitation and Exercise System (IREX) was used. Six virtual reality (VR) games were utilized (bird and balls, coconuts, drums, juggler, conveyer, and soccer).	Participants included 29 individuals following a stroke in Korea.	Both groups received traditional therapy in 30-minute sessions, 3 times a week for 4 weeks. The experimental group also received the IREX training for 60-minute sessions, 5 times per week for 4 weeks.	This was a randomized control trial, evidence level I study. Pre- and posttest scores were reviewed using the MVPT.	VR-based rehabilitation can have a positive impact on visual perceptual skills and ADLs. Significant improvements were noted specifically for visual discrimination and figure ground perception.	MVPT total score: $p < 0.001$ Visual Discrimination: $p < 0.01$ Figure Ground Perception: $p < 0.05$
Table Tennis Training (TTT) ⁴¹	Table tennis is a racket sport that has different spatial and temporal demands. TTT includes motor skill learning, numerous repetition, and multisensory feedback. Table tennis is part of the school physical education curriculum in Taiwan, where this study took place.	Participants were 91 children age 6–12 years from Taiwan for the TTT and Standard OT (SOT) groups, and 41 participants were randomly assigned to a control group. 48% had mild intellectual disability, and 52% had borderline intellectual functioning.	The TTT group had three 60-minute sessions per week for 16 weeks. Dosing was the same for the SOT group.	This was a randomized control trial, evidence level I study. Pre- and posttest scores were reviewed using the Test of Visual Perceptual Skill–Third Edition (TVPS-3).	There were improvements in visual perception and executive functions with the TTT group compared with the SOT group and the control group. The treatment was motivating for students and is a feasible modality. The moderate level of exercise required also had positive impacts on the students.	Effect size was strong (>0.8) measured on the TVPS-3 for all subtests compared with the control group and was strong for spatial relations, visual closure, and the total raw score when compared with the SOT group ($p < 0.003$).

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Visual Scanning Training (VST), Limb Activation Treatment (LAT), Prism Adaptation (PA) for Left Neglect ⁴⁴	<p>VST: training to actively explore the contralesional side in various functional tasks; guided by visual stimulus cues and feedback.</p> <p>LAT: perform voluntary movements with contralesional limb, paired with visual cues.</p> <p>PA: wear prism goggles to shift stimuli along the horizontal plane with tasks involving visual targets into the contralesional side.</p>	Thirty-one patients ranging in age from 41 to 86 years, with right hemisphere damage and left neglect from a neuropsychology department in Italy. All patients had unilateral lesions because of first stroke.	Four assessments completed with 2 weeks of training (20 sessions each) between assessments two and three. The first two assessments were to verify left neglect and the second two assessments were to verify effectiveness of treatment and lasting effects.	This was a randomized control trial, evidence level I study. Pre- and posttest scores were reviewed using the following outcome measures: the Comb and Razor Test, the Fluff Test, Picture scanning, Menu Reading, Coin Sorting, and the Catherine Bergego Scale.	All three treatments can be considered valid interventions for left neglect and the effects lasted for at least 2 weeks. However, this study did not include a control group.	The effect size was significant following intervention according to the following assessments: Picture Scanning Subtest, Menu Reading Subtest, Serving Tea Subtest, The Card Dealing Subtest, and The Catherine Bergego Scale.

Acknowledgment

We would like to acknowledge our level II fieldwork student, Colette Chapp, for her hard work on the Case Study.

Chapter 10

Cognitive Assessment

Diane Powers Drette and Guy L. McCormack

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe specific cognitive abilities and how they are used in daily occupation.
2. Analyze the occupational dysfunction that occurs as a result of cognitive impairment.
3. Identify the neurological and physiological basis of cognitive function.
4. Determine how to screen for basic cognitive abilities.
5. Select cognitive assessment methods and tools based on individual clients' characteristics and the properties of various measures.
6. Anticipate and describe factors that should be considered in interpreting the results of cognitive assessments.

CHAPTER OUTLINE

Cognitive Function and Impairment in Daily Occupation
Neurological and Physiological Basis of Cognitive Function
Screening of Cognitive Skills
Case Study

TERMINOLOGY

Attention: the cognitive ability to direct mental processes toward information. Subtypes from lowest to highest functioning include focused attention, selective attention, sustained attention, alternating attention, and divided attention.

Cognition: the mental action or process of acquiring knowledge and understanding through thought, experience, and the senses.

Executive Functions: the cognitive skills required for high-level thinking. Some examples include planning, problem solving, organization, judgment, self-regulation, flexibility, categorization, sequencing, abstract reasoning, divergent thinking, and conceptualization.

Immediate recall/sensory register: the cognitive ability to recall information without any lapse in time from processing.

Long-term memory: the cognitive ability to recall information that is stored relatively permanently.¹

Memory: the mental storage of information and the processes involved in the acquisition, retention, and retrieval of that information. Subtypes of memory include immediate recall/sensory register, working memory, long-term memory, episodic memory, procedural memory, semantic/declarative memory, prospective memory, and topographical memory.

Orientation: the cognitive ability to understand oneself and one's surroundings and circumstances. Examples include understanding person, place, time, and date.

Processing: the cognitive ability to quickly and accurately decode elements of information into meaningful terms.

Self-awareness: the cognitive ability to know one's own capacities, skills, limitations, and level of function.

Working memory: the cognitive ability to use information that is currently held "in mind."¹

Cognitive Function and Impairment in Daily Occupation

Cognition is the mental process of understanding, acquiring, and knowing information, and it is essential for all aspects of daily occupation. Being alert, attentive, and processing information are the basis of cognition and are necessary to take in the world around us. In order to learn from the environment, **memory** is used for immediate, short-term, or long-term recall. **Executive functions**

use the information that is gained to initiate, plan, problem solve, organize, categorize, sequence, judge, reason, and conceptualize actions for successful daily function. **Self-awareness** is used to determine, monitor, and adjust actions and behaviors to improve daily functions. Self-awareness makes it possible for people to form mental representations and concepts of themselves and to regulate their own behavior. In particular, self-awareness typically involves comparing oneself to goals, ideals, norms, other people, and various other standards.

When cognition is impaired, occupational dysfunction can occur in any area of daily function. The ability to perform any activity from the time a person wakes in the morning until he or she goes to sleep at night can be impacted by a cognitive impairment. The ability to get out of bed, perform self-care, prepare meals, drive or take transportation to the destination, follow a schedule, perform work or school activities, learn new tasks, participate in leisure activities, socialize with others, and maintain a home all rely on varied and integrated aspects of cognition. For example, a person who is a highly functional college student relies on cognition to perform home, school, work, leisure, and social activities. But if he or she sustains a brain injury that results in damage to the frontal lobes of the brain creating executive dysfunction, his or her ability to plan the day, problem solve what to wear or where to go and how to get there may all be limited. He or she may struggle to understand abstract concepts presented in the classroom or have difficulty with categorization and integration of the information that was presented. All aspects of his or her performance of daily activities rely on cognitive abilities.

Occupational therapists assess cognition because many people seeking occupational therapy services are likely to have some degree of cognitive impairment that influences their ability to perform daily activities.² Cognitive changes can be temporary, relatively static, or progressive. Many survivors of brain injury experience deficits in information processing, attention, memory, and executive functions that persist for months or years post injury.³ A significant number of persons who sustain a spinal cord injury also have a concurrent brain injury with similar implications for cognition.⁴ Cognitive changes may also be experienced by individuals with chronic conditions, including multiple sclerosis,⁵ Parkinson disease,⁶ cancer,⁷ epilepsy,⁸ pain,⁹ systemic lupus erythematosus,¹⁰ and human immunodeficiency virus/acquired immunodeficiency syndrome.¹¹ Even individuals with mild stroke who are independent in activities of daily living (ADL) may have memory deficits and executive dysfunction that impacts their ability to work, drive, and engage in recreational activities.¹²

Neuroplasticity

Neuroplasticity is the brain's ability to change its structure and function throughout the life span. Following an injury, such as an acquired brain injury including trauma, stroke, or brain tumor, an occupational therapist will ascertain cognitive function with the intent to provide cognitive rehabilitation focused on enhancing the recovery of deficits in cognitive function through remedial training techniques to enhance neural recovery and compensatory training to teach strategies using intact cognitive functions. There is emerging evidence that cognitive rehabilitation approaches enhance neuroplasticity.¹³ The potential benefits of cognitive rehabilitation for enhancing neuroplasticity have been found for people with stroke,¹⁴ Parkinson disease,¹⁵ schizophrenia,¹⁶ and aging adults,¹⁷ including those with Alzheimer disease.¹⁸

Cognitive Hierarchy

Cognitive abilities are conceptualized in a hierarchy with arousal, orientation, attention, and processing at the base, the varied types of memory next, and executive functions and self-awareness at the top of the hierarchy (see Fig. 10-1). The cognitive skills at each level rely on the skills below.¹⁹ For example, a person who has impaired attention and processing will not have intact working memory for learning new information, because the person will not be able to remember information that was never perceived or processed. The hierarchy continues with all the cognitive skills that underlie executive functions. If a person is unable to attend, process, or remember information, the person will not be able to work with that information to plan, problem solve, and organize an activity involving that information. Each cognitive skill relies on the one below to support cognitive function.

Figure 10-1 Cognitive hierarchy.

Integration of Cognitive Processes

In addition to the hierarchy of cognitive abilities, there is also an integration of cognitive processes.²⁰ Whereas executive functions rely on intact lower order cognitive abilities, such as attention and memory, executive functions are also integrated with attention and memory to regulate cognitive processes. When performing a task, executive functions are involved in focusing attention on relevant information and inhibiting irrelevant information, thereby regulating information that is available for working memory. Executive functions also monitor the acquisition of the contents of the information to be remembered; plan the sequence of subtasks on which to focus, process, and remember; and categorize the information that is being learned.

Attention, memory, and executive functions are also integrated with self-awareness. Attention and memory are used to comprehend the self in relation to the others and the environment. Self-regulation, planning, and problem solving are used in a feedback loop with self-awareness to improve the person's sense of self. Self-awareness and memory are used to compare the self to a given standard. If the self-awareness notes an unwanted discrepancy, the executive functions are used to initiate some action to remedy this by regulating actions, planning for differing behaviors, and problem-solving ways to make that change.²⁰

Neurological and Physiological Basis of Cognitive Function

Attention and Processing

Attention and processing can be described as either top down or bottom up (see Fig. 10-2). In top-down attention and processing, the person is aware of the need to attend and process information and uses the frontal lobes to modulate input, which includes focusing, selecting, sustaining, alternating, and dividing attention as needed. Conversely, when the person is engaged in bottom-up attention and processing, information is first perceived through the primary areas, including the occipital, temporal, and sensory motor areas.¹ Information is then filtered through the parietal lobes, which act as an interface between these primary areas and the frontal lobes.²¹

Figure 10-2 Model of attention and processing.

In bottom-up attention, the incoming information may not be conscious. For example, a person may be reading a page of text, get to the bottom of the page, and be unaware of the information that was in the text. Even when reading aloud, a person may attend to the text, but not actually process the information. Processing of information requires the interface of parietal lobes and awareness through the engagement of the frontal lobes.

Memory

There are several neurological correlates related to memory. Information that has been attended to and processed is relayed to the hippocampus and regions of the medial temporal lobes, including the entorhinal cortex, the perirhinal cortex, and the parahippocampal cortex²² (see Fig. 10-3). The right hippocampus is specific to spatial memory, and the left hippocampus is specific to memory for contextual details.²³ The parahippocampal cortex is specific to location of objects, and the perirhinal cortex is involved in the memory of object features.¹

Figure 10-3 Memory cortices. **A**, Memory cortices lateral bisection; **B**, Memory cortices frontal bisection.

Specified areas of the frontal lobes are involved in encoding information. The left ventrolateral prefrontal cortex is associated with verbal encoding, and the right ventrolateral prefrontal cortex with visual encoding. The dorsolateral prefrontal cortex (PFC) is related to the organization of information during encoding and the monitoring of the retrieval of information from **long-term memory**. Long-term memory is stored in specific posterior brain regions related to the type of information that is stored. For example, visual information is stored in the occipital lobes, and language information is stored in the left temporal lobes.

The PFC is also crucial for keeping information active for **working memory**. The dorsolateral PFC is involved in manipulating and monitoring information, whereas the ventrolateral PFC is involved in maintaining and retrieving information from long-term storage.¹

Executive Functions

The neurological correlates for executive functions lie mostly in various regions of the PFC^{20,22,24} (see Fig. 10-4). Various types of executive functions have been correlated with different, lateralized, and integrated regions of the PFC.¹ Planning that is unstructured is typically located in the right PFC, and planning that is structured in the left PFC.²⁰ The dorsolateral PFC is involved in formulation of plans, whereas the medial ventral PFC is involved in the execution of a plan. In addition, the anterior ventral lateral PFC is correlated with semantic planning, whereas the posterior ventral lateral PFC is correlated with motor planning.²⁵ Problem solving is correlated with the left dorsolateral PFC, especially for open-ended verbal problem solving.²⁶ Inhibition and monitoring of performance are correlated with the medial PFC, anterior cingulate cortex, and the presupplementary motor area, and slowed performance is noted with damage to the right lateral PFC.^{1,26} Decision making is correlated with the dorsolateral PFC, with connections to the dorsal regions of the anterior cingulate, which functions in error detection and motivation. The dorsal regions of the anterior cingulate connect with the dorsolateral PFC, parietal lobes, premotor areas, and the supplementary motor cortex to monitor cognitive responses, and the anterior regions of the anterior cingulate connect with the limbic system and orbital frontal areas to monitor affective responses. The ability to multitask has been correlated with the anterior PFC, frontal pole, and the rostral PFC.¹

Figure 10-4 Executive cortices. **A**, Executive cortices; **B**, Orbital prefrontal cortex; **C** and **D**, ventromedial prefrontal cortex.

Self-Awareness

Self-awareness of cognitive functions and self-awareness of psychosocial functions are located in different areas of the PFC. Awareness of one's own cognitive functions is correlated with the ventrolateral areas of the PFC.²⁷ Awareness of one's own psychosocial functions, however, are correlated with the anterior medial PFC, the posterior cingulate cortex,²⁸ and the ventromedial PFC,²⁷ especially on the right side.²⁹ A person who has damage to both areas may have reduced self-awareness for both cognitive and psychosocial function.

Screening of Cognitive Skills

The Process of Cognitive Assessment

The cognitive assessment process can be categorized as either top down or bottom up, but most occupational therapists will integrate the two approaches to assess the occupational performance of the client (top down) while attempting to discover the specific underlying cognitive deficits that may be causing difficulty with task completion (bottom up).¹⁹ Assessments in both top-down and bottom-up categories may be either nonstandardized or standardized. Nonstandardized assessments typically include informal observation of task performance or cognitive skills or a screening that combines observation with parts of standardized assessments. Standardized assessments are used to formally assess occupational performance or cognitive skills using a specified protocol for administration and scoring that may help reduce therapist bias. The method of administration of nonstandardized or standardized assessments can vary and may include self-report measures, dynamic assessments, functional assessments, or performance-based assessments.

Occupational therapists will typically perform a cognitive screening to ascertain occupational performance and basic cognitive functions. An occupational therapist may first have the person perform functional tasks that require cognition (e.g., planning and preparing a meal) as a top-down screening and also perform a quick screening of underlying cognitive deficits that may be impacting function as a bottom-up screening. For example, the therapist might use the Montreal Cognitive Assessment (MoCA) as a quick 10-minute screening before doing more in-depth screening and standardized testing (see Fig. 10-5). When a person demonstrates a deficit during the screening process, the person's occupational performance or cognitive skills will be tested further, sometimes with standardized assessments, to provide a more in-depth understanding of the deficits.

Figure 10-5 Client performing the Montreal Cognitive Assessment.

Factors That Influence Cognitive Function

An individual's cognitive function at any point in time is determined by many interacting variables, including affective, education, task, and environmental influences. Changes in any of these domains may improve or detract from a person's cognitive function and thereby his or her occupational performance. Therefore, to effectively assess cognition and interpret findings, occupational therapists must appreciate how variables can affect performance during cognitive assessment.

A person's emotional state has a pervasive influence on cognitive function.³⁰ Some examples include anxiety, depression, pain, and fatigue.³¹ Anxiety is linked to difficulty with attention and working memory.³² Depression is linked to memory deficits and executive functions.³³ Pain and fatigue (especially mental fatigue) interfere with working memory by occupying attention that is therefore unavailable to incoming data.³⁴ Under such circumstances, the occupational therapist may defer cognitive assessment to another time or, at a minimum, consider the influence of these factors when interpreting the assessment results.

A person's level of education may also influence the results of cognitive testing. In a study involving a random sample of age-stratified healthy older adults, younger age and higher education were associated with better performance on cognitive testing.³⁵ Because they are more familiar with testing processes, persons with higher education may score within normal limits on cognitive tests, even with decrements in their functioning, and/or persons with lower education who perform poorly on cognitive assessments may, in fact, be cognitively intact.

A person's familiarity with tasks may also influence cognitive performance. Tasks that are well-known to a person may be performed with relative ease because attention, memory, and executive functions are not as greatly taxed in familiar activities when compared with tasks that are new.³⁶ For example, if a person is asked to perform a leather lacing task by learning a stitch, the person who is already familiar with leather lacing, sewing, knitting, or crocheting may perform these stitches automatically using cerebellar pathways and motor habits that do not tax the higher cortical areas.

Finally, the environment can influence cognitive function. Variability in the structure, lighting, noise, familiarity, and presence of other people in the environment may all serve to either support or decrease the person's performance on both top-down or bottom-up assessments. The therapist will need to note all of these factors during the cognitive assessment.

Screening of Orientation, Attention, and Processing.

Orientation, attention, and processing are defined in the key terms, but there are also specific types of attention that proceed from the lowest to the highest level of attention as follows:

- **Focused attention:** The cognitive ability to be responsive to stimuli. This type of attention is also known as arousal.

- **Selective attention:** The cognitive ability to maintain focus on one stimulus despite distractions.
- **Sustained attention:** The cognitive ability to maintain focus over time. This type of attention is sometimes referred to as vigilance.
- **Alternating attention:** The cognitive ability to shift focus from one task to another.
- **Divided attention:** The cognitive ability to attend to two or more stimuli simultaneously.

Observation of a client with deficits in orientation, and lower level attention and processing may note confusion regarding person, place, and time; an inability to focus on visual or auditory stimuli; and slowed speed of processing with delays in response time during occupational performance.³⁷ As a person improves, he or she may be able to respond to stimuli and resolve some confusion regarding person, place, and time, but may have stimulus-bound attention with a need to respond to all stimuli and an inability to filter out distractions. For example, the person may respond to everything he or she sees or hears in a room or while walking down a hallway; this condition is clinically identified as stimulus-bound attention. With progress, the person will be able to focus, select, and sustain attention over time. Simultaneous improvement in the speed and accuracy of processing usually occurs through this progression. At the higher levels, the person will be able to alternate his or her attention between tasks and then ultimately divide attention between two different stimuli simultaneously (e.g., listening to a lecture and taking notes). It should be noted that divided attention is never expected for two of the same modes of attention. For example, a person cannot listen to two conversations at the same time or focus on two different visual stimuli (e.g., watching the road and a cell phone screen).

Screening of orientation, attention, and processing skills also can be completed through specific tasks as follows:

- To screen orientation and focused attention, use face-to-face positioning with observation of eye movements and focus, and questions regarding person, place, and time as appropriate to the level of communication. If the person is unable to communicate, observe the response to his or her name and the ability to appropriately use tools such as a spoon or toothbrush, keeping in mind that vision and visual perception should be evaluated before cognitive skills.
- To screen processing and selective attention, use a cancellation task. Ask the person to cancel a letter, number, or symbol on a sheet of paper. Observe the speed and accuracy of processing and the pattern of cancellation. A random pattern of cancellation may indicate deficits in attention and warrant standardized testing.
- To screen selective and sustained attention, use digit span numbers and letters (auditory, visual, and motor). Present a series of numbers, letters, or same color blocks, starting with a series of three and progressing to nine. Ask the person to repeat the series in the same order. Repeat the tasks starting with three and progressing to seven, asking the person to repeat the series backward.
- To screen alternating attention, use a Trail Making Test or the modified trail making test developed by Joan Togliola and Betty Abreu. Ask the person to draw a line, without removing the pen from the paper, which connects the numbers in order. Next, ask the person to repeat this with alteration between letters and numbers, each in order (see Fig. 10-6).

Figure 10-6 Client performing a modified Trail Making Test.

- To assess divided attention, use the Stroop Color and Word Test.³⁸ Following the standardized approach to the task, have the person perform all three sheets in order.

Screening of Memory

The terms **memory**, **immediate recall/sensory register**, **working memory**, and **long-term memory** are all defined in the key terms. Memory, however, can also be subdivided according to the type of information that is being recalled and the time at which the information was obtained. Memory for specific types of information can be immediate, working, or long-term and is categorized as follows:

- **Episodic memory:** recall of information that is related to time.
- **Procedural memory:** recall of how to perform tasks.
- **Semantic/declarative memory:** recall of word-based information (i.e., knowledge about the meanings of words, objects, and events).
- **Prospective memory:** recall of information for upcoming events (e.g., appointments).
- **Topographical memory:** recall of a spatial representation or physical layout.

The time at which the information was obtained is divided into two categories, retrograde and anterograde, as follows:

- **Retrograde memory:** recall of information obtained prior to an injury. The term remote memory is also used for this concept. Some examples include word finding, ability to recognize people, and semantic/declarative knowledge.
- **Anterograde memory:** recall of information obtained after an injury. The terms recent memory and new learning are also used for this concept.

Screening of the various types of memory in different time frames (immediate recall, working memory, and long-term) can be adequately completed using some specific tasks and subtests from the Rivermead Behavioral Memory Test (RBMT).³⁹ The RBMT assesses visual, auditory, and motor recall in the various types of memory and in the categories of retrograde and anterograde memory (see Figure 10-7). If clinical time does not allow for completion of the entire standardized test, subtests, such as first and second names, belonging, and appointment, can be selected and incorporated throughout the screening process to screen the specific types of memory as follows:

Figure 10-7 Client performing the Rivermead Behavioral Memory Test.

- To screen episodic memory, use the orientation and date sections.
- To screen procedural memory, use the route and message sections.
- To screen semantic/declarative memory, use the name, story, and orientation sections.
- To screen prospective memory, use the belonging and appointment sections.
- To screen topographical memory, use the route and belonging sections.
- To screen retrograde memory, use the orientation section.
- To screen anterograde memory, use the name, pictures, story, faces, route, and message sections.

Screening of Executive Functions

Executive functions can be subdivided into the following types: planning, problem solving, organization, judgment, self-regulation, flexibility, categorization, sequencing, abstract reasoning, divergent thinking, and conceptualization. The definitions are as follows:

- **Planning:** developing a proposal for doing or achieving something
- **Problem solving:** the process of working through an issue to find a solution
- **Organization:** the act or process of putting the different parts of something in a certain order
- **Judgment:** the ability to make considered decisions or come to sensible conclusions
- **Self-regulation:** control of one's behavior, such as inhibition and initiation of responses
- **Flexibility:** the ability to change ideas or to compromise
- **Categorization:** the ability to sort objects or ideas according to common attributes
- **Sequencing:** placing items or performing tasks in the order in which they should happen
- **Abstract reasoning:** the ability to understand subjects on a complex level
- **Divergent thinking:** a thought process or method used to generate creative ideas by exploring many possible solutions
- **Conceptualization:** the ability to invent or formulate an idea

Most functional activities that involve executive functions will require a combination of these types of cognitive skills. The full range of executive functions can be screened using the following tools:

- To screen planning, problem solving, judgment, self-regulation, and sequencing, use the physical or virtual Tower of London Task⁴⁰ (see Fig. 10-8). Although there are various forms of the test, the typical test has three rods and seven to nine disks that can be used to grade the test to make it more difficult (see Figure 10-8). Start with four disks for the screening. The objective of the test is to restack the original stack on a different rod in the order of large to small in the smallest

number of moves possible using the following rules: (a) only move one disk at a time from the top of a stack, (b) a larger disk can never be placed on a smaller disk.

Figure 10-8 Client performing the Tower of London Task.

- To screen organization, categorization, abstract reasoning, and conceptualization, use a grocery list task. The person is given a list of the following 30 grocery items and told to organize them into six categories that fit with the different sections of his or her grocery store, with one category being miscellaneous. The items include eggs, doughnuts, hamburgers, popsicles, milk, olives, creamer, bagels, apples, frozen peas, bread, chewing gum, yogurt, chicken, lettuce, apple juice, ice cream, muffins, hot dogs, potatoes, fish sticks, cheese, sausage, rolls, frozen pizza, strawberries, boxed noodles, carrots, turkey, and dog food. The categories are not given to them, but they should generate categories such as dairy, bakery, frozen, produce, meat, and miscellaneous. There will be five items in each category. To adapt the activity, the categories can be provided.
- To screen abstract reasoning, flexibility, conceptualization, and divergent thinking, use the Alternative Uses Test. Developed by J. P. Guilford in 1967, the Alternative Uses Test challenges these areas of executive functions by asking the person to think of as many uses as possible for an everyday object like a chair, coffee mug, or brick, each in 2 minutes. The person should be able to generate four to six unique uses for each object.

Screening of Self-Awareness

Self-awareness is the cognitive ability to know one's own capacities, skills, limitations, and level of function. The categories of self-awareness include sensorimotor, cognitive, and psychosocial self-awareness. In general, a person will have a better awareness of his or her sensorimotor function than of more abstract cognitive and psychosocial functions, although deficits such as homonymous hemianopia and unilateral inattention are also abstract and may result in a lack of self-awareness. The Awareness Questionnaire is a good quick screen of self-awareness, but the therapist should categorize the questions according to those three areas to gain an understanding of the categories of self-awareness that are lacking.⁴¹ On the Awareness Questionnaire, numbers 1 and 5 are general functional questions; 6 to 9 are sensorimotor questions; 2, 4, and 10 to 15 are cognitive questions; and 3, 16, and 17 are psychosocial questions. Keep in mind that people with impaired self-awareness may minimize problems on self-reports. Discrepancies among the person's self-report and that of a significant other or therapist are used to indicate the level of self-awareness,⁴² with large discrepancies indicating more impaired self-awareness.

CASE STUDY

Patient Information

Santiago, a 22-year-old male of Mexican American descent, was attending graduate school to study foreign languages. The first one in his family to receive a college degree, his goal in life was to master foreign languages so he could teach abroad. He also loved music and singing karaoke in bars in different dialects. After “partying” with his friends, he drove home “under the influence” and skidded off the road on a rainy night and hit a tree “head-on.” He was hospitalized and sustained a brain injury in the motor vehicle accident. Most of the damage was to his right hemisphere. He also had multiple basilar skull fractures, a small subarachnoid hemorrhage, and a disruption of his maxillary sinuses. The neurologist medically induced a coma for 3 weeks.

When Santiago first awoke, he was highly agitated and swore profusely. The vulgar language he used was uncharacteristic of him, given his education and working vocabulary for English. His friends and parents say he did not curse in public before the accident. His conversational language gradually returned, but he continued to have trouble remembering the names of common household items and had a loss of memory for events that occurred after the accident (anterograde amnesia). The neurologist used imaging studies, which suggested that the right-side temporal lobe damage may have affected his hippocampus, which is important in learning, memory, and navigation of the environment.²³ His loss of memory and damage to the right-side brain damage has caused some hemispatial inattention (also called unilateral neglect) on his left side. In addition, he also experienced sensory deficits involving auditory and visual memory challenges and a shortened sustained attention span. He may have some mild visual field impairment and hearing loss in the right ear. His medical insurance was dropped early in the process, forcing him to go on Medicare. Fortunately, the Bipartisan Budget Act of 2018 repealed the cap on Medicare Part B outpatient services for occupational therapy as long as the services were deemed medically necessary. The occupational therapist was able to see him in the clinic during the acute care phase, and later on she was able to visit him at home through the hospital’s home health agency.

Assessment Process

The occupational therapist first evaluated his functional cognitive skills from a top-down perspective to see if he could carry out routine daily activities related to living independently and assessed whether he could dress himself, prepare meals, and take his medications independently.⁴³ He expressed the desire to go back to graduate school where he was maintaining a 3.60 GPA in foreign languages and taking education courses to earn a teaching certificate. Unfortunately, after his injury, he had to withdraw from graduate school and was unable to continue his work study job at the university. He needed some source of employment to earn an income and to obtain student loans for college. His initial mood swings such as feelings of sadness and emotional outbursts made it difficult to maintain friendships and the romantic relationships he had in the past. His executive functions such as mood regulation, social behavior, planning, and decision making were impaired, as observed in simulated work hardening activities of routine tasks in occupational therapy. The therapist conducted a screening of vision, visual perception, and cognition; then completed standardized assessments as indicated; and conducted a home visit. The patient had to move back home in the local community because he could no longer manage living in an apartment independently.

Assessment Results

To establish a baseline, the therapist conducted the Canadian Occupational Performance Measure (COPM) to obtain information about his executive function and ascertain his self-awareness and the degree of his cognitive problems. The COPM is an evidence-based outcome measure designed to evaluate the patient’s self-perception of performance in everyday living, over time. Using this semistructured systematic interview, therapists engage the client in identifying daily occupations of importance that they want, need, or are expected to do but are unable to accomplish. The problems were identified by rating the importance of each of the occupations to his life using a 10-point rating scale. The client chose five of the most important problems: (1) Feelings of sadness or depression, (2) Lack of concentration to complete tasks, (3) Forgetting names and word-finding problems, (4) Reading comprehension, (5) Communicating effectively and controlling his emotions. The therapist entered the chosen problems and their importance

ratings in the scoring section and calculated an average COPM performance score and satisfaction score.

The therapist also administered the MoCA to screen for attention and concentration, executive functions, memory, language, visuoconstructional skills, conceptual thinking, calculations, and orientation. The MoCA assessed different types of cognitive abilities, including orientation, short-term memory, executive function, language abilities, attention, and visuospatial ability. The assessment indicated that the patient had trouble with attention, working memory, and concentration.

More in-depth testing was completed to assess attention and memory. The digit span test, modified Trail Making Test, and the Stroop Color and Word Test were completed. Santiago was able to recall seven digits forward, but struggled with digit span backward. He also demonstrated slowed speed of processing for alternating numbers and letters in the Trail Making Test, part B, and the color/word section of the Stroop. The RBMT was used to assess memory functions. Santiago performed at a screening level of 7, indicating moderate memory impairments. Difficulties were noted on naming common objects, delayed recall of names, paragraph recall, and topographical memory.

The Executive Function Performance Test (EFPT) was used to assess top-down performance-based executive functioning of four basic tasks associated with self-maintenance: simple cooking, telephone use, managing medications, and paying bills. This assessment revealed that the patient had trouble managing medications and writing checks for bills.

The Brief Neuropsychological Cognitive Examination (BNCE) evaluated major cognitive functions in one short session, yielding a general cognitive profile in about 30 minutes. Specifically, the BNCE assesses working memory, gnosis (word cognition), praxis (inability to carry out planned movements), language, orientation, attention, and executive functions. It reveals specific cognitive abnormalities that may warrant more detailed evaluation. The advantage of using this assessment is that it provides a score that calibrates a validity index and a total score that determines whether the person can live independently. The patient's score was 22 in the mild range of impairment, suggesting he was not yet able to live independently.

The Awareness Questionnaire (AQ) was completed by Santiago, his mother, and his occupational therapist. Discrepancies in the scores among the three questionnaires were noted on numbers 3 and 10 to 17, indicating reduced awareness of cognition and psychosocial functions.

Occupational Therapy Problem List

This problem list is the result of triangulation of clinical functional observation and standardized assessments.

- Attention problems (sustained, alternating, and divided)
- Difficulty in word finding or forgetting names for common objects
- Reduced topographical memory
- Feelings of sadness or depression
- Poor interpersonal communication
- Poor reasoning and judgment in managing daily living skills
- Poor medication management
- Mood dysregulation and agitation
- Reduced self-awareness

Most Commonly Used Standardized Assessments for Cognitive Function

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability
--------------------------	------------------	---------------------	----------	-------------

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability
<p>The Montreal Cognitive Assessment (MoCA)⁴⁴ www.mocatest.org/pdf_files/test/MoCA-Test-English_7_1.pdf</p>	<p>The MoCA is a brief 30-question test that takes around 10–12 minutes to complete. It was published in 2005 by a group at McGill University working for several years at memory clinics in Montreal. This is a screening tool developed to measure mild cognitive impairment. The MoCA screens attention and concentration, executive functions, memory, language, visuoconstructional skills, conceptual thinking, calculations, and orientation.</p>	<p>Approximately 10 minutes. The test is made freely available to any clinician, and its international use allows it to be administered in 35 different languages. The total possible score is 30, with any score higher than 25 considered normal. Any score of 25 or less is considered to be an indication of some form of cognitive impairment, which can predict or identify the onset of dementia in patients.</p>	<p>The MoCA has been validated on a range of patients, including those with stroke, Parkinson disease, and traumatic brain injury (TBI). Excellent concurrent validity among patients with mild Alzheimer disease ($r = 0.87$).⁴⁴ Also discriminant validity established on a variety of diagnostic groups with neurological impairments.⁴⁵ A MoCA test validation study by Nasreddine in 2005 showed that the MoCA was a promising tool for detecting MCI and early Alzheimer disease compared with the well-known Mini-Mental State Examination (MMSE).⁴⁶</p>	<p>Very good reliability inter consistency ($r = 0.83$); excellent test–retest reliability ($r = 0.92$)⁴⁴</p>
<p>Cognistat (Neurobehavioral Cognitive Status Examination)⁴⁹</p>	<p>Cognistat (Neurobehavioral Cognitive Status Examination) is a screening tool that is an efficient and metric approach that streamlines the testing process. Cognistat is available in three different formats: Cognistat Assessment System (CAS-II): a web-based, computer-assisted format with electronic data records (EDR). Cognistat Paper: the original Cognistat paper-and-pencil test. Cognistat Active Form: a new computerized PDF format that does not require web access. https://www.cognistat.com/</p>	<p>Test takes 12–15 minutes</p>	<p>Discriminant analysis: Wilcoxon analysis suggested that four of the subtests have discriminated between elderly persons with stroke and healthy independent elderly⁵⁰ statistically significant differences in mean scores for healthy controls, persons with dementia. Nabors and colleagues⁵¹ retrospectively examined the concurrent validity of the Cognistat compared with standard neuropsychological measures. The results indicated that the Cognistat is useful in detecting cognitive impairment in the adult TBI population.</p>	<p>Lannin and Scarcia⁵² evaluated the concurrent and incremental reliability of five different cognitive assessments. Cognistat was most sensitive for detecting cognitive impairment; if used with the Cognitive Assessment c Minnesota, specificity increases.</p>

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability
<p>Loewenstein Occupational Therapy Cognitive Assessment (LOTCA).⁵⁸ The LOTCA battery was developed as a measure of basic cognitive skills and visual perception in older adults with neurological impairment.</p>	<p>Microbattery consisting of 20 subtests in four areas: orientation, perception, visuomotor operations, and thinking operations.</p>	<p>Approximately 30–45 minutes. The LOTCA provides an in-depth assessment of basic cognitive abilities and can also be used in treatment planning and review of progress over time.</p>	<p>Discriminant validity: All subtests, except identification of objects, differentiated between patients with craniocerebral injury and healthy controls and stroke patients and health.⁵⁸ Katz et al. conducted a factor analysis to determine the construct validity of the original LOTCA, using two groups of patients with traumatic head injury or stroke ($n = 96$), and healthy adults ($n = 55$). The study found good validity measures.</p>	<p>Katz et al.⁵⁸ reported excellent interrater reliability for subtests of LOTCA, with strong intrate reliability (Spearman's ρ correlation coefficient ranged from 0.82 to 0.96 for various subtests).</p>
<p>Cognitive Assessment of Minnesota (CAM)⁶⁰ https://health.utah.edu/occupational-recreational-therapies/docs/...reviews/cam+.pdf</p>	<p>This test is designed to be used for adult clients who have cognitive impairments due to a cerebrovascular accident (CVA) or a TBI (Level IV through Level VII on the Rancho Los Amigos Scale of Cognitive Functioning). The CAM is a screening tool that assesses a wide range of cognitive skills. It is arranged in a hierarchy from simple to complex. The hierarchy is divided into four areas: store of knowledge, manipulation of old knowledge, social awareness and judgment, and abstract thinking.</p>	<p>Administered either as a 40-minute session, or two 20-minute sessions.</p>	<p>Validity: Concurrent, construct validity of the Cognitive Assessment of Minnesota in older adults was evaluated by Pearson product-moment correlations were calculated for total scores of the two cognitive measures (CAM and MMSE). The investigators determined the overall level of agreement of these screening measures to be valid for a group of older adults.</p>	<p>Reliability: Test-retest, internal consistency, interrater reliability has been performed. The CAM appears to be a promising measure for use with older adults with cognitive impairment, especially when used by investigators interested in functional capacity. More research is necessary for exploring the psychometric properties of the CAM to explore its full utility with diverse populations. Previously, one small study has examined psychometric properties of the CAM using the MMSE as a comparison. Rustad and colleagues⁶⁰ found a moderate correlation ($r = 0.44, p = 0.05$); however, the sample size reported in this study was small ($n = 16$), and additional examinations needed to determine whether this relationship would exist in other samples.</p>

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability
<p>Trail Making Test The Trail Making Test was originally part of the Army Individual Test Battery from 1944 and was then incorporated into the Halstead–Reitan Battery in 1985.</p>	<p>Today, the Trail Making Test is one of the most popular neuropsychological tests. The test can provide information about visual search speed, scanning, speed of processing, mental flexibility, as well as executive functioning (prefrontal lobe).</p>	<p>Trail A takes 29 seconds to complete; Trail B takes 75 seconds.</p>	<p>It is difficult to find validity scores for this assessment. Although trail making tests are very simple, they have been hypothesized to reflect a wide variety of cognitive processes, including attention, visual search, and scanning, sequencing and shifting, psychomotor speed, abstraction, flexibility, ability to execute and modify a plan of action, and ability to maintain two trains of thought simultaneously.⁶¹ Cognitive imaging may confirm this claim.</p>	<p>In one study, significant differences were found between groups for Trail A and all Stroop tasks, but in another study only differences between participants with left and right frontal trauma on the Stroop Color-Word task. Potential reasons why Trails A and B are sensitive to frontal lobe damage are discussed, such as novelty and processing speed.⁶²</p>
<p>STROOP Color and Word Test The Stroop effect is named after John Ridley Stroop, who first published the effect in English in 1935. The effect had previously been published in Germany in 1929 by other authors. When the name of a color (e.g., "red" or "blue," or "green") is printed in a color that is not denoted by the name (e.g., the word "red" printed in blue ink instead of red ink), naming the color of the word takes longer and is more prone to errors than when the color of the ink matches the name of the color.</p>	<p>The standardized version of the Stroop consists of two parts. In the Color Task, the individual reads aloud a list of 112 color names in which no name is printed in its matching color. In the Color-Word Task, the individual names the color of ink in which the color names are printed.</p>	<p>Estimates suggest it takes 5 minutes to administer, but it depends on the cognitive ability of the patient. The Stroop Interference Test, originally developed in 1935 by Stroop to measure selective attention and cognitive flexibility, may take 10 minutes to administer.</p>	<p>Discriminant validity is supported by studies on patients with MCI and dementia, postconcussion syndrome and severe TBI, ADHD (treated and untreated), and depression (treated and untreated). Pearson's <i>r</i> was calculated for all of the tests except those that were not normally distributed, for which Spearman's rho was used. The correlation coefficients are given for the individual tests and the domain scores.⁶³ Reliability and validity of a computerized neurocognitive test battery, CNS Vital Signs Impaired performance of the Stroop task may be indicative of an underlying neurological disorder related to frontal lobe dysfunction; poor performance is not sufficient for a diagnosis of ADHD.</p>	<p>For most versions of the Stroop test, there are no available estimations of reliability.</p>

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability
Rivermead Behavioral Memory Test (RBMT) ⁶⁴	Assesses working memory needed for daily living skills such as remembering appointments, travel routes around town, names, and faces.	Approximately 30–45 minutes	Wilson et al. ⁶⁴ found statistically significant differences between healthy subjects and persons with brain injury ($p < 0.001$).	Interrater reliability: 100% agreement with 40 subjects with brain injury who were scored separately but simultaneously by two raters. ⁶⁴ Reliability was good with Cronbach's α 0.84 and PSI 0.85 at admission. Fit to the Rasch model showed that one item (faces) deviated from model expectation. External construct validity was supported by expected correlations. ⁶⁵ These scales show good test-retest reliability and adequate external construct validity.

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability
Executive Function Performance Test (EFPT) ⁶⁶	A standardized top-down performance-based measure of executive functioning. The EFPT examines the execution of four basic tasks associated with self-maintenance: simple cooking, telephone use, bill paying, and medication management.	Approximately 30–45 minutes	<p>A cross-sectional study recently found the alternate, Internet-based form of the bill-paying task of the EFPT to be reliable and have construct validity for assessing executive function with people who have subacute stroke.⁶⁷ No significant differences were found between participants who performed the Internet-based version first ($t = -1.3, p = 0.187$) and those who did it second ($t = 0.3, p = 0.76$). Differences were also not found for the telephone-use total scores or time between participants who performed the Internet-based version first ($t = -1.4, p = 0.16$) and those who did it second ($t = 0.56, p = 0.57$). Criterion validity was also established for both tasks. Concurrent validity was established ($p = 0.61$) with the Assessment of Motor and Process Skills.⁶⁸ Construct validity was established by Baum et al.⁶⁹ with control EFPT total scores significantly ($p \leq 0.05$) lower (better) than mild stroke scores and moderate</p>	Not available.
			<p>stroke scores ($p \leq 0.0001$). Mild stroke scores were also significantly lower than moderate stroke scores ($p \leq 0.0001$). Construct validity was verified for bill paying, but not for telephone use. Criterion validity was verified for both tasks.</p>	

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability
Awareness Questionnaire (AQ) The AQ was developed by Sherer et al. ⁷⁰ The initial version of the AQ, as well as the results of a factor analysis that resulted in the current version of the AQ, were published in 1998.	The AQ was developed as a measure of impaired self-awareness after TBI because patients with traumatic brain injuries often show impaired awareness of their deficits.	Approximately 20–30 minutes	The AQ was developed based on previous studies of impaired awareness and the clinical experience of the authors to assure patient awareness of functioning in physical, cognitive, and behavioral domains in community activities.	Because of the nature of self-awareness, it is difficult to obtain accurate reliability measures.
Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE) The A-ONE consists of two parts: an A-ONE ADL scale and an A-ONE Neurobehavioral (NB) scale. The occupational therapist scores 22 test items based on the level of assistance needed to do ADL task as well as underlying neurobehavioral impairments impacting that performance.	The A-ONE is intended to be used only with clients with neurobehavioral disorders (e.g., stroke, brain injury, dementia). Research is ongoing to extend its application to children. The Assessment of Motor Process Skills (AMPS) is intended to be used with persons 3 to over 100 years of age, from all diagnostic groups. The A-ONE consists of two parts: an A-ONE ADL scale and an A-ONE NB scale. The occupational therapist scores 22 test items based on the level of assistance needed to do ADL tasks as well as underlying neurobehavioral impairments impacting that performance.	Approximately 75 minutes	Steultjens ⁷¹ examined the concurrent validity of the A-ONE. Comparison of the A-ONE ADL scale with the Barthel Index and comparison of NB scores with the MMSE revealed excellent correlations ($r = 0.70$ and 0.85 , respectively). The results provide minimal support for the construct validity of the A-ONE related to differentiating between ADL performance of persons with left and right CVA. ⁷²	The Mann-Whitney U test and chi-square test were used to explore possible differences between the performance of participants with left and right CVA. Descriptive statistics were calculated for demographic and for items on the Functional Independence Scale (FIS) and the Neurobehavioral Specific Impairment Subscale (NSIS). The level of significance was set at $p < 0.05$.

Chapter 11

Cognitive Intervention

Mary Vining Radomski and Gordon Muir Giles

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Discuss the field of cognitive rehabilitation in general.
2. Distinguish cognitive rehabilitation approaches used by occupational therapists from those provided by other professions.
3. Describe theoretical approaches to occupational therapy cognitive intervention.
4. Employ specific clinical interventions that are supported by theory and evidence.

CHAPTER OUTLINE

Conceptual Foundation Underlying Interventions for Cognitive Dysfunction
Approaches to Cognitive Intervention in Occupational Therapy
Evidence-Informed Cognitive Intervention in Occupational Therapy
Case Study

TERMINOLOGY

Automaticity: initiation and execution of a behavior with minimal conscious decision-making in response to a stimulus; when a behavior is automatic conscious effort is required if the response is to be inhibited.¹

Chaining: a method for training task performance in which tasks are broken down into component steps; a functional task can be thought of as a stimulus–response chain in which the completion of each activity acts as the stimulus for the next step in the chain.²

Cognitive rehabilitation: a wide range of therapeutic interventions designed to address neurocognitive impairment in one or more cognitive domain (e.g., attention, memory, or executive functions) and as a result to improve an individual’s functioning in everyday life.

Compensatory cognitive strategies: tools or methods that are used by clients to help them overcome, circumvent, or minimize the load placed on an impaired cognitive domain, such as using alarm prompts on a smartphone to keep track of time-critical activities.³

Errorless learning: a method of learning in which errors are prevented and sufficient cueing is provided to achieve correct performance on each occasion a task is practiced.⁴

Functional cognition: how people use and integrate their thinking and processing skills to perform everyday activities in clinical and community settings.⁵

Metacognitive strategy instruction (MSI): direct instruction to teach clients to regulate their own behavior by using internal thinking procedures that are applicable to many realms of everyday functioning such as specifying goals, breaking tasks into steps, self-monitoring, modifying behavior if upon reflection, the goal is not met.⁶

Post-traumatic amnesia (PTA): the period following trauma in which the acquisition of new declarative knowledge is severely impaired; PTA is said to be resolved when continuous memory for ongoing events is restored.⁷

Press: aspects of the person’s physical or social environment that influence the challenge of an activity (activity demand); reducing the press can make an activity easier to perform.

Routines: semiautomatic sequences of activities that are prompted by physical context and are fairly consistent for each individual on a day-to-day basis (e.g., a person’s morning activities of daily living [ADL] routine).

Self-awareness: the ability to perceive one's strengths, weaknesses, and vulnerabilities with relative objectivity.⁸

Conceptual Foundation Underlying Interventions for Cognitive Dysfunction

As introduced in Chapter 10, many people who are referred to occupational therapy experience permanent, temporary, and/or progressive cognitive impairment or inefficiency that interferes with their occupational performance. Cognitive dysfunction may be associated with the person's primary diagnosis (including traumatic brain injury [TBI],⁹ stroke,¹⁰ multiple sclerosis,¹¹ Parkinson disease,¹² and major neurocognitive disorder [dementia]¹³) or occur secondary to concurrent problems with pain,¹⁴ anxiety, and depression.¹⁵ Therefore, helping clients optimize their cognitive functioning is often a primary or secondary focus of occupational therapy intervention.

The central aim of this chapter is to advance evidence-informed cognitive intervention that reflects occupational therapists' focus on occupational performance. To that end, we first provide context relative to the broader cognitive rehabilitation field and then describe theory and practices associated with occupation-oriented cognitive intervention. Note that for simplicity, we use the term *client* when referring to the individual receiving occupational therapy. However, traditionally, the term *patient* is used in acute or inpatient rehabilitation medical settings, which underscores their medical and psychological vulnerability. We advise readers to use terminology that optimizes clear communication within their local practice context.

Cognitive Rehabilitation

Interest in the possibility of “reeducating” persons with a damaged brain dates back to the 1800s,¹⁶ with wars of the 20th century giving rise to worldwide research and interventions to improve cognition after penetrating brain injuries. Most notably, the needs of veterans with brain injury sustained in the 1973 Yom Kippur War led to the development of an intensive, interdisciplinary rehabilitation program in Israel that focused on patients' cognitive and behavioral disabilities.¹⁷ Similar programs were developed in the United States, ultimately legitimizing cognitive impairment as a primary focus of rehabilitation. **Cognitive rehabilitation** remains an interdisciplinary enterprise, typically involving occupational therapists, speech language pathologists, and neuropsychologists.¹⁸ As such, there is the potential for complementary, overlapping, or conflicting roles among professions.

Cognitive intervention provided by occupational therapists has a distinct focus on functional cognition. **Functional cognition** has been defined as the ability to integrate thinking and performance skills to accomplish complex everyday activities.¹⁹ This focus on functional cognition suggests two central features of cognitive intervention in occupational therapy. First, cognitive dysfunction is always addressed within the context of the client's broader capacities, concerns, resources, and relevant environments. For example, occupational therapy during inpatient rehabilitation for a young man with a moderate TBI addresses both cognitive and mobility limitations that interfere with his ability to perform ADLs and be discharged to home. Second, improvement in occupational performance is always the intended outcome of cognitive intervention within a given episode of care. For example, during outpatient occupational therapy, a woman with cancer-related cognitive dysfunction (“chemobrain”) learns to use cognitive strategies applied to work-related activities so that she will experience a decrease in the frequency of memory failures in her job as a financial manager. Occupational therapists have the education and training to provide cognitive intervention and are accountable to their clients and the profession to employ occupation-focused, evidence-based approaches and to invest in ongoing learning in this important area of rehabilitation.

Approaches to Cognitive Intervention in Occupational Therapy

In this chapter, we describe three cognitive intervention approaches that occupational therapists use to help clients improve occupational performance: skill–habit training, cognitive strategy training, and environmental modification/adaptation. Multiple approaches are often employed to help clients meet their goals. Before implementing any approach, the therapist does the following:

- collaborates with the client (and family care partner, if available/appropriate) to identify the real-life scenarios in which cognitive impairments or inefficiencies are most problematic;
- uses assessment findings to determine the cognitive focus area and the client’s current level of self-awareness;
- ascertains the client’s preferences and requirements;
- considers the outcome expectations, and anticipated intensity and duration of therapy within the context of a given episode of care (see Table 11-1).

Table 11-1. Key Features of Four Cognitive Intervention Approaches

COGNITIVE INTERVENTION APPROACH	CHARACTERISTICS OF CLIENTS	OUTCOME EXPECTATIONS	EXAMPLES OF INTENSITY AND DURATION BASED ON STUDIES DEMONSTRATING INTERVENTION EFFICACY OR EFFECTIVENESS
Skill-habit training	Individuals with a wide range of cognitive capacities can benefit, including those with major neurocognitive disorder and moderate-to-severe TBI.	The client learns a set of procedures that enable him or her to competently perform a selected task. Training on one task is not expected to transfer to competence with another.	Daily application of errorless learning principles during post-traumatic amnesia following TBI for 3–4 weeks of training accelerates recovery and may shorten rehabilitation LOS. ²⁰
Cognitive strategy training	Clients must be aware of their limitations and sufficiently motivated in order to learn and employ new techniques.	The client learns how to perform a technique, use a tool or internal thinking procedure that can be applied to improve performance in a variety of tasks, roles, and settings.	Adults with TBI received two, 1-hour, individual weekly sessions for 10 weeks of metacognitive strategy instruction based on CO-OP. ²¹ Adults with TBI received training to use their smartphone as a memory aid over a 6-week period (one individual session and five group sessions that were each 1.5 hours). ²²
Environmental modification/Adaptation	At a minimum, clients must have care partners available to modify the environment on clients’ behalf.	The care partner implements changes in the home that helps a person with progressive cognitive dysfunction maintain his or her level of functioning in the home, reduces family care partner burden, and improves their quality of life.	Use of a daily routine and regular exercise helps maintain occupational performance in persons with Alzheimer disease. ²³ Educating the care partner about how to modify the physical and social environment increases self-efficacy and reduces burden among care partners. ²⁴

CO-OP, Cognitive Orientation to Daily Occupational Performance; LOS, length of stay; TBI, traumatic brain injury.

Addressing Client Self-Awareness across Intervention Approaches

Many clients who are referred to occupational therapy for cognitive intervention are not fully aware of the cognitive problems that interfere with their performance. Clients who are hospitalized with sudden-onset neurological conditions (such as stroke or TBI from motor vehicle accidents) may have injuries to the brain’s frontoparietal control network that contribute to impaired **self-awareness**,²⁵ and the regimens and safety policies of the hospital setting rarely offer clients real-life feedback about the presence or consequences of cognitive impairments. Because impaired self-awareness is associated with poorer rehabilitation outcomes,²⁶ occupational therapists try to use a variety of techniques to help clients become more aware of their cognitive strengths and weaknesses throughout the intervention process.

- Appreciate the difference between neurologically based unawareness and adjustment-based denial. Furthermore, make an effort to determine what aspect of self-awareness may be impaired (metacognitive awareness, anticipatory awareness, error monitoring, self-regulation).^{26,27}
- Create opportunities for clients to (1) predict how well they’ll perform challenging tasks, (2) monitor their performance, (3) analyze the results of their efforts, and (4) determine what to continue or do differently next time.
- Introduce therapeutic structured failure when appropriate. That is, do not interfere with the natural consequences of the cognitive impairment during selected supervised activities. For

example, if the client fails to initiate a cognitive compensatory strategy (such as use of a memory aid), do not provide further instruction, but rather create an opportunity for the client to observe what happens when the strategy is not used.

- Offer noncritical feedback in real time regarding observations of performance or behavior. Point out strengths and evidence of improvement as well.
- Collaborate with family members to provide feedback. In some cases, family members should focus on maintaining harmony in the household and appropriately prefer that the therapist assumes the responsibility of providing any feedback about performance problems to the client. In other cases, family members or coworkers are so afraid of offending or discouraging clients that they insulate them from any and all challenges or avoid mentioning errors and, as a result, deprive them of information that might improve self-awareness.
- Respect the clients' readiness to participate in therapy. Avoid badgering clients into improved awareness of deficits by maintaining a therapeutic partnership so that they will want to return for services in the future.

Skill–Habit Training

It is widely accepted that human beings have two systems for the control and execution of behavior: a conscious, controlled, slow, effortful, and deliberative cognitive system used when people are engaged in problem-solving, and a rapid, relatively effortless, habitual, or automatic system that supports frequently performed skills, tasks, and habits.^{28,29} Solving novel problems constitutes a relatively small part of a person's life, and most of human behavior is automatic.^{30,31} Automatic habits and **routines** enable people to perform complex skills and carry out everyday tasks with little or no mental energy. For example, most people employ relatively consistent procedures for daily activities, such as showering, brushing teeth, crossing the street, and getting to work. Practice increases the availability of target responses, such that conscious decision-making is replaced by the implementation of automatic action sequences.³² When a skill becomes automatic, it becomes the easiest behavior to initiate from an array of possible behaviors, reduces interference error, and is experienced by the individual as effortless.

Helping clients develop new habits and routines that improve specific skills/behaviors (sometimes called specific skill or task-specific training)³³ is a potentially potent means of advancing occupational performance for people with cognitive impairments.^{3,20,34} Skill–habit training addresses the disruption in long-standing habits and routines that may accompany disability and neurological impairments.³⁵ Following TBI or stroke or in the context of cognitive decline, what were once automatic skills for tasks performance (e.g., street crossing, doing laundry) can lead to insurmountable challenges and loss of self-esteem for a person with newly acquired deficits in planning, problem-solving, and decision-making. The lost competence in what were once effortless skills can have a profound impact on that individual's energy level and sense of continuity, competence, and self.³⁶

The skill–habit training approach is intended to improve an individual's ability to perform a particular skill or task, but generalization to other skills is not expected. It has been suggested that improved functional competence improves self-confidence and willingness to engage in further training, but there is no expectation that skills other than the ones taught will improve. It is, therefore, important to look for areas with the client and family care partner for which improved functioning will have important outcomes for the individual. Skill–habit training, which relies on procedural and **errorless learning**, is often used with persons with severe impairment of memory or self-awareness, and/or those who have problems with ADL or simple instrumental ADL (IADL).^{3,37} However, the relevance of skill–habit training is not limited to those with disabilities because most people rely on habits to a greater or lesser extent.

Implementing This Approach in Occupational Therapy Practice

- Guided by the client (and family care partner where appropriate), the therapist selects a key skill that becomes the target of intervention.^{3,38}
- The therapist analyzes the physical and social context in which the routine or sequence is expected to occur to identify environmentally available cues or determine where to create new cues. Because routines and habit sequences are thought to be context specific, training is most effective if it occurs in the environment in which the routines will ultimately be performed.³

- A task analysis is performed that is specific to each client on the targeted skill.³ Task analysis involves breaking the skill down into discrete steps so that when each step is performed in a **chain** until the target state (e.g., bathing dressing, making a cup of coffee) is achieved. A checklist may be created to assure that the steps are practiced in a consistent sequence (see Fig. 11-1).

Morning planning checklist

Directions: each step after it is completed.

	Su	M	T	W	Th	F	Sa
1. After breakfast, open planner to yesterday's page.							
2. Check off all of the tasks you completed yesterday.							
3. Draw an arrow in front of undone or incomplete tasks.							
4. Re-write these tasks on today's page.							
5. Move the bookmark to today's planner page.							
6. Review today's schedule.							
7. Ask your wife if there are any tasks or appointments that you should write down for today.							
8. Make notes about at least things you would like to do today.							
9. Turn to tomorrow's page and make a note to remind yourself to do this checklist again.							

Wind-down checklist

Directions: each step after it is completed.

	Su	M	T	W	Th	F	Sa
1. When your phone alarm sounds at 9 pm, stop your current activity.							
2. Make notes about where you left off on your project.							
3. Put on your pajamas.							
4. Brush your teeth.							
5. Wash your face.							
6. Gather your magazines and go to your recliner.							
7. Set your alarm on your phone for 30 minutes and enjoy your magazines.							
8. When the alarm sounds, go to bed.							

Figure 11-1 Checklists like these are used to help clients re-establish task-habit sequences.

- The client must then practice the task. The therapist or family care partner cues the client through the task performance so that it is performed without errors. The number of times that the client must practice the task depends on the task's complexity and the severity of the client's impairments, but some evidence of learning is usually apparent within days to weeks. As the client consistently performs the task, learning occurs and steps begin to "chunk" together so that gradually the client goes directly into the next step in the sequence without being cued and cues can be combined and the program can be shortened.³ For some clients who have relatively intact initiation skills, once a program is established, a checklist can be used as the client checks each completed step.

Skill-habit training is a recommended, occupation-oriented approach to rehabilitation for individuals with moderate-to-severe memory or executive function impairments and for those with impaired self-awareness or who are in **PTA**. Unfortunately, skills training has often been undervalued by occupational therapists despite its alignment with occupational therapy theory and goals.

Compensatory Cognitive Strategy Training

People with neurocognitive impairment who use **compensatory cognitive strategies** experience improved cognitive functioning, confidence, and perseverance.³⁹ The therapist collaborates with the client (and family care partner, if available/appropriate) to ascertain the client's preferences and requirements for strategy use and then implements a training regimen. Sohlberg and Turkstra⁴⁰ proposed that cognitive strategy training is organized around three training phases, which are summarized as follows. Note that the case example in this chapter illustrates these phases of strategy training.

1. **Acquisition:** The therapist teaches the client about the selected cognitive strategy and how to use it. The client then practices strategy procedures, first with coaching from the therapist to minimize procedural errors. Next, the therapist provides practice opportunities to assure that the client can independently perform the strategy in response to a cue or trigger. Ideally, with the support of family care partners, clients identify opportunities to practice using the strategy at home.
2. **Mastery and generalization:** The therapist and client continue to identify contexts in which the new strategy could optimize performance and the related cues that could trigger strategy implementation. The therapist creates strategy practice opportunities with varying cues, stimuli, and contexts. The therapist’s feedback becomes less immediate and directive and more general and delayed (e.g., from “you forgot to set your alarm prompt” to “is there anything else you need to do to make sure you remember to take your medication at 2 pm?”).⁴⁰
3. **Maintenance:** It typically takes more time and repetition for a newly learned strategy to become automatic than are available during an episode of care. Therefore, the therapist sets up supports to minimize the possibility that the client will abandon the strategy when therapy is discontinued such as the following: (1) the client is scheduled for a follow-up or “booster” session a month or so after discharge; (2) the client is asked to periodically check in via email about ways in which he or she is using the new strategy after discharge; (3) the therapist identifies key people in the client’s natural environment who are willing to support continued strategy use.

In this chapter, we provide an overview of two categories of compensatory cognitive strategies: memory-related strategies and metacognitive strategies, and recommend Haskins⁴¹ for descriptions of other attention-management and executive functions-related strategies.

Memory Strategies

In this section, we discuss the use of internal and external memory strategies to advance occupational performance.

Internal Memory Strategies

Internal strategies are methods of mentally manipulating information so as to increase its depth of coding and likelihood of later recall (e.g., see Table 11-2).⁴² O’Neil-Pirozzi and colleagues⁴³ reported positive outcomes of teaching internal memory strategies to participants with TBI who were already using external memory strategies. In general, internal memory strategies are considered effortful to learn and employ and may be best used as a complement to external strategies for memory tasks that cannot be practically managed by jotting or inputting a note (such as remembering name–face associations). Use of internal strategies tends to be most effective for people who have mild-to-moderate impairments and/or some preservation of executive functions.⁴⁴

Table 11-2. Examples of Internal Compensatory Strategies

TECHNIQUE	DESCRIPTION
Rehearsal	Client repeats the information to be remembered out loud or to self.
Visual imagery	Client consolidates information to be remembered by making a mental picture that includes the information (e.g., to remember the name <i>Barbara</i> , the client pictures a barber holding the letter A).
First-letter mnemonics	The NAME mnemonic adds rules to observing features and drawing associations when remembering names: N otice the person with whom you speak. A sk the person to repeat his or her name. M ention the name in conversation. E xaggerate some special feature. The PQRST method (P review, Q uestion, R ead, S tate, T est) can be used in academic contexts for recall of more complex verbal and written information.

Based on information from Parenté R, Herrmann D. *Retraining Cognition: Techniques and Applications*. 2nd ed. Austin, TX: Pro-ed; 2002.

External Memory Strategies

External memory strategies are environmental supports or devices that optimize a person’s recall and/or follow-through on tasks or appointments by providing prompts and/or information.

- **Checklists:** A client with severe memory impairment may not remember performing a task or the sequence for doing so, resulting in either a repeat of the activity or nonengagement in the activity in the mistaken belief that it has already been performed. Being taught to mark off each instruction or activity on a checklist as it is performed may help clients successfully perform new procedures (see Fig. 11-1).
- **Timetables and Memory Books:** Many inpatient programs use timetables and/or memory books to help clients remain oriented to the events of the day. A timetable is a simplified version of a personal schedule. The timetable may include time to wake up, wash and dress, eat meals, do chores, and regularly scheduled individual and group therapy times. A memory book is typically composed of sections with orientation information (e.g., a page with information about where the client is and why) and daily log sheets, on which the client, family, or staff write down what occurs on an hour-by-hour basis. Timetables and memory books are particularly helpful to clients with severe memory impairment. Staff and family use these tools to interact with the client around orienting information, often cueing the client to look up information in the memory book or timetable. As clients recover, it becomes possible for them to review information spontaneously and make entries about ongoing events and/or progress to using a day planner/organizer.
- **Day Planners/Organizers:** Individuals with mild cognitive inefficiencies (such as those with concussion/mild TBI) or neurodegenerative conditions such as multiple sclerosis (MS) and those who are recovering from moderate-to-severe TBI are often taught to use a day planner or cognitive assistive technology (CAT) as a “memory prosthesis” to improve their functioning in daily life.^{45,46} To do this successfully, clients must be taught to recognize the type of information that is pertinent for them in real time, initiate entry of the material into the planner or device, take or input notes accurately, and establish daily procedures and/or employ alarm prompts for referring to needed information in a timely manner. As with memory books, many day planners have function-specific sections that may include daily schedule/to-do lists, checklists pertaining to frequently performed procedures, notes about projects in process, reference information about medical providers or family members, and contact information. Use of commercially available systems offers a variety of sizes and formats (see Fig. 11-2), enables clients to customize and maintain their system on a long-term basis, and minimizes the stigma of needing to write things down.

Figure 11-2 Use of function-specific sections of the planner page helps the client organize notes about the day.

- **CATs:** Clients may need or prefer to use some form of CAT as either a replacement for or complement to a planner/organizer. In fact, CAT may offer benefits to those with

neurocognitive impairment over and above that derived from day planners.⁴⁷ CAT ranges from off-the-shelf smartphones to technologies developed especially for individuals with cognitive impairment, such as NeuroPage. Smartphones may have particular appeal because of their low cost and wide acceptance as a memory aid by people with and without neurocognitive impairment. Adults with acquired brain injury value the audible and visible smartphone reminders and having an all-in-one memory device but worry about losing it.⁴⁸ Despite the widespread use of smartphones in everyday life, clients with neurocognitive deficits cannot be expected to spontaneously adopt these devices or learn their use via a simple Tip Sheet. They need training to correctly perform key procedures and apply key apps to everyday life situations and assistance to set up Cloud-based synchronization on their devices in order to back up contacts, calendar, and tasks.^{22,48} NeuroPage uses radio paging or SMS (text messaging) technology to send reminders of things to do to people with significant memory impairment. It is operated out of the Oliver Zangwill Centre for Neuropsychological Rehabilitation (the United Kingdom). The client wears an ordinary pager or mobile phone. He or she provides NeuroPage operators with a list of required date/time-specific prompts and then the system automatically sends out reminders for things like task initiation, taking medications, and sending birthday cards. NeuroPage has been studied extensively, demonstrating improved day-to-day functioning in the postacute period after TBI⁴⁹ and for people with cognitive limitations associated with MS.³⁹

Metacognitive Strategies

Metacognition refers to self-awareness and monitoring of a person's own cognitive processes. **MSI** involves teaching clients how to regulate their behavior by identifying problems, setting goals, evaluating possible solutions, and monitoring and modifying the solutions that they implement.⁶ This approach is often used to address problems with executive functions.⁶ Two MSI approaches developed with an occupation focus are Cognitive Orientation to Daily Occupational Performance (CO-OP)⁵⁰ and the multicontext approach for promoting transfer of strategy use,^{3,51} which is summarized in Table 11-3.

Table 11-3. Components of the Multicontext Treatment Approach

COMPONENT	DEFINITION	EXAMPLE
Interventions to enhance self-monitoring and self-awareness	Methods designed to enhance the client's understanding of his or her strengths and limitations that are incorporated into every treatment session	<ul style="list-style-type: none"> Asking the client to anticipate and identify specific challenges or obstacles that might occur in performance of a therapy task Instructing the client to watch the therapist perform a task during which client-relevant errors are demonstrated (such as distractibility). Asking the client to identify problems and recommend strategies
Strategy self-generation and training	Internal or external cognitive techniques that contribute to the effectiveness of performance	<ul style="list-style-type: none"> Mental repetition, visual imagery (i.e., internal processing strategies) Memory notebooks, alarm cueing devices, use of checklists (i.e., external processing strategies) Breaking projects into a list of substeps
Therapist uses task analysis to facilitate client experiences that enhance transfer	Identifying, manipulating, and/or stabilizing salient activity parameters (e.g., physical features, number of items, number of steps or choices involved in the task)	Helping client establish consistent procedures for using a checklist (read a step, do the step, check it off, read the next step, etc.) by first implementing a five-step morning hygiene checklist and then implementing a five-step breakfast preparation checklist
Promoting strategy transfer "sideways" across the continuum from near to far transfer	<p>The therapist identifies a series of tasks that decrease in degrees of physical and conceptual similarity to the original task</p> <p>Near transfer: only one or two surface characteristics changed</p> <p>Intermediate transfer: three to six surface characteristics change; tasks share some physical similarities</p> <p>Far transfer: tasks are conceptually similar; surface characteristics are different or only one surface characteristic is similar</p> <p>Very far transfer: generalization, spontaneous application of what is learned in treatment to everyday life</p>	<p>Task: donning a pullover T-shirt in the therapy area</p> <p>Donning a pullover sweater (color and texture different from T-shirt)</p> <p>Donning a button-down cotton shirt in the client's room (type of clothing, color and texture, fine motor requirements, and environment changed)</p> <p>Donning outerwear (coat, jacket), pajamas, undershirt, or camisole (different types of upper body clothing)</p> <p>Donning pants (strategy of dressing affected side first remains the same for lower body dressing). The appearance of the task changes but utilizes the same strategy</p>

COMPONENT	DEFINITION	EXAMPLE
Practice in multiple environments	Strategies are used in diverse situations (e.g., tasks and locations) to demonstrate their applicability and use to the client	Practicing of left-to-right scanning on letter cancellation tasks in the clinic and then used to locate items in a medicine cabinet or in the clients local grocery store

Adapted from Toglia J. The dynamic interactional model and the multicontext approach. In: Katz N, Toglia J, eds. *Cognition, Occupation, and Participation across the Lifespan*. 4th ed. Bethesda, MD: AOTA Press; 2018:355–385.

Cognitive Orientation to Daily Occupations

The CO-OP approach teaches a global strategy (goal, plan, do, check) in a process of “guided discovery” so that clients can develop their own domain-specific strategies to solve personally relevant, specific performance problems.⁵² CO-OP has been demonstrated to improve occupational performance for adults with TBI,²¹ stroke,⁵³ and cancer-related cognitive dysfunction.⁵⁴ The following exemplifies the CO-OP training process, with the therapist–client interaction distilled into key features, such as “One thing at a time”; “Ask, don’t tell”; “Coach, don’t adjust”; and “Make it obvious.”⁵²

1. The client sets the goals that he or she wishes to work on and then the therapist teaches the global strategy of Goal, Plan, Do, Check.
2. The client is guided in dynamic performance analysis in which he or she identifies the performance problems that interfere with goal achievement.
3. The client is further guided to identify potential strategies that may solve his or her problems. The client then implements the strategy to solve the real-world functional problem and checks to see whether it worked. The implementation of the domain-specific strategy may or may not be done in the presence of the therapist, depending on the treatment context, stage of training, and other factors.

Cognitive strategy training relies on the implementation of conscious thinking procedures and is typically applied to persons with mild-to-moderate impairment and relatively intact self-awareness.

Environmental Modification/Adaptation

Occupational performance is affected by changes in the demands of the task itself or challenges or supports associated with the environment. Therapists can advise or train family care partners to make task or environmental changes that lower the cognitive demands placed on the client (see Fig. 11-3). This type of intervention can extend to the interpersonal environment, and family care partners can be trained to use new ways of interacting with the client. In this approach, the client is not expected to learn or change, but the **press** of the task, social dynamics, and/or environment are changed to reduce the complexity of the behavior required for successful performance. In learning theory terms, this is antecedent control where the situational or other cues that are available to the person increase the chances that an appropriate behavior will be emitted. This approach is particularly appropriate for persons with major neurocognitive disorder or severe neurocognitive deficits from other causes (e.g., TBI, encephalitis, anoxia) where changes in learning and memory or executive functioning are particularly marked.

Figure 11-3 Simple changes in the kitchen lower the cognitive demands, making it easier for a person with cognitive limitations to find relevant information. **A.** High cognitive demand. **B.** Low cognitive demand.

Implementing This Approach in Occupational Therapy Practice

Environmental modification/adaptation can be used both to address occupational performance and to decrease some of the negative behaviors that can occur when an individual's cognitive capacity is insufficient for the environmental demands that he or she needs to manage. The approach is informed by the competence-environmental press framework.⁵⁵ This framework suggests that the client's excess disability and/or negative behaviors is caused by the misalignment between the client's declining cognitive ability and the unchanged demands of the physical and social environment. The client's functional performance and behavioral control may be optimized as task, and environmental demands are matched to his or her capacities.^{56,57} Simple interventions such as labeling clothing draws, preselecting clothing, removing excess clothes from closets, or laying clothes out for dressing reduce the decision-making requirement of dressing. Clothing itself can be simplified, such as having elastic waist bands on clothing rather than button-fastening jeans reducing the complexity of the task. Providing an organizational structure of the day by building in routine activities can reduce confusion in cognitively impaired clients. The client may not recognize the routine consciously, but a structure to the day maintained by the family care partner can reduce behavioral dysregulation and improves occupational performance. Occupational therapists can provide training to family care partners to reduce burden and delay institutionalization and to can also provide training to caregivers in institutional settings, such as assisted living and skilled nursing facilities. The extent to which family care partners who receive training in how to match cognitive demands to clients' capabilities are able to transfer or generalize this training to new problems or situations is not known. However, it appears that the effects of this training are time limited, and booster sessions may be needed.^{57,58}

Environmental modification/adaptation is intended to address the needs of individuals with severe impairments and is not restorative or curative. It is often, though not exclusively, used in the context of individuals with progressive major neurocognitive disorders and with those who are going to require ongoing careful management to maintain safety and some degree of functional independence. As the proportion of the population who is over 65 years old continues to grow, occupational therapy expertise in environmental modification/adaptation will remain of critical importance.

Evidence-Informed Cognitive Intervention in Occupational Therapy

Provision of intervention that is evidence based is considered critical to ethical occupational therapy practice.⁵⁹ Within the context of cognitive intervention, the three approaches presented in this chapter are supported by evidence. Strategy instruction (e.g., MSI and use of compensatory memory aids) for clients with acquired brain injury is endorsed by systematic reviews, meta-analyses, and guidelines.^{6,44,60-63} Skill-habit training and environmental modification/adaptation approaches are supported by numerous randomized controlled trials (RCTs), some of which are described in the Evidence table at the end of this chapter.

Beyond understanding what approaches are supported by evidence, it is equally imperative to be aware of what approaches do not have empirical support. Cognitive retraining exercises, often taking the form of drill and practice workbooks or computer games or simulations, that are intended to restore impaired cognitive abilities are not supported by evidence^{44,60,63,64} and thus not recommended for occupational therapy practice.

This chapter serves as a primer for evidence-informed cognitive intervention for occupational therapists. Further study and attentiveness to the emergence of new evidence are necessary for assuring competence in this important dimension of occupational therapy practice.

CASE STUDY

Client Information

Trevor is a 26-year-old single male who sustained a moderate TBI as a result of a motor vehicle accident. Records indicate that he lost consciousness for approximately 35 minutes. He also fractured his left radius. Trevor participated in inpatient rehabilitation for 2 weeks. Trevor graduated from college with a degree in law enforcement and worked in a rural community as a police officer at the time of his injury. Unable to return to his own apartment

because of concerns about safety, Trevor was discharged from the inpatient rehabilitation unit to his brother's home.

Reason for Occupational Therapy Referral

Trevor was referred to outpatient occupational therapy at the time of his discharge from inpatient rehabilitation in order to continue his recovery and improve his independence.

Assessment Process and Results

The occupational therapist accessed *at-discharge* documents in the medical record, which indicated that Trevor could perform ADLs and simple IADL (light meal preparation) with supervision. The *Cognistat*,⁶⁵ administered near the time of discharge from inpatient rehabilitation, suggested performance within the average range for orientation, comprehension, naming, construction; mild impairment in similarities, judgment, calculations, repetition; and mild-moderate impairment in attention and memory.

At the initial outpatient session, Trevor appeared motivated to participate in therapy as a means of ultimately getting his own apartment; he did not appear distracted by pain or emotional distress. He reported that he used his iPhone to keep track of contacts and appointments and wanted to continue to do so.

The therapist administered the *Canadian Occupational Performance Measure (COPM)*⁶⁶ to obtain information about the client's perceived problems and priorities and conducted an interview with his brother, Carson.

- **COPM:** Trevor indicated that his ability to function independently was limited due to a casted left forearm and radial fracture. He identified the following primary concerns: inability to drive (Performance 6; Satisfaction 1); slowness with which he dressed himself (Performance 4; Satisfaction 2); poor stamina because of his inability to workout (Performance 3; Satisfaction 1); and being unable to do previously enjoyed recreational activities (Performance 4; Satisfaction 2). When queried about known dependence on family members to take medications and his lack of initiation of everyday tasks, Trevor quickly dismissed these reports as awkwardness associated with being a guest in their home.
- **Interview with Carson:** Carson reported that Trevor seemed to have more skills that he actively used on a given day. For example, Carson observed that Trevor had the ability to perform all of his self-care tasks and even make his own light breakfast and lunch but didn't do any of these activities unless specifically instructed. Carson seemed to interpret Trevor's reticence to initiate as laziness, even though it was dramatically different from Trevor's premorbid nature. Carson seemed most interested in seeing Trevor advance to the point where he could manage his day at home safely without supervision while Carson was at work. Carson indicated a willingness to provide transportation to appointments and to attend at least weekly.

Occupational Therapy Problem List

- Cueing required for ADL and IADL likely due to problems with initiation associated with executive dysfunction
- Limited repertoire of exercise and avocational options
- Memory inefficiency and inadequate repertoire of memory compensation strategies

Occupational Therapy Goal List

The occupational therapist recommended one to two treatment sessions per week for 4 to 6 weeks to address the following goals:

- Trevor will independently initiate and carry out all self-care and selected light housekeeping tasks;
- Trevor will increase his level of productive activity at home such that he initiates an exercise program and avocational activities at least three times per week;
- Trevor will follow through on intended tasks at least 85% of the time through use of external memory aids and strategies.

The occupational therapist also requested that the physician refer Trevor for a psychological evaluation to rule out depression and determine needs for psychological support.

Intervention

The occupational therapist hypothesized that more frequent use of memory prompts would be central to Trevor's goal achievement, both in terms of initiation and task follow-through. Therefore, helping Trevor expand the use of his iPhone was the first priority of therapy (*cognitive strategy training intervention approach*). Trevor was instructed in how to set alarm prompts coupled with "appointments" as a means of remembering to perform tasks at certain times (*Acquisition*). Therapy homework provided opportunities for Trevor to practice these procedures. For example, he was assigned to call and leave a message for the therapist at preassigned dates/times. The therapist recommended creating a checklist to help Trevor establish a consistent sequence for his morning routine, which would be prompted by a recurring alarm/appointment (*skill-habit training intervention approach*). The establishment of a consistent routine would ultimately enhance **automaticity** of the ADL procedures, decrease performance time (important to Trevor), and enable Trevor to initiate these tasks without reminders (important to Carson). The occupational therapist asked Trevor to set his iPhone time/appointment alarm to prompt him to refer to his checklist, which was posted in his bathroom, at a routine time each morning. The occupational therapist brainstormed about other everyday activities that were important to Trevor and how he might use his iPhone time/appointment alarm to remind him about evening medications, performing his physical therapy exercise program, calling his mother on Sunday afternoons, and syncing his phone with his laptop every Saturday morning to back it up on the iCloud (*Mastery and Generalization*). Carson was supportive of this approach and worked with Trevor to consider other tasks for which he might use his iPhone reminders (*Maintenance*).

Checklists and iPhone alarm prompts were also used to help Trevor increase his productivity during the day while Carson was at work. The occupational therapist collaborated with Trevor's physical therapist to facilitate his performance of his exercise/fitness routine. Trevor started preparing simple meals for dinner, using a checklist to establish procedures that included cleaning up after himself and the alarm prompt to remember to start meal preparation. Trevor continued to use his iPhone to input reminders to complete his occupational therapy homework, which included a series of tasks aimed at exploring at-home avocational activities. These efforts were informed by the multicontext approach to advance transfer of learning.

Over the course of 6 weeks (and eight occupational therapy sessions), Trevor made substantive progress toward his goals. After approximately 3 weeks of therapy, he no longer required prompts for ADL or IADL or the morning routine checklist. In addition to preparing a simple dinner for his brother at least twice per week, Trevor did his own laundry, ordered groceries online, and scheduled his own appointments. Although Trevor was unable to afford to move into his own apartment, he and Carson were comfortable remaining roommates as Trevor shifted his focus toward returning to work. Prior to his discharge from occupational therapy, Carson helped Trevor obtain a volunteer job at a local animal shelter. Trevor, Carson, and the occupational therapist identified ways in which Trevor could apply his cognitive strategies to his volunteer responsibilities, which primarily involved performing routine cleaning tasks. The occupational therapist also helped them connect with a vocational counselor. They developed a plan wherein Trevor would increase his work hours over the course of the next month, and once he could manage 20 hours per week, they would begin to work with the vocational counselor to establish a longer term return to work plan. At the therapist's request, the physician also ordered an occupational therapy follow-up session in 2 months.

Evidence Table of Intervention Studies for Cognitive Impairments

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Skill-habit training ²⁰	Training using neurofunctional principles of ADL and basic IADLs during PTA	One hundred four participants with severe PTA who remained in PTA >7 days	Daily from baseline to PTA emergence	Level I, RCT, manualized intervention comparing the neurofunctional approach to treatment as usual	Intervention group had greater improvement on Functional Independence Measure (FIM) scores from baseline to PTA emergence, with no increase in agitation than treatment as usual group	Differences were significant at emergence from PTA ($p = 0.001$) with moderate effect size $d = 0.70$; 95% confidence interval (CI; 1.09–0.30), and at inpatient rehabilitation discharge ($p = 0.001$) CI ($d = 0.74$; 95% CI, 1.14–0.34)
Skill-habit training ⁶⁷	Individualized goal-setting, task-specific training, environmental or task adaptation, and use of assistive devices	Twenty-six individuals (median age 65) who were ≥ 1 year poststroke and who were attending a community rehabilitation center	Twelve weeks of neurofunctional intervention with individualized goal-setting average number of treatment sessions 9 (range 2–20)	Level I, RCT with crossover	Significant differences were obtained on measures of occupational performance using the COPM after treatment, but not on quality-of-life measures. Nontargeted goals did not improve	Differences were significant at the $p = 0.001$ level, with large effect sizes 1.9–2.35
Metacognitive strategy instruction ²¹	Occupation-based strategy instruction, an adapted version of CO-OP	Adults with chronic TBI ($n = 13$, 7 in experimental group; 6 in control group; age range 24–60 years; time since injury range 2.6–18.8 years)	CO-OP (experimental condition)—20 hours of training (two, 1-hour sessions/week) that focused on participants' top three concerns as identified via COPM interview. Control condition—no treatment	Level II, partially, pilot RCT	While there were no group differences in performance and satisfaction ratings on the three most problematic issues, there were group differences in terms of post-test ratings of performance and satisfaction of untrained goal areas, evidence of far transfer of training	Between-group differences in satisfaction ($p = 0.03$) and performance ($p = 0.04$) for untrained goal areas with large effect sizes (Cohen's d 1.53 and 1.33, respectively)

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Training in a memory aid ³⁹	Training in use of a NeuroPage, a paging system that sends audio/vibrating prompts and SMS text messages	Adults with MS who had been diagnosed at least 12 months prior to study enrollment (Group 1, <i>n</i> = 17; Group 2, <i>n</i> = 21; age range 28–72; primarily women)	At one session, all participants received instructions about the messaging system. During the treatment arm, participants received prompts for self-selected problem areas for a 2-month period. During the control arm, participants received non-memory-related text messages	Level I, single, blind, crossover RCT	There were no group differences on the Everyday Memory Questionnaire, but those in the NeuroPage condition reported fewer everyday forgetting errors and less psychological distress than those in the control condition	Group differences: General Health Questionnaire (<i>p</i> = 0.001); anxiety-depression (<i>p</i> = 0.04); percentage of daily forgetting errors (<i>p</i> = 0.01) with moderate-to-large effect sizes (Cohen's <i>d</i> = -0.47 to -0.84)
Task-environment modification training ⁵⁷	Tailored Activity Program	Veterans with motor neurone disease (MND) and their family care partners (<i>N</i> = 160 client/caregiver dyads)	Dyads received eight sessions to customize activities to the interests and abilities of the client and educate their care partners about use of customized activity in care for major neurocognitive disorder	Level I, RCT	At 4-month outcome assessment, the intervention group showed significant reduction in the number and severity of behavioral symptoms and in the number of activities with which the client needed assistance. Intervention group superiority was not maintained at 8 months	Differences in behavioral symptoms were change from baseline to 4 months = 0.68, 95% CI = 1.23–0.13, <i>p</i> = 0.02) and for reduction in need for assistance with functional activities (difference = 0.80, 95% CI = 1.41–0.20, <i>p</i> = 0.009)

Acknowledgments

Joette Zola, OTR/L of the Courage Kenny Rehabilitation Institute, provided expert guidance on the case example and we are most grateful.

Chapter 12

Sensory Assessment and Intervention

Carrie Ciro and Barbara M. Doucet

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Explain the neurological mechanisms of sensory perception and processing.
2. Describe a variety of occupations that might show impairment because of deficient sensation.
3. Select appropriate sensory assessment and interventions for patients.
4. Explain the rationale for sensory reeducation and desensitization.
5. Demonstrate a variety of sensory reeducation and desensitization strategies for patients following peripheral nerve injury or repair.
6. Name several mechanisms of damage to skin areas that result in diminished protective sensation and describe related compensatory strategies to prevent injury.
7. Demonstrate a variety of active and passive sensory training strategies for patients with sensory impairment following centrally mediated or peripheral sensory deficits.

CHAPTER OUTLINE

Sensory Function in Daily Occupation
Neurological and Physiological Basis of Sensory Function
Impairment of Centrally Mediated Sensation
Sensory Evaluation
Conceptual Foundation Underlying Intervention for Sensory Impairment
Desensitization Intervention
Sensory Reeducation Intervention
Case Study

TERMINOLOGY

- Allodynia:** a type of hypersensitivity characterized by the perception of pain in response to a non-painful stimulus.
- Centrally mediated sensation:** sensation controlled primarily by the brain and spinal cord, such as stereognosis.
- Desensitization intervention:** a type of sensory intervention that involves the application of standardized and sequential textures to relieve hypersensitivity.
- Exteroceptive sensation (or superficial sensation):** a type of peripherally mediated sensation perceived locally by sensory receptors in the skin and mucous membranes and consists of touch, pain, and temperature awareness.
- Haptic perception:** a type of centrally mediated sensation characterized by identifying and perceiving object features achieved by active exploration of the object.
- Hypersensitivity:** a response to sensory information in which ordinary stimuli produce exaggerated or unpleasant sensations.
- Hyperesthesia:** a type of hypersensitivity characterized by heightened sensitivity to tactile stimuli.
- Peripherally mediated sensation:** is sensation controlled primarily by sensory receptors in the skin, such as light touch.
- Quantitative sensory testing (QST):** type of assessment; is the standardized application of a stimulus followed by an interpretation of the patient's response in quantitative measures, such as percentage of correct responses.

Sensibility: a person's sensitivity to sensory stimulation; considered a patient factor in occupational therapy.

Sensory reeducation: a type of sensory intervention in which therapists guide the process of reteaching the brain how to feel and interpret sensory stimulation.

Sensory Function in Daily Occupation

The ability to sense, feel, see, hear, taste, and process all that we daily encounter and experience is a remarkable function of our central nervous system. Occupational therapists frequently encounter individuals who exhibit sensory impairment due to injury or disease. For example, a person with diabetes can lose sensation in the hands and feet; older adults often experience primary sensory loss in the form of low vision, reduced hearing, and impaired balance; and a brachial plexus injury to an infant during childbirth can affect upper extremity (UE) function and sensation. Therefore, a comprehensive understanding of strategies for assessment and intervention is necessary. This chapter describes the neurological basis of sensation, discusses the functional impact of sensory dysfunction on occupational performance, and provides resources for occupational therapy evaluation and intervention. The chapter content focuses on both peripheral and centrally mediated sensory processes.

Sensory function, also known as **sensibility**, is subsumed under the client factor and body function categories in the Occupational Therapy Practice Framework.¹ Sensory dysfunction can influence other body processes, including joint and muscle movement as well as mental functions—all of which, when impaired, potentially disrupt a person's habits, routines, and roles. Challenges across all aspects of task performance in daily occupations, activities of daily living (ADLs), and instrumental activities of daily living (IADLs) will typically result.

Peripheral sensation includes touch and pressure awareness, temperature, pain, and two-point discrimination. For example, a person with carpal tunnel syndrome (CTS), in which the peripheral sensory processes are affected, commonly experiences sensory loss in the thumb and digits, impairing the ability to form and maintain functional grip and pinch patterns. Alternative grasp patterns that are weak and ineffective are usually employed, which can result in further injury. Sensory loss of this type in a carpenter with CTS would create safety concerns for grasping and manipulating tools. Following a wrist fracture, motor and sensory loss in the hand typically results, creating difficulty with in-hand manipulation of fine motor activities such as buttoning or writing.

Centrally mediated sensation, involving brain and spinal cord processes, has a varying presentation and usually involves loss of proprioception (position sense) and stereognosis (blinded object awareness), and may include diminished awareness of touch or pressure in the affected UE. A person who has experienced a stroke may exhibit inattention or unawareness of the affected UE due to cortical lesion disruption of motor and sensory processing. A person with this type of centrally mediated sensory loss may fail to position the arm safely away from walls and doorframes when navigating a wheelchair, or away from stove burners when performing a cooking activity. A young mother with a degenerative disease such as multiple sclerosis, experiencing pain, numbness, and hypersensitivity throughout the trunk and extremities would have difficulty caring for an infant or performing cooking activities.

A large-scale study indicated that 94% of older adults have age-related deficits in at least one of the five primary senses—audition, vision, olfaction, touch, and gustation—and that this dysfunction can be predictive of physical and mental decline and mortality.² Job settings, exposure to environmental toxins, and even drug interactions can deteriorate auditory function, leading to hearing loss. Additionally, inner ear pathology can result in vestibular difficulty and balance deficits creating fall risks, especially in older adults.³ Although certain daily tasks are completed without vision—such as finding a key in a purse, retrieving coins from a pocket, or fastening a necklace—vision is a central sensation and the one most often used to compensate for other sensory deficits. In conditions such as diabetes, multiple sclerosis, and stroke, visual deficits are common and can profoundly impair navigation in crowded environments, or vending and automated bank teller machine use. Olfactory processes can also be impacted by disease or neurological conditions. Recent research suggests that olfactory loss can be a subclinical sign or predisposing factor for dementia,⁴ Parkinson disease (PD),⁵ and amyotrophic lateral sclerosis (ALS).⁶ Similarly, gustation loss may occur in persons with chronic kidney disease⁷ and in neurodegenerative diseases including PD and ALS.⁸

Haptic perception, or active touch, is one of the more critical senses needed for successful and safe performance of daily activities. Without the sense of touch, the amount of force needed to grip an object can be inadequate or inappropriate, resulting in objects being dropped or crushed; excessive grip forces can also create muscular fatigue in the hands from overactivity.⁹ When grip force feedback is absent, individuals compensate with stronger grips that adversely influence object manipulation accuracy.¹⁰

Neurological and Physiological Basis of Sensory Function

The human sensory system operates through the skin, muscles, and joint receptors—each specialized to receive various types of stimulation, such as touch, temperature, or pain. Table 12-1 describes the ascending neural pathways of sensory stimuli received from the periphery that travel to the cortical sensorimotor area (located in the postcentral gyrus of the parietal lobe). There is redundancy in the sensory receptor system, because each sensory neuron, and the skin area it serves, overlaps with other sensory receptor areas. A single stimulus will, therefore, activate several adjacent sensory receptor fields. *Innervation density* refers to the number of sensory units (sensory neurons and terminations) within a given area. Areas with high innervation densities such as the face, hand, and fingers are more sensitive to incoming stimuli and have a proportionately larger representation in the somatosensory cortex.¹¹ Figure 12-1 shows the sensory homunculus, a representation of sensory receptors across the sensorimotor cortex.

Figure 12-1 Sensory homunculus.

Table 12-1. Neural Pathways of Sensory Stimuli

TYPE OF SENSATION	SENSORY RECEPTOR	TYPE OF AFFERENT NEURON	PATHWAY	TERMINATION OF PATHWAY
Constant touch or pressure	Merkel's cell Ruffini's end organ	Type A- β slowly adapting I and II myelinated neurons	Ascend in dorsal column and medial lemniscus of the spinal cord in posterior pyramidal tract, cross to opposite side in medulla	Thalamus and somatosensory cortex
Moving touch or vibration	Meissner's corpuscles Pacinian corpuscles Hair follicles	Type A- β rapidly adapting I and II myelinated neurons		
Proprioception and kinesthesia	Same as both moving and constant touch or vibration plus touch receptors found in skin and joint structures	Same as for moving touch or vibration plus A- α myelinated neurons	Same as for moving touch or vibration plus spinocerebellar tract	Same as for moving touch or vibration plus cerebellum
	Muscle spindles Golgi tendon organs			
Pain (pinprick)	Free nerve endings	Type A- δ myelinated neurons	Immediately cross to opposite side and pass upward in anterior spinothalamic tracts of spinal cord	Brainstem, thalamus, and somatosensory cortex
Pain (chronic)	Free nerve endings	Type C unmyelinated fibers		

TYPE OF SENSATION	SENSORY RECEPTOR	TYPE OF AFFERENT NEURON	PATHWAY	TERMINATION OF PATHWAY
Temperature	Free nerve endings Warm receptors Cold receptors	Type A- δ myelinated neurons and type C unmyelinated fibers

The sensorimotor cortex (S1) receives incoming impulses from peripheral sensory receptors that transmit electrical impulses through a variety of neural tracts ascending to S1. These neural tracts create the connection from the external environment to our internal cortical awareness and response. In S1, impulses are decoded and processed, while additional neural transmissions occur to surrounding areas serving motor (behavioral response) and cognitive awareness (perception). For example, Meissner’s corpuscles are among the most sensitive receptors with a very low threshold of response to light touch; these receptors are typically located in skin areas where awareness of light touch is paramount (e.g., fingertips, hands, lips).¹² The corpuscles activate C fibers from the periphery when very light touch is sensed, such as snowflakes falling on the skin or feathers brushed across the hand. The cell bodies of these fibers are located in the dorsal root ganglion positioned just outside the spinal cord. Impulses travel along afferent neural pathways of varying diameter and morphology: large-diameter, myelinated axons transmit peripheral impulses to the cortex more quickly; smaller-diameter unmyelinated afferents transmit less rapidly. These signals travel to the dorsal root ganglion at the cervical spinal cord level, synapse on interneurons in the white matter, and then cross midline into the dorsal horn, traveling cortically by route of the spinothalamic tract on the contralateral side. The spinothalamic tract carries the impulse through the medulla, pons, and midbrain, and finally through the thalamus to the sensorimotor cortex. From there, the appropriate response to the stimulus is generated through cognitive awareness and a motor response.¹³

Sensory receptors are responsive to varying types of incoming stimuli. Chemoreceptors respond to neurotransmitters or other chemical substances in the body and translate these into electrical signals that can be carried to the central nervous system for interpretation and response. Chemoreceptors respond to chemical releases that occur when cells are damaged or during normal cellular processes, such as when tongue taste buds respond to ingested foods and liquids. Mechanoreceptors are activated with mechanical movement, such as when hair cells in the inner ear bend in response to sound waves. Nociceptors react to painful stimuli, and thermoreceptors detect changes in temperature.

Any interruption along the ascending sensory pathway or in the cortical sensory areas can lead to decreased or lost sensation. The extent and severity of sensory deficits can generally be predicted in accordance with the lesion or injury mechanism and location. Sensory impairment patterns are directly related to the involved neuroanatomical structures, which could be located anywhere in the central or peripheral nervous system. Somatosensory and perceptual impairments contribute to poor motor control and may impact a patient’s rehabilitation participation.¹⁴

Despite neurological injury, the central nervous system can respond to damage or pathology through the process of neuroplasticity, whereby a reorganization of axonal and dendritic structure occurs, creating new avenues of transmission and communication. Research related to neuroplasticity in the cortex poststroke demonstrates that neurophysiological adaptations occur in both damaged and perilesional tissues and that behavioral and functional changes can result from targeted interventions.¹⁵

Impairment of Centrally Mediated Sensation

Cortical Impairment

Cerebrovascular accidents (CVAs) or strokes, acquired brain injuries, and other pathology affecting cortical structures can impair sensation. Rehabilitation efforts following stroke

traditionally concentrate on motor deficits, with less attention to sensory impairment.¹⁶ Strong associations have been found between sensory impairment poststroke and functional outcomes. Persons with significant sensory deficits, visual inattention, or neglect were found to have longer inpatient rehabilitation lengths of stay and decreased probabilities of returning home after discharge.¹⁷ Although many clinicians report assessing sensory skills poststroke, assessment is often limited to light touch and proprioception and is not completed with standardized instruments.¹⁸ Disruption of the anterior cerebral artery more commonly results in sensory loss in the contralateral leg than in the arm or face.¹⁹ Lesions to the posterior thalamus can result in impaired cold and pain sensation, and in body orientation awareness deficits or “pusher” syndrome.²⁰ Sensory loss following stroke has been shown to reduce participation in desired activities.²¹ For patients with brain injury, perception of fine touch and proprioception are most affected, temperature sensation is less affected, and pain sensibility is least affected.²² Patterns of sensory loss following head injury are less predictable because of the more diffuse areas of brain damage associated with this condition.²³

Impairment of the Spinal Cord

Spinal cord injuries can be classified by the American Spinal Injury Association (ASIA) as complete or incomplete. A complete spinal injury is defined as one in which all motor and sensory functions below the lesion are lost and no preservation of function at the sacral levels exists. An incomplete spinal injury indicates that some degree of sensory sparing has occurred. In incomplete spinal injuries, the sensory impairment pattern can be determined based on the neurological tract or area damaged.

Typical sensory impairment syndromes are observed with region-specific damage. Anterior cord syndrome results from damage to the front portion of the spinal cord, leaving the dorsal column area intact. There can be a variable loss of motor function, pain, and temperature sensation, caused by damage to the corticospinal and spinothalamic tracts located in the anterior and lateral cord aspects. Touch, vibration, and proprioception remain intact below the lesion due to dorsal column sparing. Likewise, injuries to the dorsal spinal cord area result in loss of touch, vibration, and proprioception, but pain and temperature remain mostly intact. Pathology or injury that impacts the central cord results in central cord syndrome, where pain and temperature below the lesion level are lost as these fibers pass through the center of the cord to the ipsilateral side upon entering. An asymmetric cord injury often produces a Brown-Séquard syndrome presentation involving loss of touch, vibration, and proprioception on the lesion side, and loss of pain and temperature on the side opposite to the lesion. This presentation occurs because pain and temperature fibers cross to the opposite side, whereas the dorsal columns ascend to the medulla oblongata in the brainstem before crossing to the opposite side.

Sensory recovery after spinal injury typically occurs within the first year, especially in the first 3 to 6 months for those with incomplete injuries.²⁴ The following sensory areas should be assessed in patients with spinal injury: pain, light touch, temperature, and vibration (see procedures in the “Sensory Evaluation” section). These results will inform the clinician about the patient’s overall sensory awareness and assist in determining precise spinal-level function. Following incomplete spinal injury, return of sensation is dependent on several factors; however, two-thirds of individuals with sensory sparing and responsiveness to pain and pinprick in the lower extremities (LEs) following cervical injury were ambulating after a year, but less than 15% of those who showed responsiveness to light touch in the LEs regained ambulatory skills.²⁵ The ASIA motor scores for the quadriceps and gastrocnemius/soleus muscles, along with light touch scores for the L3 and S1 dermatomes, have been shown to accurately discriminate between potential walkers and nonwalkers after spinal injury.²⁶

Impairment with Loss of Limb

Following loss of limb or amputation, cortical sensory maps have been shown to adapt and remodel.²⁷ Cortical somatosensory areas that lie adjacent to the cortical amputated sensory areas demonstrate remodeling and branching that can result in phantom sensations or pain.²⁸ Similarly, changes to the damaged peripheral nerve’s axons and roots can be seen at the spinal level; these resultant changes alter pain and motor responses in the amputated limb. A common phenomenon after limb loss is phantom limb pain or phantom limb syndrome, which occurs in approximately 50% to 80% of individuals.²⁹ Symptoms can vary, but most individuals report pain in the removed limb area or a sensation of the limb’s continued presence. Various interventions, including mirror

therapy, transcutaneous electrical nerve stimulation (TENS), and graded motor imagery, have been proposed to relieve pain or decrease uncomfortable sensations; however, empirical evidence for intervention effectiveness is limited.³⁰

Impairment of Peripheral Sensation

When peripheral nerves are damaged, symptoms correspond to the area of neural distribution, or dermatome. Impairment of a single spinal cord nerve root will impact sensation on the ipsilateral side of the body over the corresponding area served by that nerve root (Fig. 12-2, dermatomal distributions). For example, in CTS, compression of the median nerve within the carpal tunnel produces numbness and tingling in the thumb, index, middle, and half of the ring finger, following the median nerve distribution. Light touch, vibration, and two-point discrimination can also be impaired in CTS.³¹ If nerve compression continues, hand function—particularly grasp and dexterity—can become impaired, and permanent sensory loss can occur. Both conservative intervention and surgery, however, can provide benefit and relief.³² Typical conservative intervention for CTS includes splinting the wrist in a neutral position or 15° of extension to decompress the median nerve. Patients are usually advised to wear the splint at night to eliminate typical nocturnal numbness and tingling, but splints can also be worn during daily activities to prevent additional pain. Conservative treatment also includes patient education to avoid activities that exacerbate pain and to reduce repetitive movements that can inflame the median nerve, such as prolonged periods of wrist flexion. Sensory recovery and return to normal activity is typical if nerve compression is brief and relieved through conservative or surgical means.

Figure 12-2 Dermatomes.

A peripheral nerve that has been completely transected has the capacity to regrow and reinnervate with surgical intervention. Typical regrowth rates average approximately 1.08 mm per day for pain fibers and 0.78 mm per day for touch fibers.³³ Sensory return typically follows a specific sequence, in which pain and temperature occur first, followed by moving touch sensation, light touch, and, finally, touch localization.³⁴ In chronic conditions such as diabetes mellitus, chronic regional pain syndrome, acquired immunodeficiency syndrome (AIDS), alcoholism, and smoking, peripheral nerve conduction and sensory responsiveness can be impacted. A common glove and stocking distribution can occur, whereby sensation gradually diminishes in the feet and hands and spreads proximally, causing pain and increased mortality.³⁵ Sensory loss can also occur

in conjunction with orthopedic fractures or traumatic crush/avulsion injuries and in patients receiving certain types of chemotherapy for cancer treatment.

Assessment of peripheral nerve injury should always prioritize delineation of protective sensation to insure patient safety and prevent further injury. Clinicians should strive to create an accurate map of intact and impaired sensory areas using the sensory evaluation techniques that follow.

Sensory Evaluation

Types of Evaluation

Quantitative sensory testing (QST) is the application of a stimulus followed by interpretation of the patient's response. QST includes a group of sensory tests that examine minimal threshold, perception, and integration of sensory stimulation. Minimal threshold tests can detect the smallest point at which sensation can be perceived. The most clinically utilized example of this is the Semmes-Weinstein Monofilament or Weinstein Enhanced Sensory Test (WEST), which both detect minimal thresholds for light and deep touch, and protective sensation. Perception tests provide basic information to determine whether sensation is perceived—important for screening, but less reliable for assessing change over time. Examples of perception tests are touch, pain, and temperature awareness. Integration of sensory stimulation is examined through assessments that first require perception and then integration of sensory information with other peripheral or cortical structures. Examples include proprioception and cortical sensory function.

Also available to occupational therapists are standardized tests examining observed or self-reported hand function, which provide insight into combined motor and sensory function. The Disabilities of the Arm, Shoulder, and Hand (DASH) and Quick DASH Outcome Measures are questionnaires designed to examine changes in UE motor and sensory function through self-reported activity and participation.³⁶ The Hand Active Sensation Test (HASTe) is a functional instrument designed to assess the haptic perception of people who sustained a stroke.³⁷ The Moberg Pick-up Test involves the picking up, holding, and identification of day-to-day objects.^{38,39}

Documenting Sensory Assessment Results

Sensory evaluation findings are often summarized as intact, impaired, or absent. Intact describes normal sensation. Sensation is impaired when the patient is able to detect some but not all of the stimuli, or when perception of the stimulus differs from that of an intact skin area. Absent describes a total loss of sensation or inability to detect a specific sensory modality.

Unless otherwise indicated, the screening score is the number of correct responses divided by the number of applied stimuli. The expected score is 100%. When applicable, impairment should be recorded by peripheral nerve distribution, or dermatome, as relevant to the diagnosis. If a screening indicates impairment, the therapist may perform or recommend further testing. For both standardized and nonstandardized tests, results from the patient's affected area can be compared with results from the corresponding, contralateral unaffected area to determine the individual's "norms."

Documentation should include the test type, skin area tested, and screening score response. An easy way to document touch threshold testing with monofilaments is to use color or pattern codes on a drawing of the body part tested (Fig. 12-3). A series of sensory maps completed over time can easily and quickly demonstrate sensory recovery. For standardized tests, results can be compared with norms; however, age should be considered because studies show a decline in sensation with age.^{40,41}

Common Procedures

Sensory testing reliability is optimized by following common procedures. The purpose of these procedures is to eliminate therapist cues and environmental/sensory distractions to ensure that patient responses accurately reflect sensory capabilities. Common procedures used across sensory testing include:

1. Choosing an environment with minimal distractions.
2. Developing a system for patient response, either verbal or nonverbal.
3. Stabilizing the body part being tested on a towel or in the therapist's hand (when pushed down with a stimulus, the body part should not move).
4. Noting differences in skin callouses on areas being tested, which can cause decreased sensation.
5. Demonstrating the test on the unaffected limb to ensure understanding of directions and elicitation of the correct response.
6. Occluding patient vision either by having patients close their eyes or hold a file to block vision.
7. Applying stimuli at uneven intervals or inserting times when no stimulus is given.
8. Avoiding giving inadvertent cues, such as auditory, visual, or facial cues.
9. Carefully observing the correctness, confidence, and promptness of each response.
10. Observing the patient for any discomfort relating to the stimuli that may signal hypersensitivity (exaggerated or unpleasant sensation).^{34,42}

Nonstandardized Assessment: Quantitative Sensory Testing and Skilled Observation within Occupational Performance

Occupational therapists screen sensory skills to consider how sensory absence or impairment impact occupational performance. Screening may occur as part of a typical evaluation. Alternatively, skilled observations during occupational performance may lead therapists to suspect sensory function problems that warrant structured screenings. This section provides an explanation of sensory skills, skilled observations that demonstrate the need to screen, and full screening procedures. An example of moving into a two-story apartment will be used throughout to illustrate how sensory skills support occupational performance.

Exteroceptive Sensation

Exteroceptive sensation, or *superficial sensation*, is perceived locally by sensory receptors in the skin and mucous membranes and consists of touch, pain, and temperature awareness.

Touch Awareness (the ability to feel light and deep touch input)

1. Specific screening instructions:
 - Gather testing instruments needed for the assessment. For touch awareness, use common items such as a cotton ball, fingertip, and pencil eraser.
 - Direct the patient to respond “yes” or make an agreed-upon nonverbal signal each time the patient feels the stimulus.
 -  Next, have the patient close the eyes and apply an object lightly to the skin; wait for his or her response (Fig. 12-4 and Video 12-1).

Figure 12-4 Screening for touch awareness.

2. Examples of skilled observations indicating dysfunction in daily occupations:
 - The therapist may observe examples of touch impairment such as difficulty feeling a button when dressing or being unaware that one's arm is stuck in the hospital bed rail.
3. How light/deep touch support occupational performance:
 - Light and deep touch are used to appreciate the weight and pressure of a box. People use touch awareness, with other senses, to gauge the amount of force needed to pick up a box.

Pain Awareness (the ability to feel topical pain)

1. Specific screening instructions:
 - All testing instruments needed for the assessment. An object with a sharp and dull side, such as a safety pin, works well for screening.
 - Direct the patient to respond "sharp" or "dull" after each stimulus.
 -  Next, have the patient close the eyes and then randomly apply sharp and blunt safety pin ends, perpendicular to the skin, at the pressure that was necessary to elicit a correct response on the uninvolved body side. The therapist should allow adequate time for a response (Video 12-2).
2. Examples of skilled observations indicating dysfunction in daily occupations:

- The therapist observes impairment in pain awareness when the patient is unable to feel a sharp knife blade as it slices the skin while cutting vegetables, or shows no response to the skin being pinched during activity.
3. How pain awareness supports occupational performance:
 - While moving to an apartment, pain awareness alerts a person carrying a box that it has a sharp corner, causing the person to shift the box and avoid skin injury.

Temperature Awareness (the ability to feel warm and cool temperatures)

1. Specific screening instructions:
 - First, gather a specific hot and cold discrimination kit or glass test tubes filled with warm (115°F–120°F) and cool (40°F) water.
 - Direct the patient to respond “hot” or “cold” after each stimulus.
 -  Alternate applying hot and cold to the patient’s skin and wait for a response (Video 12-3).
2. Skilled observations indicating dysfunction in daily occupations:
 - The therapist observes impairment in temperature awareness when the patient has difficulty differentiating water temperature for a shower or understanding that his or her hand is close to a hot stove burner.
3. How temperature awareness supports occupational performance:
 - After a long day of moving furniture to an apartment, the mover decides to take a shower. After running the water, he checks it with his hand before getting in, perceives that it is too hot, and lowers the temperature to avoid scalding.

Proprioceptive Sensation

Proprioceptive sensation, or deep sensation, is perceived locally in the muscles, tendons, ligaments, and joint structures and consists of joint position, movement, and vibration awareness.

Joint Position Awareness (the ability to understand joint position with vision occluded)

1. Specific screening instructions:
 - Hold the patient’s body segment (e.g., arm, elbow, wrist, hand, fingers) on the lateral surface and move the part into different positions; follow by holding the position. If the patient can maintain the position, remove your support. If the patient cannot maintain the position, hold the position for the patient to complete the next step.
 -  Ask the patient to mirror the position with the opposite extremity (Video 12-4).
2. Example of skilled observation indicating dysfunction in daily occupations:
 - The therapist may observe impaired joint awareness when the patient bumps his feet and legs on the bathtub wall while transferring out the tub. The patient with impaired or absent joint awareness is at risk for falls.⁴³
3. How proprioception supports occupational performance:
 - The mover in our scenario is walking through a tight doorway with a box. Because of proprioception, he knows where his hands are placed on the box and visually checks to make sure that he can clear the door opening to avoid skin injury.

Movement Awareness (kinesthesia; the ability to sense the direction of joint motion, e.g., up, down, left, right)

1. Specific screening instructions:
 - Hold the patient’s body segment (e.g., arm, elbow, wrist, hand, fingers) on the lateral surface and move the part into different positions; follow by holding the position. If the patient can maintain the position, remove your support. If the patient cannot maintain the position, hold the position for the patient to complete the next step.
 -  Ask the patient to report whether the body part is moved up, down, left, or right (Video 12-5).
2. Examples of skilled observations indicating dysfunction in daily occupations:
 - The therapist may observe impairment in kinesthesia when the patient has difficulty recognizing whether he or she is moving in the correct direction. For example, the therapist asks a patient to reach down to put socks on and the patient does not reach far enough or reaches up when he needs to reach down.

3. How kinesthesia supports occupational performance:

- A mover walks upstairs with a heavy box and partially lands on the next step. His hips and knees perceive his center of gravity moving backward and self-corrects forward in part due to kinesthesia.

Vibration Awareness (the ability to feel different ranges of vibration)

1. Specific screening instructions:

- Gather two tuning forks, one which vibrates at 30 cycles per second and the other at 256 cycles per second.
- Ask the patient to close the eyes and then strike the tuning fork against your hand with enough force to cause vibration.
- Place the prong tangentially to the fingertip of the affected and then unaffected hand and ask the patient, “Does this feel the same or different?”
-  Scoring is normal if stimuli to both hands feel the same and altered if stimuli feel different. The 30 cycles per second tuning fork is used to test the Meissner afferents, and the 256 cycles per second tuning fork is used to test the Pacinian afferents (Fig. 12-5 and Video 12-6).

Figure 12-5 Screening for vibration awareness.

2. Examples of skilled observations indicating dysfunction in daily occupations:

- The therapist may observe impairment in vibration awareness if a patient has difficulty sensing a vibrating wrist watch, or the vibration of a hand-driven mower. A patient who can no longer feel vibration and assess whether he has received too much vibration, is at risk for safety hazards.⁴⁴

3. How vibration awareness supports occupational performance:

- A mover accidentally packed his cell phone, which is on vibration mode, in one of three boxes. He has his friend call his number and locates the phone by feeling the boxes through vibration awareness.

Cortical Sensory Function

Cortical sensory function requires the parietal lobe to discriminate between different stimuli provided through individual sensory inputs (e.g., touch).

Stereognosis (blinded object awareness; the ability to discern an object without looking at it)

The absence of stereognosis is called *astereognosis*.

1. Specific screening instructions:
 - Gather commonly used objects such as a quarter, pen, and a safety pin. Show the objects to the patient before testing.
 - With the patient's vision occluded, place an object in the hand to be tested.
 - 🎥 Ask the patient to manipulate the item in the hand and name the object (Video 12-7).
2. Example of skilled observation indicating dysfunction in daily occupations:
 - A therapist may observe impairment in stereognosis when a patient has difficulty finding an object at the bottom of a purse or backpack when not looking directly into the bag.
3. How stereognosis supports occupational performance:
 - At the end of the move, the mover asks the patron to sign a billing statement. The mover reaches into his backpack and tries to locate a pen by feel through stereognosis.

Graphesthesia (ability to recognize symbols written on the skin)

The absence of graphesthesia is called *graphanesthesia*.

1. Specific screening instructions:
 - Gather a blunt object such as an eraser on a pencil or tongue depressor.
 - Instruct the patient that you will draw a number or letter on the patient's palm and will disclose the number or letter orientation. For example, "The number will be right side up," in accordance with the patient's orientation.
 - With the patient's vision occluded, draw the numbers or letters on the hand to be tested.
 - 🎥 Give the patient two trials to identify the correct letter or number (Video 12-8).
2. Example of skilled observation indicating dysfunction in daily occupations:
 - Graphesthesia is difficult to tie to specific foundations for occupational performance and appears to be important diagnostically. Impairments in graphesthesia indicate parietal lobe damage opposite of the hand being tested and has been hypothesized to be an early indicator of Alzheimer disease.⁴⁵

Two-Point Discrimination (ability to recognize simultaneous stimulation by two different points either statically or dynamically)

Testing is most reliable on the fingers and hand.

STATIC TWO-POINT DISCRIMINATION

1. Specific screening instructions:
 - Gather the Disk-Criminator or Aesthesiometer.
 - Testing begins with a 5-mm separation of points. Lightly (just to the point of blanching) apply one or two points (randomly sequenced) in a transverse or longitudinal orientation on the hand.
 - Hold the pressure for at least 3 seconds or until the patient responds. Gradually adjust separation distance to find the least distance at which the patient can correctly perceive two points.
 - Direct the patient to respond by saying, "one," "two," or "I can't tell."
 - 🎥 The final score is the smallest distance at which the perception of one or two points is better than chance. When the patient's responses become hesitant or inaccurate, require 2 of 3, 4 of 7, or 7 of 10 correct responses (Fig. 12-6 and Video 12-9).

Figure 12-6 Screening for two-point discrimination.

2. Norms:

- 3 to 5 mm on the fingertips for ages 18 to 70 years⁴⁶; 5 to 6 mm on the fingertips for ages 70+.⁴⁰
- 5 to 9 mm on the middle and proximal phalanges in adults 18 to 60 years; 0 to 12 mm on the middle and proximal phalanges for ages 60+.⁴⁷

DYNAMIC TWO-POINT DISCRIMINATION

1. Specific screening instructions:

- Gather the Disk-Criminator or Aesthesiometer.
- Testing begins with a 5 to 8 mm separation of points. Apply moving pressure of one or two points randomly from proximal to distal on the distal phalanx with points side-by-side and parallel to the long axis of the finger. Apply just enough pressure for the patient to appreciate the stimulus.
- Hold the pressure for at least 3 seconds or until the patient responds. Then gradually adjust the separation distance to find the least distance at which the patient can correctly perceive two points.
- Direct the patient to respond by saying, “one,” “two,” or “I can’t tell.”
- The final score is the smallest distance at which perception of one or two points is better than chance. When the patient’s responses become hesitant or inaccurate, require 2 of 3, 4 of 7, or 7 of 10 correct responses.

2. Norms:

- 2 to 4 mm for ages 4 to 60.⁴⁸
- 4 to 6 mm for ages 60+.^{40,48}

3. Example of skilled observation indicating dysfunction in daily occupations:

- Static and dynamic two-point discrimination are difficult to connect to specific foundations for occupational performance and appear to be important as a contributor to other sensory skills (e.g., localization and spatial discrimination) and to monitor the progression of neural recovery in the hand.⁴⁹

Touch Localization (ability to localize where stimuli is “placed” on the body)

The absence of touch localization is topagnosia.

1. Specific screening instructions:

- Gather a Semmes-Weinstein monofilament number 4.17, pen, or pencil eraser.
- Apply touch to the patient's skin with vision occluded.
- Ask the patient to remember the stimulus location. With vision no longer occluded, instruct the patient to use the index finger to point to the spot just touched.
- The score is the measured distance in millimeters between stimulus and response locations.
-  Normal response is approximately 3 to 4 mm on digit tips, 7 to 10 mm on palm, and 15 to 18 mm on forearm^{50,51} (Fig. 12-7 and Video 12-10).

Figure 12-7 Screening for touch localization.

2. Examples of skilled observations indicating dysfunction:
 - A therapist may observe impairment in touch localization when a patient has difficulty understanding where his or her elbow grazed the wall when using a wheelchair.
3. How touch localization supports occupational performance:
 - While unpacking a box, a mover feels something crawling on his arm. He quickly swipes the area using touch localization.

Conceptual Foundation Underlying Intervention for Sensory Impairment

Choosing an Intervention Strategy

The selection of interventions for sensory impairment is based on diagnosis, prognosis, and evaluation findings. Diminished or lost protective sensation, the inability to feel pain in response to potentially damaging stimuli, suggests a need to teach patients and/or caregivers compensatory interventions to prevent injury. Findings of discomfort associated with touch (**hypersensitivity**) suggest a need for **desensitization intervention**. **Sensory reeducation** interventions (passive and active sensory training) are provided for patients who have some sensation and the potential for improved sensation or interpretation of sensory information. The following is a review of interventions designed to compensate for or improve sensory abilities.

Compensatory Intervention

The primary goal of treatment for patients with diminished or absent protective sensation is to educate to avoid injury. Protective sensations are pain and temperature extremes that signal tissue damage threat. When the brain receives this message, the normal response is to move the body part away from the stimulus source. Without this message, tissue damage can quickly occur. Treatment consists of teaching the patient and/or the caregiver precautions necessary to prevent injury to any body part with compromised protective sensations.

The secondary goal of treatment is to teach the patient how to compensate for absent sensation. The therapist should teach the patient compensation strategies, such as (1) using vision to compensate for lack of sensation; (2) learning to use the sensate hand for tasks that require temperature or pain detection; (3) checking the insensate body part for abrasions, cuts, or burns; (4) wearing protective garments that prevent injury; and (5) modifying the task to avoid injury.

Desensitization Intervention

Desensitization is used when sensory evaluation reveals an area of hypersensitivity, in which ordinary stimuli produce exaggerated or unpleasant sensations.⁵² Hypersensitivity includes **allodynia**, which is the perception of pain in response to a non-painful stimulus, and **hyperesthesia**, which is a heightened sensitivity to tactile stimuli. Desensitization intervention is designed to decrease discomfort associated with touch in the hypersensitive area. Desensitization

programs generally include repetitive stimulation of the hypersensitive skin region with items that provide a variety of sensory experiences, such as textures ranging from soft to coarse.⁵³

Sensory Reeducation Intervention

Because of recent research evidence regarding brain reorganization in response to lack of stimuli, repetitive stimuli, and problem-solving, sensory training currently consists of two approaches: passive sensory training and active sensory training. Sensory reeducation is an appropriate and commonly used treatment for a variety of peripheral nerve injuries, including nerve lacerations, and neural compressions and injuries, resulting in replantation, toe-to-thumb grafting, and skin grafting.⁵⁴ Sensory reeducation is also used for diminished or distorted sensation secondary to cerebral insults, such as stroke and traumatic brain injury. The techniques for both interventions are similar but different based on the nuances of retraining peripheral versus cortical structures.

Rationale for Sensory Reeducation after Peripheral or Cortical Injury

Hand representation in the somatosensory cortex has been found to reorganize as a result of peripheral nerve and cortical injuries.⁵⁴⁻⁵⁶ In children, this reorganization is sufficient for return of normal sensory interpretation without sensory retraining. In adults, neural reorganization requires sensory reeducation.^{54,57,58}

The return of sensation following hand injury or insult is a complex process. In peripheral nerve injuries, recovery involves both peripheral reinnervation and cortical somatosensory reorganization. Following nerve laceration and surgical repair, some sensory fibers, given sufficient time, regenerate. Peripheral nerves regenerate at a rate of 1 mm per day or 1 inch per month.⁵⁴ Sensory return is limited by scar tissue production along axonal sheaths and misdirection of growing fibers. Fibers usually do not regrow to innervate the same sensory receptors that they innervated preinjury.^{57,59} This results in sensory coverage gaps in areas not fully reinnervated.

Conversely, peripheral nervous system structures, such as axons and sensory receptors, remain intact after cortical injury. Impaired neural structures lead to changes in the way the body appropriately interprets stimuli and withdrawals from danger. Lack of sensation, as in peripheral nerve injury, results in shrinkage of corresponding sensory homunculus regions. The return of sensation following cortical insult requires interventions that expand sensory cortical representation. Because sensation and motor use of the hand are highly correlated, functional use of the UE with reduced sensation is possible, but spontaneous use is limited. Without training, there is a tendency to refrain from using the extremity; learned nonuse leads to further loss of sensory and motor abilities and disrupted cortical representation.^{60,61} Therapists may alter the cortical map by directing the sensory experiences of the patient.⁶²

Sensory Reeducation Intervention Procedures

In the past, sensory reeducation was delayed until adequate sensation had returned.⁶³ However, in newer approaches, based on current knowledge of neuroplasticity, sensory reeducation is begun immediately through two sequential phases. Phase 1 (passive) focuses on maintaining sensory cortical representation by either providing directed sensory stimulation or by making the brain believe that no sensory changes have occurred.^{57,63} Phase 2 (active) occurs when patients can appreciate some sensation and can learn to differentiate between sensation types. At first, in phase 2 of reeducation, patients learn to match their tactile perception of stimuli with their visual or auditory perception. Alternative senses, vision and hearing, are used to retrain sensation and improve tactile discrimination.⁶³ After time, when reinnervation allows for the perception of light nonmoving touch with good touch localization, the focus of intervention changes to more functional tasks, such as object identification through touch.⁵⁴

Phase 1: Intervention

During phase 1, the formerly innervated body part is without sensation, and cortical representation undergoes rapid remodeling. The passive treatment techniques used in phase 1 are intended to maintain cortical hand representation.^{63,64}

Mirror Visual Feedback Therapy

Mirror visual feedback (MVF) therapy was first proposed as a means to relieve amputee phantom limb pain in the 1990s. Therapists have increasingly used it to treat a range of other chronic pain conditions and as a means to reeducate sensorimotor abilities in patients with peripheral and

central nerve injury.⁶⁵ MVF therapy is thought to work by improving sensory perception of the affected limb through false but congruent visual feedback of the unaffected limb, thereby restoring the normal sensory feedback–motor intention linkage. A mirror box is placed in front of the patient, and the sensory-deprived hand is hidden within it (Fig. 12-8). The reflection of the unaffected hand is visible in the mirror and appears as if it was the affected hand. Touching the unaffected hand provides the illusion that the affected hand has been touched. MVF protocols instruct the patient to (1) look at and perceive the reflected image to be the affected hand; (2) perform small then larger movements with the affected hand, and perceive the reflected image to be the affected hand; and (3) move both hands bilaterally while the affected hand remains occluded. Therapists can also address sensation by applying different textures to the unaffected hand as it is reflected in the mirror and by instructing the patient to perceive the sensation as if it was occurring to the affected hand. There is promising evidence that sensation improves through MVF protocols.⁶⁶

Figure 12-8 Mirror visual feedback therapy.

Phase 2: Techniques

Active sensory reeducation is the process of involving patients in activities designed to facilitate detection of and discrimination between sensory inputs.⁵⁴ The perception of moving touch is needed to begin phase 2, and steps occur sequentially after each preceding skill is achieved by the patient. First, the therapist develops a moving and constant touch sequence in which the patient must identify touch type with eyes closed, followed by eyes open, and concluding with eyes closed. Smaller and lighter stimuli should be used as the patient improves, with a goal of touch localization that is near the light touch threshold. Next, the therapist should present activities that force discrimination of similar and different textures using sandpaper, fabrics, and coin edges. The patient should touch various textures and discriminate between each, then advance to being touched by various textures, and finally identify each texture and area of localization. Progression in the active sensory reeducation sequence leads the patient to practice shape or letter block identification with vision occluded.

In later training stages, patients feel for objects buried in containers filled with sand or rice and identify objects by touch before using visual feedback (Fig. 12-9). Finally, patients practice daily living activities, particularly those in which the hand is visually occluded. A number of different active sensory reeducation protocols exist with varying levels of evidence (see the Evidence table at the end of this chapter).

Figure 12-9 Active sensory reeducation. Patient feels for objects in containers filled with sand or rice.

Task-Specific Sensory Training

Sensory reeducation after CVA is less well defined than protocols described for peripheral injuries. Carr and Shepherd, in their book *Neurological Rehabilitation* (2010),⁶⁷ emphasize that task-specific sensory training should occur concurrently with motor learning. They advocate for the use of meaningful and relevant sensory and motor experiences very early in rehabilitation. Use of the more involved hand in bimanual tasks, such as opening jars and using eating utensils, is recommended. They suggest that patients be cued to attend to both task goals and object tactile qualities (e.g., weight, texture, slipperiness, temperature). Therapists should carefully structure therapy to include a variety of sensory inputs within occupational activities. For example, a therapist may ask a patient to remove items from the refrigerator having different tactile qualities, such as a stick of butter, a full milk gallon, and a jelly jar. Each object provides the opportunity for patients to express and feel differences across objects. Task-specific sensory training can be applied across varying occupations and contexts.

CASE STUDY

Patient Information

Dolores is a 55-year-old, left-handed African-American female admitted to an in-patient rehabilitation unit 3 days following right parietal lobe stroke. Past medical history includes right carpal tunnel surgery (1-year post) and hypertension.

Assessment Process and Results

Occupational Profile

Dolores has been married to her husband Ed for 30 years. They have two grown daughters who live close by. Their oldest daughter, Maya, has one son Alex who is 9. Dolores works as an elementary school teacher. Her work involves grading papers and standing at the front of the class to write on the board. She hopes to work until age 65. At home, Dolores is responsible for laundry, cleaning, and yard work and enjoys playing with Alex.

Occupational Performance

Objective Functional Independence Measure (FIM) Scores: Feeding, Dressing, Toileting, Grooming, and Bathing: (4/7) Minimal Assist/cues. Toilet, shower and bed transfers: (4/7) and Ambulation (4/7) with 4-point cane.

Subjective Report of Occupational Performance: The therapist used the Canadian Occupational Performance Measure (COPM) to identify Dolores' priority goals during rehabilitation and report her performance and satisfaction in each area.

Top Priority Areas	Performance (1–10)	Satisfaction with Performance (1–10)
Write on dry-erase board with left hand	3	1
Play simple board games with grandson	4	1
Feed self without assistance	4	1
Complete full ADL routine prior to work	6	1

Patient Factor Screening and Assessments

Cognitive Screening: Scored 30/30 on the Montreal Cognitive Assessment indicating no signs of dementia or mild cognitive impairment. In ADLs, she can initiate, sustain, and complete tasks independently.

Psychosocial Screening: Scored 13/15 on the Geriatric Depression Scale (Short Form) indicating very few depressive symptoms.

Visual Perception Assessment: Dolores demonstrated below average abilities in visual perception using the Motor Free Visual Perception Test–Revised. Visual memory is a strength, and areas of concern include visual figure ground, closure, discrimination, and spatial relations.

Sensory Screening: Dolores demonstrated mild-moderate deficits in sensation as evidenced by the following sensory screening assessments.

Sensory Awareness	Norms	Results (R)	Results (L)	Observation during Occupation
Touch	Perceives 100% of stimuli correctly	80%	20%	Squeezing too hard or too little resulting in grasp difficulty; doesn't always feel object in hand such as fork, dry-erase marker.
Pain	Perceives 100% of stimuli correctly	80%	40%	Does not feel pain when hand/arm in compromised position
Temperature	Perceives 100% of stimuli correctly	80%	20%	Difficulty sensing difference in hot/cold water temps for shower
Joint position	Perceives 100% of stimuli correctly	100%	20%	Over and under reaches for objects; can visually correct if watching arm
Kinesthesia	Perceives 100% of stimuli correctly	100%	20%	
Stereognosis	Perceives 100% of stimuli correctly	80%	10%	Has to look for objects when reaching into her purse

Sensory Awareness	Norms	Results (R)	Results (L)	Observation during Occupation
Two-point discrimination	3–5 mm on the fingertips for ages 18–70 years; 5–6 mm on the fingertips for ages 70+	6 mm on fingertips	8 mm on fingertips	

Notes: Patient has history of right carpal tunnel release, which may explain mild impairment on unaffected right side.

Joint Range of Motion (ROM): Passive ROM is within normal limits in bilateral UE and LE.

Muscle Strength:

	Right (Unaffected Side)	Left (Affected Side and Dominant Hand)
Shoulder (all movements)	5/5	3–/5
Elbow flexion/extension	5/5	3–/5
Forearm pronation/supination	4/5	3–/5
Wrist flexion/extension	4/5	3–/5
Grip strength	Average of three trials: 56#	Average of three trials: 25#
Pinch	Tip: 8# Lateral: 10# Tripod: 11#	Tip: 2# Lateral: 5# Tripod: 5#

Occupational Therapy Strengths and Problems List

Strengths That Support Performance	Problems That Are Barriers to Performance
Motivation for independence Intact cognition No signs of clinical depression Supportive family system and personal resources	Visual perception skills Impairment in protective sensation Impairment in sensory discrimination Mild weakness in dominant UE Mild balance deficits

Occupational Therapy Goal List

Occupational therapy goals were developed based on Dolores' priority areas determined through the COPM.

Long-Term Goals:

1. Dolores will complete ADLs with modified independence.
2. Dolores will perform activities that support the occupation of teaching with modified independence.

Short-Term Goals:

1. Dolores will complete her morning routine with SBA using modifications, adaptive equipment, and techniques.
2. Dolores will write on a dry-erase board in standing using her left hand/arm with SBA using modifications, adaptive equipment, and techniques.

3. Dolores will play Connect Four using her left hand with verbal cues on the use of sensory and visual compensatory techniques.

Intervention

Choice of intervention strategies included sensory interventions as part of a holistic treatment plan for Dolores after her stroke.

To address impairment in protective sensation, the therapist chose compensatory strategies. Using an educational approach, strategies were taught to protect Dolores' arm from harm. For example, when addressing showering, the therapist facilitated the integration of interventions such as checking water temperature with her right hand, improving shower transfers, visually locating the correct objects for washing hair, and scrubbing with the left hand.

To address impairments in interpretation of sensory stimulation, the therapist chose a sensory reeducation approach. In the passive phase of sensory reeducation, the therapist used MVF therapy to prevent loss of cortical sensory representation that also supported improvement in motor skills. In the active phase of sensory reeducation, the therapist began by addressing tactile discrimination. Preparatory methods and activities included identifying textures and shapes with the Dolores' eyes closed. Using an occupation-based intervention, the therapist addressed Dolores' ability to write on the dry-erase board by reaching for the dry-erase pen with vision occluded (as she might do when paying attention to students), standing at the board, encouraging use of the left hand and arm, and staying within dotted lines to write legibly.

These examples illustrate that sensory interventions can be delivered through preparatory methods, activities, and occupation-based practice. When appropriate for the level of recovery, embedding sensory interventions into occupation-based interventions provides patients with effective and personally meaningful care.

Most Commonly Used Standardized Assessment

Instrument Name	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Semmes-Weinstein Monofilaments or Weinstein Enhanced Sensory Test (WEST)	Measure of threshold of light touch sensation ⁴⁶	Typically 10–15 minutes; may be variable depending on the extent of assessment needed	For construct validity, low correlation ($r = 0.17$) between pressure sensitivity and threshold	Inter-observer reliability — $ICC = 0.965$ (0.934) ⁷²	81%–82% sensitivity has been reported when filament 2.83 used as upper limit of normality ⁷³	Strengths: Inexpensive, easy to use, portable Weaknesses: Practice needed to administer effectively and interpret results
Modified Pick-Up Test ⁷⁴	Dellon's modification of the Moberg Pick-Up Test measures the interpretation of sensation in the distribution of the median nerve	Approximately 5–10 minutes	Discriminative validity between healthy and young, middle-aged, and elderly persons with CTS showed significant differences ($p = 0.06$, $p < 0.1$, and $p < 0.05$, respectively)	Test–retest reliability, 0.91 in patients with CTS; Inter-rater $p = 0.67$ for eyes open, 0.80 eyes closed ³⁹	No sensitivity data available	Strengths: Inexpensive, easy to use, portable Weaknesses: Ceiling effect, sensitivity may be limited
Erasmus MC–Revised Nottingham Sensory Assessment ⁷⁵	Quantitative functional measure of sensation after stroke. Sensations assessed include light touch, pinprick, pressure, two-point discrimination, and proprioception	10–15 minutes	No validity data available	Inter-tester reliability $k > 0.75$; Test–retest reliability, $k > 0.75$ ⁷⁵	No sensitivity data available	Strengths: Establishes protocol/systematic procedure for tactile sensation measures; hierarchical Weaknesses: Administration time can vary

Instrument Name	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Fugl-Meyer Upper Extremity Sensory Subsection ^{76,77}	Assessment for persons with stroke; also measures motor function, balance, and joint movement	Approximately 30 minutes	Concurrent validity with Motor Assessment Scale ($r = 0.06$)	Inter-rater reliability ($r = 0.98-0.99$)	No sensitivity data available; however, responsiveness at 14-180 days (SRM = 0.67) and MDC at 90 days, 3.2 pts, have been reported	Strengths: Rates quality of specific movement patterns Weaknesses: Lengthy; Sensation subsection less suited for this instrument
Graded and Redefined Assessment of Strength, Sensibility and Prehension (GRASSP) ^{77,78}	Assessment for cervical tetraplegic population; also measures motor and prehensile skills	45 minutes	Concurrent validity with Spinal Cord Independence Measure sensation subtest (0.74)	Test/retest (ICC = 0.86-0.98); Inter-rater (ICC = 0.84-0.96)	No sensitivity data available	Strengths: Specific sensory testing for spinal injured Weaknesses: Length

CTS, carpal tunnel syndrome; DPN, diabetic peripheral neuropathy; ICC, intraclass correlation coefficient; MDC, minimal detectable change; SRM, standard response mean.

Evidence Table of Studies Supporting Interventions for Disorders of Sensation

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit and Statistical Significance
Electrical stimulation ⁶⁸	Explored whether electrical stimulation (ES) improved peripheral nerve regeneration following nerve transection	Thirty-six patients following peripheral nerve transection	Fine wire electrodes were implanted following nerve transection surgery; patients randomized to receiving 1 hour of 20 Hz continuous ES or sham stimulation over 6 months	Level I: Randomized controlled trial	Patients receiving ES showed significant improvement in cold detection ($p < 0.001$) and tactile discrimination and pressure detection ($p < 0.001$); functional improvements were noted, but not significant. Subcutaneous ES delivered following peripheral nerve transection can improve sensibility.
Mirror therapy combined with TENS ⁶⁹	Investigated whether mirror therapy and TENS improved phantom limb pain (PLP)	Twenty-six participants with PLP	Patients with PLP randomized to either a mirror therapy group (Grp I) or TENS group (Grp II) for 4 days of treatment	Level I: Randomized controlled trial	Both groups showed significant decreases in pain on VAS (I— $p = 0.003$, II— $p = 0.003$) and UPS (I— $p = 0.001$, II— $p = 0.002$); no difference between groups. Mirror therapy and TENS can improve patient perceptions of PLP.
Perceptual learning-based sensory program ⁷⁰	Explored whether a perceptual learning-based sensory program was more effective than passive repeated sensory exposure for improving hand function after stroke	Fifty poststroke patients with UE sensory deficits	Two groups randomized to receive somatosensory discrimination program (SENSe) or repeated sensory exposure for ten 1-hour sessions; measured change in SSD index after intervention and at 6 weeks and 6 months	Level II Evidence: Two group randomized design with between-group comparisons	Significantly greater improvement in sensory capacity in sensory discrimination group ($p = 0.004$) with a mean change 11.1 SSD index; improvements maintained at 6-weeks and 6-months follow-up. Findings provide support for effectiveness of SENSe program for rehabilitation of sensory issues after stroke.

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit and Statistical Significance
Self-massage and graded texture presentation ⁵³	Investigated whether self-massage and graded texture presentation was effective for reducing hypersensitivity after surgery	Thirty-nine patients after hand surgery	Patients experiencing pain in scar area from hand surgery massaged area 3×/day with textured material 2–5 minutes. Pain assessed with VAS; size of painful area measured in mm; OP measured with COPM	Level III: Single group, pretest–posttest design	Significant improvement in pain level, size of pain area, and higher OP scores on COPM after intervention. Further research with larger group needed to confirm findings.
Sensory reeducation training tool ⁷¹	Studied whether hollow tubes made of various materials with 12 tactile stimulation elements of varying textures improved sensory deficits of the UE in persons with MS	Twenty-five persons with relapsing-remitting MS who report sensory deficits in UE	After a 7 week control baseline period, participants practiced with the tool for 20 minutes/day, 5 days/week for 3 weeks	Level III: Single group, pretest–posttest design	Participants demonstrated an improvement in the Nine-Hole Peg (26.8 vs 22.6 [SD = 3.2]); mean difference ($p = 0.03$) and functional dexterity tests (38.6 vs 33.8 [SD = 4.9]); mean difference ($p = 0.02$) at the end of the sensory reeducation phase. No differences were observed as to the monofilaments and two-point discrimination tests.

COPM, Canadian Occupational Performance Measure; ES, electrical stimulation; MS, multiple sclerosis; OP, occupational performance; PLP, phantom limb pain; SSD, somatosensory deficit index; TENS, transcutaneous electrical nerve stimulation; UE, upper extremity; UPS, universal pain score; VAS, visual analog scale.

Chapter 13

Motor Function Assessment: Range of Motion, Strength, and Endurance

Veronica T. Rowe and Tracey L. Zeiner

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Determine when evaluation of motion, strength, and endurance is appropriate and the best methods for obtaining such data.
2. Evaluate range of motion of the upper extremity using a goniometer.
3. Evaluate underlying causes of decreased motion and strength including edema, scar tissue, and pain.
4. Perform a manual muscle test to evaluate strength of the upper extremity.
5. Determine functional endurance level.
6. Interpret the findings of the evaluations described in this chapter.

CHAPTER OUTLINE

Functional Upper Extremity Screening
Functional Lower Extremity Screening
Impact of Motor Function on Occupational Performance
Range of Motion Measurement
Muscle Strength Measurement
Endurance Measurement
Case Study

TERMINOLOGY

- Cardiorespiratory endurance:** the ability of the circulatory and respiratory system to supply oxygen during a time period while performing a task.
- Dynamometer:** a measure of applied force converted to a moment of force by multiplying by the perpendicular distance from the force to the axis of the lever.
- End-feel:** the resistance in the joint that the therapist feels at the end range of the passive limits of motion.
- Goniometer:** common instrument used for measuring limb joint motion, which has a protractor, an axis, and two arms.
- Manual muscle testing:** procedure for the evaluation of the strength of muscles depending on the performance of a movement in relation to the forces of gravity and manual resistance.
- Maximum voluntary contraction (MVC):** the greatest amount of tension a muscle can generate and hold only for a moment, such as in muscle testing.
- Volumetric:** measurement that documents changes in the mass of a body part by use of water displacement.
- Within functional limits (WFL):** represents capacities that may be less than normal limits, but sufficient for the client to participate in meaningful occupations to his or her own satisfaction.
- Within normal limits (WNL):** represents capacities that fall in the range of what has been determined to be normal depending on mean average ranges.

Functional Upper Extremity Screening

Depending on the reason for the referral to occupational therapy services, a preliminary screening of motion and functional strength may be more appropriate than an in-depth evaluation of individual measurements at each joint and muscle. It is often appropriate to screen some areas while taking formal measurements of others, which is why therapists will often begin with a functional

screening. For example, a client may be referred to therapy following a distal radius fracture. When individuals have a cast on their wrist, they may lose motion at the shoulder and elbow as well because of nonuse and protective posturing. It would be appropriate to screen the shoulder and elbow and compare bilaterally to ensure motion is **within functional limits (WFL)** and then do specific range of motion (ROM) measurements at the wrist and hand. If deficits are noted during the screen at the shoulder or elbow, then it would also be appropriate to complete specific measurements of the joints where the limitations are noted.

Similarly, a gross screening of upper extremity (UE) strength may be more appropriate than testing individual muscles. This screening is often appropriate in inpatient and rehabilitation settings in which the client may be experiencing gross motor weakness from debilitation. During the screening, if the therapist determines any patterns such as weakness in one specific nerve distribution, he or she may wish to then do more specific **manual muscle testing (MMT)** of muscles innervated by that nerve.

 The following instructions can be used as a functional screening of ROM and strength of the UE (see Video 13-1):

- The client should be seated, if possible.
- The client should perform the motions bilaterally, if possible. If not, the unimpaired or least impaired side should move first to set a baseline for normal for this person.
- Observe for complete movements, symmetry of movements, and timing of movements.
- Demonstrate the movements if the client has a language barrier or cognitive deficits.
- To estimate the amount of active movement and strength in the following motions, give instructions to the client, as shown in Box 13-1.

Box 13-1

Client Instructions for Functional Screening of ROM and Strength of Upper Extremity

- **Shoulder flexion:** Lift your arms straight up in front of you and reach toward the ceiling. Now, with your arms straight in front of you, do not let me push your arms down.
- **Shoulder abduction:** Move your arms out to the side. Now reach over your head. Next, with your arms straight out, do not let me push your arms down.
- **Shoulder horizontal abduction and adduction:** Raise your arms forward to shoulder height. Move each arm out to the side, and then back again while keeping your arm level. Push your arms against mine in both directions.
- **External rotation:** Touch the back of your head with your hand like you are washing your hair. Now push against me like you were going to throw a ball overhand.
- **Internal rotation:** Touch the small of your back with your hand like you are tucking in your shirt. Now push against my hand.
- **Elbow flexion and extension:** Start with your arms straight down by your sides. Now bend your elbows so your hands touch your shoulders. Push and pull against me starting with your arm flexed like you are making a muscle.
- **Forearm supination and pronation:** With your arms at your side and your elbows flexed to 90°, rotate your forearms so the palms of your hands face the floor and then the ceiling. Now, like we are shaking hands, resist my motion.
- **Wrist flexion and extension:** Move your wrists up and down. Now, resist my pressure.
- **Finger flexion and extension:** Make a fist, and then open your fingers. Squeeze my hands (ensure your hand is interlocked in the web space to avoid injury of your own hand).
- **Finger opposition:** Touch your thumb to the tip of each finger one at a time. Now, try to hold your thumb to your index finger and small finger without letting me break the circle.

Functional Lower Extremity Screening

Physical therapists typically complete any needed formal measurements of ROM and strength of the lower extremities (LEs). However, there is a role for occupational therapists in the functional assessment of the LEs insofar as they are commonly consulted regarding return to independence in activities of daily living (ADL) and instrumental activities of daily living (IADL) for clients with; for example, various orthopedic, neurological, and other debilitating conditions. In these cases,

evaluation of LE function is typically done with the demonstration of ADL/IADL tasks and functional transfers. Occupational therapists are more interested in whether motion allows the individual to transfer to and from a toilet or complete dressing independently and safely, for example, rather than the exact degree of motion at the hip, knee, or ankle.

Instructions as outlined in Box 13-2 can be used as a functional screening of ROM and strength of the LE.

Box 13-2

Client Instructions for Functional Screening of ROM and Strength of Lower Extremity

- **Hip:** Show me how you would move from lying down to sitting on the edge of the bed.
 - How would you get on and off the commode?
 - Show me how you would get in and out of the tub.
 - How would you get something from a bottom shelf?
- **Knee:** Show me how you would put on your socks.
 - How would you get on and off the commode?
 - How would you get something from a bottom shelf?
- **Ankle:** Show me how you will wash your feet.
 - Show me how you would put on your socks.
- **Functional transfers:** Show me how you would get in and out of bed (assess bed mobility, supine to sit, sit to stand, stand to sit, and sit to supine).
 - Show me how you would sit on the commode (assess stand to sit and sit to stand with toilet or bedside commode transfers).
 - Show me how you will get in and out of the shower (assess shower bench or transfer bench or safety in getting in and out of tub or walk-in shower as appropriate to client).
 - Show me how you will get in and out of the car (use real or simulated car).
 - Show me how you will get up from this chair (cushioned seating vs. solid chair).

Impact of Motor Function on Occupational Performance

The assessments presented in this chapter are appropriate for clients who are unable to do or are restricted in doing the occupational tasks and activities important to them because of range of joint motion, strength, or endurance impairments. For the completion of most occupational tasks, it is essential to be able to move with adequate mobility and ROM, have enough strength to use extremities against resistance, and to be able to maintain endurance for an extended period of time. For example, a person who cannot fully flex the elbow, is too weak to lift a spoon to the mouth, or is too fatigued to lift a utensil repeatedly cannot eat a meal independently. Because deficits in these abilities and capacities may lead to impaired occupational functioning, it is within the realm of occupational therapy to assess them. Keep in mind that occupational therapy assessments of mobility, strength, and endurance focus on how deficits in these areas impact occupational functioning. Occupational therapists also consider other variables in the overall evaluation, including environmental and contextual constraints that contribute to performance ability. The majority of this chapter focuses on evaluating limitations that impact UE function and occupational performance.

Additional underlying causes can affect motor function. These may include bony blocks to motion, capsular tightness around the joint, tightness of the muscle-tendon unit, edema, contractures, or extensive scar tissue. Changes in tone can also significantly limit motor function, especially ROM. Hypertonicity and hypotonicity from neurological impairments affect how one is able to complete a functional task. Distinguishing the difference in the effects of upper motor neurons and lower motor neurons is also important. Although insults to both types of neurons may affect ROM, muscle strength should be assessed appropriately with MMT for deficits from lower motor neuron injury, and tone should be assessed for deficits resulting from upper motor neuron

injuries. A manual muscle test following an upper motor neuron insult would yield inconclusive results because of changes in tone, not necessarily in muscle strength. Therefore, MMT is inappropriate following a neurological event with resultant changes in tone.

Use of the assessments described in this chapter allows for the establishment of the client's baseline abilities. Reassessments at later dates allow documentation of progress or lack thereof as well as return to function **within normal limits (WNL)** or WFL. With the demands for efficiency in health care delivery, it is essential that occupational therapists be skilled in their evaluations of clients to justify continuation or discharge of therapy services.

Range of Motion Measurement

Measurement of joint range may be done actively or passively. Passive range of motion (PROM) is the amount of motion at a given joint when the joint is moved by an outside force. Typically, the outside force comes from the therapist or therapeutic equipment. Active range of motion (AROM) is the amount of motion at a given joint achieved when the client contracts the muscles that control the desired motion. Additional types of ROM include self-range of motion, where the client performs ROM on one side using the opposite side, and active assistive range of motion where the therapist, the client, or another caregiver may provide support during active motion to allow the client to move beyond the current AROM limits. These are not typically measured in an evaluation but may be used in treatment to improve deficits in ROM. It is normal to have slightly more PROM than AROM; however, if AROM is significantly less than PROM, there is a problem with how the underlying structures are functioning.

If limitations in AROM are observed, they are formally measured and documented. If there are no contraindications, the therapist then attempts to move the joint through its full PROM. If the joint is free to move to the end range, the problem is with active motion. If the end range cannot be attained when the therapist moves the limb, the problem is with passive motion, and the PROM limitation is measured and recorded.

Precautions to note in the evaluation of AROM and PROM:

- Carefully review consult/referral to therapy and note any contraindications to motion or restrictions in motion by the referring provider.
- Limited motion protocols may require that motion only be tested within the limits prescribed even if the client feels he or she can move beyond these limits. For example, following tendon repair, the surgeon may prescribe a limited arc of motion to avoid overstressing the repair during the healing process.
- Avoid pushing PROM when the underlying cause of the limitation is unknown, particularly with trauma.
- Avoid increasing edema or pain for the sake of a measurement. For example, immediately following casting, the therapist would expect tightness of the tissues that have been immobilized, and AROM measurements may be all that is needed to set baseline goals. It may be appropriate to try a heat modality (if edema does not contraindicate this) and then remeasure AROM to see whether increasing the extensibility of the soft tissues helps improve ROM.

End-Feel

When recording PROM, the therapist should also note any abnormal **end-feel**. Cyriax,¹ Kaltenborn,² and Paris³ are three different classification systems of end-feel. All three require more research into the reliability of the classifications, but in general have found good intrarater and poor interrater reliability.^{4,5} Commonly used terms for end-feel, mostly based on the Cyriax¹ and Kaltenborn² systems, include the following:

- **Bone-to-bone hard end-feel** is a stop in movement as the bony surfaces meet (normal for elbow and knee extension).
- **Soft-tissue approximation** is a stop in movement due to soft tissue (normal for elbow and knee flexion).
- **Capsular end-feel** is a movement that is somewhat firm or leathery but has some give (normal for shoulder external rotation and hip internal rotation).
- **Spasm end-feel** is a tissue response with a harsh movement in the opposite direction; passive movement stresses a fracture or inflamed joint (always abnormal).
- **Springy end-feel** is some hard rebound at the end ROM (always abnormal).
- **Empty end-feel** is no "feel," but rather the client asks to stop because of pain (always abnormal).

Although some of these may be a normal end-feel, it is important to note when they are abnormal. For example, a bony end-feel before full wrist extension may indicate underlying pathology, or a capsular end-feel during elbow extension when the elbow is at 30° may be the result of capsular tightness from immobilization. When pain occurs during PROM, the classification of end-feel is more difficult to determine.⁵

Goniometry

A **goniometer** is the most common tool used for measuring joint motion of the UE. Most goniometers are plastic or metal and come in many shapes and sizes. Every goniometer has a protractor, an axis, and two arms. The stationary arm extends from the protractor, on which the degrees are marked. The movable arm has a center line, or pointer, to indicate angle measurement. The axis is the point at which these two arms are riveted together. A full-circle goniometer, which measures 360°, or 0° to 180° in each direction, permits motion measurement in both directions, such as flexion and extension, without repositioning the tool. When using an opaque half-circle goniometer (such as one made of metal), the protractor must be positioned opposite to the direction of motion so that the indicator remains on the face of the protractor. A transparent, half-circle goniometer (such as one that is plastic), allows the examiner to read the pointer or the center line in either direction. A finger goniometer is designed with a shorter movable arm and flat surfaces to fit comfortably over the finger joints. Figure 13-1 shows examples of these types of goniometers. It is important to match the size of the goniometer to the size of the joint (e.g., use a larger goniometer for the shoulder and a smaller goniometer for the wrist and digits).

Figure 13-1 Types of goniometers. The small finger goniometer (top) has flat arms that fit over the fingers. The small half-circle goniometers are used to measure small joints, such as the wrist. The small and large full-circle goniometers are used to measure with the 360° method and for larger joints.

Some clinics use a manual or electronic inclinometer rather than a goniometer to measure ROM. These devices use gravity rather than the therapist's visual skills to determine the starting position for measurement and, therefore, can improve accuracy, particularly in more complex motions such as compound spine motions.⁶⁻⁸ It is important to note that the position of the individual being measured may need to change with the use of an inclinometer because gravity is used to obtain the starting position. Applications for the smartphone can become inclinometers using the device's built-in tilt-sensitive systems.^{9,10} These easily accessible electronic applications increase the clinical utility of inclinometers.

Another potential tool is the electrogoniometer. This tool can offer continuous, dynamic joint measurement of ROM once positioned and calibrated.¹¹ This may be particularly helpful in work- and industry-type settings where repetitive work tasks and ergonomic impact are being assessed.¹² When using the electrogoniometer, the therapist should calibrate the instrument for the task being performed to decrease errors often seen at angles greater than 45°.¹³ With the advancement in technology and access to digital cameras, photography-based goniometry has also been found to be an accurate and reliable measure of clinical goniometry for measuring ROM.¹⁴⁻¹⁶

Three-dimensional (3D) motion analysis is another way in which ROM can be measured. A benefit of 3D motion analysis is the capturing of dynamic movements in real time. With this type of analysis, both static joint position and the dynamic course of movement from a joint can be assessed.¹⁷ Optical systems with reflective markers are the most common technique.¹⁸ Because the

goniometer is most commonly used in occupational therapy practice and the general principles apply to the alignment of other instruments, the figures depicting ROM measurement in this chapter include standard goniometers.

General principles to follow when using the goniometer include the following:

- Place the axis of the goniometer over the axis of motion. The axis of motion for some joints coincides with bony landmarks, but for others it must be found by observing movement and finding the point around which the movement occurs. In that case, the axis of motion can change position during movement, so it is acceptable for the goniometer to be repositioned at the end of range. When the two arms of the goniometer are placed correctly, they intersect at the axis of motion, so it is more important to have the arms line up correctly. The axis placement then automatically falls in line.
- Position the stationary arm parallel to the longitudinal axis of the body segment proximal to the joint being measured, although there are some exceptions.
- Position the movable arm parallel to the longitudinal axis of the body segment distal to the joint being measured, with some exceptions.

Range of Motion of the Upper Extremity

For the measurements given here, unless otherwise noted, the client is seated with trunk erect against the back of an armless straight chair, although the measurements can be taken with the client standing or supine, if necessary. This procedure can be done actively or passively. For active movement, take special care to ensure that there are no substitutions of movement. A substitution or compensatory movement is the use of an alternate muscle or position to complete a motion, possibly preventing measurement of the true limits of motion. To avoid this error, the therapist should watch the individual as the motion is completed rather than focusing too intently on the goniometer. For PROM, the tester supports both the body part and the goniometer proximal and distal to the joint, leaving the joint free to move. Comfortable handling of the goniometer together with the movable body segment may require practice.

On the pages that follow, the reader will find narrative and pictorial descriptions to help in understanding and practicing measurement of UE ROM. The narrative descriptions frequently use the sagittal, transverse, and frontal planes of motion to describe the motion being measured (see Fig. 13-2 for pictorial clarification of these planes of motion).

Body planes

Figure 13-2 Planes of motion of the body.

Shoulder Flexion (0°–180°)

Movement of the humerus anteriorly in the sagittal plane, which represents both glenohumeral and axioscapular motion (Figs. 13-3 and 13-4).

Figure 13-3 Shoulder flexion, start position.

Figure 13-4 Shoulder flexion, end position.

Goniometer Placement

- **Axis:** A point through the lateral aspect of the glenohumeral joint; at the start of motion, it lies approximately 1 inch below the acromion process with arm in neutral rotation. At the end position, the axis has moved, and the goniometer must be repositioned to align with the center of the humeral head.
- **Stationary arm:** Parallel to the lateral midline of the trunk.
- **Movable arm:** Parallel to the longitudinal axis of the humerus on the lateral aspect.

Possible Substitutions

- Trunk extension and shoulder abduction.

Shoulder Extension (0°–60°)

Movement of the humerus posteriorly in the sagittal plane with the arm in neutral (Figs. 13-5 and 13-6).

Figure 13-5 Shoulder extension, start position.

Figure 13-6 Shoulder extension, end position.

Goniometer Placement

- **Axis:** A point through the lateral aspect of the glenohumeral joint approximately 1 inch below the acromion process.
- **Stationary arm:** Parallel to the lateral midline of the trunk.
- **Movable arm:** Parallel to the longitudinal axis of the humerus on the lateral aspect.

Possible Substitutions

- Trunk flexion, excessive scapular elevation and downward rotation, and shoulder abduction.

Shoulder Abduction (0°–180°)

Movement of the humerus laterally in the frontal plane, which represents both glenohumeral and axioscapular motion (Figs. 13-7 and 13-8).

Figure 13-7 Shoulder abduction, start position.

Figure 13-8 Shoulder abduction, end position.

Goniometer Placement

- **Axis:** A point through the anterior or posterior aspect of the glenohumeral joint approximately 1 inch below the acromion process.
- **Stationary arm:** Along the trunk, parallel to the spine.
- **Movable arm:** Parallel to the longitudinal axis of the humerus.

Possible Substitutions

- Lateral flexion of trunk, scapular elevation, and shoulder flexion or extension. If excessive lateral flexion of the trunk is noted, the arm not being actively tested may be stabilized at 90° of abduction against a wall or other stable object to prevent trunk motion.

Horizontal Abduction (0°–45°)

Movement of the humerus posteriorly on a horizontal (transverse) plane from 90° of shoulder abduction (Figs. 13-9 and 13-10).

Figure 13-9 Shoulder horizontal abduction, start position.

Figure 13-10 Shoulder horizontal abduction, end position.

Goniometer Placement

- **Axis:** On top of the acromion process.
- **Stationary arm:** To start, the stationary arm is parallel to the shaft of the humerus on the superior aspect and remains perpendicular to the body as the humerus moves posteriorly.

- **Movable arm:** Parallel to the longitudinal axis of the humerus on the superior aspect.

Possible Substitutions

- Trunk rotation and scapular motion.

Horizontal Adduction (0°–140°)

Movement of the humerus anteriorly on a horizontal (transverse) plane from 90° of shoulder abduction through 90° of shoulder flexion, across the trunk to the limit of motion (Figs. 13-11 and 13-12).

Figure 13-11 Shoulder horizontal adduction, start position.

Figure 13-12 Shoulder horizontal adduction, end position.

Goniometer Placement

- **Axis:** On top of the acromion process.
- **Stationary arm:** To start, the stationary arm is parallel to the longitudinal axis of the humerus on the superior aspect and remains perpendicular to the body as the humerus moves anteriorly.
- **Movable arm:** Parallel to the longitudinal axis of the humerus on the superior aspect.

Possible Substitution

- Trunk rotation and scapular motion.

Internal Rotation (0°–70°)

Rotational movement of the humerus medially or downward toward the ground in the 90° abducted start position around the longitudinal axis of the humerus (Figs. 13-13 and 13-14). Preferably, the zero start position is with the arm abducted to 90° and elbow flexed at 90° with the forearm moving toward the floor from this starting position.

Figure 13-13 Shoulder internal rotation, start position.

Figure 13-14 Shoulder internal rotation, end position.

Goniometer Placement

- **Axis:** Olecranon process of the ulna.
- **Stationary arm:** Perpendicular to the floor, which will be parallel to the lateral trunk if the client is sitting up straight with hips at 90° .
- **Movable arm:** Parallel to the longitudinal axis of the ulna.

Possible Substitutions

- Scapular elevation and downward rotation, trunk flexion, and elbow extension.

External Rotation (0° – 90°)

Rotational movement of the humerus laterally or upward from the ground in the 90° abducted start position around the longitudinal axis of the humerus (Figs. 13-15 and 13-16). Preferably, the zero start position is with the arm abducted to 90° and elbow flexed at 90° with the forearm moving away from the floor from this starting position.

Figure 13-15 Shoulder external rotation, start position.

Figure 13-16 Shoulder external rotation, end position.

Goniometer Placement

- **Axis:** Olecranon process of the ulna.
- **Stationary arm:** Perpendicular to the floor, which will be parallel to the lateral trunk if the client is sitting up straight with hips at 90°.
- **Movable arm:** Parallel to the longitudinal axis of the ulna.

Possible Substitutions

- Scapular depression and upward rotation, trunk extension, and elbow extension.

Internal and External Rotation: Alternative Method

If shoulder limitation prevents positioning for the previously described method, the client may be seated with the humerus adducted to the side and elbow flexed to 90° with forearm in neutral (Figs. 13-17 to 13-19). The American Academy of Orthopedic Surgeons (AAOS)¹⁹ and the American Medical Association (AMA)²⁰ do not provide norms for internal and external rotation in this position. Instead, the examiner measures the maximal possible ROM as available. Because there are no norms for this movement, the measurements are used to measure progress only.

Figure 13-17 Shoulder internal and external rotation, alternative method, start position.

Figure 13-18 Shoulder internal rotation, alternative method, end position.

Figure 13-19 Shoulder external rotation, alternative method, end position.

This method is inaccurate for internal rotation if the UE is obstructed, such as if the client has a large abdomen.

Goniometer Placement

- **Axis:** Olecranon process of the ulna.
- **Stationary arm:** The stationary arm is along the longitudinal axis of the ulna on the inferior surface of the forearm and remains in that position, although the ulna moves away.
- **Movable arm:** Parallel to the longitudinal axis of the ulna and moves toward the abdomen during internal rotation and away from the abdomen during external rotation.

Possible Substitutions

- Trunk rotation, scapular retraction for external rotation, scapular protraction for internal rotation, and shoulder flexion.

Elbow Extension–Flexion (0° – 150°)

Movement of the supinated forearm anteriorly in the sagittal plane (Figs. 13-20 and 13-21).

Figure 13-20 Elbow flexion, start position (elbow extension).

Figure 13-21 Elbow flexion, end position.

Goniometer Placement

- **Axis:** Lateral epicondyle of the humerus.
- **Stationary arm:** Parallel to the longitudinal axis of the humerus on the lateral aspect.
- **Movable arm:** Parallel to the longitudinal axis of the radius.

Forearm Supination (0°–80°)

Rotation of the forearm laterally around its longitudinal axis from midposition so that the palm of the hand faces up (Figs. 13-22 and 13-23). Starting position is with the humerus stabilized against the body, elbow flexed to 90°, and forearm in neutral.

Figure 13-22 Supination, start position.

Figure 13-23 Supination, end position.

Goniometer Placement

- **Axis:** Longitudinal axis of the forearm displaced toward the ulnar side.
- **Stationary arm:** Perpendicular to the floor, which should also be parallel with the humerus if no substitution movements are allowed.
- **Movable arm:** Across the distal radius and ulna on the volar surface.

Possible Substitutions

- Adduction and external rotation of the shoulder.

Forearm Pronation (0°–80°)

Rotation of the forearm medially around its longitudinal axis from neutral so that the palm of the hand faces down (Figs. 13-24 and 13-25).

Figure 13-24 Pronation, start position.

Figure 13-25 Pronation, end position.

Goniometer Placement

- **Axis:** Longitudinal axis of forearm displaced toward the ulnar side.
- **Stationary arm:** Perpendicular to the floor, which should also be parallel with the humerus if no substitution movements are allowed.
- **Movable arm:** Across the distal radius and ulna on the dorsal surface.

Possible Substitutions

- Abduction and internal rotation of the shoulder.

Supination and Pronation: Alternative Method

Although the distal forearm method described here for supination and pronation has been the gold standard, two additional methods (the handheld pencil and plumbline goniometer methods) have shown high interrater and intrarater reliability in a more functional measure of supination and pronation.²¹ The handheld pencil method (Figs. 13-26 to 13-28) can be easily used in the clinic to determine functional forearm rotation. The standardized method is to have the client seated with hips and knees at 90°, feet flat on the ground, arms adducted to the sides with elbow flexed to 90°, and forearm unsupported in neutral. The client holds a standard 15-cm pencil in a tight fist, with the pencil extending from the radial aspect of the hand. The goniometer is aligned with the axis at the head of the third metacarpal, stationary arm perpendicular to the floor, and movable arm parallel to the pencil.

Figure 13-26 Forearm supination and pronation, alternative method, start position.

Figure 13-27 Forearm supination, alternative method, end position.

Figure 13-28 Forearm pronation, alternative method, end position.

Wrist Flexion (Volar Flexion) (0° – 80°)

Movement of the hand volarly in the sagittal plane (Figs. 13-29 and 13-30). Start with the forearm in mid position on a table surface with the wrist in neutral. Keep the digits in a relaxed or an extended position to prevent any negative impact of the tenodesis effect on demonstrating the limits of motion.

Figure 13-29 Wrist flexion, start position.

Figure 13-30 Wrist flexion, end position.

Goniometer Placement

- **Axis:** On the dorsal aspect of the wrist joint in line with the base of the third metacarpal in the proximal capitate region. (*Note:* The lunate protrudes as the wrist is flexed forward, and the capitate is located distal to the lunate and proximal to the base of the third metacarpal.)
- **Stationary arm:** Along the midline of the dorsal surface of the forearm.
- **Movable arm:** Parallel to the longitudinal axis of the third metacarpal.

Wrist Extension (Dorsiflexion) (0°–70°)

Movement of the hand dorsally in the sagittal plane (Figs. 13-31 and 13-32). Again, prevent the tenodesis effect by reminding the client to relax or flex the fingers rather than trying to maintain them in full extension while measuring wrist motion.

Figure 13-31 Wrist extension, start position.

Figure 13-32 Wrist extension, end position.

Goniometer Placement

- **Axis:** On the volar surface of the wrist in line with the palmaris longus tendon in line with the third metacarpal at the level of the carpal bones.
- **Stationary arm:** Along the midline of the volar surface of the forearm.
- **Movable arm:** Parallel to the longitudinal axis of the third metacarpal. The movable arm may need to rest between the third and fourth digits if the digits prevent correct alignment.

Wrist Flexion and Extension: Alternative Method

Although the volar/dorsal method described here for wrist flexion and extension is the preferred method according to the American Society of Hand Therapists (ASHT), a lateral approach (Figs. 13-33 to 13-35) is acceptable if wounds or edema affect goniometer placement.²² Start with the forearm and wrist resting on the table in neutral.

Figure 13-33 Wrist flexion and extension, alternative method, start position.

Figure 13-34 Wrist flexion, alternative method, end position.

Figure 13-35 Wrist extension, alternative method, end position.

Goniometer Placement

- **Axis:** Over the styloid process of the radius, which is located on the lateral aspect of the wrist at the anatomical snuff box.
- **Stationary arm:** Parallel to the longitudinal axis of the radius.
- **Movable arm:** Parallel to the longitudinal axis of the second metacarpal.

Wrist Ulnar Deviation (0°–30°)

Movement of the hand toward the ulnar side in a frontal plane (Figs. 13-36 and 13-37). Starting position is with the forearm pronated on a table surface, wrist in neutral, and fingers extended.

Figure 13-36 Wrist ulnar deviation, start position.

Figure 13-37 Wrist ulnar deviation, end position.

Goniometer Placement

- **Axis:** On the dorsal aspect of the wrist joint in line with the base of the third metacarpal over the capitate bone where the motion is observed.
- **Stationary arm:** Along the midline of the forearm on the dorsal surface. After positioning the client, stabilizing the forearm can assist in isolating motion to the wrist.
- **Movable arm:** Along the midline of the third metacarpal. (*Note:* Do not be distracted by additional abduction of the third digit, and palpate the third metacarpal to ensure alignment.)

Possible Substitutions

- Wrist extension and wrist flexion.

Wrist Radial Deviation (0°–20°)

Movement of the hand toward the radial side in a frontal plane (Figs. 13-38 and 13-39).

Figure 13-38 Wrist radial deviation, start position.

Figure 13-39 Wrist radial deviation, end position.

Goniometer Placement

- **Axis:** On the dorsal aspect of the wrist joint in line with the base of the third metacarpal over the capitate.
- **Stationary arm:** Along the midline of the forearm on the dorsal surface. After positioning the client, stabilizing the forearm can assist in isolating motion to the wrist.
- **Movable arm:** Along the midline of the third metacarpal.

Possible Substitution

- Wrist extension.

Thumb Carpometacarpal Flexion (0°–15°)

Movement of the thumb across the palm in the frontal plane (Figs. 13-40 and 13-41).

Figure 13-40 Thumb carpometacarpal flexion, start position.

Figure 13-41 Thumb carpometacarpal flexion, end position.

Goniometer Placement

- **Axis:** On the radial side of the wrist at the junction of the base of the first metacarpal and the trapezium.
- **Stationary arm:** To achieve proper alignment, place the shorter arm of the goniometer parallel to the longitudinal axis of the radius.
- **Movable arm:** Place the longer arm of the goniometer parallel to the longitudinal axis of the first metacarpal. For accuracy, the arms of the goniometer must remain in full contact with the skin surface over the bones.

Thumb Carpometacarpal Extension/Radial Abduction (0°–50°)

Movement of the thumb away from the palm in the frontal plane (Figs. 13-42 and 13-43).

Figure 13-42 Thumb carpometacarpal extension/radial abduction, start position.

Figure 13-43 Thumb carpometacarpal extension/radial abduction, end position.

Goniometer Placement

- **Axis:** On the dorsal side of the wrist at the junction of the base of the first metacarpal and the trapezium.
- **Stationary arm:** Parallel to the second metacarpal.
- **Movable arm:** Parallel to the first metacarpal.

Thumb Carpometacarpal Extension/Radial Abduction: Alternative Method

See Figures 13-44 and 13-45 for alternative methods.

Figure 13-44 Thumb carpometacarpal extension/radial abduction, alternative method, start position.

Figure 13-45 Thumb carpometacarpal extension/radial abduction, alternative method, end position.

Goniometer Placement

- **Axis:** On the dorsal side of the wrist at the junction of the base of the first metacarpal and the trapezium.
- **Stationary arm:** Parallel to the longitudinal axis of the radius.
- **Movable arm:** Parallel to the longitudinal axis of the first metacarpal.

Thumb Carpometacarpal Abduction/Palmar Abduction (0°–50°)

Movement of the thumb perpendicular to the palm in the sagittal plane (Figs. 13-46 and 13-47).

Figure 13-46 Thumb carpometacarpal abduction/palmar abduction, start position.

Figure 13-47 Thumb carpometacarpal abduction/palmar abduction, end position.

Goniometer Placement

- **Axis:** On the radial side of the wrist at the junction of the base of the first metacarpal and the trapezium.
- **Stationary arm:** On the radial surface parallel to the second metacarpal.
- **Movable arm:** Parallel to the first metacarpal.

Thumb Carpometacarpal Abduction/Palmar Abduction: Alternative Method

See Figures 13-48 and 13-49 for alternative methods.

Figure 13-48 Thumb carpometacarpal abduction/palmar abduction, alternative method, start position.

Figure 13-49 Thumb carpometacarpal abduction/palmar abduction, alternative method, end position.

Goniometer Placement

- **Axis:** On the radial side of the wrist at the junction of the base of the first metacarpal and the trapezium.
- **Stationary arm:** Parallel to the longitudinal axis of the radius.
- **Movable arm:** Parallel to the longitudinal axis of the first metacarpal.

Thumb Metacarpophalangeal Extension–Flexion (0°–50°)

Movement of the thumb across the palm in the frontal plane (Figs. 13-50 and 13-51).

Figure 13-50 Thumb metacarpophalangeal flexion, start position (extension).

Figure 13-51 Thumb metacarpophalangeal flexion, end position.

Goniometer Placement

- **Axis:** On the dorsal aspect of the metacarpophalangeal (MP) joint.
- **Stationary arm:** On the dorsal surface along the midline of the first metacarpal.
- **Movable arm:** On the dorsal surface along the midline of the proximal phalanx of the thumb.

Thumb Interphalangeal Extension–Flexion (0°–80°)

Movement of the distal phalanx of the thumb toward the volar surface of the proximal phalanx of the thumb (Figs. 13-52 and 13-53).

Figure 13-52 Thumb interphalangeal flexion, start position (extension).

Figure 13-53 Thumb interphalangeal flexion, end position.

Goniometer Placement

- **Axis:** On the dorsal aspect of the interphalangeal (IP) joint.
- **Stationary arm:** On the dorsal surface along the proximal phalanx.
- **Movable arm:** On the dorsal surface along the distal phalanx. (*Note:* If the thumbnail prevents full goniometer contact, shift the arms laterally to increase accuracy. Also, thumb MP and IP flexion and extension can be measured on the lateral aspect of the thumb using lateral aspects of the same landmarks.)

Opposition: Ruler Measurements

The pad of the thumb rotates to meet the pad of each finger. The little finger rotates to better meet the pad of the thumb. As a summary measure of opposition, record the distance from the tip of the thumb pad (not the thumbnail) to the tip end of the little finger (Fig. 13-54) or base of the little finger.

Figure 13-54 Measurement of opposition to the little finger using a centimeter ruler.

Finger Metacarpophalangeal Extension–Flexion

See Table 13-1 for ROM norms for fingers. Movement of the finger at the MP joint toward the palmar surface of the hand (Figs. 13-55 and 13-56 and Table 13-1). Hyperextension is normal at this joint.

Figure 13-55 Finger metacarpophalangeal flexion, start position (extension).

Figure 13-56 Finger metacarpophalangeal flexion, end position.

Table 13-1. Range of Motion Norms for Fingers

	INDEX	LONG	RING	SMALL
Metacarpophalangeal flexion	0°–86°	0°–91°	0°–99°	0°–105°
Metacarpophalangeal hyperextension	0°–22°	0°–18°	0°–23°	0°–19°
Proximal interphalangeal flexion	0°–102°	0°–105°	0°–108°	0°–106°
Distal interphalangeal flexion	0°–72°	0°–71°	0°–63°	0°–65°

Goniometer Placement

- **Axis:** On the dorsal aspect of the MP joint of the finger being measured.
- **Stationary arm:** On the dorsal surface along the midline of the metacarpal of the finger being measured.
- **Movable arm:** On the dorsal surface along the midline of the proximal phalanx of the finger being measured.

Finger Metacarpophalangeal Hyperextension

Movement of the finger at the MP joint toward the dorsal surface of the hand (Figs. 13-57 and 13-58 and Table 13-1). The IP joints remain extended.^{19,20}

Figure 13-57 Finger metacarpophalangeal hyperextension, start position.

Figure 13-58 Finger metacarpophalangeal hyperextension, end position.

Goniometer Placement

- **Axis:** On the volar aspect of the MP joint of the finger being measured.
- **Stationary arm:** On the volar surface along the midline of the metacarpal of the finger being measured.
- **Movable arm:** On the volar surface along the midline of the proximal phalanx of the finger being measured.

Finger Proximal Interphalangeal Extension–Flexion

Movement of the middle phalanx toward the palmar surface of the proximal phalanx (Figs. 13-59 and 13-60 and Table 13-1).

Figure 13-59 Proximal interphalangeal flexion, start position (extension).

Figure 13-60 Proximal interphalangeal flexion, end position.

Goniometer Placement

- **Axis:** On the dorsal aspect of the proximal interphalangeal (PIP) joint of the finger being measured.
- **Stationary arm:** On the dorsal surface along the midline of the proximal phalanx of the finger being measured.
- **Movable arm:** On the dorsal surface along the midline of the middle phalanx of the finger being measured.

Finger Distal Interphalangeal Extension–Flexion

Movement of the distal phalanx toward the palmar surface of the middle phalanx (Figs. 13-61 and 13-62 and Table 13-1).

Figure 13-61 Distal interphalangeal flexion, start position (extension).

Figure 13-62 Distal interphalangeal flexion, end position.

Goniometer Placement

- **Axis:** On the dorsal aspect of the distal interphalangeal (DIP) joint of the finger being measured.
- **Stationary arm:** On the dorsal surface along the midline of the middle phalanx of the finger being measured.
- **Movable arm:** On the dorsal surface along the midline of the distal phalanx of the finger being measured. (*Note:* If the fingernail prevents full goniometer contact, shift the arms laterally to increase accuracy. Finger PIP and DIP flexion and extension can be measured from the lateral aspect of each finger using the lateral aspect of the same landmarks. This method may be more accurate when joints are enlarged or when there is diffuse edema noted along the digit.)

Composite Measurement and Recording of Total Finger Flexion

A method of recording composite digital motion used by hand therapists is to sum the values for the degrees of flexion motion of the MP, PIP, and DIP joints, taking into consideration extension deficits.²³ Total active motion (TAM) or total passive motion (TPM) can then be expressed by a single number. The formula for calculating these values is as follows: (MP + PIP + DIP flexion) – (MP + PIP + DIP extension deficits) = TAM or TPM.

Another method for measuring combined flexion of the PIP and DIP joints or combined flexion of the MP, PIP, and DIP joints using a centimeter ruler is illustrated in Figures 13-63 and 13-64.

Figure 13-63 Proximal and distal interphalangeal combined finger flexion; ruler measurement placed at the distal palmar crease.

Figure 13-64 Metacarpophalangeal and proximal and distal interphalangeal combined finger flexion; ruler measurement placed at the proximal palmar crease.

Finger Abduction and Adduction

Movement of the index, ring, and little fingers away from (abduction) (Fig. 13-65) or toward (adduction) the midline of the hand in a frontal plane. The middle finger, which is the midline of the hand, abducts in both radial and ulnar directions.

Figure 13-65 Finger abduction and adduction, ruler measurement.

The AAOS¹⁹ does not provide norms for this movement. Instead, the examiner measures the distance from the tip of the index finger to the tip of the little finger. The distance between individual fingers can be measured from tip to tip also. Because there are no norms for this movement, the measurements are used to measure progress only.

Metacarpophalangeal Deviation Correction Measurement

When there is ulnar deviation deformity of the MP joints, often seen in rheumatoid arthritis, this additional measurement is taken (Figs. 13-66 and 13-67).

Figure 13-66 Metacarpophalangeal deviation correction, start position.

Figure 13-67 Metacarpophalangeal deviation correction, end position.

The AROM is compared with the PROM to determine whether muscle weakness is present. PROM is compared with the norm of 0° deviation to determine whether a fixed deformity exists.

Goniometer Placement

- **Axis:** Over the MP joint of the finger being measured.
- **Stationary arm:** Placed along the dorsal midline of the metacarpal.
- **Movable arm:** Placed along the dorsal midline of the proximal phalanx.

Accuracy

The therapist must place the axis and arms appropriately to ensure accuracy and reliability. The specific placement of the goniometer for each joint is described and demonstrated in this chapter. In

addition to goniometer placement, multiple client-related and environmental factors can affect accuracy and reliability of ROM measurements. Client-related factors include pain, fear of pain, fatigue, and feelings of stress or tension. For the most accurate and reliable results, every effort should be taken to make the client physically and emotionally comfortable, including talking to the client and describing the procedure that is to follow. Environmental factors include time of day, temperature of the room, type of goniometer used, and training and experience of the tester. However, owing to the effect of various factors influencing ROM measurements, clinicians should adopt standardized methods of testing and should interpret and report goniometric results as ROM measurements only, not as measurements of factors that may affect ROM.²⁴

Intrarater reliability is consistently higher than is interrater reliability for ROM testing using a universal goniometer. Intrarater reliability refers to *one* therapist consistently measuring the same joint angle over multiple trials, whereas interrater reliability concerns *multiple* therapists consistently measuring the same joint angle. It is advantageous to have the same therapist measuring a client's ROM repeatedly over time, rather than have multiple therapists, whenever possible.

AROM measurements are more reliable than are PROM ones. PROM measurements have the potential to be less reliable because of variability of the applied force.²⁴ This may be due to the position of the client affecting ROM. Therefore, therapists should record the testing position, and the same position should be used each time the client is retested.²⁵

There are innovative instruments for measuring ROM. Clinicians must evaluate the efficacy and clinical utility of each as they arise. For example, the digital goniometer has adequate concurrent criterion-related validity as a tool for assessment of joint ROM and equivalent interrater and intrarater reliability to the universal goniometer. User surveys indicated that several of the novel features of the digital goniometer contributed to a higher likelihood that the device would be used by clinicians.²⁶ In addition, applications installed on smartphones are becoming more of a viable substitute for using a universal goniometer or an inclinometer. Research has shown that smartphone-based goniometers can yield the same accurate results of angular changes when compared to multiple examiners.²⁷ In another study, smartphone applications and visual inspection measurements of the finger joints with the radiographic measurements determined interrater reliability for these measurement tools agree and correlate well.²⁸ These studies suggest that new smartphone applications hold promise for providing accurate and reliable measures of ROM.

It is commonly believed that experience plays a major role in the reliability of ROM measurements. Increasing amounts of practice is an effective strategy for improving the accuracy of ROM measurements.²⁹ Thus, interrater reliability may be most dependent on practice.

Recording Range of Motion

Depending on the facility, ROM may be documented electronically or on paper, making it a part of the medical record and a legal document. This form should include the date that the measurements were taken, whether the measurements represent AROM or PROM, the starting and ending position for each movement, whether the right versus the left side was tested, and the physical or electronic signature of the therapist performing the measurements. A sample form is provided in Figure 13-68. When reading the goniometer, always state your results as a range using two numbers. The first number is the starting position of the extremity, and the second number is the limit of motion at end range. At reevaluation, compare the initial evaluation measurements to evaluate progress.

Patient's Name _____
 Type of motion: AROM _____
 PROM _____

LEFT		Joint To Be Measured	RIGHT	
Date	Date		Date	Date
Shoulder				
		Flexion	0-180	
		Extension	0-60	
		Abduction	0-180

Figure 13-68 Sample range of motion recording form.

The most common method of determining ROM is the neutral zero method recommended by the Committee on Joint Motion of the AAOS.¹⁹ The ROM normative data presented in this chapter is from the AAOS, as well as the AMA.²⁰ It is important to note that other sources have documented these averages differently, and these sources may be seen in practice as well. In the neutral zero method, the anatomical position is considered to be "0°" (zero start), or if a given starting position is different from anatomical position, it is defined as "0°." Measurement is taken from the stated starting position to the stated end position. If the client cannot achieve the stated starting and end positions, the actual starting and end positions are recorded to indicate limitations in movement. An example using elbow flexion is as follows:

- 0° to 150°: No limitation
- 20° to 150°: A limitation in extension (problem with the start position)
- 0° to 120°: A limitation in flexion (problem with the end position)
- 20° to 120°: Limitations in flexion and extension (problems with start and end positions)

To record hyperextension of a joint, which may be occasionally seen in MP and elbow joints, the AAOS recommends a separate measurement to describe the available ROM without confusion. For example, if 20° of elbow hyperextension (an unnatural movement) is noted, it should be recorded as follows:

0° to 150° of flexion
0° of extension
0° to 20° of hyperextension

If a joint is fused, the starting and end positions are the same, with no ROM. This is recorded as “fused at X°.” If a joint that normally moves in two directions cannot move in one direction, the ROM-limited motion is recorded. For example, if wrist flexion is 15° to 80° with a 15° flexion contracture, the wrist cannot be positioned at zero or be moved into extension; therefore, wrist extension is –15° or a 15° extension lag.

Because there are various systems of notations, each having its own meaning, it is important to clarify the intended meaning to ensure consistency among therapists and physicians within the same facility.

Interpreting the Results

The initial evaluation is interpreted by reviewing the recording form to identify which joints have significant limitation. A significant limitation is one that decreases occupational functioning or may lead to deformity. Limits of motion scores can be used in several ways. The therapist can compare the scores of the involved to the uninvolved extremity. Some ranges of motion are different between dominant and nondominant sides; however, when these differences exist, they are minimal and may not be clinically significant. These results support the practice of using the opposite side of the body as an indicator of movement experienced preinjury or normal extremity ROM.³⁰ Another way in which to assess limitations of motion is to compare the client’s scores with the average limits (norms) expected for each motion. The average limits stated by the Committee on Joint Motion of the AAOS¹⁹ are commonly used and are included in this chapter with the directions for ROM of each joint.

The emphasis in occupational therapy is to enable occupational functioning. It is important to note that clients may be functional with less ROM than is noted in the norms for particular joints. A recent study quantified the motion requirements for the full upper limb and trunk during ADLs in healthy adults.³¹ ROMs found in Gates et al. for the shoulder, elbow, and wrist were similar to those published previously.³² The results of these studies justify clinicians’ comparison of their clients’ ROM with functional norms to evaluate impairments or assess the effects of interventions.

Comparing initial evaluation scores to mid- and posttreatment scores is important to assess the outcome and redirect treatment, if necessary. Interpretation of a reevaluation that shows improvement following treatment must be tempered with the realization that changes may occur because of instrumentation and procedures, differences among joint actions and body regions, passive versus active measurements, intrarater versus interrater measurements, and different client types.²⁴ For example, for ROM measurements to reflect actual change, the amount of change must exceed measurement error, which was found to be 5° for both the UEs and LEs.³³ Thus, an increase of 10° in shoulder flexion is considered an improvement, but 5° may be accounted for by measurement error.

Edema

Volumetric Measurement

Edema is one cause of limited ROM that can be quantified. Volumetric measures document changes in the mass of a body part by use of water displacement and is most often used to measure arm and hand edema. A water vessel that is large enough to allow submersion of the whole hand is used, as shown in Figure 13-69, and one that can be used to assess the whole arm is shown in Figure 13-70. When the limb is placed in the vessel, water is displaced and spills out into a collection beaker via the spout near the top and is then measured with a graduated cylinder. An edematous limb displaces more water than does a limb without swelling, so a lower reading is considered an improvement.

Figure 13-69 Measuring edema of the hand using a volumeter. Note the water being displaced into the graduated beaker as the hand is submerged.

Figure 13-70 Measuring edema of the hand and arm using a volumeter. Note the water being displaced into the graduated beaker as the hand and arm are submerged.

Precaution should be used with volumetry measurements. Immersing the hand in water is sometimes contraindicated, such as with open wounds or skin conditions, immediately postoperatively, with percutaneous pinning and external fixation devices, healing skin grafts, and suspicion of infection. It is also inappropriate if having the extremity in the dependent position during testing significantly increases pain and edema or if spasticity or paralysis impacts the measurement.³⁴

Dodds et al.³⁴ examined therapists' ability to orient the extremity consistently within the volumeter and to measure the displaced water accurately. Following this protocol in the clinic setting, the therapist should follow the steps outlined in Box 13-3.

Box 13-3

Steps for Volumetry Measurements

1. An adjustable table should be set at a height that allows the client to keep the shoulder in neutral position when placing the hand in the volumeter on the tabletop. The therapist should ensure that the volumeter is stable, and the table is level.
2. The volumeter should be filled with room-temperature water to the point of overflow. Any excess water should be wiped out of the collection beaker.
3. The client should be positioned parallel to the volumeter with the volar forearm and palm of the hand facing his or her body. The client should stand to the side of the table that will allow his or her thumb to face the spout of the volumeter.
4. The client should be instructed to note the dowel in the volumeter and slowly lower his or her hand into the volumeter at a rate that allows the water to collect in the beaker below the spout until the web space between the third and fourth digits rests on the dowel and the water stops dripping. Tell the client to avoid touching the sides of the volumeter during the test.
5. The therapist should stand behind the client to support the trunk and prevent any rotation or leaning and can provide verbal cues to the client to prevent excess motion and ensure the hand is properly positioned. Instruct the client to remain silent until the test is complete to avoid motion from talking.
6. After the client removes his or her hand from the volumeter and dries it (provide a towel), the therapist uses the graduated cylinder to measure the amount of displaced water to the nearest 5 mL. The use of a 10-mL micropipette allows the therapist to measure the displaced water to the nearest 1 mL, thereby increasing accuracy. Occasionally, if more water is displaced than the cylinder will hold, multiple graduated cylinders will be needed, or the graduated cylinder must be dried out, and the remaining water measured and added.

To improve the reliability of volumetric measurement, modifications to the abovementioned instructions can include measurement of displaced water volume by means of a digital scale, utilization of a 3D anatomical marking system, and repositioning of the overflow spout and addition of a flow gate to a standard volumetric tank.³⁵

If edema is found to be present, the short-term goal of treatment may be to decrease edema more than 10 mL, which is more than the standard error of measurement of less than 3 mL. However, it is important to remember the reasoning behind wanting the decrease in edema. The entire short-term goal may be written as, "The client will demonstrate a 10-mL decrease in volumeter measurement of edema of the right hand in order to increase hand function with dressing tasks."

Circumferential Measurement

Another method of measuring edema is the circumferential assessment. Volumetric and circumferential measurements have been found to be positively correlated.³⁶ A millimeter tape is used to measure the circumference of a body part not easily submerged (as required by volumetric measurement) or when the edema is very localized (such as to a single digit, making measurement of the entire hand unnecessary). With circumferential measurements (see Fig. 13-71 for an example of circumferential measurement), it is essential to measure at exactly the same place from test to test. Using anatomical landmarks can assist in the placement, such as over the third digit PIP joint or 5 cm proximal to the ulnar styloid.

Figure 13-71 Measuring edema using circumferential method.

Another method of measuring edema circumferentially is the figure-of-eight technique³⁷ (see Fig. 13-72). This method is typically used to measure the whole hand and is based on the understanding that edema of the hand tends to collect more dorsally. Using a 1/4-inch-wide tape measure with the wrist in neutral and fingers adducted, the tape is started at the medial aspect of the wrist just distal to the ulnar styloid. The tape is then run across the volar surface of the wrist to the most distal point of the radial styloid and then run diagonally across the dorsum of the hand to the fifth MP joint. The tape is then run across the heads of the metacarpals to the second MP joint and then back across the dorsum of the hand to the starting point. The measurement recorded is the distance measured by the tape in centimeters.

Figure 13-72 Measuring edema of the hand using the figure-of-eight method.

The figure-of-eight measurement technique may be especially appropriate when volumetry is contraindicated. Volumetry has been correlated with the figure-of-eight method³⁸; however, the figure-of-eight method is easier to use, more time efficient, and cost-effective, particularly in the intensive care unit setting.

The perometer (see Fig. 13-73) is an optoelectronic automated method of measuring UE edema and has been shown to be a quick, hygienic, and a less operator-dependent method of limb volume assessment.^{39,40} It is similar to computer-assisted tomography, but uses infrared beams to rapidly and automatically estimate limb volume. The volume of any part of the limb can be measured, the shape of the limb or limb segment can be displayed, and accurate calculations of change in volume can be made in seconds.⁴⁰ This automated method of measuring limb volume is a useful alternative in suitable clients in clinical and research applications.³⁹

Figure 13-73 Perometer. (Picture courtesy of Pero-System Messgeraete.)

Typically, to interpret edema measurements, comparisons are made between the assessments of right and left limbs. It has been an accepted practice to assume that limbs are symmetrical or at least identical in volume. In fact, for the specific diagnosis of lymphedema, only a 2-cm circumferential difference or 200-mL limb volume difference must be noted.⁴¹ When this assumption is challenged and the potential of asymmetry is considered, the next assumption is that the dominant limb is larger than the nondominant limb—with limb volume difference sometimes estimated to be up to 200 mL due to dominance.⁴⁰ Continued bilateral measurements over time are necessary to properly assess a limb volume change during follow-up evaluations, because it is important for documenting therapeutic progress.

Scar Tissue

Scar tissue, particularly scars that cross joints or run along tendons, can significantly impact motion. All wounds will heal with scar tissue, but not all scar tissue will impact motion. The size, color, and pliability of any wounds or scars should be described⁴² with regard to how they affect joint motion during initial and subsequent evaluations. Typically, by manipulating the scar tissue with the fingers and pinching the skin around the scar, a therapist can determine whether any significant scar adhesions exist. Skin puckering around the scar with motion can also be a sign of adhesions. Adhesions will contribute to decreased ROM around a joint.

Muscle Strength Measurement

Muscular strength is the ability to perform activities that require high levels of muscular force—a key component of muscular fitness.⁴³ Weakness is a lack or reduction of the power in a muscle or muscle group. When weakness limits or impairs the individual's occupational functioning, determining the degree and distribution of weakness to establish an appropriate intervention plan is necessary. Treatment can be focused on remediating the weakness, or it can focus on alternative ways of accomplishing the task (compensation). Weakness can manifest in several forms. It can be general, such as being deconditioned after an illness, or it can be local, such as with a peripheral nerve lesion. In the former case, muscles throughout the body are assessed; in the latter case, just the muscles innervated by the involved nerve are tested. In both cases, the muscles to be tested are the ones contributing to the functional limitations on which treatment will focus.

A **maximum voluntary contraction (MVC)**, the maximum amount of tension that can be produced under voluntary control, is commonly used to measure strength.⁴⁴ Because muscle testing is a measurement of voluntary contraction of an isolated muscle or a muscle group, strength testing is inappropriate for clients who lack the ability to contract a single muscle or a muscle group in isolation such as clients who exhibit patterned movement. For example, clients who have a difference in muscle strength due to a central nervous system event such as a stroke may exhibit patterned movement from hypertonicity. This results in a change in muscle tone that should not be tested with traditional MMT. That is, an increase in involuntary muscle tone cannot be equated with voluntary muscle contraction.

In this chapter, a technique called the “break test” is used. In the break test, the muscle to be tested is positioned at its greatest mechanical advantage and then an external force is applied. Once the extremity is positioned, the client is asked to hold the position as the tester imparts external force (i.e., his or her hand and own strength) to overcome the contractile force of the muscle or muscle group. Resistance applied at the end of the tested range is termed a *break test*. Resistance applied throughout the range is termed a *make test*.⁴⁵ The results of the strength testing differ depending on the method used. The isometric hold (break test) shows the muscle to have a higher test grade than does the resistance given throughout the range (make test). The make/break tests are both useful for assessing muscle strength and of being relatively comparable to the routine clinical strength examination.⁴⁶

The therapist must ensure that providing resistance is not contraindicated by the diagnosis or the surgeon's orders for therapy. For example, putting resistance against a client with a healing fracture, following various surgeries such as tendon or nerve repairs, after chest/heart/lung surgery, initially after myocardial infarction, where there is a history of bone metastasis, or after recent back/neck surgery is contraindicated. Precautions should also be taken with various neurodegenerative disorders so as not to stress fatigued or weakened muscles.

The term *mechanical advantage* refers to the length–tension relationship of a muscle. The passive tension exerted by the elastic components in the lengthened muscle and surrounding tissue and the active tension generated by the contractile elements of the contracting muscle contribute to the total

tension of a muscle.⁴⁷ A muscle is able to generate its greatest total tension or sustain the heaviest load when positioned at a length that gives it optimal mechanical advantage. This is usually slightly (10%) longer than resting length. Developed (active) tension, which is the total tension minus the elastic contribution, is greatest at resting length but decreases as the muscle shortens or lengthens. The length–tension principle is used to elicit the best response from prime movers, or muscles that have the sole or principle responsibility of the action, during muscle testing. Furthermore, this principle is used to reduce the contribution of synergist muscles (i.e., muscles that contribute to similar movements) when testing the prime mover (i.e., a muscle that contributes the most to a specific movement). Synergist muscles are placed at a mechanical disadvantage (either lengthened or shortened), whereas the prime mover is asked to resist the applied force.⁴⁷ For muscles or muscle groups too weak to resist an external force, muscle strength is evaluated by isotonic contraction, in which the muscle is required to move the mass of the body part against gravity without applied resistance or with the effect of gravity decreased.^{48,49}

Gravity as resistance is considered an important variable and is used to test all motions when practical. Standard procedures for evaluation against gravity and with gravity eliminated are described in this chapter. Tests of the UE described here, for the most part, are motion tests for the purpose of evaluating strength in terms of functional ability. Tests of individual muscles in the wrist and hand are included because of the often increased responsibility of the occupational therapist in the rehabilitation of hand injuries. The specific movements of the face, head, neck, and trunk are important in the assessment of some clients; however, these movements are usually assessed as a whole for functional activities in many clients. Information on details of measuring these movements can be found in references listed at the end of this chapter.

Before the start of MMT, a ROM screen should be done to determine what ROM is available at each joint. Although the available range is considered to be full ROM for the purposes of muscle testing, notation should be made of any limitation. The muscle or muscle group is assigned a grade according to the amount of resistance it can take. Two grading systems are presented here: Table 13-2 equates the Medical Research Council⁵⁰ Oxford system with a descriptive grading system.⁵¹

Table 13-2. Muscle Testing Grading System

NUMERICAL GRADE	DESCRIPTIVE GRADE	DEFINITION
5	Normal	The part moves through full ROM against gravity and takes maximal resistance.
4	Good	The part moves through full ROM against gravity and takes moderate resistance.
4–	Good minus	The part moves through full ROM against gravity and takes less than moderate resistance.
3+	Fair plus	The part moves through full ROM against gravity and takes minimal resistance before it breaks.
3	Fair	The part moves through full ROM against gravity and is unable to take any added resistance.
3–	Fair minus	The part moves less than full range of motion against gravity.
2+	Poor plus	The part moves through full ROM in a gravity-eliminated plane, takes minimal resistance, and then breaks.
2	Poor	The part moves through full ROM in a gravity-eliminated plane with no added resistance.
2–	Poor minus	The part moves less than full ROM in a gravity-eliminated plane, no resistance.
1	Trace	Tension is palpated in the muscle or tendon, but no motion occurs at the joint.
0	Zero	No tension is palpated in the muscle or tendon, and no motion occurs.

ROM, range of motion.

The sequence of steps for testing every muscle or muscle group to ensure reliability and accuracy is outlined in Box 13-4.

Box 13-4

Steps for Testing Every Muscle or Muscle Group

1. Explain the procedure and demonstrate the desired movement.
2. Position the client so that the direction of movement will be against gravity.
3. Stabilize proximal to the joint that will move to prevent substitutions.

4. Instruct the client to move actively to the end position. If the client cannot move actively against gravity, place the client in a gravity-eliminated position, and ask him or her to move actively in this position.
5. If the client can move actively against gravity, tell the client to hold the contraction at the desired position.
6. Apply resistance:
 - a. to the distal end of the segment into which the muscle inserts
 - b. in the direction the movement came from
 - c. by starting with light resistance and increasing to maximal resistance over a 2- to 3-second period
7. Palpate over the prime mover to determine whether the muscle is contracting or whether gravity and/or synergistic muscles are substituting.
8. Record the appropriate grade according to the resistance tolerated before the muscle broke or by the amount of movement achieved without resistance in an against-gravity or gravity-eliminated position.

There are additional considerations when performing an MMT. First, although fatigue differs for each person and each muscle, a rest of 2 minutes between maximum effort contractions of the same muscle is considered adequate.⁵² Second, for the comfort and convenience of the client, all testing in one position is done before the client changes to another position.

To clarify among other systems, the scale proposed by the Medical Research Council (MRC) uses the numeral grades 0 to 5,⁵⁰ Kendall and McCreary use percentages,⁴⁹ and Daniels and Worthingham use differentiation between Normal, Good, Fair, Poor, Trace, and Zero.⁴⁸ In modified versions of the MRC scale, ROM is defined because it can be quantified more easily than resistance, even in clinical routine.⁵³ Another method to reflect muscle strength in general is to add together multiple measures from the MRC-sumscore which has excellent interrater reliability and is more easily assessed and sensitive when clients are bedridden or have significantly limited potential for movement.⁵⁴

Manual Muscle Testing of the Upper Extremity

On the pages that follow, the reader will find narrative and pictorial descriptions to help in understanding and practicing measurement of UE strength.

Scapular Elevation

Prime Movers

Upper trapezius and levator scapulae.

Against-Gravity Position

- **Start position:** Client sitting erect with arms relaxed at side.
- **Stabilize:** Trunk is stabilized against the chair back.
- **Instruction:** "Lift your shoulders toward your ears like you are shrugging. Do not let me push them down."
- **Resistance:** The therapist places his or her hands over each acromion and pushes down toward scapular depression.
- **Substitution:** It could appear that the client's shoulders are elevated if he or she places hands on legs to push the shoulders into elevation (Fig. 13-74).

Figure 13-74 Scapular elevation against gravity.

Gravity-Eliminated Position

- **Start position:** Prone with arms at side and therapist supporting under the shoulder.
- **Stabilize:** The trunk is stabilized against the mat or plinth.
- **Instruction:** “Lift your shoulder toward your ear.”
- **Palpation:** The upper trapezius is palpated on the shoulder at the curve of the neck (Fig. 13-75). The levator scapula is palpated posterior to the sternocleidomastoid on the lateral side of the neck.

Figure 13-75 Scapular elevation, gravity eliminated.

Scapular Depression

Prime Movers

Lower trapezius and latissimus dorsi.

Resistance Test

- **Start position:** This movement is tested in a gravity-eliminated position because the client cannot be positioned to move against gravity. The client lies prone with arms by the sides.
- **Stabilize:** The trunk is stabilized by the mat or plinth.
- **Instruction:** “Reach your hand down toward your feet.”
- **Resistance:** The therapist’s hand cups the inferior angle of the scapula; the therapist pushes up toward scapular elevation. When the inferior angle is not easily accessible because of tissue bulk, apply resistance at the distal humerus if the shoulder joint is stable and pain free.
- **Palpation:** Palpate the lower trapezius lateral to the vertebral column as it passes diagonally from the lower thoracic vertebrae to the spine of the scapula (Fig. 13-76). Palpate the latissimus dorsi along the posterior rib cage or in the posterior axilla as it attaches to the humerus.

Figure 13-76 Scapular depression.

Scapular Adduction/Retraction

Prime Movers

Middle trapezius and rhomboids.

Against-Gravity Position for the Middle Trapezius

- **Start position:** Prone with the shoulder abducted to 90° and externally rotated with the elbow flexed to 90°. Head is turned to contralateral side.
- **Stabilize:** The trunk is stabilized against the mat or plinth.
- **Instruction:** “Raise your elbow toward the ceiling. Do not let me push it down.”
- **Resistance:** Apply resistance laterally at the vertebral border of the scapula or, if the shoulder is stable and pain free, apply resistance downward at the distal humerus (Fig. 13-77).

Figure 13-77 Scapular adduction against gravity, test for middle trapezius.

Against-Gravity Position for the Rhomboids

- **Start position:** Prone on the mat with the shoulder internally rotated and with the back of the hand resting on the lumbar region.
- **Stabilize:** The trunk is stabilized against the mat or plinth.
- **Instruction:** “Lift your hand off of your back. Do not let me push it down.”
- **Resistance:** Apply downward resistance against the distal humerus or, if the shoulder is unstable or painful, against the vertebral border of the scapula in the direction of scapular abduction (Fig. 13-78).

Figure 13-78 Scapular adduction against gravity, test for rhomboids.

Gravity-Eliminated Position for the Middle Trapezius and Rhomboids

- **Start position:** Sitting erect with the humerus abducted to 90° and supported.
- **Stabilize:** The trunk is stabilized by the chair. Note a table or the therapist’s arm can be used to support the arm of the individual being tested.
- **Instruction:** “Try to move your arm backward.”
- **Grading:** If the scapula moves toward the spine, give a grade of 2. If no movement is noted, palpate the scapular adductors.

- **Palpation:** Palpate the middle trapezius between the vertebral column and vertebral border of the scapula at the level of the spine of the scapula (Fig. 13-79). Palpate the rhomboids along the vertebral border of the scapula near the inferior angle. The rhomboids are located deep to the trapezius and cannot be easily palpated in the gravity-eliminated position. Positioning of the hand in the small of the back allows the trapezius to remain relaxed so the rhomboids can be palpated.

Figure 13-79 Scapular adduction, gravity eliminated. The therapist is pointing to the middle trapezius.

Scapular Abduction/Protraction

Prime Mover

Serratus anterior.

Against-Gravity Position

- **Start position:** Supine with the humerus flexed to 90°. The elbow may be flexed or extended.
- **Stabilize:** The trunk is stabilized on the mat or plinth.
- **Instruction:** “Reach your arm toward the ceiling.”
- **Resistance:** Resist this motion by grasping the distal humerus or by cupping the hand over the client’s elbow and pushing down toward scapular adduction. If the glenohumeral joint is unstable or painful, resistance should be applied along the axillary border of the scapula (Fig. 13-80).

Figure 13-80 Scapular abduction against gravity.

Gravity-Eliminated Position

- **Start position:** Sitting erect with the humerus flexed to 90° and supported.
- **Stabilize:** The trunk is stabilized against the chair.
- **Instruction:** “Try to reach your arm forward.”
- **Grading:** Movement of the scapula into abduction receives a grade of 2. If no movement occurs, palpate the serratus anterior.
- **Palpation:** Palpate the serratus anterior on the lateral ribs just lateral to the inferior angle of the scapula.
- **Substitution:** In the gravity-eliminated position, this motion can be achieved by inching the arm forward on a supportive surface using the fingers (Fig. 13-81).

Figure 13-81 Scapular abduction, gravity eliminated.

Shoulder Flexion

Prime Movers

Anterior deltoid, coracobrachialis, pectoralis major (clavicular head), and biceps brachii.

Against-Gravity Position

- **Start position:** Sitting in a chair with the arm down at the side. Forearm in pronation to prevent substitution of the biceps brachii.
- **Stabilize:** Over the clavicle and the scapula.
- **Instruction:** “Lift your arm in front of you to shoulder height. Do not let me push it down.”
- **Resistance:** The therapist’s hand, placed over the distal end of the humerus, pushes down toward extension. Movement above 90° involves scapular rotation; these motions are separated for muscle testing, although they are not separated for ROM measurement.
- **Substitutions:** Shoulder abductors, scapular elevation, or trunk extension (Fig. 13-82).

Figure 13-82 Shoulder flexion against gravity.

Gravity-Eliminated Position (Fig. 13-83)

Figure 13-83 Shoulder flexion, gravity eliminated.

- **Start position:** Lying on the side with the arm along the side of the body in neutral position; therapist supports the arm under the elbow.
- **Instruction:** “Try to move your arm so your hand is at the level of your shoulder.”
- **Palpation:** Palpate the anterior deltoid immediately anterior to the glenohumeral joint (Fig. 13-83). The coracobrachialis is too deep to easily palpate. The pectoralis major may be palpated below the clavicle, just medial to the anterior deltoid.

Shoulder Extension

Prime Movers

Latissimus dorsi, teres major, and posterior deltoid.

Against-Gravity Position

- **Start position:** Sitting with the arm by the side and the humerus internally rotated (palm facing posteriorly).
- **Stabilize:** Over the clavicle and scapula; make sure the client remains upright.
- **Instruction:** “Move your arm straight back as far as it will go. Keep your palm facing behind you.”
- **Resistance:** The therapist’s hand, placed over the distal end of the humerus, pushes forward toward flexion.
- **Substitutions:** Shoulder abductors, anterior tilting of the shoulder, and trunk flexion (Fig. 13-84).

Figure 13-84 Shoulder extension against gravity.

Gravity-Eliminated Position (Fig. 13-85)

Figure 13-85 Shoulder extension, gravity eliminated.

- **Start position:** Lying on the side with the arm along the side of the body and in internal rotation. Therapist supports the elbow during the motion.
- **Instruction:** “Try to move your arm backward.”

- **Palpation:** The latissimus dorsi and teres major form the posterior border of the axilla (Fig. 13-85). The latissimus dorsi is inferior to the teres major. The posterior deltoid is immediately posterior to the glenohumeral joint.

Shoulder Abduction

Prime Movers

Supraspinatus and middle deltoid.

Against-Gravity Position

- **Start position:** Sitting erect with the arm down at the side and in neutral position.
- **Stabilize:** Over the clavicle and the scapula.
- **Instruction:** “Raise your arm out to the side to shoulder level. Do not let me push it down.”
- **Resistance:** The therapist’s hand, placed over the distal end of the humerus, pushes the humerus down toward the body. Movement above 90° involves scapular rotation and is not measured.
- **Substitutions:** The long head of the biceps can substitute if the humerus is allowed to move into external rotation; trunk lateral flexion (Fig. 13-86).

Figure 13-86 Shoulder abduction against gravity.

Gravity-Eliminated Position

- **Start position:** Supine with the arm supported at the side in neutral position. The therapist supports the elbow during the motion.
- **Instruction:** “Try to move your arm out to the side.”
- **Palpation:** The supraspinatus lies too deep for easy palpation. Palpate the middle deltoid below the acromion and lateral to the glenohumeral joint (Fig. 13-87).

Figure 13-87 Shoulder abduction, gravity eliminated.

Shoulder Adduction

Prime Movers

Pectoralis major, teres major, and latissimus dorsi.

Gravity-Eliminated Position

The client cannot be positioned for this motion against gravity.

- **Start position:** Supine with the humerus abducted to 90° and the forearm in midposition.
- **Stabilize:** The trunk is stabilized by the mat.
- **Instruction:** “Bring your arm down to your side, and do not let me pull it away.”
- **Resistance:** The therapist’s hand, placed on the medial side of the distal end of the humerus, attempts to pull the humerus away from the client’s body.
- **Palpation:** The pectoralis major forms the anterior border of the axilla, where it may be easily palpated (Fig. 13-88). The latissimus dorsi and teres major form the posterior border of the axilla. The latissimus dorsi is inferior to the teres major.

Figure 13-88 Shoulder adduction.

- **Grading:** Antigravity grades can only be estimated; a question mark should be indicated in documentation. With experience, the therapist develops the skill to estimate reliably.
- **Substitutions:** On a supporting surface, the arm can be adducted with the use of the fingers.

Shoulder Horizontal Abduction

Prime Movers

Posterior deltoid, teres minor, and infraspinatus.

Against-Gravity Position

- **Start position:** Prone with the humerus abducted to 90° and supported by the mat. The elbow is flexed to 90° and is hanging over the edge of the table.
- **Stabilize:** The scapula and trunk are stabilized by the mat. Counterpressure over the contralateral scapula is helpful during action and resistance.
- **Instruction:** “Raise your elbow toward the ceiling.”
- **Resistance:** The therapist’s hand, placed on the posterior surface of the distal end of the humerus, pushes the arm down toward horizontal adduction (Fig. 13-89).

Figure 13-89 Shoulder horizontal abduction against gravity.

Gravity-Eliminated Position

- **Start position:** Sitting in a chair with the humerus supported in 90° of flexion and the elbow straight. The therapist supports the elbow.
- **Stabilize:** The trunk is stabilized against the back of the chair.
- **Instruction:** “Try to move your arm out to the side.”
- **Palpation:** Palpate the posterior deltoid immediately posterior to the glenohumeral joint.
- **Substitution:** Trunk rotation (Fig. 13-90).

Figure 13-90 Shoulder horizontal abduction, gravity eliminated.

Shoulder Horizontal Adduction

Prime Movers

Pectoralis major and anterior deltoid.

Against-Gravity Position

- **Start position:** Supine with the humerus abducted to 90° in neutral rotation and the elbow extended.
- **Stabilize:** The table stabilizes the scapula and trunk. If the elbow extensors are weak, be sure to support the distal end of the forearm so the hand does not fall into the client's face during horizontal adduction.
- **Instruction:** "Move your arm in front of you and across your chest."
- **Resistance:** The therapist's hand, placed on the anterior surface of the distal end of the humerus, pulls the arm out toward horizontal abduction (Fig. 13-91).

Figure 13-91 Shoulder horizontal adduction against gravity.

Gravity-Eliminated Position

- **Start position:** Sitting in a chair with the arm abducted to 90°.
- **Stabilize:** The trunk is stabilized against the back of the chair. The therapist supports the arm under the elbow.
- **Instruction:** “Try to bring your arm across your chest.”
- **Palpation:** Palpate the pectoralis major along the anterior border of the axilla. The anterior deltoid is immediately anterior to the glenohumeral joint below the acromion process and superior to the pectoralis major (Fig 13-92).

Figure 13-92 Shoulder horizontal adduction, gravity eliminated.

- **Substitution:** Trunk rotation.

Shoulder External Rotation

Prime Movers

Infraspinatus, teres minor, and posterior deltoid.

Against-Gravity Position

- **Start position:** Prone with the humerus abducted to 90° and supported by the mat. A towel roll may be placed at the distal humerus for support to increase comfort. The elbow is flexed to 90° and is hanging over the edge of the table.
- **Stabilize:** The humerus is held just proximal to the elbow to allow only rotation.
- **Instruction:** “Lift the back of your hand toward the ceiling.”
- **Resistance:** The therapist’s hand, placed on the dorsal surface of the distal end of the forearm, pushes toward the floor. The therapist’s other hand keeps the client’s elbow supported and flexed to 90° to prevent supination.
- **Substitutions:** Scapula adduction combined with downward rotation can substitute. The triceps may substitute when resistance is applied (Fig. 13-93).

Figure 13-93 Shoulder external rotation against gravity.

Gravity-Eliminated Position

- **Start position:** Prone with the entire arm hanging over the edge of the mat. The arm is in internal rotation.
- **Stabilize:** The trunk and scapula are stabilized on the mat.
- **Instruction:** “Try to turn your palm outward.”
- **Palpation:** Palpate the infraspinatus inferior to the spine of the scapula (Fig. 13-94). The posterior deltoid can be palpated immediately posterior to the glenohumeral joint, as previously described. Palpate the teres minor between the posterior deltoid and the axillary border of the scapula; it is superior to the teres major.

Figure 13-94 Shoulder external rotation, gravity eliminated.

- **Substitution:** Supination may be mistaken for external rotation in a gravity-eliminated position.

Alternative Gravity-Eliminated Position

- **Start position:** Sitting in a chair with the humerus adducted to the side and the elbow flexed to 90°.
- **Stabilize:** The distal end of the humerus is held against the body to allow only rotation.
- **Instruction:** “Try to move the back of your hand out to the side.”
- **Palpation:** Same as previously described.
- **Substitutions:** Trunk rotation, scapular adduction, and elbow extension (Fig. 13-95).

Figure 13-95 Shoulder external rotation, alternative position (shoulder adducted) with gravity eliminated.

Shoulder Internal Rotation

Prime Movers

Subscapularis, teres major, latissimus dorsi, pectoralis major, and anterior deltoid.

Against-Gravity Position

- **Start position:** Prone with the humerus abducted to 90° and supported by the mat. A towel roll may be placed at the distal humerus for support to increase comfort. The elbow is flexed to 90° and hangs over the edge of the mat.
- **Stabilize:** The humerus is held just proximal to the elbow to allow only rotation.
- **Instruction:** “Lift the palm of your hand toward the ceiling.”
- **Resistance:** The therapist’s hand, placed on the volar surface of the distal end of the forearm, pushes toward the floor. The therapist’s other hand keeps the client’s elbow supported and flexed to 90° to prevent supination.
- **Substitutions:** Scapular abduction combined with upward rotation can substitute. The triceps can substitute as in external rotation (Fig. 13-96).

Figure 13-96 Shoulder internal rotation against gravity.

Gravity-Eliminated Position

- **Start position:** Prone with the entire arm hanging over the edge of the mat. The arm is in external rotation.
- **Stabilize:** The trunk and scapula are stabilized by the mat.
- **Instruction:** “Try to turn your palm inward.”
- **Palpation:** The subscapularis is not easily palpated but may be found in the posterior axilla; otherwise, palpate the pectoralis major at the anterior border of the axilla.
- **Substitutions:** Scapular abduction combined with upward rotation can substitute. Pronation may be mistaken for internal rotation in a gravity-eliminated position (Fig. 13-97).

Figure 13-97 Shoulder internal rotation, gravity eliminated.

Alternative Gravity-Eliminated Position

- **Start position:** Sitting in a chair with the humerus adducted to the side and the elbow flexed to 90°.
- **Stabilize:** The distal end of the humerus is held against the body to allow only rotation.
- **Instruction:** “Try to move the palm of your hand in toward your stomach.”
- **Palpation:** Same as previously described.
- **Substitutions:** Scapular protraction, trunk rotation (Fig. 13-98).

Figure 13-98 Shoulder internal rotation, alternative position (shoulder adducted) with gravity eliminated.

Elbow Flexion

Prime Movers

Biceps brachii, brachialis, and brachioradialis.

Against-Gravity Position

- **Start position:** Sitting in a chair with the arm at the side. The position of the forearm determines which muscle is working primarily: (1) forearm in supination, biceps; (2) forearm in pronation, brachialis; and (3) forearm in neutral, brachioradialis.
- **Stabilize:** Stabilize the distal end of the humerus during the action. While applying resistance, provide counterpressure at the front of the shoulder.
- **Instruction:** While the client is in each of the three forearm positions, say, “Bend your elbow, and do not let me pull it back down.”
- **Resistance:** For each of the three positions, the therapist’s hand is placed on the distal end of the forearm and pulls out toward extension (Fig. 13-99).

Figure 13-99 Elbow flexion against gravity.

Gravity-Eliminated Position

- **Start position:** Sitting with the arm supported by the therapist in 90° of abduction and elbow extension. The position of the forearm determines which muscle is working, as described earlier.
- **Stabilize:** Distal humerus.
- **Instruction:** “Try to bend your elbow.”
- **Palpation:** The biceps is easily palpated on the anterior surface of the humerus (Fig. 13-100). With the forearm pronated, palpate the brachialis just medial to the distal biceps brachii tendon. With the forearm in neutral, palpate the brachioradialis along the radial side of the proximal forearm.

Figure 13-100 Elbow flexion, gravity eliminated.

- **Substitution:** In a gravity-eliminated plane, the wrist flexors may substitute.

Elbow Extension

Prime Mover

Triceps brachii.

Against-Gravity Position

- **Start position:** Prone with humerus abducted to 90° and supported on the table. The elbow is flexed, and the forearm is hanging over the edge of the table.
- **Stabilize:** Support the arm under the anterior surface of the distal humerus.
- **Instruction:** “Straighten your arm, and do not let me push it back down.”
- **Resistance:** Apply resistance with the elbow at 10° to 15° less than full extension so that the elbow does not lock into position. The therapist’s hand, placed on the dorsal surface of the client’s forearm, pushes toward flexion (Fig. 13-101).

Figure 13-101 Elbow extension against gravity.

Gravity-Eliminated Position

- **Start position:** Sitting with the humerus supported by the therapist in 90° of abduction. The elbow is fully flexed.
- **Stabilize:** The humerus is supported and stabilized.
- **Instruction:** “Try to straighten your elbow.”
- **Palpation:** The triceps is easily palpated on the posterior surface of the humerus.
- **Substitutions:** In the gravity-eliminated position, no external rotation of the shoulder is permitted, so as to avoid letting the assistance of gravity produce extension (Fig. 13-102).

Figure 13-102 Elbow extension, gravity eliminated.

Pronation

Prime Movers

Pronator teres and pronator quadratus.

Against-Gravity Position

- **Start position:** Sitting with the humerus adducted, elbow flexed to 90°, and forearm supinated. The wrist and fingers are relaxed.
- **Stabilize:** The distal humerus is stabilized to keep it adducted to the body.
- **Instruction:** “Turn your palm to the floor, and do not let me turn it back over.”
- **Resistance:** The therapist’s hand encircles the client’s volar wrist, with the therapist’s index finger extended along the forearm. The therapist applies resistance in the direction of supination. An alternate method of applying resistance is to position the distal forearm between the therapist’s opposing palms. The therapist applies resistance in the direction of supination.
- **Substitutions:** Shoulder abduction or internal rotation; wrist and finger flexors may substitute (Fig. 13-103).

Figure 13-103 Pronation against gravity.

Gravity-Eliminated Position

- **Start position:** Sitting with the humerus flexed to 90° and supported. The elbow is flexed to 90°, and the forearm is in full supination. The wrist and fingers are relaxed.
- **Stabilize:** The humerus is stabilized.
- **Instruction:** “Try to turn your palm away from your face.”
- **Palpation:** The pronator teres is palpated medial to the distal attachment of the biceps tendon on the volar surface of the proximal forearm. The pronator quadratus is too deep to palpate (Fig. 13-104).

Figure 13-104 Pronation, gravity eliminated.

Supination

Prime Movers

Supinator and biceps brachii.

Against-Gravity Position

- **Start position:** Sitting with the humerus adducted, elbow flexed to 90°, and forearm pronated. The wrist and fingers are relaxed. (*Note:* To differentiate the supinator from the supination function of the biceps, isolate the supinator by extending the elbow. The biceps does not supinate the extended arm unless resisted.)⁴⁹
- **Stabilize:** The distal humerus is stabilized.
- **Instruction:** “Turn your palm up toward the ceiling, and do not let me turn it back over.”
- **Resistance:** The therapist’s hand encircles the client’s volar wrist, with the therapist’s index finger extended along the forearm. The therapist applies resistance in the direction of pronation. An alternate method of applying resistance is to position the distal forearm between the therapist’s opposing palms. The therapist applies resistance in the direction of pronation.
- **Substitutions:** Shoulder adduction or external rotation; wrist and finger extensors may substitute (Fig. 13-105).

Figure 13-105 Supination, against gravity.

Gravity-Eliminated Position

- **Start position:** Sitting with the humerus flexed to 90° and supported. The elbow is flexed to 90°, and the forearm is in full pronation. The wrist and fingers are relaxed.
- **Stabilize:** The humerus is stabilized and supported.
- **Instruction:** “Try to turn your palm toward your face.”
- **Palpation:** The supinator is palpated on the dorsal surface of the proximal forearm just distal to the head of the radius. The biceps brachii is easily palpated on the anterior surface of the humerus (Fig. 13-106).

Figure 13-106 Supination, gravity eliminated.

Wrist and Hand Measurement

Because many tendons of the wrist and hand cross more than one joint, test positions for individual muscles must include ways to minimize the effect of other muscles crossing the joint. In general, to minimize the effect of a muscle, place it opposite the prime action. For example, to minimize the effect of the extensor pollicis longus (EPL) on extension of the proximal joint of the thumb, flex the distal joint.

Wrist Extension

Prime Movers

Extensor carpi radialis longus (ECRL), extensor carpi radialis brevis (ECRB), and extensor carpi ulnaris (ECU).

Against-Gravity Position

- **Start position:** The forearm is supported on a table in full pronation with fingers and thumb relaxed or slightly flexed. The hand may hang over the edge of the table.
- **Stabilize:** The forearm is stabilized on the table.
- **Instruction:** “Lift your wrist as far as you can, and keep your fingers relaxed. Do not let me push it down.”
- **Resistance:** Apply resistance to the distal metacarpals of the fingers toward flexion. Muscles individually as follows: To test the ECRL and ECRB, which extend and radially deviate, apply resistance to the dorsum of the hand on the radial side in the direction of flexion and ulnar deviation. To test the ECU, which extends and ulnarly deviates, apply resistance to the dorsum of the hand on the ulnar side and push in the direction of flexion and radial deviation.
- **Substitutions:** Extensor pollicis longus (EPL) and extensor digitorum communis (EDC) (Fig. 13-107).

Figure 13-107 Wrist extension, against gravity.

Gravity-Eliminated Position

- **Start position:** The forearm is supported on the table in neutral with the wrist in a slightly flexed position.
- **Instruction:** “Try to bend your wrist backward.”
- **Palpation:** Palpate the tendons at the dorsal wrist and the muscle bellies at the proximal dorsal forearm. Specifically, the tendon of the ECRL can be palpated at the base of the second metacarpal and the tendon of the ECRB at the base of the third metacarpal adjacent to the ECRL. The muscle belly of the ECRL is adjacent to the brachioradialis. The muscle belly of the ECRB is distal to the belly of the ECRL. Palpate the ECU tendon between the head of the ulna and the base of the fifth metacarpal. The muscle belly is approximately 2 inches distal to the lateral epicondyle of the humerus (Fig. 13-108).

Figure 13-108 Wrist extension, gravity eliminated.

Wrist Flexion

Prime Movers

Flexor carpi radialis (FCR), palmaris longus, and flexor carpi ulnaris (FCU).

Against-Gravity Position

- **Start position:** The forearm is supinated, the wrist is extended, and the fingers and thumb are relaxed.
- **Stabilize:** The forearm is stabilized on the table with the back of the hand hanging off the table to allow the wrist to go into slight extension.
- **Instruction:** “Bend your wrist all the way forward, and keep your fingers relaxed. Do not let me push it back.”
- **Resistance:** Apply resistance to the distal metacarpals of the fingers toward extension. To test the FCR and palmaris longus, the therapist applies resistance over the heads of the metacarpals on the volar surface of the hand toward extension. To test for the FCU, the therapist applies resistance over the head of the fifth metacarpal on the volar surface of the hand toward wrist extension and radial deviation.
- **Substitutions:** Abductor pollicis longus (APL), flexor pollicis longus (FPL), flexor digitorum superficialis (FDS), and flexor digitorum profundus (FDP) (Fig. 13-109).

Figure 13-109 Wrist flexion, against gravity.

Gravity-Eliminated Position

- **Start position:** Forearm in neutral, wrist extended, and fingers and thumb relaxed.
- **Stabilize:** The forearm rests on the table.
- **Instruction:** “Try to bend your wrist forward.”
- **Palpation:** Palpate the tendons at the volar wrist. Specifically, the tendon of the FCR can be palpated at the base of the second metacarpal, radial to the palmaris longus (if present) and the tendon of the FCU just proximal to the pisiform bone on the ulnar aspect of the volar wrist. The palmaris longus is a weak wrist flexor. The tendon crosses the center of the volar surface of the wrist. It is not tested for strength and may not even be present; if it is present, it will stand out prominently in the middle of the wrist when wrist flexion is resisted or the palm is positioned with the thumb and fifth digit opposed to one another ((Figs. 13-110 and 13-111).

Figure 13-110 Wrist flexion, gravity eliminated.

Figure 13-111 The therapist is pointing to the tendon of the palmaris longus as the client cups her hand to make this tendon stand out.

Finger Metacarpophalangeal Extension

Prime Movers

Extensor digitorum communis (EDC), extensor indicis proprius (EIP), and extensor digiti minimi (EDM).

Against-Gravity Position

- **Start position:** The forearm is pronated and supported on the table. The wrist is supported in neutral position, and the finger MP and IP joints are in a relaxed flexed posture.
- **Stabilize:** Wrist and metacarpals.
- **Instruction:** “Lift this knuckle up as far as it will go (touch the finger that is to be tested). Keep the rest of your fingers bent. Do not let me push your knuckle down.” (*Note:* Be sure to demonstrate this action.)
- **Resistance:** Using one finger, the therapist pushes the head of each proximal phalanx toward flexion, one at a time.
- **Substitution:** Apparent extension of the fingers can result from the rebound effect of relaxation following finger flexion. Flexion of the wrist can cause finger extension through tenodesis action (Fig. 13-112).

Figure 13-112 Finger metacarpophalangeal extension, against gravity.

Gravity-Eliminated Position

- **Start position:** Forearm supported in neutral, wrist in neutral position, and fingers flexed.
- **Stabilize:** Wrist and metacarpals.

- **Instruction:** “Try to move your knuckles back as far as they will go, one at a time. Keep the rest of your fingers bent.”
- **Palpation:** The tendons of the EDC are readily seen and palpated on the dorsum of the hand (Fig. 13-113). Both the EIP tendon and the EDM tendon are ulnar to the EDC tendon of their respective digits. Palpate the muscle belly of the EDC on the dorsal–ulnar surface of the proximal forearm. Often, the separate muscle bellies are discernible. Palpate the belly of the EIP muscle on the mid- to distal dorsal forearm between the radius and ulna (Fig. 13-113).

Figure 13-113 Finger metacarpophalangeal extension, gravity eliminated.

Finger Metacarpophalangeal Flexion

Prime Movers

Flexor digitorum profundus (FDP), flexor digitorum superficialis (FDS), dorsal interossei, palmar interossei, and flexor digiti minimi. The tests for the first four muscles are discussed under their alternative actions. The flexor of the little finger has no other action and is described here.

Against-Gravity Position for the Flexor Digiti Minimi

- **Start position:** Forearm supported in supination.
- **Stabilize:** Other fingers in extension.
- **Instruction:** “Bend the knuckle of your little finger toward your palm while you keep the rest of the finger straight.”
- **Resistance:** Using one finger, the therapist pushes the head of the proximal phalanx toward extension. The therapist must be sure the IP joints remain extended.
- **Substitutions:** The FDP, FDS, or third palmar interosseus may substitute (Fig. 13-114).

Figure 13-114 Finger metacarpophalangeal flexion, against gravity for the flexor digiti minimi.

Gravity-Eliminated Position

- **Start position:** Forearm supported in neutral.
- **Stabilize:** Other fingers in extension.
- **Instruction:** “Try to bend the knuckle of your little finger toward your palm while you keep the rest of the finger straight.”
- **Palpation:** The flexor digiti minimi is found on the volar surface of the hypothenar eminence (Fig. 13-115).

Figure 13-115 Finger metacarpophalangeal flexion, gravity eliminated.

Finger Proximal Interphalangeal Flexion

Prime Movers

Flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP).

Against-Gravity Position for the Flexor Digitorum Superficialis

- **Start position:** Forearm supinated and supported on the table; wrist and MP joints relaxed. To rule out the influence of the FDP when testing the FDS, hold all IP joints of the fingers not being tested in full extension to slight hyperextension. Because the FDP is essentially one muscle with four tendons, preventing its action in three of the four fingers prevents it from working in the tested finger. In fact, the client cannot flex the distal joint of the tested finger at all. In some people, the FDP slip to the index finger is such that this method cannot rule out its influence on the PIP joint of the index finger. This should be documented.
- **Stabilize:** All IP joints of the other digits of the hand.
- **Instruction:** Point to the PIP joint and say, “Bend just this joint.”
- **Resistance:** Using one finger, the therapist applies resistance to the head of the middle phalanx toward extension.
- **Substitutions:** FDP. Wrist extension causes tenodesis action (Fig. 13-116).

Figure 13-116 Finger proximal interphalangeal flexion, against gravity. The flexor profundus is prevented from substituting because the therapist is holding in extension all fingers not being tested.

Gravity-Eliminated Position

- **Start position:** Forearm supported in neutral with the wrist and MP joints relaxed in neutral position. Again, rule out the influence of the FDP by holding all the joints of the untested fingers in extension.
- **Stabilize:** Proximal phalanx of the finger being tested as well as all IP joints of the other digits of the hand.
- **Instruction:** Point to the PIP joint and say, “Try to bend just this joint.”
- **Palpation:** Palpate the FDS on the volar surface of the proximal forearm toward the ulnar side (Fig. 13-117) and the tendons at the wrist between the palmaris longus and the FCU.

Figure 13-117 Finger proximal interphalangeal flexion, gravity eliminated.

Finger Distal Interphalangeal Flexion

Prime Mover

Flexor digitorum profundus (FDP).

Against-Gravity Position

- **Start position:** Forearm supinated and supported on a table; wrist and IP joints relaxed.
- **Stabilize:** Firmly support the middle phalanx of each finger as it is tested to prevent flexion of the proximal IP joint; the wrist should remain in neutral position.
- **Instruction:** “Bend the last joint on your finger as far as you can.”
- **Resistance:** The therapist places one finger on the pad of the client’s finger and applies resistance toward extension.

- **Substitutions:** Rebound effect of apparent flexion following contraction of extensors. Wrist extension causes tenodesis action (Fig. 13-118).

Figure 13-118 Finger distal interphalangeal flexion, against gravity. The other joints of the finger are prevented from flexing.

Gravity-Eliminated Position

- **Start position:** The forearm is in neutral, resting on the ulnar border on a table. The wrist and IP joints are relaxed in neutral position.
- **Stabilize:** Firmly support the middle phalanx of each finger as it is tested to prevent flexion of the proximal IP joint; the wrist should remain in neutral position.
- **Instruction:** “Bend the last joint on your finger as far as you can.”
- **Palpation:** Palpate the belly of the FDP just volar to the ulna in the proximal third of the forearm. The tendons are sometimes palpable on the volar surface of the middle phalanges (Fig. 13-119).

Figure 13-119 Finger distal interphalangeal flexion, gravity eliminated.

Finger Abduction

Prime Movers

Dorsal interossei (4) and abductor digiti minimi (ADM).

Gravity-Eliminated Position

These muscles are tested for all grades in the gravity-eliminated position.

- **Start position:** The pronated forearm is supported with the wrist neutral. The fingers are extended and adducted. Be sure the MP joints are in neutral or slight flexion.

- **Stabilize:** The wrist and metacarpals are gently supported.
- **Instruction:** “Spread your fingers apart, and do not let me push them back together.”
- **Action:** The action of each finger is different because the midline of the hand is the third finger and abduction is movement away from midline. It is important to know which dorsal interosseus you are testing. The first dorsal interosseus abducts the index finger toward the thumb. The second dorsal interosseus abducts the middle finger toward the thumb. The third dorsal interosseus abducts the middle finger toward the little finger. The fourth dorsal interosseus abducts the ring finger toward the little finger. The ADM abducts the little finger ulnarly.
- **Resistance:** The therapist applies resistance at the radial or ulnar side of the head of the proximal phalanx in an attempt to push the finger toward midline. Applying resistance to the radial side of the heads of the index and middle fingers tests the first and second dorsal interossei. Applying resistance to the ulnar side of the middle, ring, and little fingers tests the third and fourth dorsal interossei and the ADM.
- **Substitutions:** Extensor digitorum communis (EDC).
- **Grading:** Normal finger abductors do not tolerate much resistance. If the fingers give way to resistance but spring back when the resistance is removed, the grade is 5. The grade is 4 if the muscle takes some resistance. The grade is 3 when there is full AROM. The grade is 2 if there is partial AROM. The grade is 1 when contraction is felt with palpation. The grade is 0 when no contractile activity is palpable.
- **Palpation:** Palpate the first dorsal interosseus on the dorsal web space and the ADM on the ulnar border of the fifth metacarpal. The other interossei lie between the metacarpals on the dorsal aspect of the hand, where they may be palpated; on some people, the tendons can be palpated as they enter the dorsal expansion near the heads of the metacarpals. When the dorsal interossei are atrophied, the spaces between the metacarpals on the dorsal surface appear sunken (Fig. 13-120).

Figure 13-120 Finger abduction.

Finger Adduction

Prime Movers

Palmar interossei (3).

Gravity-Eliminated Position

These muscles are tested for all grades in the gravity-eliminated position.

- **Start position:** The forearm is pronated, and the MPs are abducted and in extension.
- **Stabilize:** Both of the therapist’s hands are needed for resistance. The forearm and wrist can be supported on a table.
- **Instruction:** “Bring your fingers together and hold them. Do not let me pull them apart.”
- **Action:** The action of each finger is different because the midline of the hand is the third finger and adduction is movement toward midline. The first palmar interosseus adducts the index finger toward the middle finger. The second adducts the ring finger toward the middle finger, and the third adducts the little finger toward the middle finger.

- **Resistance:** The therapist holds the heads of the proximal phalanx of two adjoining fingers and applies resistance in the direction of abduction to pull the fingers apart. For the index and middle finger pair, the first palmar interosseus is tested. For the middle and ring finger pair, the second palmar interosseus is tested. For the ring and little finger pair, the third palmar interosseus is tested.
- **Substitutions:** Extrinsic finger flexors.
- **Grading:** Normal finger adductors do not tolerate much resistance. If the fingers give way to resistance but spring back when the resistance is removed, the grade is 5. The grade is 4 if the muscle takes some resistance. The grade is 3 when there is full AROM. The grade is 2 if there is partial AROM. The grade is 1 when contraction is felt with palpation. The grade is 0 when no contractile activity is palpable.
- **Palpation:** The palmar interossei are usually too deep to palpate with certainty. When these muscles are atrophied, the areas between the metacarpals on the volar surface appear sunken (Fig. 13-121).

Figure 13-121 Finger adduction.

Thumb Metacarpophalangeal Extension

Prime Movers

Extensor pollicis brevis and extensor pollicis longus (EPL).

Against-Gravity Position

- **Start position:** Forearm supported in neutral, MP and IP joints flexed.
- **Stabilize:** Firmly support the first metacarpal in abduction.
- **Instruction:** “Straighten your thumb.”

To isolate the extensor pollicis brevis, instruct the client: “Straighten the knuckle of your thumb while keeping the end joint bent.” (*Note:* You may have to move the thumb passively a few times for the client to get the kinesthetic input regarding this movement.)

- **Resistance:** The therapist’s index finger, placed on the dorsal surface of the head of the proximal phalanx, pushes toward flexion.
- **Substitution:** EPL for the extensor pollicis brevis (Fig. 13-122).

Figure 13-122 Thumb metacarpophalangeal extension, against gravity. The therapist is pointing at the extensor pollicis longus.

Gravity-Eliminated Position

- **Start position:** Forearm pronated or supinated, MP and IP joints flexed.
- **Stabilize:** First metacarpal in abduction.
- **Instruction:**
 - EPL—“Try to straighten your thumb.”
 - Extensor pollicis brevis—“Try to straighten the knuckle of your thumb while keeping the end joint bent.”
- **Palpation:** Palpate the tendon of the EPL on the medial border of the anatomical snuffbox (Fig. 13-123). The tendon of the extensor pollicis brevis can be palpated on the lateral border of the anatomical snuffbox just medial to the tendon of the APL (Fig. 13-123).

Figure 13-123 Thumb metacarpophalangeal extension, gravity eliminated.

Thumb Metacarpophalangeal Flexion

Prime Movers

Flexor pollicis brevis (FPB) and FPL.

Against-Gravity Position for the Flexor Pollicis Brevis

- **Start position:** Elbow flexed and supported on the table. Shoulder externally rotated and forearm supinated so that the palmar surface of the thumb faces the ceiling; thumb is extended at both the MP and IP joints.
- **Stabilize:** Firmly support the first metacarpal.
- **Instruction:** “Bend your thumb across your palm, keeping the end joint of your thumb straight. Do not let me pull it back out.”
- **Resistance:** The therapist’s finger pushes the head of the proximal phalanx toward extension.
- **Substitutions:** FPL; the abductor pollicis brevis (APB) and the adductor pollicis through insertion into the extensor hood (Fig. 13-124).

Figure 13-124 Thumb metacarpophalangeal flexion, against gravity.

Gravity-Eliminated Position

- **Start position:** Forearm supinated to 90° so that the thumb can flex across the palm.
- **Stabilize:** First metacarpal.
- **Instruction:** “Try to bend your thumb into your palm, keeping the end joint of your thumb straight.”
- **Palpation:** Palpate the FPB on the thenar eminence just proximal to the MP joint and medial to the APB (Fig. 13-125).

Figure 13-125 Thumb metacarpophalangeal flexion, gravity eliminated.

Thumb Interphalangeal Extension

Prime Mover

Extensor pollicis longus (EPL).

Against-Gravity Position

- **Start position:** Forearm supported in neutral, wrist flexion of 10° to 20°, and thumb MP and IP flexion.
- **Stabilize:** Proximal phalanx into MP flexion.
- **Instruction:** “Straighten the end of your thumb.”
- **Resistance:** The therapist places one finger over the dorsum of the distal phalanx (thumbnail) and pushes only the DIP toward flexion.
- **Substitutions:** Relaxation of the FPL produces apparent extensor movement as a result of a rebound effect. The APB, adductor pollicis, and FPB insert into the lateral aspects of the dorsal expansion, so they may produce thumb IP extension when the EPL is paralyzed (Fig. 13-126).

Figure 13-126 Thumb interphalangeal extension, against gravity.

Gravity-Eliminated Position

- **Start position:** Forearm pronated or supinated, thumb flexed.
- **Instruction:** “Try to straighten the end of your thumb.”
- **Palpation:** The tendon of the EPL may be palpated on the ulnar border of the anatomical snuffbox and on the dorsal surface of the proximal phalanx of the thumb (Fig. 13-127).

Figure 13-127 Thumb interphalangeal extension, gravity eliminated.

Thumb Interphalangeal Flexion

Prime Mover

Flexor pollicis longus (FPL).

Against-Gravity Position

- **Start position:** Elbow flexed and supported on a table. Forearm supinated so that the palmar surface of the thumb faces the ceiling; thumb extended at the MP and IP joints.
- **Stabilize:** Proximal phalanx, holding MP joint in extension.
- **Instruction:** “Bend the tip of your thumb as far as you can, and do not let me straighten it.”
- **Resistance:** The therapist’s finger pushes the head of the distal phalanx toward extension.
- **Substitution:** Relaxation of the EPL causes apparent rebound movement (Fig. 13-128).

Figure 13-128 Thumb interphalangeal flexion, against gravity.

Gravity-Eliminated Position

- **Start position:** Forearm supinated to 90° so that the thumb can flex across the palm.
- **Stabilize:** Proximal phalanx, holding MP joint in extension.
- **Instruction:** “Try to bend the tip of your thumb as far as you can.”
- **Palpation:** Palpate the FPL on the palmar surface of the proximal phalanx (Fig. 13-129).

Figure 13-129 Thumb interphalangeal flexion, gravity eliminated.

Thumb (Palmar) Abduction

Prime Movers

Abductor pollicis longus (APL) and abductor pollicis brevis (APB).

Against-Gravity Position

- **Start position:** Forearm is supported in supination, wrist in neutral position, and thumb adducted.
- **Stabilize:** Support the wrist in neutral position by holding it on the dorsal and ulnar side.
- **Instruction:** “Lift your thumb directly out of the palm of the hand. Do not let me push it back in.”
- **Resistance:** The therapist’s finger presses the head of the first metacarpal toward adduction.
- **Substitutions:** APL may substitute for a weak APB, and APB may substitute for a weak APL; however, it is difficult to assess these muscles separately. The extensor pollicis brevis may also substitute (Fig. 13-130).

Figure 13-130 Thumb (palmar) abduction, against gravity.

Gravity-Eliminated Position

- **Start position:** Forearm and wrist are supported in neutral, thumb adducted.
- **Stabilize:** Support the wrist in neutral position by holding it on the dorsal and ulnar side.
- **Instruction:** “Try to move your thumb away from the palm of your hand.”
- **Palpation:** Palpate the APL at the most lateral border of the anatomical snuffbox (Fig. 13-131) and the APB over the center of the thenar eminence.

Figure 13-131 Thumb (palmar) abduction, gravity eliminated.

Thumb Adduction

Prime Mover

Adductor pollicis.

Against-Gravity Position

- **Start position:** Forearm pronated, wrist and fingers in neutral position, thumb abducted, and MP and IP joints of the thumb in extension.
- **Stabilize:** Metacarpals of fingers, keeping the MP joints in neutral.
- **Instruction:** “Lift your thumb into the palm of your hand, and do not let me pull it out.”
- **Resistance:** The therapist grasps the head of the proximal phalanx and tries to pull it away from the palm toward abduction.
- **Substitutions:** The EPL, FPL, or FPB may substitute (Fig. 13-132).

Figure 13-132 Thumb adduction, against gravity.

Gravity-Eliminated Position

- **Start position:** Forearm in midposition, wrist and fingers in neutral position, thumb abducted, and MP and IP joints of the thumb in extension.
- **Stabilization:** Metacarpals of fingers, keeping the MP joints in neutral.
- **Instruction:** “Try to bring your thumb into the palm of your hand.”
- **Palpation:** Palpate the adductor pollicis on the palmar surface of the thumb web space (Fig. 13-133).

Figure 13-133 Thumb adduction, gravity eliminated.

Opposition

Prime Movers

Opponens pollicis and opponens digiti minimi.

Against-Gravity Position

- **Start position:** Forearm supinated and supported, wrist in neutral position, thumb adducted and extended.
- **Stabilize:** Hold the wrist in a neutral position.
- **Instruction:** “Touch the pad of your thumb to the pad of your little finger. Do not let me pull them apart.”
- **Resistance:** To test the opponens pollicis, the therapist holds along the first metacarpal and attempts to pull the thumb away from the little finger. To test the opponens digiti minimi, the therapist holds along the fifth metacarpal and attempts to pull the little finger away from the thumb. These can be resisted simultaneously using both hands.
- **Substitutions:** The APB, FPB, or FPL may substitute (Fig. 13-134).

Figure 13-134 Opposition, against gravity.

Gravity-Eliminated Position

- **Start position:** Elbow resting on the table with forearm perpendicular to the table, wrist in neutral position, thumb adducted and extended.
- **Stabilize:** Hold the wrist in a neutral position.
- **Instruction:** “Try to touch the pad of your thumb to the pad of your little finger.”
- **Palpation:** Place fingertips along the lateral side of the shaft of the first metacarpal where the opponens pollicis may be palpated before it becomes deep to the APB. The opponens digiti minimi can be palpated volarly along the shaft of the fifth metacarpal (Fig. 13-135).

Figure 13-135 Opposition, gravity eliminated.

Accuracy

Accuracy of MMT is essential for meaningful evaluation. Strict adherence to the exact procedures of testing is most important to the reliability of the scores with repeated tests.⁴⁸ In addition, reliability of muscle testing scores is affected by the interest and cooperation of the client and by the experience and tone of voice of the tester, with higher volume eliciting greater muscle contractions.⁵⁵ The most suitable environment is free of distractions, is at a comfortable temperature, and has proper lighting. Other factors known to affect outcome are posture, fatigue, the client's ability to understand directions, the therapist's operational definitions of various grades, and test positions.⁴⁹ For reliability, these variables must be controlled from test to test and among therapists at the same facility. It is necessary for the inexperienced therapist to develop a kinesthetic sense of minimal, moderate, and maximal resistances by working with experienced therapists, each testing the same client and discussing the grade to be assigned.⁵¹

Recording Muscle Strength Scores

Muscle strength must be accurately documented in the medical record, identifying muscle or muscle group tested, grades assigned to the right and left sides, date of testing, and electronic or physical signature of the therapist performing the evaluation. A sample form is presented in Figure 13-136. On that form, the peripheral nerve and spinal segmental levels are listed beside each muscle to assist the therapist in interpreting the results of the muscle test.

Figure 13-136 Sample form for recording manual muscle strength. (Reprinted with permission from Pansky B. *Review of Gross Anatomy*. 6th ed. New York, NY: McGraw-Hill; 1996.)

Interpreting the Results

After recording all muscle test scores, the therapist reviews the scores and looks for the weak muscles and the distribution and significance of the weakness. Any muscle that grades “good minus” (4-) or below is considered weak. “Good plus” (4+) muscles are functional and usually require no therapy. “Good” (4) muscles may or may not be functionally adequate for the client, depending on his or her occupational task requirements.^{48,50,51} The pattern of muscle weakness is important. The pattern may indicate general weakness caused by disuse secondary to immobilization, or it may reflect the level of spinal innervation in a client after spinal cord injury or the distribution of a peripheral nerve in the case of peripheral nerve injury. A pattern of imbalance of forces in agonist muscles (i.e., muscles that contract to make a movement) and antagonist muscles (i.e., muscles that relax to allow a movement) may be deforming; therefore, counter positioning or splinting should be considered along with strengthening of the weak muscles.

The pattern of significant strength is also important. For example, a muscle test of a client with an injured spinal cord that indicates some strength in a muscle innervated by a segment below the diagnosed level of injury is hopeful for more recovery. For muscles that are reinnervated proximally to distally after peripheral nerve injury, recording the pattern of return of strength in particular muscles helps track the progress of nerve regeneration.

Short-term goals move the client from the level of strength determined by testing to the next higher level. For example, if a muscle grades 3, the short-term goal is to improve strength to 3+; if it grades 3+, the goal is to increase strength to 4-, and so on. However, the goal should not purely reflect the numerical increase in the muscle strength. Improved strength should instead be reflected in some sort of functional task. For example, the short-term goal may state that the client will demonstrate an increase in left elbow muscle strength to 3+, as needed for independent hygiene tasks of brushing the teeth and washing the face. The required strength for occupational functioning must always be kept in mind when establishing goals.

If the muscle is being reevaluated, the scores are compared with those of the previous test. The frequency of reevaluation depends on the nature of expected recovery. Expected rapid recovery requires frequent reevaluation. For example, in a young, healthy individual recovering from a fracture that has been cleared by the surgeon to begin strengthening, it may be appropriate to reevaluate every 2 weeks until full strength is returned. However, in an individual recovering from a peripheral nerve injury when nerve healing is slow and expected to only heal 1 inch every month, it may be more appropriate to wait 4 weeks between reevaluations. If significant gains are noted in therapy and the client would benefit from a change in the treatment plan, then a reevaluation should be completed to document these gains and the change in treatment plan. If the repeated muscle test shows that the client is making gains, the program is considered beneficial, and its demands are upgraded. If repeated muscle tests show no gains despite program adaptations, the client is considered to have reached a plateau and to no longer benefit from remedial therapy. In that case, the focus of treatment shifts to teaching the client compensatory strategies and the use of adaptive equipment to enable participation in desired tasks and activities, as addressed in the rehabilitative frame of reference.⁵⁶

There are, of course, exceptions to these standards. Clients with degenerative diseases are expected to get weaker; therefore, therapy is aimed at maintaining their strength and function for as long as possible, and efficacy is confirmed with repeat tests. A plateau for these clients is desirable; it indicates that the therapy is effective for maintaining strength and should be continued. Documentation of how this maintenance of strength impacts independence in ADL and IADL tasks should also be used to justify continued services. These clients often benefit from rehabilitation to maintain their current level of independence as well as learn compensatory techniques to conserve energy and maintain independence.⁵⁶

Dynamometry

Other methods of muscle testing can provide more specific data regarding strength, such as isokinetic testing with Cybex and Biodex machines.⁵⁷ In addition, a strain gauge device or handheld dynamometer has been used for isometric strength testing. This type of dynamometer is placed directly against the body part being tested to register specific muscle strength when resistance is applied.^{58,59} This is a different type of device from the dynamometer frequently used to measure grip strength (see Fig. 13-137).

Figure 13-137 Example of handheld dynamometer for isometric strength testing. (Picture courtesy of Hoggan Scientific.)

Use of the handheld dynamometer includes placing it perpendicular to the limb segment with the joint in a gravity-eliminated position. The client is asked to build a maximum contraction against the dynamometer for a 1- to 2-second period and then to hold that contraction against the dynamometer for 4 to 5 seconds. The recorded measure is the maximum isometric value that was achieved by the client. This type of measurement is particularly helpful for quantifying antigravity strength, grades 3+ to 5.⁶⁰ The standardized positions and handheld dynamometer placement for each muscle group tested are described in detail by Hébert et al.⁶¹ Owing to the expense, time required, and lack of correlation with MMT, all of these alternative methods of evaluating proximal muscle strength (Cybex, Biodex, and handheld dynamometry) are generally limited to research protocols.⁶²

Grip and Pinch Strength Measurement

More specific measurements beyond MMT grading can demonstrate more discrete changes in grip and pinch strength. The ASHT recommends procedures for hand-grip strength, pinch strength, methods, and equipment.²² Grip- and pinch-strength assessments can be compared to established norms or with measurements from the client's opposite hand (if the client does not fit the norms criteria) to ascertain whether there is a significant limitation. Normative data for both grip and pinch strength has long been established and frequently used as a reference for adults.⁶³ Other studies of normative values from heterogeneous populations are also available for reference.⁶⁴⁻⁷⁰ Tables 13-3 and 13-4 list means and standard deviations (SD) for grip and pinch (tip, lateral, and palmar) measures from 628 adults, aged 20 to 75+.⁶³

Tip pinch average standard deviation (SD): men, 4.0; women, 2.5. Lateral pinch average SD: men, 4.6; women, 3.0. Palmar pinch average SD: men, 5.1; women, 3.7. *N* = 628; age range = 20 to 94.

Reprinted with permission from Mathiowetz V, Kashman N, Volland G, Weber K, Dowe M, Rogers S. Grip and pinch strength: normative data for adults. *Arch Phys Med Rehabil.* 1985;66:69–74.

When individual scores are outside of these established norms, an individual with unilateral injury may also be compared to himself or herself using the 10% rule. In right-handed individuals, the dominant side is typically 10% stronger than is the nondominant side, although left-handed individuals typically demonstrate equal strength bilaterally.⁷¹ For example, imagine a client recovering from a metacarpal fracture that can now demonstrate a full composite fist. He has an average score of 50 lb on the right dominant hand, and an average of 100 lb on the left nondominant hand. Using the 10% rule, the therapist would anticipate that 110 lb was the client’s right-hand strength before injury. The therapist’s assessment could be written as, “Client is 7 weeks post-metacarpal fracture with good return of motion. He demonstrates 45.5% of right-hand strength compared to the left and 42.7% compared to established norms for his age and gender. The client would benefit from continued occupational therapy services to increase strength needed for work and daily tasks.” Grip and pinch measurements can be quickly and easily reevaluated over time to monitor the progress of the client and the effectiveness of the treatment plan.

Instruments

Grip-strength norms were originally established using the Jamar **dynamometer**.⁶³ This type of dynamometer is the most commonly used device for measuring grip strength in research,^{64,70,72–75} and is recommended for clinical use by the ASHT.²² However, interinstrument reliability, or the ability of multiple instruments to be used interchangeably, has been established between devices with various levels of confidence (see Table 13-5 for a listing of instruments used to measure grip strength).^{71,76} There is a difference between electronic and hydraulic dynamometers with grip-strength measurements being approximately 10% higher when using hydraulic dynamometers.⁷⁷ Therefore, the same instrument should be used throughout each client’s therapy. Although these instruments can be used with various levels of confidence against the norms, the selected instrument still must be calibrated every 4 to 12 months.⁷⁸ It is recommended to use the same instrument⁷⁹ at the same time of day using a standard protocol and instructions for body and instrument position when evaluating and reevaluating individual clients.^{22,80} In the use of the Jamar dynamometer, there are five grooves along the handle used to select the grip position. The second grip position from the gauge is the standard position used for previous normative data and is recommended to increase reliability.^{76,80} The assessment of grip strength with the Jamar Plus+ dynamometer is easier and faster if a single, standard handle position is used rather than multiple different positions. As well as providing accurate results, a single, standard handle position also reduces fatigue and increases the comparability of results to norms.⁸¹ However, hand size⁸² and nail length⁸³ may impact which position allows for maximum grip strength, so Boadella et al.⁸⁴ suggested that it may be more advantageous to allow the client to self-select their hand-grip position. It was also recommended that a change in score of at least 6 kg or 13 lb is needed to be clinically significant.⁸⁵

Roberts HC, Denison HJ, Martin HJ, et al. A review of the measurement of grip strength in clinical and epidemiological studies: towards a standardised approach. *Age Ageing*. 2011;40(4):423–429. doi:10.1093/ageing/afr051; Sousa-Santos AR, Amaral TF. Differences in handgrip strength protocols to identify sarcopenia and frailty—a systematic review. *BMC Geriatr*. 2017;17(1):238. doi:10.1186/s12877-017-0625-y.

In the past, it was thought that the vigorimeter could not be used interchangeably with a dynamometer.⁷¹ However, it has always been an acceptable alternative hand strength-measuring device for clients whose diagnoses contraindicate stress on joints and/or skin, because it requires the client to squeeze a rubber bulb rather than a steel handle. More recently, the Jamar dynamometer and the vigorimeter have been found to have aspects of comparable validity, reliability, and responsiveness.⁸⁶ In fact, the vigorimeter has been found to be just as reliable as the dynamometer and more practical for populations that have difficulty adhering to the administrative constraints of the dynamometer.⁸⁷ The vigorimeter is a commercially available instrument for which norms have been published.⁸⁸

The pinch norms can be used with the B & L, JTech, and NK pinch meters because they have been found to be interchangeably reliable.⁸⁹ However, there is a significant difference between the use of the commonly available mechanical pinch gauges and the newer electronic pinch gauges, with lateral pinch-strength measurements measuring approximately 18% higher with mechanical pinch gauges.⁷⁷ Therefore, it is recommended to always use the same instrument for each client for best reliability.

Calibration

As with any tool of measurement, the instrument must be calibrated and set at zero to start. Dynamometers and pinch meters can be calibrated by placing known weights on or suspending them from the compression part of the meter.⁷⁸ With this procedure, the Jamar dynamometer was found to be accurate to within 7%,⁹⁰ and the B & L pinch meter was found to be accurate within 1%.⁹¹ Clinically this means that, if a client registered 50 lb for grip strength, the actual strength may range from 46.5 to 53.5 lb. Grip and pinch scores are considered abnormal if they are associated with a functional limitation and/or if they are three SD from the mean. For example, suppose a 40-year-old man had a mean average grip score of 50 lb after three trials for his dominant right hand. Table 13-3 shows that the mean average score for his age group is 117 lb, so the client's grip score was 67 lb less than is the mean normal score on the table. When the difference in his score is divided by the SD given in the table (21), he is 3.2 SD below the mean. He would be considered to have a significant limitation because his grip score is more than 3 SD below the mean.

Assessment of Grip Strength

There is significant clinical importance to following the standardized testing procedures for grip- and pinch-strength measurement as recommended by the ASHT.²² Great attention should be paid to specific placement of the UE during testing, such as wrist,⁹² forearm,⁹³ elbow,^{94–96} and shoulder⁹⁷ positions. In addition, verbal instructions and encouragement can also alter outcomes.⁵⁵ To obtain the maximal hand-grip strength, at least three attempts or trials should be recorded.⁹⁸

The specific protocol for testing grip strength according to the ASHT²² is as follows:

1. The dynamometer should be calibrated and set on the second rung (if a different rung is used, such as for large hands, it should be noted and justified).
2. The dynamometer's dial should be turned away from the client and the examiner should gently support the base of the dynamometer.
3. The client should be seated in a chair without armrests, with feet fully resting on the floor, hips as far back in the chair as possible, and the hips and knees positioned at approximately 90°.
4. Shoulders should be adducted and neutrally rotated with the elbow flexed at 90° and the forearm in neutral position.
5. The wrist should be between 15° and 30° of extension (dorsiflexion) and 0° to 15° of ulnar deviation.
6. The task is demonstrated to the client.

7. After the dynamometer is positioned in the client's hand, the therapist says, "This test will tell me your maximum grip strength. When I say go, grip as hard as you can until I say stop. Before each trial, I will ask you, 'Are you ready?'" and then tell you 'Go.' Stop immediately if you experience any unusual pain or discomfort at any point during testing. Do you have any questions? Are you ready? Go!" "Harder...harder...harder...Relax."
8. The client squeezes the dynamometer with as much force as he or she can three times, with each trial acquisition time being at least 3 seconds.
9. A rest break of at least 15 seconds is given between trials.
10. The score is the mean average of the three successive trials.

An alternative procedure that can be used is the Southampton protocol.⁷¹ The main differences of the Southampton protocol are that the client's forearms are rested on the armrests of the chair, three trials on each side are elicited alternating sides (starting with the right hand), and the results are maximal grip score from all six trials. Note that research has suggested that a single trial is as reliable as multiple trials,⁹⁹ which may be appropriate for cases in which multiple trials would cause undue pain or stress; however, to assess maximal hand-grip strength, at least three attempts are needed.⁹⁸ See Figure 13-138 for standardized position for grip-strength testing, and Table 13-3 for grip-strength normative data.

Figure 13-138 Measuring grip using a dynamometer. The client's upper arm is close to his body, and the elbow is flexed to 90°.

Assessment of Pinch Strength

Three types of pinch are typically evaluated because they are involved in accomplishing occupational tasks and activities efficiently: the tip pinch, the lateral pinch, and the palmar pinch. The seating and positioning of the arm should be the same as with grip testing, with the addition that the fingers should be allowed to flex. With both tip and palmar pinch, it is important to note that to keep the forearm in a neutral position, the pinch gauge must be held vertically, and the wrist will naturally extend to assume the best testing position.⁸⁹ The following instructions are based on the ASHT²² recommendations.

Tip Pinch

The pinch gauge is presented on its side at an angle of approximately 45°. The client pinches the ends of the pinch gauge between the tips of the thumb and index finger. The index finger is on the dial side and the fingertips must stop at the finger groove (as if the client is making an “O”). The thumb and index IP joints must be flexed. The middle, ring, and little fingers are flexed in the palm. The test is administered by first giving the client instructions and a demonstration. Next, the therapist says, “Are you ready? Pinch as hard as you can.” The client is urged on as he or she attempts to pinch. Three trials, with a rest between each trial, are completed. The mean average of three trials is recorded. It is important to observe for any compensation techniques because some clients will naturally try to use the middle finger to assist without recognizing their deviance from the instructed test position. See Figure 13-139 for standardized position for tip pinch-strength testing, and Table 13-4 for tip pinch-strength normative data.

Figure 13-139 Measuring tip pinch strength with a pinch gauge.

Lateral Pinch: Key Pinch

The pinch gauge is presented in line with the forearm with the dial facing up. The client pinches the gauge between the pad of the thumb and the radial side of the middle phalanx of the index finger. The thumb is on the dial side and must stop at the finger groove. The IP joint of the thumb must be flexed. The fingers are flexed in the palm. The instructions and procedure are the same as for tip pinch, but the pinch gauge is held horizontally, as if holding a key. Interestingly, in a study of key pinch in children aged 5 to 12 years, differences were found according to age, but no significant differences were found by hand or gender in this age range. On the basis of these findings, comparing the right to left side in this age range should be possible as long as the injury or condition is not bilateral.¹⁰⁰ See Figure 13-140 for standardized position for lateral pinch-strength testing, and Table 13-4 for key pinch-strength normative data.

Figure 13-140 Measuring lateral pinch strength with a pinch gauge.

Palmar Pinch: Three-Jaw Chuck

The pinch gauge is presented on its side at an angle of approximately 45°. It is held between the pulp of the thumb and the pulp of the index and middle fingers. The index and middle fingers are on the dial side and the fingertips must stop at the finger groove. The thumb and fingers IP joints must be slightly flexed. The ring and little fingers are flexed in the palm. The client pinches the meter between the pad of the thumb and the pads of the index and middle fingers. The instructions and procedure are the same as for tip pinch. See Figure 13-141 for standardized position for palmar pinch-strength testing, and Table 13-4 for palmar pinch-strength normative data.

Figure 13-141 Measuring palmar pinch (or three-jaw chuck pinch) strength with a pinch gauge.

Endurance Measurement

Occupational therapists treat clients with a variety of conditions that can impact an individual's endurance, including cardiac or pulmonary impairments, a major trauma or illness requiring bed rest, loss of significant muscle function, or the need to use a prosthesis or adaptive equipment. There are two components of endurance. The first is **cardiorespiratory (CR) endurance**, which is the ability of the circulatory and respiratory system to supply oxygen during a task.¹⁰¹ The second is muscular endurance, in which muscles continue to perform without fatigue.¹⁰¹ Both of these aspects of endurance are vital to engage in ADL and IADL tasks, which is why occupational therapists refer to it as activity tolerance. Focusing on activity tolerance distinguishes the goal of occupational therapy from the goals of other professions that also address endurance. The therapist may evaluate one aspect or both depending on the client's symptoms.

Cardiorespiratory Aspects

The role of the occupational therapist here is most clearly seen in the role of therapists in cardiac rehabilitation programs, although these same principles may apply to an individual receiving therapy after prolonged bed rest or to an individual in home health with decreased endurance. Once an individual is cleared to begin a cardiac rehabilitation program from his or her physician following a cardiac event, activities that test CR fitness should progress slowly in terms of frequency, intensity, and time (duration) or FIT of exercise.¹⁰¹ Activities to test CR fitness can begin with very light or light self-care tasks, progressing to moderately difficult IADLs, such as household management tasks, and then assessing vigorous activities such as return to work. The occupational therapist should assess the client's environment in which he or she performs tasks, such as the home and the workplace. This allows the occupational therapist to gain a better understanding of the activity demands and use task analysis to develop a program to return the client to the endurance level needed to complete tasks.

Another way to assess endurance is to ascertain the individual's perception of how hard he or she is working. Scales of perceived exertion, such as the rating of perceived exertion,¹⁰² are based on psychophysics or the relating of a physical property to a subjective property via scaling procedures.¹⁰³ The Borg (15-point) scale of perceived exertion ranges from 6 (no exertion at all) to 20 (maximal exertion). This scale allows the person to assign one of a consecutive set of numbers with a corresponding descriptor of amount of exertion to the ongoing activity (e.g., 11, fairly light; or 17, very hard). Although subjective, multiplying the rating of exertion by 10 can provide a rough

estimate of heart rate.¹⁰⁴ Therapists should be aware that perceived exertion for a given level of oxygen uptake is higher for arm work than for leg work.¹⁰³ The therapist should orient the client to the scale using the standardized instructions published by Borg¹⁰⁴ before the start of the activity. The scale should be enlarged and posted so that it can be seen easily from where the person is engaging in activity. At appropriate intervals depending on the task, the therapist prompts the client to rate exertion at that moment. The decision to continue depends on the goal and precautions for the particular client.

Another measure easily used when engaging in functional tasks is the talk test.¹⁰⁵ The client should be able to continue talking in full sentences during engagement in therapeutic tasks. This is correlated with the ventilator threshold, and when the client can no longer talk comfortably he or she has passed this threshold.¹⁰⁵

These scales provide a good estimate when used repeatedly for the same client and therefore may be used clinically during ongoing continuous activity, such as walking, bicycling, scrubbing floors, painting a wall, mowing the lawn, raking leaves, and calisthenic exercises. Scales of perceived exertion do not apply to activities composed of sporadic variable movements, such as those that have frequent changes in intensity.

Muscular Aspects

Muscular fitness is a combination of muscular strength and muscular endurance.¹⁰¹ This chapter has already explored the evaluation of muscular strength with MMT, grip, and pinch-strength testing. Muscular endurance is the ability of the muscle to perform multiple repetitions of a contraction without fatigue.¹⁰¹ Endurance may be decreased because of local trauma or reduction of nerve innervation. In normal muscle contraction against low resistance, only a few of the available motor units are needed at any one time. The active and resting units take turns. If the person sustains a contraction that exceeds 15% to 20% MVC for the muscle group involved, blood flow to the working muscle decreases, causing a shift to anaerobic metabolism, which limits duration of contraction. The limitation is signaled by symptoms of muscle fatigue (cramping, burning, and tremor, which are secondary to the accumulation of lactic acid) and slowed nerve conduction velocity to the muscle fibers, which reduce tension and eventually result in an inability to hold the contraction.¹⁰¹ Strength and endurance are closely related. As muscle gains strength, its endurance for a given level of work also increases. It is important to note that for neurologically disadvantaged muscles, such as after a stroke, fewer motor units or muscle fibers may be available than are required for daily activity. Such muscles work at as much as 50% to 75% MVC to do otherwise low-intensity work.¹⁰⁶

Muscle endurance can be measured dynamically or statically. Dynamic assessments include the number of repetitions per unit of time. Static assessment is the amount of time a contraction can be held.^{101,107} Frequency, intensity, and time (duration) of the activity are considerations when evaluating endurance. Intensity is related to both resistance and speed. The heavier the resistance or the faster the pace (speed), the higher the intensity. The intensity of the test activity must be kept constant from test to test to gauge improvement.

The decision to measure dynamically or statically depends on the functional goal of the client and his or her cardiopulmonary status. If the client's self-advancement and self-enhancement roles require mostly isotonic activity, endurance should be evaluated dynamically. To measure endurance in terms of number of repetitions, use a light repetitive activity such as sitting to fold washcloths. An activity like this can be adapted to measure UE endurance for light work by counting the number of washcloths the client can fold before becoming fatigued.

For some individuals, decreased endurance might need to be assessed with heavier repetitive tasks such as those that simulate their ability to return to work. In these cases, a functional capacity evaluation (FCE) may be appropriate. FCEs measure a client's occupational performance to participate in work or in the worker role. As a whole, it assesses the client's impairment (such as endurance), occupational performance overall, and the role performance of the work to which the client wants to return.¹⁰⁸ There are multiple components that are assessed in an FCE, including the record review, interview (of the client and employer), physical measures/musculoskeletal assessment, physiological measures, functional measures, and comparisons of testing with job requirements. Each feature of an FCE should be considered with care.¹⁰⁹

A commonly used piece of equipment that may be used in an FCE is the Baltimore Therapeutic Equipment (BTE) work simulator. This equipment can be set up to simulate a variety of work and daily tasks, such as digging with a shovel, turning a knob, climbing a ladder or rope, and using a

steering wheel (among other things). It is a helpful device to use when it is not feasible to perform the actual work task, or if the client needs to work on a specific component of the work task. A static trial can be completed to gain a numeric value for the individual's MVC for that task. Then, to test endurance, the therapist can set the resistance level at 20% to 30% of that maximum. The therapist can see on the equipment if the client is decreasing in speed and showing fatigue. The time, repetitions, and weight can be documented for later comparison to show progress in the area of endurance. Although these numbers can be used clinically to demonstrate progress, the therapist should use caution when relating them to work capacity.

If the client expects to return to a job or hobby that requires isometric contractions, such as maintaining grasp or holding loads, static endurance should be tested. To measure statically, the amount of time a person can hold an object or position requiring a certain level MVC is noted. Normally, a person can hold 25% MVC for 5 to 6 minutes, 50% MVC for 1 to 2 minutes, and 100% MVC only momentarily.¹⁰¹

Isometric holding increases blood pressure and stresses the cardiopulmonary system.¹¹⁰ This is true especially if the person holds his or her breath (Valsalva maneuver) while holding the contraction. Therefore, clients being tested should talk (e.g., count or sing) while doing an isometric contraction to preclude breath holding. Isometric testing can produce arrhythmias and, therefore, electrocardiogram and blood pressure should be monitored during isometric testing of clients with heart disease or abnormalities. The results of isometric testing cannot be extrapolated to gauge isotonic aerobic exercise capacity.¹¹⁰ However, blood pressure measurements performed during isometric hand-grip exercises may be a useful screening tool in evaluating prehypertensive individuals.¹¹¹

CASE STUDY

Client Information

Pat is a 42-year-old, right-handed person, who is 8 weeks status post open reduction internal fixation of a right humerus fracture following a gunshot wound during an assault in a parking lot in the city (about 45 minutes away). Pat's radial nerve (which is frequently injured during humerus fractures) was not lacerated, but Pat did have wrist drop for a week following the injury and surgery that has slowly been improving (neuropraxia). Pat complains of UE weakness, stiffness, and decreased motion. Pat also complains of pain and fatigue that are increasingly limiting ADLs, IADLs, and participation in meaningful activities.

Pat is a dental hygienist, who has a life partner who frequently travels for work. They live in a one-story house. Pat has two grown children and enjoys gardening, working out at the gym, and shopping. Pat was previously seen at another facility recommended by the injury lawyer but has decided to transfer to a new facility because it is closer to Pat's home. Pat recently had a follow-up with the surgeon, who referred Pat to occupational therapy for evaluation and to begin strength training.

Assessment Process

To determine Pat's perception of occupational dysfunction and Pat's priorities, the therapist administered the Canadian Occupational Performance Measure (COPM). To determine the extent that motion, strength, and endurance problems affected Pat's occupational functioning, AROM assessment, a manual muscle test on selected muscle groups, grip- and pinch-strength assessments, and engagement in 1 minute of wrist activity on the BTE for endurance during work tasks were administered.

Assessment Results

The results of the COPM are as follows:

- Difficulty holding dental hygienist tools for prolonged periods (performance 3, satisfaction 2).
- Difficulty with morning ADL, including showering and dressing. Pat has problems squeezing bottles, bathing the left side of the body such as the armpit and back, and putting on jewelry (performance 6, satisfaction 5).
- Difficulty engaging in shopping tasks because of the fear associated with it. Pat was on a shopping trip when the trauma occurred (performance 5, satisfaction 4).

- Inability to do heavy meal preparation activities, including cutting vegetables and carrying dishes (performance 6, satisfaction 4).
- Unable to garden as desired, specifically planting, digging with a trowel, and weeding (performance 3, satisfaction 2).

Grip and Pinch Strength

	Right	Left
Grip	18	58
Tip pinch	3	12
Lateral pinch	5	14
Palmar pinch	4	13

Active Range of Motion

Shoulder, wrist, and hand AROM within normal limits
 Elbow extension–flexion right: 30°–120°
 Elbow flexion left: 0°–150°
 Elbow hyperextension left: 0°–5°
 Supination right: 0°–60°
 Supination left: 0°–90°
 Pronation right: 0°–80°
 Pronation left: 0°–90°

Pat has a 22-cm scar along the dorsal aspect of the arm that is red in appearance and flat. There is mild adhesion noted along the scar, and the scar does pucker with elbow motion.

Select Manual Muscle Strength

	Right	Left
Shoulder flexion	5	5
Shoulder abduction	4–	5
Elbow flexion	4	5
Elbow extension	4	5
Forearm supination	4	5
Forearm pronation	4	5
Wrist flexion	5	5
Wrist extension	3+	5
Digital extension	3+	5

Using the BTE, Pat demonstrated only five repetitions of wrist motion during 1 minute when set at 70% of Pat's MVC, which was 3 lb.

Occupational Therapy Problem List

- Decreased ability to perform morning ADL, including bathing and dressing, because of decreased motion, weakness, and low endurance.
- Decreased ability to perform meal preparation tasks because of weak grasp and pinch on the dominant side.
- Decreased ability to perform work-related tasks, including manipulating tools for prolonged periods of time because of weakness and decreased endurance of the muscles innervated by the radial nerve.
- Decreased ability to garden because of weakness and pain.
- Decreased engagement in shopping tasks depending on psychosocial factors.

Most Commonly Used Standardized Assessments for Motor Function

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Range of motion ^{19,20}	Measurement of joint range of motion	Full evaluation of all joints in the UE, 45 minutes to an hour	The concurrent validity between goniometry and digital inclinometry (for shoulder mobility) is good (intraclass correlation coefficient [ICC] ≥ 0.85) ¹¹²	Interrater reliability for the measurement of passive movements of upper extremity joints varies with the method of measurement ⁴	In the upper and lower extremities, measurement error is estimated at 5° ³³	Strengths: Relatively fast and inexpensive measure. Measurements are consistently more accurate when done by the same therapist with the client in the same position from test to test Weaknesses: Interrater reliability is consistently lower than is intrarater reliability. Accuracy of measurement dependent on consistent placement of goniometer
Hand volumetry ³⁴	Edema measurement through the displacement of water	10–20 minutes	Water displacement correlated with geometric measurements in the arm ($r = 0.97$ – 0.98) and in the hand ($r = 0.81$ – 0.91) ³⁶	Test–retest reliability ($r = 0.999$) ³⁵	Variation of measurement 3–5 mL ³⁴	Strength: Easily accessible way to obtain accurate measurements of edema Weakness: Hand must be immersed in water, so therapist must be aware of any contraindications. Takes considerable time
Figure-of-eight technique ³⁷	Edema measurement of the hand with circumferential tape assessment	1–4 minutes	Correlation coefficient between figure-of-eight technique and hand volumetry ICC = 0.83 – 0.95 ^{37,38}	Intratester ICC for figure-of-eight ICC = 0.96 – 0.99 ; intertester reliability ICC = 0.94 – 0.99 ^{37,113}	Recommend change of 1.16 cm to be clinically significant in clients with burns to the hands ¹¹⁴	Strengths: Fast measurement. Can be used on individuals with open wounds and skin conditions. Weakness: Larger studies on various client populations needed
Manual muscle testing ^{48,53,115}	Strength test of individual muscles and muscle groups	Depending on the number of muscles being tested, up to 1 hour	Spearman's correlation coefficients of the maximal relative force measurements with the median Medical Research Council and modified Medical Research Council score were both 0.78 ⁵³	In a reliability test for intrinsic hand muscles, intrarater ($r = 0.71$ – 0.96) and interrater ($r = 0.72$ – 0.93) reliability. ¹¹⁶ In an evaluation of reliability for the deltoid muscles, Pollard et al. ¹¹⁷ found that two testers agreed exactly 82% of the time, ($\kappa = 0.62$)	Not established	Strength: No equipment needed Weakness: Dependent on training and experience of tester

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Handheld dynamometry ⁶¹	Interval scale; measurement is in kilograms	Depending on the number of muscles being tested, up to 1 hour	Mean concurrent validity (ICC) varied from 0.78 to 0.93 ¹¹⁸	Interrater reliability ICC = 0.79–0.96, and intratester reliability ICC = 0.87–0.98 ¹¹⁹	Norms established ⁵⁹	<i>Strength:</i> Reliable test device <i>Weakness:</i> Expense of device
Grip strength test ^{22,80}	Measurement of grip strength by resistance in pounds or kilograms	5 minutes	Recommended by American Society of Hand Therapists as a valid measure of hand strength ²²	Test–retest reliability Jamar dynamometer $r > 0.8$, ^{80,120} and interrater reliability $r = 0.9$ ^{71,76}	Norms established with gold standard Jamar dynamometer ^{63,65} ; recommend 13-lb change for clinical significance ⁷¹	<i>Strengths:</i> Quick and easy measure. Norms available <i>Weakness:</i> Dynamometer need to be calibrated regularly in order to be accurate
Pinch strength tests ^{22,80}	Measurement of pinch strength (tip, lateral, and palmar) by resistance in pounds or kilograms	5 minutes	Recommended by American Society of Hand Therapists as a valid measure of pinch strength ²²	Interrater reliability $r = 0.98$; test–retest reliability was $r = 0.81$ ⁸⁰	Norms established ^{63,65}	<i>Strengths:</i> Quick and easy measure. Norms available <i>Weakness:</i> Pinch meters need to be calibrated regularly in order to be accurate
Borg rating of perceived exertion scale ¹⁰³	Measurement of perceived cardiorespiratory and muscular exertion	1 minute	Valid measure of exercise intensity. ¹²¹ Correlates with heart rate and oxygen uptake ^{122,123}	Reliable at high levels of exercise intensity ¹²²	More applicable at lower exercise levels with practice ¹²²	<i>Strength:</i> Good measure for individual <i>Weakness:</i> Not consistent between individuals

Chapter 14

Motor Function Intervention

Michael J. Borst

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Explain the biomechanical and physiological mechanisms that underlie occupational performance and therapeutic exercise.
2. Apply the conceptual framework for therapeutic occupation to conceptualize frames of reference, intervention approaches, and occupational performance.
3. Use methods to decrease edema and minimize contracture to prevent range of motion loss.
4. Apply principles from the biomechanical and motor learning frames of reference to occupation synthesis in order to improve range of motion, strength, and/or endurance.
5. Design interventions for clients who have impairments in edema, range of motion, strength, and/or endurance as needed to improve occupational performance.

CHAPTER OUTLINE

Musculoskeletal System
Therapeutic Intervention for Edema
Therapeutic Intervention for ROM
Therapeutic Intervention for Impaired Muscle Performance
Considerations for Client Training Handouts
Case Study

TERMINOLOGY

- Client factors:** basic structures and functions of a person that are used for occupational performance; edema, range of motion, strength, and endurance are all client factors¹
- Mechanical advantage (MA):** ratio that describes how easily a force can move a resistance using a lever
- Moment arm:** the perpendicular distance from the axis of rotation to the line of force (force vector)² on a lever
- Muscle endurance:** the ability of a muscle to contract repeatedly or over time without a decrease in force produced³
- Muscle strength:** the maximum amount of force that is produced by a muscle in a single contraction³
- Range of motion (ROM):** the arc of rotational motion through which a bone moves around a joint; usually measured in degrees
- Strain:** the change in shape of an object that results from the stress placed on it⁶
- Stress:** the force acting on an object, divided by the cross-sectional area of that object⁶
- Torque:** the extent to which a force causes an object to rotate around an axis²

Introduction

Occupational performance is influenced by **client factors** such as edema, **range of motion (ROM)**, **muscle strength**, and **muscle endurance**.¹ Occupational therapists sometimes help clients restore or establish these factors by synthesizing occupations, activities, or preparatory tasks designed to create change within the client.^{1,4}

Musculoskeletal System

Occupational therapists need to understand the biomechanical and physiological principles behind musculoskeletal system function. This understanding allows occupational therapists to analyze and synthesize occupations to promote successful occupational performance.

Biomechanical Aspects

Biomechanics applies the principles of physics (such as motion and force) to the human body. Kinematics is the study of the motion of an object without regard to the forces that produced the motion.² In the human body, we see two types of motion, translation and rotation. Translation occurs when an object or body part moves in a straight line. Rotation occurs when an object or body part moves in a circular motion around an axis. For example, when you walk down a hallway, your head is moving down the hall in a translational manner. In contrast, rotational motion is occurring at your hip joints, knee joints, and ankle joints as each flexes and extends around an axis.² Translation and rotation often occur at the same time in the human body.

Kinetics is the study of forces on an object and how those forces change the motion of the object.² With regard to the human body, these forces might include muscle contraction, gravity, friction, and any external push or pull on a body part.

Most occupations involve motions and forces. For example, when a person places a glass on a cupboard shelf, muscles in the trunk (internal forces) coactivate to create stability before any arm motion is initiated. Muscles in the shoulder girdle activate synergistically to create force couples (two or more muscles pulling in different linear directions to create rotation in the same direction) that move the sternoclavicular, acromioclavicular, and glenohumeral joints. To raise the glass, the elbow flexor muscles activate concentrically causing elbow joint flexion (rotary motion). To cause this rotation, the elbow flexors must generate enough force to create sufficient internal **torque** to overcome the external torque created by the force of gravity acting on the glass's mass. The movement of the glass upward to the cupboard is an example of translational motion, in which the glass moves in a more or less linear manner, rather than rotating around an axis.

Torque

Any analysis of rotary motion requires an understanding of torque. There are two factors of torque: force and distance. Torque is created when a linear force acts on an object at a certain distance from that object's axis of rotation; this distance is measured perpendicular to the direction of the force. This perpendicular distance between the axis of rotation and a force's line of action (vector) is called the **moment arm**. Torque is calculated by multiplying the linear force by the distance from the line of force to the axis of rotation. Thus, in mathematical terms:

$$\text{torque} = \text{force times the moment arm}$$

In the metric system, force is measured in newtons, and the moment arm is often measured in meters. In the English system, force is measured in pounds, and the moment arm is often measured in feet. Torque is therefore often expressed in newton·meters or foot·pounds.

It is critical to understand the difference between force and torque. A force acts in a linear direction and tends to cause translation motion when directed at the center of an object's mass. In contrast, torque involves rotation around an axis, and the moment arm is just as important as the force in determining how much torque is produced. Returning to our example of lifting a glass up to a shelf, there are two torques involved at the elbow joint: an internal torque and an external torque. The internal torque is the product of the internal (biceps brachii) force acting on the radius bone times the internal moment arm (of the biceps) in relation to the elbow joint (Fig. 14-1A; we are considering only one elbow flexor muscle for the sake of simplicity). The external torque is the product of the external force (the combined weight of the glass, forearm, and hand) times the external moment arm (of gravity) in relation to the elbow joint (Fig. 14-1B). If the internal torque is greater than the external torque, the muscle will activate concentrically (shorten) and the glass will go up. If the internal torque is less than the external torque, the muscle will activate eccentrically (lengthen while "trying" to shorten) and the glass

will go down. If the internal torque is equal to the external torque, the muscle will activate isometrically (stay the same length), and the glass will be held still in midair.

Figure 14-1 Internal and external torque. **A.** Internal (effort) torque. IF, internal force—Line of pull of biceps brachii. IMA, internal moment arm—Perpendicular distance between the IF of the biceps brachii and the axis of rotation. **B.** External (resistance) torque. EF, external force—Line of pull of combined weight of glass, hand, and forearm. EMA, external moment arm—Perpendicular distance between the EF and the axis of rotation.

To make an object easier to lift, we can reduce the external torque. This can be done in either of two ways: reduce the weight (force) of the object or reduce the distance (moment arm) between the object and the joint(s) responsible for the lifting. This is why therapists will teach clients to lift heavy objects closer to the body. Reducing the external moment arm will reduce the external torque and therefore also the internal torques required of the client's body. Similarly, when a therapist assists a client during a stand and pivot transfer, the therapist will stand as close to the client as is practicable in order to reduce the external moment arm and thus reduce the external torque, which in turn reduces the internal torques required of the therapist's body.

Levers

Another way to analyze torque production in rotary movement is through the description of levers. A lever consists of a rigid bar (such as a bone), an axis of rotation (such as a joint), and two opposing forces: effort and resistance. Effort is the force that causes movement, and resistance is the force that tends to keep an object from moving.⁷ Sometimes, the effort force is simply termed force, and the resistance force is simply termed resistance. When analyzing human occupation, the force generated by muscles is termed internal force, and the force generated by objects outside of the body is termed external force. There are three classes of levers.

A first-class lever has the axis of rotation between the effort and resistance forces.² A common example of a first-class lever is the seesaw (Fig. 14-2A). A seesaw remains in balance, with no movement, if two children of the same weight sit the same distance from the axis. This balance, or equilibrium, is maintained because the torque on one side of the seesaw equals the torque on the opposite side of the seesaw. The weight of child 1 times the perpendicular distance from the axis of rotation to child 1 equals the weight of child 2 times the perpendicular distance from the axis of rotation to child 2. Because the torques are equal, the children balance, and there is no movement. If one of the children were heavier, he or she would have to move closer to the axis (shorten his or her moment arm) to decrease his or her torque and maintain equilibrium (Fig. 14-2B).

Figure 14-2 First-class lever. **A.** A seesaw as a first-class lever. Balanced equilibrium depicted by children on a seesaw. Both children weigh 60 lb, and they are equidistant from the axis. **B.** A seesaw as a first-class lever. The heavier child must be closer to the axis of the seesaw (shorten his moment arm) to maintain the equilibrium. A, Axis.

A second-class lever has the resistance force between the axis of rotation and the effort force.² A classic example of a second-class lever is a wheelbarrow used to move soil when gardening (Fig. 14-3). The resistance force (the pull of gravity on the soil) is between the axis and the effort force. Because the resistance moment arm (the perpendicular distance between the wheel and the resistance force of the soil) is considerably shorter than the effort moment arm (the perpendicular distance between the wheel and the effort force from the person lifting the handles), the person can lift the handles with considerably less force than the actual weight of the soil. Second-class levers are often used in assistive devices such as a key turner, jar opener, or doorknob lever. One disadvantage of second-class levers is that the arc of movement where the effort force is applied is always greater than the arc of movement where the resistance is applied. Thus, the end of a handheld jar opener must be moved several inches in order to move the jar lid itself only an inch.

Figure 14-3 Second-class lever. A wheelbarrow as a second-class lever. The resistance force (from the soil) is between the axis (at the wheel) and the effort force (at the handles). Because the effort moment arm is longer than the resistance moment arm in a second-class lever, $MA > 1$, and less effort force is required to lift the resistance provided by the soil.

A third-class lever has the effort force between the axis of rotation and the resistance force.² A shovel can be a third-class lever, if the person uses his or her back hand to stabilize the shovel and the front hand to do the lifting (Fig. 14-4). Because the resistance moment arm is longer than the effort moment arm, more effort force is required to lift the soil in the shovel; however, the soil will also move a greater distance than the hand that is doing the lifting moves. Third-class levers are often used in situations where the physical constraints of the lever require the effort moment arm to be shorter than the resistance moment arm. Most muscles in the human body are attached to bones in such a way as to create third-class levers, because the muscles need to be inside the body. Because the effort moment arm of a third-class lever is always shorter than the resistance moment arm, third-class levers always require the effort force to be greater than the resistance force in order to create an effort torque that is greater than the resistance torque. One advantage of third-class levers is that the arc of movement where the resistance is applied is always greater than the arc of movement where the effort force is applied. Thus the elbow flexor muscles can move the hand through an arc of about 2 feet with a muscle contraction of only a few inches.

Figure 14-4 Third-class lever. A shovel can be a third-class lever, if the back hand is used to stabilize the shovel and the front hand to do the lifting.

Mechanical Advantage

Mechanical advantage (MA) is a ratio that describes how easily a force can move a resistance using a lever. MA can be expressed in terms of the length of the moment arms ($MA = \text{effort moment arm} / \text{resistance moment arm}$) or in terms of the force produced by the lever ($MA = \text{force out of the lever} / \text{force applied to the lever}$).²

A key turner extends the effort moment arm of the key (the distance between where effort force is applied to the key and the longitudinal axis of the key as it is turned), thus increasing the MA of the key (Fig. 14-5).

Figure 14-5 Mechanical advantage (MA). **A.** Opening a door with a key. The effort moment arm is half the width of the head of the key. **B.** Adding a key turner. The key turner doubles the effort moment arm, doubling the MA and cutting the effort force required by half.

Physiological Aspects

A muscle–tendon unit consists of two components: elastic connective tissue that runs throughout the muscle belly and forms the tendons at the ends of the muscle–tendon unit, and muscle fibers that contract when stimulated by an alpha (lower) motor neuron. Both of these components are important in overall muscle–tendon unit functioning.

Elastic Connective Tissue Lengthening

In order to understand and evaluate interventions designed to increase ROM, it is essential to first review some basic definitions and principles of tissue biomechanics.⁸ Active range of motion (AROM) occurs when the client uses his or her own muscles to actively move. Passive range of motion (PROM) occurs when an external force (such as the therapist or the client's other arm) causes the movement. Active assistive range of motion (AAROM) is a treatment technique used when a client does not have adequate strength to complete full AROM, and the client attempts to move actively while receiving passive assistance as well.

Stress and Strain

Stress is “the force acting on an object, divided by the cross sectional area” of that object.^{6(p116)} The terms *stress*, *force*, and *load* are sometimes used interchangeably, but that is technically incorrect because force is a component of stress. **Strain** has to do with the resulting deformation of the object and is “the change in length of the object divided by the original length.”^{6(p116)}

The typical relationship between stress and strain in elastic connective tissue is shown in the stress–strain curve (Fig. 14-6). The *neutral zone* (NZ) represents the unfolding of the collagen fibers as stress is applied.⁹ The NZ is also called the “toe” region of the curve.^{2,10} As stress increases, the collagen fibers align along the line of stress,⁹ and the tissue enters the “elastic zone” (EZ). The beginning of the EZ is where tissue resistance is first felt when a therapist performs PROM on a client's joint. The end of the EZ is the end of joint PROM. Application of increased stress after the end of the client's joint PROM can result in tissue microfailure (trauma)⁹; this is called the plastic zone (PZ). Because the tissue tears at a microscopic level in the PZ, the tissue elongation (strain) is permanent; however, that strain comes at the cost of inflammation and scar proliferation. The EZ and PZ probably overlap to some extent, and the clear border in Figure 14-6 is only for illustration. If yet more stress is applied, the failure point is reached, and gross rupture of the tissue occurs.

Figure 14-6 Stress–strain curve.

Viscoelasticity: Creep and Stress Relaxation

Some materials, including biologic tissues, are viscoelastic. This means that the strain (or deformation) of the tissue is a function of time as well as stress.¹¹ Viscoelastic tissues do not release their elastic or plastic strain all at once; instead, these changes occur more slowly over time. Viscoelasticity can be demonstrated in two ways with the example of a tree branch (Fig. 14-7). If an object were hung on the branch (providing a constant stress), the weight of the object would result in some immediate deformation (strain), and additional deformation would

occur over time as the object continued to hang on the branch. The additional deformation that occurs over time is due to viscoelasticity. This method of using viscoelasticity by applying a constant stress is called creep.⁹⁻¹¹

Figure 14-7 Viscoelasticity through creep and stress relaxation. **A.** Creep (constant stress). **B.** Stress relaxation (strain is held constant). **C.** Result of stress relaxation after the “hold” is removed.

Alternatively, if the tree branch were placed in the position that would result initially if the object were attached (but without the weight of the object) and held there by an external structure (thus maintaining a constant strain or deformation), the branch would adapt to that positioning and would not instantly return to its original position when the object constraining its movement were removed. This method of using viscoelasticity by maintaining a constant strain is called stress relaxation, because the stress decreases over time while the positioning (strain) is held constant.⁹⁻¹¹ Both stress relaxation and creep result from the viscoelastic nature of biologic materials.¹¹

Some scholars have advocated creep as a method of permanently elongating biologic viscoelastic materials with stress¹⁰; however, others equate creep with plastic deformation

caused by tissue microfailure and strongly caution against creep as a method of tissue elongation.⁹ Still others define creep in biologic tissues as reversible elongation of a viscoelastic material over time in response to a continuous load.² It is critical to remember that when creep is used to elongate tissues, the point at which the tissue starts in the stress–strain curve is not stable; rather, it shifts to the right over time, moving closer to or into the PZ, as the tissue continues to deform in response to a constant load.^{9–11} Thus, the use of creep to elongate tissue carries with it significant risk of tissue trauma, inflammation, and scarring or adhesion.

When stress relaxation is used to elongate tissues, the point at which the tissue starts in the stress–strain curve shifts downward over time, staying in the EZ as the tissue adapts to a held position (a constant amount of strain).^{9–11} Thus, the use of stress relaxation to elongate tissue carries much less risk of tissue trauma.

Stimulating Tissue Growth

When adaptive shortening of elastic connective tissue creates a PROM deficit (as in a joint contracture), it is critical to understand that the preferred mechanism of elongation is tissue growth, instead of plastic or elastic changes caused by either creep or stress relaxation.^{9,12,13} In order to promote tissue growth, Dr. Paul Brand advocated holding the tissue in “only a slightly lengthened position (within its elastic limit) for a period of hours or days” (using a constant strain, similar to stress relaxation, instead of a constant stress, as in creep).⁹ An example of this method of stimulating tissue growth is the wearing of plugs of gradually increasing size (gauges) in the earlobes over time in order to create a large hole in intact earlobes (Fig. 14-8).

Figure 14-8 Tissue growth stimulated by the use of sequentially larger earlobe gauges to hold the tissue in an elongated position. (Shutterstock/Oleksii Fedorenko.)

Prolonged Strain in the EZ

“Low-load prolonged stress”^{13–17} is commonly advocated for remodeling elastic connective tissue. Although the concept is sound, the term is redundant and unclear, as load is a component of stress, and “low” is undefined, leaving it unclear whether the stress places the tissue in the elastic or PZs. Sometimes, the term *low-load prolonged stretch* is used, but this term should be avoided, as it is unclear whether *stretch* refers to the force on the object (stress) or the resulting change in length (strain). A more helpful term for the mechanism of stimulating tissue growth would be *prolonged strain in the elastic zone*.

Contractile (Muscle) Tissue

Skeletal muscle provides the force to produce movement of a bony lever around its joint axis. A muscle’s strength and endurance depend on multiple factors, such as the size and type of

muscle fibers, the number and frequency of motor units firing, and the length–tension relationship of the muscle. It is important to understand the basic contractile elements within muscle tissue.

The sarcomere (made up of actin and myosin filaments) is the basic contractile element of skeletal muscle and is located within the myofibril (Fig. 14-9). A motor unit consists of a single alpha motor neuron and the muscle fibers innervated by that neuron. When the alpha motor neuron is depolarized and causes the muscle fiber membrane to depolarize, calcium ions are released throughout the muscle fiber, causing the myosin heads to “grab” and “pull” on the actin filaments, shortening the sarcomere.¹⁸

Figure 14-9 Sarcomere structure.

Considerations for Lengthening Contractile (Muscle) Tissue

When stretching muscle tissue, the actin–myosin cross-bridges release and the sarcomeres lengthen temporarily.¹⁹ The amount of lengthening available through this mechanism is proportional to the number of sarcomeres lined up end to end (in series) in an individual muscle. Thus, a fusiform muscle that has relatively many sarcomeres lined up end to end will have more range of muscle length than a pennate muscle.²⁰ For example, biceps brachii is a fusiform muscle that has a great range of muscle length as it activates across both the shoulder and the elbow joints simultaneously. The number of sarcomeres in series can decrease if a muscle is immobilized in a shortened position,¹⁹ and prolonged strain in the EZ can increase the number of sarcomeres in series.²¹

Considerations for Strengthening Muscle Tissue

The nature of a muscle’s performance is influenced by the number and type of muscle fibers found in a single motor unit. Large muscles that typically contract with great force (such as gluteus maximus) have a greater proportion of motor units that have large neurons and up to 2,000 muscle fibers per motor unit.²² These fibers are also typically fast-twitch fibers, which are capable of producing more force more quickly and also fatigue faster.²² On the other hand, smaller muscles that typically contract with less force but produce more finely controlled movements (such as some facial muscles) have a greater proportion of motor units that have small neurons and as few as five muscle fibers per motor unit.²² These fibers are typically slow-twitch fibers, which provide smaller, more controlled forces and do not fatigue as rapidly.²²

The amount of force produced by a muscle activation is controlled through recruitment (the number of motor units that are activated) and rate coding (how frequently each motor unit is activated).²² If more force is required, the brain can activate more motor units and/or activate each motor unit more frequently. Small motor units that produce less tension and thus require less energy are usually recruited first, but if they cannot produce adequate force, larger motor units are recruited to complete the action.

The force production of an individual muscle is proportional to the cross-sectional area of its muscle fibers. Because pennate muscles (in which the fibers attach to a tendon at an angle) can pack more muscle fibers in a given area, they tend to produce more force than fusiform muscles.²² For example, the palmar and dorsal interosseous muscles are pennate muscles that pack a lot of fibers into a small space in the hand.

Finally, a muscle's ability to produce force depends on the length of its sarcomeres when it is activated. This phenomenon is illustrated using the active length–tension curve (Fig. 14-10). If a muscle is already fully shortened, its sarcomeres do not have room to shorten any further and thus cannot produce any additional force or tension (see the left side of the active length–tension curve). This phenomenon is called active insufficiency, and will result in apparent weakness in a multijoint muscle–tendon unit that has been shortened over all its joints simultaneously, even though the muscle's ability to produce force in a more neutral position is normal.²⁰ Muscles that cross only one joint tend not to have active insufficiency. If a muscle is fully passively lengthened, it will not be able to produce much force because most of the myosin heads are not in contact with the actin filaments and therefore cannot “pull” on the actin filaments to produce contractile force (see the right side of the active length–tension curve). If a muscle is in the middle of its length range, it has the greatest potential for force production, with enough actin–myosin cross-bridges to generate a lot of force and plenty of potential to shorten (see the middle of the active length–tension curve).

Figure 14-10 Active length–tension curve. The position of the myosin heads in relation to the actin filament determines the potential for force generation at a given muscle length.

Therapeutic Intervention for Edema

According to the biomechanical FOR, edema reduction is always a priority once structural stability has been addressed. Prompt edema management will result in improvements in ROM and pain, whereas unmanaged edema will worsen these issues and eventually result in contractures and adhesions between structures in the limb.²⁷ Edema management varies depending on the stage of the edema and the vascular status of the body part.

Vascular Status

🚫 Vascular flow may be impaired if there was damage to vascular structures or if a client has peripheral vascular disease. If vascular flow is impaired, interventions that involve limb compression, elevation, cold, or heat may be contraindicated.²⁷ Vascular status of a finger can be assessed using the capillary refill test, in which the client's fingertip is compressed so that it turns pale and then the time it takes for blood flow to return (as evidenced by the color returning in the fingertip pulp or under the fingernail) is measured. If it takes longer than 2 seconds for blood flow to return to the fingertip, vascular status is impaired (see Video 14-1).²⁸ Vascular status of the entire hand can be assessed by the Modified Allen's Test, in which firm pressure is placed over the client's radial and ulnar arteries just proximal to the volar wrist creases, the client flexes the digits into a fist and extends them again several times until the volar hand is pale, the pressure is released from one of the two arteries (radial or ulnar), and the time it takes for blood flow to return (as evidenced by the color returning in the volar palm and digits) is measured. If it takes longer than 5 seconds for blood flow to return to the palm and digits, vascular status is impaired (see Video 14-2).²⁸

Stages of Edema

Edema is interstitial fluid between the cells in the body and can be classified into three stages: acute, subacute, and chronic.²⁹ Acute edema is still quite fluid and mobile. In acute edema, the tissue pits (indents readily when pressed) deeply and rebounds quickly. The edema can be moved around with pressure or massage. Subacute edema has accumulated more protein and is more viscous as a result. In subacute edema, the tissue pits but is slow to rebound.

Chronic edema has accumulated even more protein, to the point that fibrotic adhesions start to form. In chronic edema, the tissue pits minimally, and the tissues may feel hard or leather-like. Measurement of edema is covered in Chapter 13; however, interstitial fluid can increase by 30% before being detected,²⁷ so edema measurement is not a valid method of ruling out the presence of edema.

Interventions for Acute Edema

📌 For acute edema, the limb is elevated above the heart in order to use gravity to improve venous and lymphatic flow and reuptake of interstitial fluid.²⁷ Sometimes allied health professionals will consider a sling to be a form of elevation, but a sling often worsens arm edema because it holds most of the arm below the heart and also prevents active motion. Light compression with form-fitting garments can be helpful, such as gloves (Fig. 14-11) or hosiery, tubular sleeves such as Tubigrip (Mark One Health Care Products, Philadelphia, PA), or elastic wraps such as Coban (3M, St. Paul, MN). The therapist must be careful to keep the compression light, as compression above 60 mmHg will collapse the lymphatic pathways, inhibiting the body's natural pathways for resorbing edema, and compression above 75 mmHg can damage the lymphatic capillaries.³⁰ The garment or sleeve should be easily pulled away from the skin slightly, yet provide some compression.²⁹ Edema gloves often do not compress adequately in the webspaces between the fingers, and gauze 2 × 2s can be placed in the webspaces before donning the glove to improve the compression in this area, or the therapist can apply small (about 1 × 4 inches) hourglass-shaped strips of Kinesio Tape (Kinesio Holding Corporation, Albuquerque, NM) under light (10%) tension to the webspaces before donning the glove (Fig. 14-11). Sometimes, the proximal edge of Tubigrip or a compression glove will roll over, and this should be avoided by cutting a longitudinal slit in the sleeve or glove so the proximal edge can splay instead of rolling over. A rolled proximal edge will create a high-pressure area that will hinder the flow of edema through the lymphatic system. When using a self-adhesive elastic bandage such as Coban, start at the distal end of the limb or digit and wrap proximally with no tension, because self-adhesive bandages tend to tighten up on their own (see Video 14-3). When wrapping a digit, leave the tip open to observe skin color and circulation. In the inflammatory stage of wound healing (typically lasting 3–5 days after injury or surgery), cryotherapy can be used to prevent edema accumulation (see Chapter 24). AROM (especially overhead) and PROM can also decrease acute edema, but during the inflammatory stage of healing, immobilization is more appropriate to preserve structural stability and avoid increasing inflammation.

Figure 14-11 Edema glove compression. **A.** Edema glove. **B.** Kinesio Tape application for use under an edema glove.

Interventions for Subacute Edema

Subacute edema contains more protein, which cannot be resorbed by the venous system, and thus requires techniques that utilize the lymphatic system. The lymphatic system consists of tiny initial lymphatic capillaries in the interstitium that are connected to surrounding tissues by anchor filaments. When tension is put on the surrounding tissues (usually by limb movement and muscle contraction), these anchor filaments open the initial lymphatic capillaries so they

can extract the protein-laden interstitial fluid.²⁹ Thus, most of our interventions for subacute edema involve some method of putting tension on these anchoring filaments so they can open the initial lymphatics, without applying so much compression that the lymphatic capillaries collapse.

AROM, PROM, and even light isometric exercise are methods the client can use to open the lymphatic capillaries. Kinesio Tape can also be used to provide light tension on the skin that may help open the initial lymphatics. Apply the Kinesio Tape with no stretch to skin that is stretched (i.e., with joints bent away from the surface you are taping) so that the tape wrinkles after application (Fig. 14-12). This method will provide light tension and light pressure with movement of the limb. Compression (as described under section Interventions for Acute Edema) can also be used in the same way for subacute edema. A “chip bag” or pad containing varying densities of foam chips can be used under a compressive glove or sleeve to help soften edema that has become more viscous. Chip bags can be fabricated easily by cutting scrap foam into small pieces and placing them in stockinette or between two layers of light tape such as Kinesio Tape (Fig. 14-13). After the tissues are well past the inflammatory stage of healing, mild heat (96°F–100°F) can be used to soften edema before exercise²⁹; even the “neutral warmth” reflected by a pressure garment or very thin neoprene sleeve can help soften viscous edema.

Figure 14-12 Kinesio Tape application for hand edema.

Figure 14-13 Construction of a chip bag using various densities of foam. The tape would be folded over to seal the foam chips in.

Manual Edema Mobilization

 Manual edema mobilization (MEM) is a set of techniques designed to promote normal functioning of the lymphatic system (see Video 14-4). MEM can move large amounts of interstitial fluid into the cardiovascular system in a short period, so it is contraindicated if the

client has congestive heart failure or other severe cardiac problems, renal failure or other severe kidney problems, liver disease, or severe pulmonary problems; if the client has active cancer; if an infection is present; if a hematoma or blood clot is present; or over areas of inflammation (MEM proximal to areas of inflammation may be helpful).³⁰ MEM should be used with caution if the client has diabetes, because it may cause alterations in blood sugar; if the client has low blood pressure, because it may decrease blood pressure further; and if the client is pregnant, because it may increase feelings of morning sickness.³⁰

MEM Principles

In contrast to the cardiovascular system, which uses the heart to *push* blood through the blood vessels, the lymphatic system uses pressure gradients to *pull* or *draw* the lymph proximally to areas of lower pressure. Thus, the techniques used in MEM are designed to create small pressure differentials to promote proximal lymphatic flow and to put light tension on the anchor filaments to open the superficial initial lymphatic capillaries. Furthermore, proximal areas must be cleared of lymph (creating lower proximal pressure) before lymph can flow out of distal areas. Finally, extra attention is paid to areas where lymph tends to accumulate, such as lymph nodes.

MEM Techniques

MEM techniques are used roughly in the following order, although they can be modified to fit each client's unique situation, as long as the basic principles listed previously are followed. First, deep diaphragmatic breathing is done for a couple of minutes to try to clear the proximal deep lymphatic structures. Second, shoulder AROM or PROM exercises are performed to further assist the proximal clearing.

Third, light skin-tractioning massage and ROM exercise is used to apply tension to the anchor filaments and open the lymphatic capillaries. The skin-tractioning massage should be applied directly to the skin (not through clothing) if at all possible. The pressure should be just enough to move the skin (rather than slide over the skin) and no more than that. More contact area between the massaging hand and the area being treated will result in more lymphatic capillaries being opened, so it is important for the therapist to use the entire surface of his or her relaxed palm and fingers to apply the light skin-tractioning massage. The massage is applied in a circular or U-shaped pattern with the top of the U pointing proximally. Each body segment (chest, upper arm, forearm, hand, digit) is divided into three sections, and five light skin-tractioning U's are applied in each section. Each body segment is first cleared by massaging the proximal section, then the middle section, and then the distal section. After clearing each segment, AROM or PROM of the adjacent joints is performed to further clear that segment. Once one segment is cleared with massage and exercise, then flow massage is performed. Flow massage involves the same light skin-tractioning U's to the same sections, but they are applied starting at the most distal section just cleared and then the next proximal section, and so on all the way to the contralateral chest. When performing the flow massage, one repetition is used in each section (instead of five), but the entire flow sequence is performed five times. Once a segment has been both cleared and flowed using this procedure, the next distal segment is cleared and flowed (e.g., after the upper arm is cleared and flowed, then the forearm is cleared and flowed).

Fourth, lymph nodes and other areas of potential lymph congestion (called pump points in MEM) are massaged using both hands simultaneously for a total of 20 to 30 U's. This massage can be done with slightly more pressure, but it is still important to keep the pressure light, remembering that you are not trying to push or force fluid proximally, but pull or draw it from more distal areas by creating lower pressures at the pump points. Pump points are located at the anterior shoulder and axilla, the medial elbow, the wrist, and the dorsal hand. Pump point massage can be incorporated into the light skin-tractioning massage between the clearing and flowing U's. More detailed information about MEM is available from other sources.^{29,30}

MEM can and should be taught to outpatient clients as part of a home program as well. Although clients might not perform MEM exactly "by the book," in my experience, self-MEM can be very effective as long as the principles of clearing before flowing, light skin-tractioning massage, and AROM or PROM exercise are followed.

Interventions for Chronic Edema

Chronic edema has accumulated a substantial amount of protein that is becoming fibrotic. As a result, it can be very difficult to reduce. Hopefully, very few patients will reach this stage, but edema management does not always happen promptly. All of the interventions for subacute edema noted earlier are also appropriate for chronic edema. Additionally, low stretch or short stretch bandaging techniques can be used to treat chronic edema.³⁰

Lymphedema

Lymphedema is edema that results from a lymphatic system that is not functioning properly because of damage from trauma, surgery, radiation therapy, and the like. Sometimes, the lymphatic system is congenitally inadequate. Whatever the cause, lymphedema requires the therapist to train the client in self-management techniques that work around the lymphatic system rather than with the lymphatic system, and therefore this area of practice requires specialized training.²⁹

Therapeutic Intervention for ROM

Therapeutic Intervention to Prevent Loss of PROM

A client may be at risk for loss of PROM because of a variety of factors related to immobility, including coma, being on complete bed rest, paralysis, and trauma or surgical repair.³¹ In these situations, elastic and contractile connective tissue can shorten, causing contracture, or lose elasticity, causing stiffness. Cartilage can thin, soften, and lose its ability to absorb the loads placed on it.³² In some (but not all) situations, PROM intervention to prevent these impairments may be appropriate.

First, contraindications and precautions related to PROM must be considered. Remembering the first consideration of the biomechanical FOR (structural stability), the occupational therapist must be certain that the tissues involved can withstand any forces placed on them. If one is unsure what the movement and positioning restrictions are after surgery, it is the therapist's responsibility to contact the surgeon and find out. If, for example, a therapist were to move a client's fingers and/or wrist into full extension within a few weeks after a flexor tendon repair, he or she would likely rupture the repair. By breaking what the surgeon fixed, the therapist has created the need for a tendon reconstruction, involving multiple additional surgeries and several additional months of therapy. On the other hand, if the fingers and wrist are not ranged in a controlled fashion within safe limits, the repaired tendon will adhere to the surrounding tissues, and the outcome will be poor.

Shoulder PROM and AROM is another area where precautions need to be carefully considered. Shoulder motion is a complex phenomenon consisting of movements at the glenohumeral, acromioclavicular, and sternoclavicular joints. Normal shoulder motion is dynamically controlled by several different muscles that create appropriate scapulohumeral rhythm.³³ If a therapist were to flex or abduct a client's shoulder by passively moving the humerus, he or she would likely cause impingement of the rotator cuff and long head of biceps brachii tendons in the subacromial space. If the client's shoulder musculature is paralyzed (e.g., after stroke, spinal cord injury, or while comatose), the shoulder should not be ranged above 90°. If there is shoulder weakness and the therapist is performing AAROM, then he or she should have one hand on the scapula to check whether scapular upward rotation occurs with proper timing and magnitude.

PROM is not the same as stretching. PROM involves taking a joint through its available ROM without overpressure at the end of the range. This is accomplished with an external force: usually the therapist, a caregiver, or the client's other arm. Stretching, on the other hand, uses a prolonged hold in the EZ (near the end of the PROM).¹⁹

In order to maintain cartilage health, tissue length, and tissue elasticity, 5 to 10 repetitions of PROM in each available direction at each joint is recommended.³¹ PROM should never be forced or cause pain. The total number of repetitions per day or week will depend on the client's situation. For example, a client with burns will need considerably more intensive intervention to prevent loss of ROM, and orthoses are often used to hold tissues in an elongated position for long periods.

Therapeutic Intervention for Limited ROM

Limited AROM or PROM at a joint can occur for a variety of reasons and become a concern when it causes a limitation in occupational performance. Full AROM is sometimes not required in order for a person to successfully complete his or her occupations and fulfill necessary roles. *Functional ROM* refers to the amount of AROM at a particular joint that is required to complete most activities of daily living (ADLs); however, what constitutes functional ROM depends on the occupations a client desires to perform. For example, a recent study indicated that elbow AROM of $-27^{\circ}/149^{\circ}$ (give or take $5^{\circ}-7^{\circ}$) was functionally adequate for basic ADLs (tying shoes, drinking, eating, and using a mobile phone).³⁴ However, some people may desire to perform occupations that require more elbow extension or flexion than that. When ROM impairments result in occupational performance limitations, those impairments become a concern for the occupational therapist and the client.

Differential Diagnosis of AROM Limitations

It is important to differentiate joint contracture from extensor lag, passive insufficiency, or tendon adhesion. Each of these causes is described next in more detail, and a differential flowchart for AROM loss is shown in Figure 14-14.

Figure 14-14 Differential diagnosis of limited AROM. AROM, active range of motion; PROM, passive range of motion.

A lag exists when there is a loss of joint AROM in the direction of the active muscle (the agonist) but there is full passive motion.³⁵ A lag may be caused by agonist tendon adhesion, agonist muscle weakness, or some other factor that decreases the agonist force to the joint. A joint friction problem may exist when PROM is nearly normal but AROM is difficult and muscle weakness does not seem to be the problem.

Passive insufficiency occurs when an antagonist multijoint muscle–tendon unit that has become too short prevents full PROM in the direction of the agonist.²⁰ Passive insufficiency is easily diagnosed by changing the positioning of the other joints that are crossed by the antagonist multijoint muscle–tendon unit. If changing the position of one of these other joints changes the PROM available at the joint in question, then passive insufficiency is the cause. Tendon adhesion of the antagonist may appear similar to passive insufficiency, depending on the location of the adhesion.

A viscosity problem resulting from edema can sometimes look like a contracture. If PROM is limited and does not change with repositioning of other joints, preconditioning with 20 minutes of mild heat and AROM followed by about 10 minutes of stress applied in the EZ (e.g., a mild weighted stretch) can help differentiate between viscosity issues and joint contracture. If this preconditioning results in PROM gains of 20° or more, then the problem is likely increased viscosity from edema rather than a fixed contracture.^{9,12}

If none of the preceding factors explain the limited AROM, it is likely that a joint contracture exists because of shortened elastic connective tissue such as ligaments, joint capsule, fascia, skin, or other connective tissues.

Intervention for a Lag

 If a client has a lag that appears to result from muscle weakness (typically 2–/5 on the muscle strength grading scale in Chapter 13), then AAROM is appropriate (see Video 14-5). In AAROM, the client moves the joint as far as possible on his or her own (actively), then gently assists it with the other hand to complete the ROM, while still trying to move it actively. Another method used for finger flexion or extension lag is called a place and hold. In a place and hold, the digit(s) are passively placed in the position that the client cannot achieve actively, and then the client tries to hold the digit(s) in that position while the support is released. Finally, if the client has 2/5 to 3–/5 muscle strength, light resistance can be used as tolerated for strengthening in a gravity-minimized plane.

Intervention for Tendon Adhesion

Tendon adhesion (in which scarring has developed between a tendon and surrounding tissue) can be difficult to treat and becomes more difficult as more time passes. Remembering the biomechanical FOR, our first priority is structural stability, so the therapist makes sure that any healing structures can withstand the stresses in the interventions described next. Therapy after a tendon repair is beyond the scope of this chapter, and other resources should be consulted in this situation.^{36,37}

The goal with tendon adhesion is to elongate the adhesion so that it no longer restricts tendon excursion. Methods to do this include AROM and strengthening of the muscle–tendon unit that is adherent in order to put tension on the adhesion itself. Heat before exercise can help improve tissue extensibility as well (see Chapter 24). Finally, the tissues to which the tendon is adherent can be massaged in such a way as to pull them away from the tendon, putting tension on the adhesion.

Intervention for Muscle Shortness or Passive Insufficiency

 A short or stiff muscle–tendon unit can limit AROM during occupational performance, particularly when it crosses multiple joints. Stretching is the initial option for lengthen a muscle–tendon unit. When stretching, the therapist or client uses a prolonged hold in the EZ (near the end of the PROM) in order to lengthen the muscle–tendon unit. To stretch, the joint(s) that the muscle–tendon unit crosses are held in a position opposite the action of that muscle–tendon unit. For example, if flexor digitorum profundus (which flexes the wrist and the finger metacarpophalangeal, proximal interphalangeal, and distal interphalangeal joints) is too short, those four joints would simultaneously be placed in extension and held there for a

while to stretch the muscle–tendon unit (Fig. 14-15). If intrinsic musculature (which taken together flexes the finger metacarpophalangeal joints and extends the proximal interphalangeal and distal interphalangeal joints) is too short, those joints would simultaneously be placed in a position opposite the combined action of the intrinsics to stretch those muscle–tendon units (Fig. 14-16). *Active stretching* refers to stretching a muscle by performing and holding the opposite movement actively. *Passive stretching* refers to using an external force (such as the other hand) to hold the position and tends to involve greater forces than active stretching (see Video 14-6).

Figure 14-15 Passive stretch of flexor digitorum profundus.

Figure 14-16 Passive stretch of the intrinsic muscles.

A static stretch is held for 15 to 60 seconds (60-second stretches may be needed for older clients)³⁸ and repeated three to five times, 3 to 6 days a week, depending on the client's condition. It is essential that the stretch be applied slowly and gently without bouncing to avoid a stretch reflex that would hinder elongation of the muscle belly.¹⁹ It is also essential that the stretch isolate the structures that need elongation. Without proper positioning and stabilization, the therapist can unwittingly overstretch or damage adjacent structures.¹⁹

 Additional techniques that increase the range of shortened muscle are the proprioceptive neuromuscular facilitation techniques called contract relax (CR) and hold relax (HR) (see Video 14-7).^{39,40} CR involves a maximal concentric contraction of the short muscle, usually performed at the point of limitation. The muscle is contracted concentrically and maximally for 5 to 8 seconds against resistance provided by the therapist and then relaxed. During the relaxation phase, the therapist gently moves the part in the direction opposite to the contraction and holds it there to stretch the muscle–tendon unit. For example, if there is a contracture of the elbow flexors, the elbow is passively extended as far as possible. The patient is instructed to contract the flexors maximally while the therapist provides resistance and then relax, at which point the therapist smoothly extends the elbow into a greater range. The CR technique

can be repeated multiple times. HR is an essentially identical technique, except that it is done with a maximal isometric contraction against resistance provided by the therapist, rather than a concentric contraction. HR is used when the joint is painful or damaged in some way.

Joint Mobilization

Sometimes, altered arthrokinematics (the roll, slide, and spin of joint surfaces as a person moves) is the cause of limitations in joint ROM, especially after trauma such as a fracture. Arthrokinematic movements cannot be performed voluntarily, and therefore active movement or stretching cannot remediate arthrokinematic problems. Joint mobilization techniques are required to address altered arthrokinematics, and although these techniques are beyond the scope of this chapter, they are well addressed elsewhere.⁴¹

Intervention for Joint Contracture

When tissues have shortened to the point that they create a contracture at a joint, intermittent stretching is not likely to result in satisfactory improvement, and orthotic intervention is indicated. In order to improve the contracture, the tissues need prolonged strain in the EZ so that the body can grow new tissue in response to the strain (refer to section “Physiological Aspects”). This is most effectively done with either a static progressive orthosis or a serial static orthosis. Dynamic orthoses apply creep to the contracted tissues, which over time will move the tissues into the PZ, resulting in inflammation and scar proliferation.^{9,42}

Therapeutic Intervention for Impaired Muscle Performance

Parameters for Therapeutic Exercise

When an occupational therapist designs an exercise program for a client, a number of interacting parameters need to be considered. *Resistance* or *intensity* refers to the external torque the client must overcome when doing the exercise and includes the force of gravity acting on a weight that might be held or strapped to a client’s arm along with the weight of the arm itself, the tension in a TheraBand (The Hygenic Corporation, Akron, OH), or, in the case of an isometric exercise, an immovable object such as a desk or wall against which the client pushes. It is important to remember that external torque is the product of the external force and the external moment arm. The perpendicular distance between the joint axis of rotation and the external force’s line of action is just as important as the external force itself. This is especially important to remember when using a cuff weight wrapped around an arm or a leg. If the cuff weight moves proximally on the extremity, the external moment arm will decrease and thus the external torque will decrease as well. Additionally, therapists sometimes instruct a client to hold a dumbbell in his or her hand with the arm at his or her side and the elbow positioned in 90° of flexion and then to rotate the forearm between pronation and supination to strengthen the pronator and supinator musculature. However, in this position, the weight will provide no resistance torque to pronation or supination because the center of gravity of the weight is in the middle of the hand, roughly in the same place as the forearm’s axis of rotation, and thus the external moment arm is essentially zero.

Repetitions refers to the number of times an exercise is completed before a break, and that number is considered one set. Additional sets of repetitions may be completed after a rest break. Taken together, repetitions times sets times resistance = exercise volume. *Frequency* refers to the number of times a day or week the exercise routine is completed. The amount of rest between sets or exercise sessions is also an important consideration, especially in clients whose health is compromised or older clients. All of these parameters will vary depending on intervention goals (strength vs. endurance) as well as the health of the client.³

Two additional concepts need to be considered when designing intervention for impaired muscle performance. The overload principle states that in order to increase muscle performance, the demands on the muscle must be greater than the normal everyday demands to which the muscle is accustomed. Muscle demands may be increased by increasing resistance, repetitions, sets, or frequency. The Specific Adaptation to Imposed Demands (SAID) principle states that improvements in muscle performance will match (be specific to) the type of muscle activation, speed of muscle contraction, the joint positioning, the client’s body position, and so on. Generalization of improvements to activities with different muscle demands will be

limited. This principle provides a compelling argument for using occupational performance as a means to improve muscle performance.³

Types of Exercise

Static (Isometric) exercise is used when joint motion is painful or contraindicated because of joint instability. Isometric exercise can also remediate weakness at a particular point in the ROM. Isometric exercise is more effective with deconditioned individuals than with conditioned individuals. When designing an isometric exercise program to improve muscle performance, keep the following guidelines in mind⁴³:

- Maximal isometric contractions against an immobile object will result in the quickest strength gains.
- Hold each contraction for 6 seconds, and no longer than 10 seconds.³
- Perform isometric holds every 15° to 20° throughout ROM, if possible.
- Repeat frequently throughout the day.
- Contraindication for isometric exercise: Clients with a history of cardiac or vascular disorders should avoid high-resistance isometric exercise.³
- Precaution for isometric exercise: Clients should not hold their breath, but instead count out loud and exhale while performing the exercise to avoid a Valsalva response, which increases blood pressure.³

Dynamic (Concentric and Eccentric) exercises are commonly used to promote strength gains throughout the arc of motion. In a concentric activation, the internal torque produced by the muscle is greater than the external torque produced by the resistance, so the muscle “wins.” In an eccentric activation, the internal torque produced by the muscle is less than the external torque produced by the resistance, so the muscle “loses.” Many exercises consist of a concentric phase immediately followed by an eccentric phase. During the eccentric phase, the therapist should instruct the client to slowly allow the resistance to “win” in order to ensure good eccentric muscle activation. If free weights are used to provide the resistance, the weight moves up when the muscle wins and moves down when the muscle loses (Fig. 14-17A). This, however, is not always the case with other methods of providing resistance. Elastic exercise bands can be anchored anywhere and will pull toward their anchor point (Fig. 14-17B). Thus with elastic bands, when the band is being lengthened by the client, the muscle is winning (concentric). When the band is shortening even though the muscles are trying to lengthen it, the muscle is losing (eccentric) (Fig. 14-17 B).

Figure 14-17 Methods of resistance. A. A dumbbell always exerts a downward force. B. An elastic resistance band pulls toward the place where it is anchored.

- Contraindications for dynamic exercise: Severe or acute joint or muscle pain during exercise; inflammation of joints and muscles; or severe cardiopulmonary disease³
- Precautions for dynamic exercise: Clients should not hold their breath, but instead count out loud and exhale while performing the exercise; avoid high resistance for clients with osteoporosis, children, and older adults; initiate exercise with low- to moderate resistance; correct substitutions; do not apply resistance to an unstable joint or healing fracture; avoid exercise volumes that excessively fatigue the client; and discontinue exercise if dizziness, pain, or unusual shortness of breath occurs.³

Methods of Resistance

In rote exercise, free weights and elastic bands such as TheraBand are often used because they are inexpensive and reasonably portable. Free weights also have the advantages of providing consistent resistance force and requiring dynamic stabilization similar to that which the client will need for occupational performance. Elastic bands are more portable and can be anchored anywhere (often between a closed door and its doorframe), allowing options for directions of resistance not easily achieved with free weights. On the other hand, elastic bands are quite variable in the amount of resistance they provide—when elongated to twice their resting length, they provide two to three times more resistance force than they provided initially when the slack was taken up.⁴³

Occupation-Based Exercise

These same parameters and concepts will be considered when the occupational therapist synthesizes an occupational form in order to elicit a certain occupational performance from a client, although in a less formal way. Consider the occupation of making a simple meal in a kitchen. The therapist will take into account the weight of the utensils, any pots or pans that will be required, and the ingredients (that is, resistance); the number of times the client will likely have to lift or move these items in order to perform the occupation (that is, repetitions); the naturally built-in rest breaks, and so on. These parameters are probably not explicitly communicated to the client during occupational performance; however, the therapist carefully considers them when developing a treatment plan for the client.

Strength Training versus Endurance Training

Strengthening and endurance training are done at similar exercise volumes; however, strengthening is done with higher resistance and fewer repetitions, while endurance training is done with lower resistance and more repetitions.³

The concept of a repetition maximum (RM) is used when determining the appropriate resistance for a client. A RM is the most weight a client can lift (or resistance a client can move) with good form for a certain number of repetitions before fatigue begins to set in and the quality of the movement degrades. For example, a 1 RM would be the most weight a client can lift once with good form, with performance degrading on the second repetition. A 10 RM would be the most weight a client can lift 10 times with good form, with performance degrading on the 11th repetition. A client's 1 RM can be estimated by giving them a weight you think he or she will be able to lift 5 to 10 times and counting the actual number of repetitions completed before performance degrades. Use the Holten curve⁴⁴ to correlate the number of repetitions performed with a percentage of 1 RM (Table 14-1) and then divide the weight lifted by that percentage to estimate the client's 1 RM. For example, if a client could lift a 6 lb weight (at a particular joint in a particular direction) just 12 times, then 6 lb would be about 80% of the 1 RM. Dividing 6 lb by 0.8 would equal 7.5 lb, which is the estimated 1 RM.

Table 14-1. Holten Curve

PERCENTAGE OF 1 RM (%)	NUMBER OF REPETITIONS
100	1
95	2
90	4

PERCENTAGE OF 1 RM (%)	NUMBER OF REPETITIONS
85	7
80	11
75	16
70	22
65	25

Intervention to Prevent Loss of Muscle Strength

To prevent loss of muscle strength, the client must perform some type of muscle activation. When illness or injury results in immobilization or disuse, type I muscle fibers (which specialize in endurance and posture) atrophy before type IIA and B fibers (which specialize in power and strength).^{3,19} Thus, exercises focusing on endurance with 30% to 40% of the client's 1 RM, 25 to 50 repetitions, and one to two sets may be most appropriate initially.³ If the exercises are for maintenance of the client's current performance, the frequency of exercise can be as little as two to three times per week.³ Clients that have recently been critically ill may require almost all of their available energy for healing and may thus not tolerate this exercise. The occupational therapist must consider the health, age, preillness conditioning level, and the client's response to exercise (including monitoring vital signs).

Sometimes during postoperative immobilization, a client is permitted to do "setting" (nonresisted isometric coactivation) exercises in order to prevent disuse atrophy. In this situation, just a few repetitions performed several times a day with no resistance may be appropriate,³ but the therapist must check with the surgeon first to make sure these exercises will not compromise structural stability.

Intervention to Increase Muscle Endurance

For unconditioned and deconditioned clients, children, or the elderly, exercise that focuses on endurance with resistance that is 30% to 40% of 1 RM is most appropriate and may result in significant strength gains as well.³ As the client gains endurance and strength, the therapist should first increase repetitions or sets before increasing resistance.³ Three to five sets of up to 50 repetitions can be used before increasing resistance. When resistance is increased, repetitions are initially decreased and then gradually increased again as the client improves.

Occupational performance is ideal for increasing endurance. Many everyday occupations involve repeated motions against light resistance, so it is easy to develop a treatment plan that will elicit this type of performance in the clinic or as a home program. When clients perform occupations that have many meaningful past associations, they will generally have a greater sense of purpose related to the impact of the occupation and will therefore perform it longer than they might perform a rote exercise.

Cardiovascular endurance is a related but different concept from muscle endurance. Increasing cardiovascular endurance is not addressed in this chapter.

Intervention to Increase Muscle Strength

As mentioned earlier, for deconditioned individuals, strengthening starts with increasing muscle endurance. When the client is ready for a strengthening regime, Progressive Resistive Exercises (PREs) provide one method of determining appropriate parameters.⁴³ The "DeLorme" PRE program involves three sets of 10 repetitions each: the first set is performed at 50% of the 10 RM, the second set at 75% of the 10 RM, and the third set at 100% of the 10 RM. This PRE program has the advantage of a built-in warm-up in the first two sets, but the client may be too fatigued to complete a third set at 100% of the 10 RM. The "Oxford" PRE program also involves three sets of 10 repetitions each, but the first set is performed at 100% of the 10 RM, the second set at 75% of the 10 RM, and the third set at 50% of the 10 RM. This

PRE program accommodates client fatigue nicely, but would require a warm-up exercise beforehand to increase circulation and ready the muscles for work. Resistance should be increased gradually in increments of 5% to 10% of the client's 1 RM,^{3,43} although somewhat larger increases might be acceptable when clients are just beginning resistive exercises and are using small (1–2#) weights.

Occupational performance can also be used to increase muscle strength and is often done when preparing clients to return to a job or sport. Throwing or hitting a ball, stacking boxes of various weights, and shoveling gravel are some examples. For clients with lower strength demands in their daily activities, making a meal in the kitchen may provide the appropriate resistance to increase muscle strength.

Considerations for Client Training Handouts

Anytime a client is trained in an exercise or other home program, materials must be provided for the client to keep. Verbal instruction is never enough, no matter how well the client appears to understand the instructions during the therapy session. If these instructions are provided in written form, they should be written at or below a fifth grade reading level. In a Microsoft Word document, you can check the Flesch–Kincaid Grade Level by enabling “Show Readability Statistics” in Word “Options” and performing a spelling and grammar check. Strategies for lowering the reading level include using only one- and two-syllable words and shortening sentence length.⁴⁵

CASE STUDY

Patient Information

Bernard is an 89-year-old right-handed married man who fell in front of his house while watering some plants, sustaining a left distal radius fracture with multiple bone fragments and damage to the articular cartilage. He was hospitalized and had surgery to stabilize the fracture fragments with a plate and screws on the volar side of the radius. A temporary plaster splint was placed after surgery. After the surgery, he was discharged to a subacute rehabilitation facility for occupational therapy and physical therapy in order to improve his balance, general conditioning, and safe independence in self-care activities before returning home. At the subacute facility, his left arm was placed in a sling, and he was encouraged not to move it.

Assessment

The subacute occupational therapist observed Bernard performing basic ADLs and determined that he required total assistance with dressing his upper and lower body, putting on and taking off shoes and socks, and showering with his left arm bagged to keep water off the healing incisions. He required moderate assistance for shaving, brushing teeth, combing hair, eating, and toileting. He required minimal assistance for ambulation with a cane, but could walk only about 10 feet before requiring a rest break. Transfers to and from the bed required moderate assistance. Bernard spent most of the day in bed or in a wheelchair.

On the 10th day after surgery, an occupational therapist specializing in hand therapy was consulted. Bernard's left hand was swollen and discolored (see Fig. 14-18A), and his left fingers, wrist, elbow, and shoulder were all stiff. His left wrist had 30° of flexion and 10° of extension AROM, while his right wrist had 70° of flexion and 60° of extension AROM. He could wiggle his left fingers and thumb, but could not perform any functional grasp or pinch because of stiffness. Strength was not assessed in view of postoperative restrictions. Bernard was unable to use his left arm to perform any ADLs.

Figure 14-18 Edema intervention. **A.** Untreated edema in the left hand 10 days after surgery for a distal radius fracture. Note the discoloration, loss of wrinkles over the joints, and the loss of definition around the extensor digitorum (ED) tendons. **B.** Edema 1 day later, after one brief MEM treatment and discontinuing the sling. Note the increase in skin wrinkles, definition of the ED tendons, and more normal color. **C.** Continued reduction of edema 2 days later, after one additional brief MEM treatment.

Short-Term Goals

Initial short-term goals set by the subacute occupational therapist included the following:

- Client will perform shaving, brushing teeth, and combing hair while standing at bathroom sink with minimal assistance within 2 weeks.
- In order to perform self-care occupations, client will ambulate from bedside to bathroom (about 20 feet) with minimal assistance within 2 weeks.
- In order to perform ADLs, client will participate in 20 minutes of light aerobic exercise a day.

The following goals were added after the occupational therapist specializing in hand therapy was consulted:

- In order to dress and feed self independently, client will perform AROM of all left arm joints and self-PROM of left fingers and thumb daily with supervision within 2 days.
- In order to dress and feed self independently, client will don and doff custom thermoplastic volar wrist orthosis with supervision within 1 week.

Intervention

In addition to initial interventions aimed at general conditioning (recumbent bicycle), functional mobility, and self-care, the consulting occupational therapist recommended the following at 10 days after surgery (all with written approval from the hand surgeon):

- Replacing the temporary plaster splint with a custom thermoplastic volar wrist orthosis that would be easier to maintain and allow more finger motion
- Discontinuing the sling because it worsened the edema and joint stiffness in Bernard's left arm, as well as unnecessarily restricted his occupational performance
- Initiating MEM performed by the occupational therapist once daily
- Adding AROM for all joints of the left arm, from shoulder to fingers, with shoulder and elbow AROM performed overhead
- Adding self-PROM exercises for fingers and thumb

Progress

Twenty-four hours after discontinuing the sling and initiating a very brief MEM and AROM session, the edema in the left hand was considerably reduced (see Fig. 14-18B). Forty-eight hours after discontinuing the sling, and after two brief MEM and AROM sessions, the edema was reduced even more, and the color in the hand was returning to normal (see Fig. 14-18C). The stiffness in the shoulder and elbow was resolved within 2 weeks. Blocking exercises that isolated thumb interphalangeal joint AROM were initiated because of adherence of the flexor pollicis longus (FPL) tendon to the surgically placed volar plate. (FPL is the deepest tendon in the carpal tunnel and thus rests directly on the volar plate that was placed to stabilize the distal radius fracture.) Six weeks after surgery, hand strengthening with yellow (soft) Therapy Putty and passive wrist stretches were initiated. As Bernard's client factors improved, he was encouraged to perform his ADLs independently with less reliance on caregivers. After 2 months in subacute rehabilitation, the client performed shaving, brushing teeth, combing hair, dressing upper and lower body, and feeding self with supervision, and was discharged home.

Best Evidence for Motor Function Intervention

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Occupation-Based Intervention ⁴⁶	Varied in the included studies: typing, handwriting, simulated ADLs, occupation as means/purposeful activity, playing games, modified constraint-induced movement therapy with occupation, and origami	Clients with upper extremity musculoskeletal disorders	Varied in the included studies; randomized controlled trials ranged from 3 to 6 weeks of occupation-based intervention	Systematic review of studies ranging from randomized controlled trials to case studies. Level I	Four of five randomized controlled trials found a significant benefit of occupation-based intervention (usually in addition to therapeutic exercise) versus therapeutic exercise alone.	Meta-analysis was not completed because of heterogeneity of studies.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Manual Edema Mobilization ⁴⁷	MEM + conventional therapy vs. conventional therapy	Clients with distal radius fracture and surgical intervention	Three times/week for 4 weeks, then 2 times/week for 2 weeks, then per therapist assessment	Randomized controlled trial. Level I	Clients treated with MEM + conventional therapy required 20% fewer visits and improved their ADL performance more quickly than those treated with conventional therapy alone.	Statistically significant difference in favor of the MEM group for number of edema treatments required ($p = 0.03$, effect size 5.1 edema treatments), and inability to perform ADLs at 3 weeks (but not 6 or 9 weeks) after inclusion in the study ($P = 0.03$, effect size NR). No statistically significant difference was found between groups in total number of therapy sessions ($P = 0.13$).
ROM, Stretching, Strengthening, and Joint Mobilization ⁴⁸	Varied in the included studies	Adults with musculoskeletal disorders of the shoulder	Varied in the 76 included studies	Systematic review of level I, II, and III studies. Level I	ROM, stretching, joint mobilization, and physical agents were beneficial for clients with adhesive capsulitis. Stretching, strengthening, and joint mobilization were beneficial for clients with general shoulder pain. ROM, stretching, strengthening, and joint mobilization were beneficial for clients with subacromial impingement syndrome.	Meta-analysis was not completed because of heterogeneity of studies.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
DeLorme and Oxford PRE Programs ⁴⁹	DeLorme and Oxford PRE programs for knee extension with 2.75 kg increases each week (as tolerated)	Healthy adults (both male and female)	3 days a week for 9 weeks	Randomized controlled trial. Level I	Both PRE programs increased strength by 66.5%–96%. No difference was found between the two programs.	Difference between PRE programs in 10 RM increase after 9 weeks ($P < 0.65$). The study was underpowered to find such differences.

NR, not reported.

Chapter 15

Motor Control Assessment

Dawn M. Nilsen and Glen Gillen

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Understand how motor control supports occupational performance.
2. Understand the neurological and physiological basis of motor control.
3. Describe the classic signs associated with upper and lower motor neuron lesions.
4. Describe the various types of motor dysfunction seen in patients with central nervous system lesions.
5. Describe evaluation procedures used to assess motor control impairments.
6. Correctly interpret the results of motor control assessments.

CHAPTER OUTLINE

Introduction
Neurological and Physiological Basis of Motor Control
Impact of Motor Control Dysfunction on Daily Occupation
Motor Control Assessment
Case Study

TERMINOLOGY

Apraxia: the inability to perform purposeful actions despite having normal muscle and sensory functions.

Ataxia: unsteadiness, incoordination, or clumsiness of movement.

Bradykinesia: slowness of movement.

Chorea: characterized by brief, abrupt, irregular, unpredictable, purposeless movements, primarily in the extremities and face.

Dysmetria: an improper measuring of distance during motor acts; results in overshooting (hypermetria) or undershooting (hypometria) a specific target.

Flaccidity: a state characterized by a complete absence of muscle tone.

Paresis/plegia: weakness or paralysis.

Rigidity: sustained muscle tension, causing the affected body part to become stiff and inflexible.

Spasticity: a velocity-dependent increase in tonic stretch reflexes; also denotes a form of muscular hypertonicity with exaggeration of tendon reflexes.

Tremor: involuntary rhythmic, oscillatory movements of the body or limbs; tremors that occur during precise intentional movements are known as intention tremors; tremors that occur at rest and stop upon the initiation of voluntary movements are called resting tremors.

Introduction

In all of our daily activities, we interact with the environment by sensing information and then acting on this information through the appropriate activation of the motor system. Sometimes, the relationship between what we sense in the environment and how we respond to it is very simple and direct. For example, when we inadvertently touch a hot stove while preparing breakfast, we will, without thought, quickly pull our hands away from the danger. Likewise, if we stand while riding a bus or train, our postural control system will respond to the train perturbations, allowing us to maintain an upright posture or protect ourselves should a sudden loss of balance occur. These movements are examples of reflexive movements. Reflexive movements are involuntary (performed without conscious control), stereotyped movements that are made in direct response to a sensory stimulus. They represent the simplest form of interaction with the world around us.

Although reflexive movements clearly serve a purpose during daily activities, most of our interactions with the environment are performed consciously and in very complex ways. For example, if we see or feel raindrops, we might respond to this sensory information by opening an umbrella, putting on our coat hood, or running to seek shelter. Each of the above actions represents a different response to the same sensory stimuli (raindrops), and each of these actions requires a unique set of voluntary movements. Unlike reflexive movements, voluntary movements are performed under conscious control. They are purposeful, goal-directed movements that are flexible and modifiable depending on the person and context. Voluntary movements allow us to interact with the environment we sense in a multitude of ways.

Most of our time is spent engaging in occupations that require an interplay between voluntary and reflexive movements to support performance. For example, this evening, we may have taken the train home, walked from the train station to our apartment, and rode the elevator to our apartment on the fourth floor. Once inside, we may have taken off our coat, slipped out of our shoes, and began preparing dinner by gathering necessary items from the refrigerator and cabinets. Activation of our postural control system combined with voluntary skilled limb movements were needed to support our functional mobility and engagement in these activities. As we can see from the previous example, any change in motor control can have tremendous impact on our ability to engage in daily occupations. Because occupational therapists treat various conditions that result in lost motor control (e.g., stroke, neurodegenerative diseases, spinal cord injuries), we must become proficient in the ability to identify, assess, and treat motor control impairments. This chapter provides an overview of (1) the neurological and physiological basis of motor control, (2) impact of motor control dysfunction on daily occupation, and (3) evidence-based assessment of motor control impairments. Interventions that address motor control impairments that interfere with daily occupational engagement are the focus of Chapter 16.

Neurological and Physiological Basis of Motor Control

According to Shumway-Cook and Woollacott, motor control is “the ability to regulate or direct the mechanisms essential to movement.”¹ These researchers further stipulate that movement emerges from the interaction of multiple systems, including sensory/perceptual, cognitive, and motor/action systems.¹ These systems involve multiple brain regions working together in a cooperative manner, as illustrated in Figure 15-1. Central nervous system (CNS) regions important to the control of movement include the¹:

Figure 15-1 Regions of the central nervous system that are important to the control of movement. (Adapted from Purves D, Augustine GJ, Fitzpatrick D, Hall WC, LaMantia AS, White LE. *Neuroscience*. 5th ed. Sunderland, MA: Sinauer Associates; 2012.)

- Spinal cord
- Brainstem
- Cerebellum
- Basal ganglia

- Sensorimotor areas of the cerebral cortex, including, but not limited to, the primary motor cortex, premotor cortex, supplementary motor area, and parietal cortex.

The interaction between the above regions involves both hierarchical and parallel processing.¹ In hierarchical processing, a signal is processed in a serial manner between higher and lower level brain regions. Higher levels of the motor hierarchy include cerebral cortex areas, such as the premotor cortex and supplementary motor area. These areas play important roles in the planning and programming of actions. Signals from these structures are conveyed to the primary motor cortex, which is thought to specify important execution commands (e.g., movement extent, direction, force, speed). Commands from higher centers are conveyed to lower levels of the motor hierarchy: the spinal cord via the corticospinal tract and the brainstem via multiple tracts (i.e., corticobulbar, corticoreticular, corticopontine, and corticorubro).¹ Ultimately, signals from the spinal cord and brainstem are sent to muscles for the generation of head, face, trunk, and limb movement (see Fig. 15-1).

Motor neurons that convey signals from higher to lower centers are called upper motor neurons (UMNs), whereas motor neurons that convey the final output signal to muscles are called lower motor neurons (LMNs).^{2,3} Generally speaking, UMN cell bodies are contained in the gray matter of cerebral cortex motor areas and specific brainstem nuclei. The axons of these neurons are contained in the white matter and traverse the neuroaxis as descending motor tracts (i.e., corticospinal, corticobulbar, vestibulospinal, reticulospinal, and rubrospinal tracts).³ LMN cell bodies are contained in the gray matter of the spinal cord (anterior horn) and brainstem motor nuclei of select cranial nerves (see Chapter 20). The axons of these neurons are contained in spinal nerves and select cranial nerves.²

In contrast to hierarchical processing, parallel processing involves multiple brain regions that simultaneously process the same signal.¹ For example, both the cerebellum and the basal ganglia process information from cerebral cortical regions, and both send signals that modulate higher brain region activity, thereby regulating different aspects of motor control.¹ Both hierarchical and parallel processing in the motor system allow us to produce effective and efficient movements that underlie occupational performance. The following summarizes primary functions associated with key motor system regions:

- **Cerebral cortex:** Considered the highest level of the motor hierarchy. Includes (1) sensorimotor areas (e.g., premotor cortex, parietal cortex, supplementary motor area) that are involved in identifying the location of targets in space, choosing a course of action, and programming movements; and (2) the primary motor cortex that contains UMNs that convey signals that modulate lower level brain region activity.^{1,3}
- **Spinal cord:** Considered the lowest level of the motor hierarchy. Contains LMNs that send final commands to muscles for reflexive and voluntary control of posture and limb movements. Receives and begins to integrate somatosensory input from the muscles, joints, and skin (via sensory neurons).^{1,2}
- **Brainstem:** Contains important nuclei involved in the regulation of posture and movement (i.e., vestibular nuclei, reticular nuclei, pontine nuclei, red nucleus, and substantia nigra). Also contains cranial nerve nuclei (1) that receive somatosensory information from the head and face and that (2) control motor output to the neck, head, and face muscles.¹⁻³
- **Cerebellum:** Receives information from the cerebral cortex about intended motor plans and compares that information with sensory information received from the spinal cord and brainstem. Sends information to cerebral cortex motor areas and the brainstem to modulate UMN activity. Plays an important role in modulating motor responses, updating motor plans, and motor learning.^{1,4}
- **Basal ganglia:** Receives input from many cerebral cortex areas and sends information back to cerebral cortex motor areas to modulate UMN activity. Plays an important role in motor strategy planning, appropriate motor plan selection, and movement initiation and termination.^{1,5}

Damage to any of the above brain regions will adversely affect their functions and negatively impact motor control. The following section provides an overview of motor control dysfunction that results from damage to key brain regions.

Impact of Motor Control Dysfunction on Daily Occupation

Classic signs are associated with damage to select motor system regions. Knowledge of these differences aid therapists in both the selection of appropriate assessments and the interpretation of assessment results. The following section describes classic UMN and LMN signs; highlights the differences in motor dysfunction caused by cortical, cerebellar, and basal ganglia lesions (Box 15-1); and provides examples of how motor dysfunction impacts daily occupational engagement (Table 15-1).

Box 15-1

Motor Dysfunction Caused by Central Nervous System Lesions

Cortical Lesions

- **Hemiplegic posture or pattern of spasticity** includes retraction and depression of the scapula; internal rotation of the shoulder; flexion of the elbow, wrist, and fingers; pronation of the forearm; lateral flexion of the trunk toward the involved side; elevation and retraction of the pelvis; internal rotation of the hip; extension of the hip and knee; supination of the foot; and plantar flexion of the ankle and toes (Bobath, 1990).
- **Hypotonia** (decreased muscle tone) is less-than-normal resistance to passive elongation; the affected limb feels limp and heavy.
- **Hypertonia** (increased muscle tone) is more-than-normal resistance of a muscle to passive elongation. Both neural (spasticity) and mechanical (soft-tissue stiffness) factors contribute to this.
- **Spasticity**, the neural component of hypertonus, is characterized by a velocity-dependent increase in tonic stretch reflexes and exaggerated tendon reflexes (Nagaoka & Kakuda, 2008). It is commonly accompanied by muscle clonus and clasp-knife reflex.
- **Clonus** is the oscillating contraction and relaxation of a limb segment caused by the alternating pattern of stretch reflex and inverse stretch reflex of a spastic muscle.
- **Clasp-knife phenomenon or reflex** is resistance to passive stretch of a spastic muscle that suddenly gives way, like the blade of a jackknife.
- **Weakness** is the inability to generate the necessary force for effective motor action.
- **Loss of fractionation** is the inability to move a single joint without producing unnecessary movements in other joints, resulting in stereotyped movement patterns instead of selective, flexible movement patterns.
- **Apraxia** is the inability to perform goal-directed motor activity in the absence of paresis, ataxia, sensory loss, or abnormal muscle tone. Apraxia is characterized by omissions, disturbed order of submovements within a sequence, clumsiness, perseveration, and inability to gesture or use common tools or utensils.
- **Lead pipe rigidity** is characterized by hypertonus in both agonist and antagonist muscles, with resistance to movement that is not velocity dependent and that is felt throughout the range of motion.

Cerebellar Lesions

- **Intention tremor** is the rhythmic oscillating movement that develops during precise intentional movements caused by involuntary alternating contractions of opposing muscles.
- **Dysmetria** is the inability to judge distances accurately; it results in overshooting or undershooting a specific target.
- **Decomposition of movement, or dyssynergia**, is characterized by movements that are broken up into a series of successive simple movements rather than one smooth movement involving multiple joints.
- **Dysdiadochokinesia** is impairment in the ability to perform repeated alternating movements, such as pronation and supination, rapidly and smoothly.
- **Adiadochokinesia** is the loss of ability to perform rapid alternating movements.
- **Ataxia** is unsteadiness, incoordination, or clumsiness of movement.
- **Ataxic gait** is a wide-based, unsteady, staggering gait with a tendency to veer from side to side.

Lesions of the Basal Ganglia

- **Tremors at rest** or **nonintentional tremors** stop at the initiation of voluntary movement but resume during the holding phase of a motor task when attention wanes or is diverted to another task. Tremors at rest are fatiguing.
- **Cogwheel rigidity** is characterized by rhythmic interrupted resistance of the muscles being stretched when the wrist or elbow is flexed quickly.
- **Hypokinesia** is slowness or poverty of movement. It includes *akinesia*, difficulty initiating voluntary movements, and *bradykinesia*, slowness in carrying out movements. These symptoms are reflected in lack of facial expression, monotone speech, reduced eye movements, diminished arm swing during walking, and decreased balance and equilibrium responses seen in Parkinson disease.
- **Festinating gait** is characterized by small, fast, shuffling steps that propel the body forward at an increasing rate and by difficulty stopping or changing directions.
- **Athetosis** is characterized by slow, writhing involuntary movements, particularly in the neck, face, and extremities. Muscle tone may be increased or decreased. Athetosis ceases during sleep.
- **Dystonia** is characterized by powerful, sustained contractions of muscles that cause twisting and writhing of a limb or of the whole body, often resulting in distorted postures of the trunk and proximal extremities.
- **Chorea** is characterized by sudden involuntary purposeless, rapid, jerky movements and/or grimacing, primarily in the distal extremities and face (e.g., Huntington chorea).
- **Hemiballismus** is unilateral chorea in which there are violent, forceful, flinging movements of the extremities on one side of the body, particularly involving the proximal musculature.

Table 15-1. Impact of Common Motor Control Impairments on Daily Occupational Engagement

MOTOR CONTROL IMPAIRMENT	EXAMPLES OF IMPACT OF IMPAIRMENT ON FUNCTION
Apraxia	<ul style="list-style-type: none"> • Using awkward grasp and pinch patterns when retrieving objects for self-feeding • Difficulty maintaining the orientation of grooming objects toward the body • Difficulty with in-hand manipulation, such as handling coins and playing cards
Ataxia	<ul style="list-style-type: none"> • Presents with a wide-based, unsteady gait • Not able to coordinate reach patterns during bathing or leisure activities • Nystagmus may interfere with reading, bill paying, etc.
Bradykinesia	<ul style="list-style-type: none"> • Increased time needed to perform daily activities • Difficulty getting up and down from a chair • Difficulty throwing and catching a ball
Chorea, Athetosis, and Ballismus	<ul style="list-style-type: none"> • Interference with sleep/rest patterns due to flailing limbs • Impaired feeding and swallowing ability • Inability to participate in written communication (e.g., writing, keyboarding, texting)
Dysmetria	<ul style="list-style-type: none"> • Overshooting or undershooting items when attempting to retrieve them from cabinets during meal preparation • Overshooting or undershooting curbs and difficulty climbing steps during functional mobility
Hypotonicity	<ul style="list-style-type: none"> • Decreased ability to maintain an upright posture while seated in a chair • Decreased ability to maintain a standing position while preparing meals
Intention tremor	<ul style="list-style-type: none"> • Spillage of food from a spoon during feeding • Difficulty putting toothpaste on a toothbrush • Difficulty typing on a computer key board
Paresis	<ul style="list-style-type: none"> • Decreased ability to stabilize or manipulate grooming objects • Decreased ability to retrieve items from the refrigerator during meal preparation • Difficulty standing and weight shifting while manipulating clothing during toileting
Spasticity and rigidity	<ul style="list-style-type: none"> • Difficulty opening the hand or positioning the arm to wash and dry the affected upper extremity during bathing • Difficulty placing the affected limbs into clothing during dressing • Difficulty turning in bed

UMN versus LMN Signs

As indicated earlier, UMN cell bodies are located in the gray matter of the cerebral cortex and the brainstem; the axons of these neurons make up the descending motor tracts (e.g., corticospinal tract, corticobulbar tract, vestibulospinal tract).³ Damage to either the cell bodies or axons of these neurons, proximal to the anterior horn cells in the spinal cord, produces UMN signs.³ Typical UMN signs include³ (1) weakness (**paresis**) or paralysis (**plegia**) and disuse atrophy (muscle wasting), (2)

spasticity, (3) hypertonicity, (4) hyperreflexia (exaggerated reflexes), and (5) a positive Babinski's sign (i.e., dorsiflexion of the great toe and outward fanning of the rest of the toes in response to firm stroking along the lateral aspect of the foot's sole). UMN signs are commonly seen after traumatic injuries (e.g., stroke, traumatic brain injury, spinal cord injury) that damage the motor cortex or corticospinal tract in the brain or spinal cord,³ or as the result of diseases that damage UMN (e.g., multiple sclerosis, primary lateral sclerosis).

Conversely, damage to LMN cell bodies (e.g., anterior horn cells located in the spinal cord) or axons (spinal, cranial, or peripheral nerves) results in LMN signs.³ Typical LMN signs include³ (1) flaccid paralysis followed by atrophy, (2) fibrillations or fasciculations (involuntary muscle contractions involving one or multiple groups of motor units, respectively), (3) hypotonia, and (4) hyporeflexia (diminished reflexes) or areflexia (absence of reflexes). LMN signs are associated with peripheral nerve injuries (e.g., median or radial nerve injury) or disease processes that damage LMNs (e.g., Guillain-Barré, spinal muscular atrophy).

Combinations of the abovementioned signs may present under certain circumstances. For example, disease processes that damage both types of motor neurons (e.g., amyotrophic lateral sclerosis) produce a combination of UMN and LMN signs. Likewise, a combination of signs is seen in spinal cord injuries that cause damage to descending motor tracts and anterior horn cells.

Dysfunction Caused by Cortical Lesions

Damage to cerebral cortex motor regions or the corticospinal tract most often results in UMN signs that are seen contralateral to the injury side.³ In addition to these signs, the inability to fractionate movements, the development of stereotypical postures and movement patterns, and **apraxia** are common cortical lesion consequences.¹

Cortical lesion deficits result in an inability to plan and produce effective and efficient movements, limiting daily occupational engagement. For example, paresis and tonal changes on one side of the body often negatively impact a person's ability to transfer, walk, and use his or her involved arm and hand to perform activities of daily living (ADLs).

Dysfunction Caused by Cerebellar Lesions

Damage to the cerebellum produces a variety of motor control impairments that generally impact coordination (ability to produce accurate, smooth, and controlled movements) and postural control, limiting occupational engagement.⁴ For example, intention **tremor**, **dysmetria**, dysdiadochokinesia, movement decomposition, limb and truncal **ataxia**, and nystagmus are common after cerebellar damage. In addition, hypotonia and decreased deep tendon reflexes may be present.^{1,4}

These coordination deficits can interfere with engagement in a wide range of activities. For example, intention tremors can cause spillage of food during feeding, and dysmetria can result in overshooting or undershooting target objects during ADL performance. Ataxic gait is common after cerebellar damage and is characterized by a wide base of support and unsteady gait pattern that increase fall risk. Nystagmus (rapid involuntary eye movements) may also be present and adversely impact vision, making tasks such as reading or computer use difficult.

Dysfunction Caused by Basal Ganglia Lesions

Basal ganglia damage can occur as a consequence of stroke, traumatic brain injury, or neurodegenerative disorders such as Parkinson or Huntington disease.⁵ Basal ganglia lesions produce movement disorders that are generally described as hypokinetic (decreased motor activity) or hyperkinetic (increased motor activity) in nature.⁵ Hypokinetic movement disorders are characterized by reduced voluntary movements and diminished or slowed automatic movements.⁵ Conversely, hyperkinetic movement disorders are characterized by excessive involuntary movements. Clinical signs associated with basal ganglia lesions vary depending on lesion location and include resting or nonintentional tremors, **rigidity**, **bradykinesia**, athetosis, **chorea**, dystonia (sustained muscle contractions causing limb/body twisting and writhing), ballismus (flailing/flinging limb movement), and festinating gait (small, fast, shuffling steps).^{1,5}

Like dysfunction caused by cortical or cerebellar damage, hypokinesia and hyperkinesia can negatively impact engagement in daily occupations. For example, bradykinesia can increase the time needed to complete daily activities, resulting in fatigue, whereas excessive involuntary movements can make performing tasks such as feeding, bathing, and dressing difficult or even impossible.

Motor Control Assessment

Because motor control impairments can deleteriously effect occupational performance, it is essential to assess patients' motor control. To develop effective intervention plans, therapists must determine which specific aspects of motor control are impaired—for example, poor coordination, impaired postural control, inability to motor plan, impaired upper and lower limb function, and spasticity. The following sections describe specific assessment procedures and review standardized assessments related to motor control.

Assessment of Motor Control Skills in Daily Living

It is critical for therapists to understand various body systems as they relate to occupational performance. Several standardized, valid, and reliable motor assessments allow therapists to assess patients during natural or simulated ADL performance.

The Assessment of Motor and Process Skills (AMPS)⁶ is an example of an assessment that measures motor skills in a naturalistic setting using client-chosen occupations. Therapists evaluate motor and process skills within the context of basic and instrumental activities of daily living (IADL). The quality of patient ADL performance is assessed by rating the effort, efficiency, safety, and independence of 16 ADL motor (and 20 ADL process) skill items while performing chosen, familiar, and life-relevant ADL tasks. There are more than 100 tasks to choose from, ensuring a client-centered assessment approach. Evaluated motor skills include skills related to body position (stabilizes, aligns, positions), obtaining and holding objects (reaches, bends, grips, manipulates, coordinates), moving self and objects (moves, lifts, walks, transports, calibrates, flows), and sustaining performance (endures, paces).⁶

The Motor Assessment Scale (MAS)⁷ is also a performance-based measure that evaluates motor function as it relates to everyday life (Box 15-2). It evaluates eight different areas of motor function⁷:

Box 15-2

Abridged Criteria for Scoring Motor Assessment Scale

The score assigned on each item is the highest criterion met on the best performance of three. A 0 score is assigned if the patient is unable to meet the criteria for a score of 1.

1 2 3 4 5 6

Supine to Side Lying to Intact Side

1. Pulls self into side lying with intact arm, moving affected leg with intact leg.
2. Moves leg across actively and lower half of body follows. Arm is left behind.
3. Lifts arm across body with other arm. Moves leg actively; body follows in a block.
4. Actively moves arm across body; rest of body follows in a block.
5. Rolls to side, moving arm and leg; overbalances. Shoulder protracts and arm flexes.
6. Rolls to side in 3 seconds. Must not use hands.

Supine to Sitting on Edge of Bed

1. After being assisted to side lying, lifts head sideways; cannot sit up.
2. Side lying to sitting on edge of bed with therapist assisting movement.
3. Side lying to sitting on edge of bed with standby help assisting legs over side of bed.
4. Side lying to sitting on edge of bed with no standby help.
5. Supine to sitting on edge of bed with no standby help.
6. Supine to sitting on edge of bed within 10 seconds with no standby help.

Balanced Sitting

1. Sits only with support after therapist assists.
2. Sits unsupported for 10 seconds.
3. Sits unsupported with weight well forward and evenly distributed.
4. Sits unsupported with hands resting on thighs; turns head and trunk to look behind.
5. Reaches forward to touch floor 4 inches in front of feet and returns to starting position.

6. Sitting on stool, reaches sideways to touch floor and returns to starting position.

Sitting to Standing

1. Gets to standing with help (any method).
2. Gets to standing with standby help.
3. Gets to standing with weight evenly distributed and with no help from hands.
4. Gets to standing; stands for 5 seconds, weight evenly distributed, hips and knees extended.
5. Stands up and sits down with no help; even weight distribution; full hip and knee extension.
6. Stands up and sits down with no help three times in 10 seconds; even weight distribution.

Walking

1. Stands on affected leg with hip extended; steps forward with other leg (standby help).
2. Walks with standby help from one person.
3. Walks 10 feet alone. Uses any walking aid, but no standby help.
4. Walks 16 feet with no aid in 15 seconds.
5. Walks 33 feet, picks up small sandbag from floor, turns around, walks back in 25 seconds.
6. Walks up and down four steps with or without an aid three times in 35 seconds. May not hold rail.

Upper Arm Function

1. Supine, protracts shoulder girdle. Tester places arm in 90° flexion and supports elbow.
2. Supine, holds shoulder in 90° flexion for 2 seconds. (Maintains 45° external rotation and 20° elbow extension.)
3. From position in level 2, flexes and extends elbow to move palm to forehead and back.
4. Sitting, holds arm in 90° shoulder flexion with elbow extended, thumb pointing up, for 2 seconds. No excess shoulder elevation.
5. Achieves position in level 4; holds for 10 seconds; lowers arm. No pronation allowed.
6. Standing, arm abducted 90°, with palm flat against wall. Maintains hand position while turning body toward wall.

Hand Movements

1. Sitting, lifts cylindrical object off table by extending wrist. No elbow flexion allowed.
2. Sitting, forearm in midposition. Lifts hand off table by radially deviating wrist. No elbow flexion or forearm pronation allowed.
3. Sitting, elbow into side, pronates and supinates forearm through three-quarters of range.
4. Sitting, reaches forward to pick up 5-inch ball with both hands and puts ball down. Ball placement requires elbow extension. Palms stay in contact with ball.
5. Sitting, picks up plastic foam cup from table and puts it on table across other side of body.
6. Sitting, continuous opposition of thumb and each finger more than 14 times in 10 seconds.

Advanced Hand Activities

1. Reaches forward arm's length; picks up pen top; releases it on table close to body.
2. Picks up a jellybean from teacup with eight jellybeans and places it in another cup. Cups are at arm's length.
3. Draws horizontal lines to stop at a vertical line 10 times in 20 seconds.
4. Makes rapid consecutive dots with a pen on a sheet of paper. (Picks up and holds pen without assistance; at least two dots per second for 5 seconds; dots, not dashes).
5. Takes a dessert spoon of liquid to the mouth, without spilling. (Head cannot lower toward spoon).
6. Holds a comb and combs hair at the back of head. (Shoulder is externally rotated, abducted at least 90°; head is erect.)

- Supine to side lying

- Supine to sitting over the edge of a bed
- Balanced sitting
- Sitting to standing
- Walking
- Upper arm function
- Hand movements
- Advanced hand activities.

Each task is performed three times, and best performance is recorded. All eight items are assessed using a 7-point scale, ranging from 0 to 6. A score of 6 indicates optimal motor behavior⁷ (see the Assessment table at the end of this chapter).

The Action Research Arm Test (ARAT)⁸ is a quick and easily administered assessment that uses simulated everyday activities to evaluate upper limb motor function. The ARAT consists of 19 items grouped in four categories: grasp, grip, pinch, and gross movement that generate 4 subscale scores. Test items include reaching, grasping, and transporting various size objects (i.e., blocks, marbles, cup with water). Items are timed (maximum allowable time is 60 seconds) and graded on a 4-point scale, ranging from 0 (unable to perform) to 3 (performs normally). Subscale scores range from 0 (unable to perform any item) to 18 (performs all items normally) for the grasp and pinch subscales, 0 to 12 for the grip subscale, and 0 to 9 for the gross movement subscale. Total scores range from 0 to 57, with higher scores indicating greater functional upper limb capacity.⁸ The test is most useful for patients with some distal function (see the Assessment table).

Similarly, the Wolf Motor Function Test (WMFT)⁹ has been used to document outcomes related to upper limb interventions and includes a variety of tasks such as basic reaching tasks (e.g., lifting arm from lap to table, extending elbow with and without a weight attached) and more functional activities involving fine motor control (e.g., picking up a pencil, turning a key in a lock). All tasks, excluding one, are unilateral and appropriate for both the dominant and nondominant arm. Because many tasks do not require distal control, it is appropriate for patients with a more involved upper extremity (UE). The therapist times task performance (maximum allowable time is 120 seconds) and qualitatively grades movement using a 6-point ordinal scale, ranging from 1 (doesn't attempt to use the UE for the task) to 6 (does attempt, movement appears normal)⁹ (see the Assessment table).

It is also important to document clients' perception of their upper limb function. The Motor Activity Log (MAL)¹⁰ is a self-report questionnaire (report by patient or family) related to actual use of the involved UE outside structured therapy time. The MAL uses a semi-structured interview format. Quality of movement ("How well" or quality of use scale) and amount of use ("How much" or amount of use scale) are graded on a 6-point ordinal scale. At present, there are 14-, 28-, and 30-item versions of the instrument.¹⁰⁻¹² Sample items include hold book, pick up a phone, use a towel, pick up a glass, write/type, steady myself, and use a television remote.¹⁰

Muscle Tone and Deep Tendon Reflexes

Muscle tone is defined as the involuntary resistance of a muscle to passive stretch. This resistance is felt when a body part is passively moved by an examiner. Normal muscle tone relies on the functioning of multiple motor system regions and is dependent on both neural factors (motor unit activity and the stretch reflex) and mechanical factors (muscle viscoelastic properties).¹

Characteristics of normal muscle tone include the feeling of slight resistance to passive joint movement, and the ability to maintain body part position against gravity if support is removed. When muscle tone is normal, therapists will feel slight resistance when a muscle is passively stretched. Abnormalities in muscle tone often accompany damage to the motor system.^{1,3} An increase in muscle tone (more than normal resistance to passive stretch) is called hypertonia. A decrease in muscle tone (less than normal resistance to passive stretch) is called hypotonia. Spasticity may accompany hypertonia. Spasticity is a velocity-dependent increase in the stretch reflex coupled with an exaggeration of deep tendon reflexes.^{1,3}

Deep tendon reflexes involve direct activation of the stretch reflex, also known as the monosynaptic stretch reflex.^{2,13} The stretch reflex is mediated by a two-neuron reflex arch involving the spinal or brainstem segment innervating the muscle. The sensory neuron innervates the muscle spindle, which is a complex sensory receptor found in skeletal muscle. The muscle spindle continuously provides the CNS with information about changes in muscle length. When the muscle spindle is lengthened (as occurs when a muscle tendon is tapped briskly with a reflex hammer), the sensory receptor discharges and excites the alpha motor neuron (located in either the anterior horn

of the spinal cord or brainstem nuclei depending on the muscle involved), causing the muscle to contract.² Motor areas of the cerebral cortex and brainstem modulate stretch reflex activity, and this modulation plays an important role in the regulation of reflexive and voluntary movements.³

When deep tendon reflexes are normal, a brisk tap of a muscle's tendon will result in contraction of that muscle.¹³ However, damage to the motor system may disrupt modulation of the stretch reflex, causing abnormalities in muscle tone and deep tendon reflexes. An increase in deep tendon reflexes (as occurs with spasticity) is called hyperreflexia. A decrease in deep tendon reflexes is called hyporeflexia, and an absence of deep tendon reflexes is termed areflexia.¹³

A severe form of hypertonicity is rigidity.¹ Common forms of rigidity include lead pipe rigidity, cogwheel rigidity, decorticate rigidity, and decerebrate rigidity.^{2,3} In lead pipe rigidity, hypertonus is present in both the agonist and antagonist muscles (e.g., flexors and extensors of the elbow joint), and resistance is felt throughout the entire range of motion (ROM). In cogwheel rigidity, passive movement of the limb elicits ratchet-like, start-and-stop movements as tension in the muscle gives way and then increases again. These ratchet-like start-and-stop movements can be felt throughout the ROM.³ Decorticate rigidity is characterized by abnormal flexor tone and abnormal flexor posturing of the upper limbs, and increased extensor tone and extensor posturing of the lower limbs.² This type of rigidity is associated with brain lesions that occur above the midbrain level, resulting in the removal of cortical influence on brainstem nuclei. Decerebrate rigidity is characterized by abnormal extensor tone and posturing of the upper and lower limbs in extension. This type of rigidity is associated with lesions impacting the brainstem.²

 Muscle tone is assessed clinically by observing a muscle's response to passive stretch.¹ For example, when testing tone of the biceps muscle, therapists should place patients in a supine or seated position, place the elbow joint in a maximally flexed position, and then passively move the joint to a position of maximal extension over a period of ~1 second with repetition as needed to make an accurate determination; repetition should be kept to a minimum¹⁴ (see Video 15-1).

The Modified Ashworth Spasticity Scale (MASS)¹⁴ is a subjective rating scale that is often used to describe muscle tone and spasticity. As illustrated earlier, therapists attempt to move the part through its full ROM and the amount of resistance felt during passive movement is scored using a 6-point ordinal scale, ranging from 0 (no increase in muscle tone) to 4 (affected part is rigid in flexion or extension) (Box 15-3).¹⁴ Evidence suggests the MASS is a reliable instrument for assessing tonal changes in patients with stroke¹⁵ and those with profound intellectual and multiple disabilities¹⁶; however, its clinical utility with respect to other patient populations may be limited¹⁷ (see the Assessment table).

Box 15-3

Modified Ashworth Scale for Grading Spasticity

Grade	Description
0	No increase in muscle tone
1	Slight increase in muscle tone manifested by a catch and release or by minimal resistance at the end of the range of motion (ROM) when the affected part or parts are moved in flexion or extension
1+	Slight increase in muscle tone manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the ROM
2	Marked increase in muscle tone through most of the ROM, but affected parts are easily moved
3	Considerable increase in muscle tone; passive movement difficult
4	Affected part or parts rigid in flexion or extension

Deep tendon reflexes are assessed by properly positioning the patient, palpating a muscle tendon, and tapping the muscle tendon briskly with a reflex hammer.¹³ Figure 15-2 shows common testing positions for assessing the four common UE deep tendon reflexes. Box 15-4 highlights deep tendon reflexes commonly assessed in the upper and lower limbs, along with the grading scale used for reflex rating.

Figure 15-2 Testing positions for assessing the deep tendon reflexes in the upper extremity. A. Biceps. B. Triceps. C. Brachioradialis. D. Finger flexors.

Box 15-4

Assessment of Deep Tendon Reflexes

Deep Tendon Reflex with Spinal Segment ¹³	Grading of Deep Tendon Reflexes
Biceps (C5, C6)	4+ = very brisk, hyperactive, clonus may be present
Triceps (C7–C8)	3+ = brisker than average (hyperreflexia)
Brachioradialis (C5–C6)	2+ = average, normal
Finger flexors (C7–C8)	1+ = diminished, low normal (hyporeflexia)
Quadriceps (patella) (L2–L4)	0 = no response
Gastrocnemius (Achilles) (S1)	

 In addition to testing deep tendon reflexes, tests administered to determine the presence of pathological reflexes, such as a Hoffman's¹⁸ or Babinski's sign,¹⁸ can be useful to screen for UMN signs in the upper and lower limbs, respectively. The Hoffman's test is conducted by placing the patient in a comfortable standing or seated position. The therapist stabilizes the proximal interphalangeal joint of the third digit (middle finger) and applies a stimulus to the finger by "flicking" the fingernail between the therapists thumb and index finger¹⁸ (Fig. 15-3). If the pathological reflex is present, adduction of the thumb and flexion of the index finger (positive Hoffman's sign) will occur in response to the stimulation (see Video 15-2). No movement of the thumb or index finger is considered normal (negative Hoffman's sign).¹⁸ The Babinski's test is conducted with the patient in a supine or long sitting position. The therapist supports the patient's foot in neutral and applies stimulation to the plantar aspect of the foot, typically moving lateral to medial from the heel to the metatarsals, with the blunt end of a reflex hammer¹⁸ (Fig. 15-4). If the pathological reflex is present, the great toe will extend along with fanning of the second through fifth toes (positive Babinski's sign).¹⁸ A normal response is flexion of the toes (plantar reflex and negative Babinski's sign)¹³ (see Video 15-3).

Figure 15-3 Testing position for administering the Hoffman's test.

Figure 15-4 Testing position for administering the Babinski's test.

Postural Control

According to Shumway-Cook and Woollacott, postural control “involves controlling the body’s position in space for the dual purposes of stability and orientation.”¹ Normal postural control involves multiple body systems and senses working together to allow one to maintain a steady state in sitting and standing, react to perturbations to balance, and, most importantly, prevent falls. During development, major milestones such as lifting the head, crawling, and walking all contribute to postural control development. During this time, righting, equilibrium, and protective responses also develop. Righting reactions support positioning of the head vertically in space, alignment of head and trunk, and alignment of trunk and limbs. Equilibrium responses occur when posture is perturbed. Lastly, protective reactions occur to protect the face and head when equilibrium

reactions fail.¹ Examples of standardized assessments for assessing postural control include the Berg Balance Scale¹⁹ and the Functional Reach Test²⁰ (see the Assessment table and Fig. 15-5). Readers should see Chapter 17 for details on balance assessment.

Figure 15-5 Functional Reach Test. **A.** Starting position: The assessor records the starting position at the third metacarpal head on the yardstick (or meter stick) and instructs the patient to “Reach forward as far as you can without taking a step.” **B.** Ending position: The assessor records the location of the third metacarpal head on the yardstick (or meter stick). Scores are determined by assessing the difference between the start and end position in the reach distance.

Paresis and Selective Motor Control

As indicated earlier, weakness and the inability to fractionate or selectively control joint movement are common after damage to the descending motor system. These impairments are typically assessed by observing the resting posture of the limbs and trunk and by assessing patients’ ability to produce voluntary movements during ADL performance.

For example, therapists may observe patients during activity engagement, such as feeding or grooming, while noting whether there is evidence of the following: (1) abnormal posturing of the limbs (see Box 15-1) or deviations in trunk alignment; (2) compensatory motor strategies (e.g., forward flexion of the trunk or hiking of the shoulder while reaching for objects); (3) weakness in specific muscle groups (e.g., inability to stabilize or hold objects in the hand because of weak finger flexors); (4) inability to selectively control certain joints (e.g., inability to grasp objects without flexing the elbow); (5) incorrect timing of movement components (e.g., finger closure prior to making appropriate contact with an object); and (6) inability to appropriately coordinate movement at adjacent joints (e.g., inability to hold objects in the hand while simultaneously extending the elbow and flexing the shoulder). If these deficits interfere with task performance, therapists may wish to perform additional testing. For example, manual muscle testing can be used to determine muscle strength (see Chapter 13), and standardized assessments, such as the Fugl-Meyer Assessment,²¹ can be used to objectively measure the extent to which patients can isolate and coordinate individual joint movements.

The Fugl-Meyer Assessment (FMA) is a widely used instrument designed to evaluate motor recovery after stroke.²¹ The test is based on earlier research describing the natural course of motor recovery following stroke and Brunnstrom motor recovery stages.²² The FMA assesses UE motor function, lower extremity (LE) motor function, balance, sensation, and joint function. Maximum points are 66 for the UE, 34 for LE, 14 for balance, 24 for sensation, 24 for position sense, 44 for ROM, and 44 for joint pain (total possible score = 250). Each section can be scored separately.²² The motor subtests have established reliability²³ and validity,²⁴ and they are responsive to changes overtime for stroke patients at various recovery stages^{25–27} (see the Assessment table).

Coordination

As discussed earlier, coordination is the ability to produce accurate, smooth, and controlled movements. Like paresis, and the ability to fractionate movement, coordination is assessed by observing patients engaged in ADLs while noting movement quality or characteristics. For

example, therapists may observe patients during activity participation (e.g., simple meal preparation or dressing) and note whether the patients have difficulty initiating or terminating movements, and whether movements appear slow or jerky. If coordination deficits interfere with function, therapists may further examine the extent of deficits. Examples of more formal clinical tests of coordination include the following¹:

- **Finger-to-Nose:** The shoulder is abducted to 90° with the elbow in extension. Patients are asked to bring the tip of their index finger to the tip of their nose. Alterations in the initial start position can be made to assess coordination in different movement plans.
- **Finger-Nose-Finger:** With patients in a seated position and therapists seated in front, patients are asked to move their index finger from their nose to the therapists' finger (Fig. 15-6). Position of the therapist's finger can be altered to change the distance and direction of the movement.

Figure 15-6 Finger-Nose-Finger test. Illustrates movement from patient's nose (A) to the therapist's finger (B).

- **Pronation/Supination:** With the elbows flexed to approximately 90° and held close to the body, the patient alternately turns the palms up and down (see Video 15-4). Speed can be gradually increased.
- **Mass Grasp:** The patient alternates between opening and closing the hand. Speed can be gradually increased.
- **Finger Opposition:** The patient touches the tip of the thumb to the tips of the fingers in sequence. Speed can be gradually increased.
- **Tapping (Hand or Foot):** Patients are asked to tap their hand on their knee or the ball of their foot on the floor while maintaining the heel in contact with the floor.
- **Heel-Shin:** With the patient in supine, the heel of one foot is slid up and down the shin of the opposite LE.

Performance on the above clinical tests is typically graded subjectively using the following ordinal scale¹: 5 = normal, 4 = minimal impairment, 3 = moderate impairment, 2 = severe impairment, and 1 = cannot perform.

In addition, standardized assessments such as the Box and Blocks Test (BBT),²⁸ Purdue Pegboard Test,²⁹ and Nine-Hole Peg Test²⁸ can be used to assess eye–hand coordination and manual dexterity. The BBT requires patients to move, one by one, the maximum number of wooden blocks from one compartment of a box to another of equal size, within 60 seconds. Patients are scored based on the number of blocks they transfer from one compartment to the other in the allotted time. Higher scores indicate better manual dexterity.²⁸ The BBT has established reliability, validity, and normative data and is responsive to change overtime as a measure of manual dexterity²⁸ (see the Assessment table).

The Purdue Pegboard consists of a board with 4 cups across the top and 2 vertical rows of 25 small holes centrally located on the board. The outside cups each contain 25 pins, the cup to the immediate left contains 40 washers, and the cup to the immediate right of center contains 20 collars. Patients are required to move as many pins as possible from the cups into the holes within 30 seconds. The test is performed with the right hand, left hand, and then both hands simultaneously. In the final subtest, patients use both hands to assemble as many pins, washers, and collars as possible within 60 seconds.²⁹

The Nine-Hole Peg Test consists of a plastic board with a shallow round dish that contains pegs and nine holes oriented in three rows positioned below the cup. Patients are instructed to move the

pegs into the holes, one by one, as quickly as possible; and then to move the pegs, one by one, back into the cup. The time required to complete the task is recorded.²⁸

Motor Planning

The ability to motor plan and store motor plans allows one to effectively and efficiently interact with the environment. The saying “Once you learn how to ride a bicycle, you never forget” provides insight into motor plan function. When we repetitively practice a motor task, the plan to perform it, the sequence of one’s movements, and the organization of movements all become stored as procedural memory. We develop motor plans throughout our life course. These motor plans, or praxicons, are thought to be stored in the left inferior parietal lobe. Destruction of praxicons or loss of the ability to access them can result from multiple brain trauma types. When this occurs, patients present with motor apraxia (or ideomotor apraxia).³⁰ During occupational performance, motor apraxia presents as clumsy and slower movements, simplified prehension patterns, inability to coordinate oral musculature (oral apraxia), inability to coordinate total body patterns such as rolling and supine-to-sit, poor gesture production, inability to coordinate joints and body parts, and poor task performance initiation.³¹

Several standardized evaluations relate to motor planning assessment. Although they differ in the number and order of items, they use similar procedures to detect motor apraxia. Procedures include imitation of gestures, performing transitive (with an object such as teeth brushing) and nontransitive (without an object such as saluting) movements on command, or via demonstration. Specific instruments include:

- Cambridge Apraxia Battery³²
- Limb Apraxia Test³³
- Kaufman Hand Movement Test³⁴
- Ideomotor Apraxia Test³⁵
- Florida Apraxia Screening Test³⁶

The above-noted instruments screen for motor apraxia out of context. As occupational therapists, it is important that we adopt instruments that directly examine the impact of motor apraxia during ADL and IADL performance. Two such instruments are the ADL Observations to Measure Disabilities in those with Apraxia,³⁷ and the ADL-focused Occupation-based Neurobehavioral Evaluation (A-ONE, formerly known as the Árnadóttir OT-ADL Neurobehavioral Evaluation).³¹

The ADL Observations to Measure Disabilities in those with Apraxia is based on the structured observation of four activities: washing face and upper body, putting on a shirt or blouse, preparing food, and an individualized task chosen by the therapist. Scoring is based on independence, initiation, execution, and control. Items are scored from 0 to 3, with higher scores indicating more severe impairment.³⁷ The A-ONE is able to detect and document the impact of motor apraxia on basic ADLs.³¹ The A-ONE’s Independence Scale ranges from 0 (dependent) to 4 (independent). The Neurobehavioral Impairment Scale ranges from 0 (no neurobehavioral impairment detected) to 4 (unable to perform because of neurobehavioral impairment; needs maximum assistance).³¹

CASE STUDY

Patient Information

Nakai is a 34-year-old Native American male who was diagnosed with multiple sclerosis 2 years prior to this inpatient rehabilitation admission. His initial symptoms began approximately 3 years prior to this admission and consisted of diplopia, gait impairments, and problems with upper limb coordination. Nakai was admitted to the hospital because of worsening symptoms and an inability to complete basic self-care tasks such as feeding, grooming, dressing, and toileting.

Assessment Process and Results

The therapist began the assessment process by observing Nakai engaging in his morning self-care routine. She scored his performance using the Functional Independence Measure (FIM), because this is the standardized assessment typically used on the rehabilitation unit. Nakai’s FIM scores were as follows:

- Feeding: 3 (moderate assistance)
- Grooming: 3 (moderate assistance)

- Bathing: 3 (moderate assistance)
- Upper body dressing: 4 (minimal assistance)
- Lower body dressing: 3 (moderate assistance)
- Toileting: 3 (moderate assistance)

Impairments in upper limb coordination appeared to be the significant limiting factor for the majority of activities observed. For example, while observing Nakai eating breakfast, she noted that he overshot items on his food tray when reaching with either his right or left hand. Attempts at hand-to-mouth patterns resulted in utensil stabbing around the mouth, and food and drink spillage. In an apparent attempt to control these jerky movements, Nakai often leaned on his forearms and brought his head toward his cup and spoon when attempting to eat or drink, rather than bringing the cup or spoon to his mouth. Because attempts to eat and drink continued to fail, Nakai became very frustrated and refused to continue eating. When observing Nakai attempt to toilet himself, she noted that he assumed a wide base of support and needed to use the grab bar to stabilize himself. Nakai was unable to manipulate his clothing or effectively perform toilet hygiene. Based on her observations, she decided to perform a formal assessment of Nakai's upper limb coordination to determine the extent of his deficits. The following clinical and standardized tests were performed:

- Finger-Nose-Finger
- Pronation/Supination (rapid alternating movements)
- BBT

Nakai was observed to have intention tremors and dysmetria, characterized by oscillating movements and overshooting of targets during Finger-Nose-Finger testing. Both his tremors and dysmetria increased as movement speed and distance requirements increased, or as movement direction changed. These deficits were present bilaterally and were only slightly more pronounced in the left UE. Nakai also had difficulty performing rapid alternating movements, particularly as movement speed increased, indicating the presence of dysdiadochokinesia. Again, these deficits were present bilaterally. Based on these tests, the therapist graded Nakai as having moderate impairments in bilateral upper limb coordination. BBT results revealed that Nakai was only able to transfer 50 blocks with his right hand and 46 with his left hand. Both of these scores are well below the norms for a 34-year old man, indicating manual dexterity impairment.

Occupational Therapy Problem List

- Decreased independence in the performance of basic self-care activities
- Bilateral impairment in upper limb coordination
- Bilateral impairment in manual dexterity

Occupational therapy (OT) interventions to address the above problem list are described in the case study presented in Chapter 16.

Examples of Commonly Used Standardized Motor Control Assessments

Instrument	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
------------	------------------	---------------------	----------	-------------	-------------	--------------------------

Instrument	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
ADL Observations to Measure Disabilities in those with Apraxia ³⁸	Structured observation of four activities: washing face and upper body, putting on a shirt or blouse, preparing food, and an individualized task chosen by the OT; each task is scored based on independence, initiation, execution, and control	Approximately 30–45 minutes based on impairment severity	Discriminant: Able to differentiate between those with and without apraxia. Construct: Highly associated with impairment tests of apraxia and the Barthel Index ³⁸	High internal consistency ($\alpha = 0.94$). ³⁸ High inter-rater reliability for total score ($ICC = 0.98$). ³⁸	Sensitive for detecting disabilities in those with cognitive impairment compared to the Barthel Index and Motricity Index ³⁹	Strengths: Provides information related to how apraxia impacts everyday living. Weaknesses: Warrants further investigation
Action Research Arm Test (ARAT) ⁸	Performance-based measure of UE capacity consisting of 19 items that are timed and rated on a 4-point ordinal scale: 0 = unable to perform any part of the task to 3 = performs normally	An average of 7–10 minutes. If all 19 items are tested, it takes ~20 minutes.	Adequate-to-high concurrent ($r = -0.55$ to -0.80) and convergent ($r = -0.38$ to -0.96) validity reported among stroke patients ^{40–42}	High internal consistency ($\alpha = 0.98$), ⁴³ high test–retest reliability for both total score ($ICC = 0.98–0.99$) ^{23,41,42} and subscale scores ($ICC = 0.95–0.99$), ^{41,42} and high inter-rater reliability for both total score ($ICC = 0.92–0.99$) ^{41–43} and subscale scores ($ICC = 0.93–0.99$) ^{41,42}	Sensitive for detecting change in hand dexterity (standardized response mean [SRM] = 0.79), ⁴⁴ and UE motor function ($SRM = 0.68$) ²³ after stroke. Established MCID for acute (12–17 points) ⁴⁰ and chronic (5.7 points) ⁴⁵ stroke patients	Strengths: Established validity, reliability, and MCID across various stages of stroke recovery; administration of the ARAT is quick and easy. Weaknesses: Items are simulated ADLs and require the use of standardized equipment that can be costly.
Box and Block Test (BBT) ²⁸	Performance-based measure of manual dexterity that requires patients to transfer as many blocks from one compartment of a wooden box to another within 60 seconds	2–5 minutes	Predictive: The BBT, when performed at 1-week poststroke, is the best predictor of upper limb function at 5-months poststroke compared to grip strength, 9-Hole Peg Test, and the Stroke Rehabilitation Assessment of Movement. ⁴⁶ High convergent validity between BBT and Minnesota Rate of Manipulation Test ($r = 0.91$) ⁴⁷	High test–retest reliability ($ICC = 0.97$; $ICC = 0.96$) for the right and left hand, respectively. ⁴⁸ High inter-rater reliability ($r = 1.0$ and 0.99 , right and left hands, respectively) ²⁸	Sensitive for detecting change in hand dexterity poststroke. ($SRM = 0.74$) ⁴⁴	Strengths: Quick and reliable administration. Weaknesses: Contrived task

Instrument	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Berg Balance Scale (BBS) ¹⁹	Performance-based measure of balance consisting of 14 items graded on a 5-point ordinal scale with descriptors that vary based on item being scored	10–15 minutes	High concurrent ($r = 0.65–0.92$) and convergent ($r = 0.62–0.94$) validity reported among stroke patients. ^{19,49,50} Predictive validity for risk of falling in elderly, ¹⁹ adequately predictive of length of stay in rehabilitation unit, ⁵¹ and high predictive validity for motor ability 180 days after stroke ⁴⁹	High internal consistency ($\alpha > 0.83, 0.97$) for elderly long-term care residents and patients with stroke, respectively, ⁵² and high test-retest reliability ($ICC = 0.88$) ⁵⁰ and inter-rater reliability ($ICC = 0.92$) among patients poststroke ⁵³ and patients with PD ($ICC = 0.95$) ⁵⁴	Several studies have demonstrated that BBS is responsive to change over time in patients poststroke. ⁵⁰ Established minimal detectable change (MDC) in acute (6.9 points) ⁵³ and chronic (4.13 points) ⁵⁰ stroke patients	Strengths: Established validity, reliability, and MDC; utilizes functional mobility task; quick, easy, and low cost to administer. Weaknesses: Significant ceiling effects noted for community-dwelling older adults and patients poststroke. Not suitable for severely affected patients because it assesses only one item related to balance while sitting.
Fugl-Meyer Assessment (FMA) ²¹	Performance-based measure of motor impairment after stroke that consists of 50 (33 UE and 17 LE) items; the majority of items are scored on a 3-point ordinal scale: 0 = cannot perform to 2 = performs fully	30–45 minutes for the UE and LE subtests	Actual motor recovery poststroke parallels test items. ²¹ Adequate-to-high concurrent validity with MAS FMA-UE ($r = -0.50$) and FMA-LE ($r = -0.60$). ²⁴ High convergent validity between the FMA-UE and the ARAT ($r = 0.77–0.87$) and adequate ($r = 0.54$) convergent validity between the FMA-UE and ADL subscores of the Functional Independence Measure (FIM) ²³	High inter-rater FMA-UE ($ICC = 0.97$) and FMA-LE ($ICC = 0.92$). High intra-rater reliability: UE ($r = 0.99$) and LE ($r = 0.96$) subtests ⁵⁵	Responsiveness of FMA has been reported for evaluating UE recovery in acute ($SRM = 0.74$) ²³ and chronic ($SRM = 0.87$) ²⁷ stroke patients. MCID has been established for acute (10 points) ²⁶ and chronic (UE: 4.25–7.25 points ²⁵ and LE: 6 points) ⁵⁶ stroke patients	Strengths: Established reliability and validity and MCID across various stroke recovery stages. Administration times for UE and LE subtests are acceptable and low cost. Weaknesses: Test items are impairment focused and have little relevance to everyday activities.
Functional Reach Test ²⁰	Measures maximal forward reach distance while in standing position	~5 minutes	High concurrent validity with mobility skills ($r = 0.65$) and IADL ($r = 0.66$) and adequate concurrent validity with physical ADLs ($r = 0.48$). ⁵⁷ Discriminant validity: significant difference between persons with high and low risk of falls. Predictive validity: score of 6 inches predictive of falls in the elderly ²⁰	High test-retest reliability: ($ICC = 0.92$) ²⁰ and high inter-rater reliability ($r = 0.98$) ²⁰ and intra-rater reliability ($r = 0.90$) ⁵⁸	Marginal significant change ($p = 0.07$) after physical rehabilitation, responsiveness index = 0.97 ⁵⁹	Strengths: Established reliability and validity; quick, easy, and low cost to administer; a modified version exists for patients who cannot stand. ⁶⁰ Weaknesses: Sensitivity is borderline

Instrument	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Modified Ashworth Spasticity Scale ¹⁴	Assess muscle tone using a 6-point ordinal scale: 0 = normal muscle tone to 4 = rigid in flexion or extension	1–2 minutes per motion tested	High convergent validity with the FMA ($r = 0.94$); electromyography ($r = -0.79$); Box-Block Test ($r = -0.83$). ⁶¹ MASS was also negatively correlated with the FMA-UE ($r = -0.72, p < 0.05$) and the ARAT ($r = -0.41, p < 0.05$) ⁶²	Moderate test–retest reliability ($K = 0.47–0.62$), in adults with severe brain injury. ⁶³ High inter-rater ($K_w = 0.84$) and intra-rater reliability ($K_w = 0.83$) for patients poststroke. ¹⁵ Adequate test–retest and inter-rater reliability ($K = 0.53–0.77$) for assessing spasticity in LE of patients with spinal cord injuries. ⁶⁴ High inter-rater and intra-rater reliability $K_w = 0.8$ and $ICC = 0.8$ for persons with profound intellectual disabilities. ¹⁶ Reliability appears to be inadequate for children with cerebral palsy ¹⁷	Sensitivity of the MASS is unclear as findings are mixed with respect to its ability to measure change overtime ^{65,66} .	Strengths: Established validity and reliability for several patient populations; easy, quick, and low cost to administer. Weaknesses: Data on sensitivity is mixed
Motor Assessment Scale ⁷	Performance-based measure of motor function consisting of eight items rated on a 7-point hierarchical scale: 0 = easiest task, 6 = hardest task	15–60 minutes for total MAS	High concurrent validity with FMA total scores ($r = 0.96$); adequate-to-high item-level validity between MAS and similar FMA items ($r = 0.65–0.93$); poor validity ($r = -0.10$) with FMA sitting balance ²⁴	High test–retest reliability ($r = 0.87–1.00$) and inter-rater reliability ($r = 0.89–0.99$) ⁷	Medium-to-large effect sizes ($d = 0.50–1.03$) for six items and small effect sizes ($d = 0.36–0.43$) noted for two items ⁶⁷	Strengths: Established validity, reliability, and sensitivity; test items are functionally relevant; and easy and low cost to administer. Weaknesses: Sequence of scoring hierarchy of hand function and advanced hand activities scales are questioned; although a new hierarchical scoring system based on Rasch analysis has been developed. ⁶⁸

Instrument	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Motor Activity Log (MAL) ¹⁰	Self-report measure of UE function that consists of 13 daily tasks rated using two 6-point ordinal scales that measure amount of UE use (AOU) and quality of UE movement (QOM)	20–30 minutes	High concurrent validity of the QOM scale with an objective accelerometer-based measure of arm movement: ($r = 0.91$) ¹¹	High internal consistency for AOU ($\alpha = 0.88$) and QOM ($\alpha = 0.91$). ⁶⁹ Adequate-to-high test-retest reliability for the MAL-AOU ($r = 0.70$ – 0.85) and MAL-QOM ($r = 0.61$ – 0.71) subscales ⁶⁹	MAL is responsive to changes overtime SRM, and RR >1 at postintervention and ES, SRM, and RR >1 at 3-months follow-up. ⁷⁰ MCID for QOM = 1.0–1.1 in acute stroke patients ⁷¹	Strengths: Established validity, reliability, and sensitivity; measures patient's perception of actual use of poststroke affected UE in real-life situations; quick, easy and low cost to administer. Weaknesses: Subjective measure
Wolf Motor Function Test (WMFT) ⁹	Performance-based measure of UE capacity that consists of 2 strength items and 17 items that are timed and rated on 6-point ordinal scale, yielding a functional ability score (FAS) and a time score	30–45 minutes	Discriminates between healthy persons and those poststroke ($p \leq 0.05$). ⁹ Construct validity is supported by sensorimotor and kinematic measures of reach and grasp. ⁷² Moderate-to-high concurrent validity between ARAT total score and total WMFT FAS ($r_s = 0.86$, $p < 0.01$) and between ARAT score and WMFT median time score ($r_s = 0.89$, $p < 0.01$) ⁴³	High internal consistency ($\alpha = 0.96$ – 0.98). ⁷² High Inter-rater reliability: ($r = 0.95$ – 0.99) ⁹	WMFT is responsive to changes overtime FAS ($d = 1.09$ – 1.63) and time ($d = 0.61$ – 0.85). MCID = 1.0–1.2 ⁷¹	Strengths: Established validity, reliability, and sensitivity; easy to administer, but requires standardized table template for item placement. Weaknesses: Several items assess at the impairment level and have little to do with function.

Chapter 16

Motor Control Intervention

Dawn M. Nilsen and Glen Gillen

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe interventions that are commonly used to treat patients with motor control deficits.
2. Describe the characteristics of task-oriented training approaches used to remediate motor skill performance.
3. Describe how specific cognitive strategies can be implemented to supplement task-oriented training.
4. Describe how technology can be used to enhance task-oriented training approaches.
5. Describe interventions that target specific underlying neurological impairments.
6. Develop targeted intervention plans to improve motor skill performance in patients with neurological dysfunction.

CHAPTER OUTLINE

Introduction
Task-Oriented Training Approaches
Augmenting Task-Oriented Approaches
Management of Specific Neurological Impairments
Case Study

TERMINOLOGY

Action observation (AO): a multisensory approach thought to promote neural reorganization via activation of the mirror neuron system; involves a patient watching another person engage in task performance with the intention of imitating the task performance. Observation is typically followed by the patient physically performing the task.

Cognitive strategy training (CST): an intervention that consists of teaching internal and external compensatory approaches to execute activities of daily living (ADLs).

Constraint-induced movement therapy (CIMT): an intervention designed to overcome learned nonuse of an impaired limb; involves restraint of the less impaired limb and massed practice of the impaired limb via shaping and standard task practice.

Experience-dependent neuroplasticity: the brain's ability to change in response to environmental stimuli, experience, and learning.

Gesture training (GT): a behavioral training program consisting of gesture-production exercises (i.e., transitive, intransitive-symbolic, intransitive-nonsymbolic gestures).

High-amplitude movement training: a training approach that targets production of large amplitude movements, sensory recalibration to recognize these movements as normal, and self-cueing to maintain gains.

Mental practice (MP): an intervention that uses the cognitive rehearsal of an action in the absence of physical movements to improve task performance.

Mirror therapy (MT): an intervention that uses mirror visual feedback to create the illusion that an impaired limb is moving normally; involves placement of the impaired limb behind a mirror and the patient concentrating on the mirrored reflection of movements made by the less impaired limb in front of the mirror.

Motor apraxia: a disorder of the production praxis system; loss of access to praxicons (motor plans) so that purposeful movement cannot be produced or achieved because of defective planning and sequencing of movements, even though idea and task purpose are understood.

Task-oriented training (TOT): involves practicing common daily-life tasks with the intention of acquiring or reacquiring a skill.

Introduction

As indicated in Chapter 15, deficits that result from damage to the motor system (e.g., paresis, changes in muscle tone, incoordination, apraxia) can have a tremendous impact on our ability to engage in daily occupations. Thus, addressing motor skill performance and these underlying deficits is an important component of occupational therapy (OT) interventions for patients with motor control impairments.

It should be pointed out that various intervention approaches may be used when working with patients with motor control impairment. Often, these approaches are combined or the therapist may switch from one to another based on the patient’s response or preference (see Section 5: Frames of Reference for Physical Disability Rehabilitation). For example, a combination of remediation and compensatory approaches may be used to improve occupational performance of patients with hemiparesis poststroke or those with bradykinesia and rigidity secondary to Parkinson disease (PD).

This chapter provides an overview of interventions that are commonly used to treat patients with deficits in motor control, including (1) task-oriented training (TOT) approaches; (2) approaches that combine TOT with cognitive strategies or that utilize technology to augment TOT; and (3) interventions targeting specific neurological impairments, specifically paresis and the inability to fractionate movement, changes in muscle tone, deficits associated with hyperkinetic and hypokinetic movement disorders (e.g., incoordination, bradykinesia), and apraxia.

Task-Oriented Training Approaches

Task-oriented training approaches are considered to be the most current approach related to the remediation of motor skill impairments.¹ Various terms have been used to describe TOT approaches in the literature. Examples include¹⁻³ task-specific training, repetitive task practice, repetitive task training, and functional task practice. A common thread in these approaches is the assumption that movement emerges as an interaction between many systems in the brain, is organized around a specific goal, and is constrained by the environment.⁴ These approaches stress the importance of high-intensity repetitive practice of functional tasks that are chosen to address the motor deficits and goals of the patient.³ The tasks are designed to challenge patients’ current motor capabilities without overwhelming them; often referred to as the “just-right challenge.”⁵ In addition, training is structured to promote variability in practice, and feedback and coaching are strategically used to motivate the patient and provide useful performance-related information (see Chapter 34). This type of training is thought to promote **experience-dependent neuroplasticity** that remodels the brain after damage and results in recovery of lost function. Kleim and Jones⁶ identified 10 key principles of experience-dependent neural plasticity (Table 16-1). Many of these principles are incorporated into TOT approaches.

Table 16-1. Principles of Experience-Dependent Plasticity

PRINCIPLE	DESCRIPTION
Use it or lose it	<ul style="list-style-type: none"> Failure to drive brain functions can lead to functional degradation—over time, neural circuits not engaged in the performance of an activity will begin to degrade (e.g., failure to use the impaired limb after stroke may reduce the size of the cortical representation of that limb in the sensorimotor cortices)

PRINCIPLE	DESCRIPTION
Use it to improve it	<ul style="list-style-type: none"> • Training that drives a specific brain function can lead to an enhancement of that function—stresses the importance of practice to strengthen neural connections (e.g., playing the piano with the right hand may increase the size of the cortical representation of the right hand in the sensorimotor cortices and improve accuracy of playing the piano).
Specificity	<ul style="list-style-type: none"> • The nature of the training experience dictates the nature of the plasticity—learning, as opposed to rote use, is required to change neural connectivity; changes are dependent on the specific kinds of experience (e.g., learning to perform sit-to-stand transfers is needed to improve performance of transfers, as opposed to simply performing hip and knee flexion/extension exercises).
Repetition matters	<ul style="list-style-type: none"> • Induction of neural plasticity requires repetition—simple engagement of a neural circuit is insufficient to drive plasticity—stresses the importance of repeating a newly acquired skill for a period of time, so that the level of performance and brain reorganization is sufficient for the patient to continue to use the affected function outside therapy and to maintain gains.
Intensity matters	<ul style="list-style-type: none"> • Induction of plasticity requires sufficient training intensity—stresses the importance of high-intensity training and progression to continually challenge the patient.
Time matters	<ul style="list-style-type: none"> • Different forms of plasticity occur during different times during training—stresses the importance of recognizing that recovery of function after brain injury is a process and that there may be time windows during which certain types of training might be most beneficial.
Salience matters	<ul style="list-style-type: none"> • The training experience must be sufficiently salient to induce plasticity—stresses the importance of selecting tasks that are motivating, stimulating, and important to the patient.
Age matters	<ul style="list-style-type: none"> • Training-induced plasticity occurs more readily in younger brains—important to keep in mind that change may occur more slowly as the brain ages.
Transference	<ul style="list-style-type: none"> • Plasticity in response to one training experience can enhance the acquisition of similar behaviors—stresses the importance of previous behavioral experiences and their ability to influence performance of related tasks.
Interference	<ul style="list-style-type: none"> • Plasticity in response to one experience can interfere with the acquisition of other behaviors—important to be aware of the fact that therapy that benefits one skill may interfere with performance of another skill.

TOT approaches have been used to improve upper extremity (UE) function, balance and mobility, and performance of activities of daily living (ADLs).^{2,3} Components of TOT, as described in the literature, are contained in Box 16-1,⁷ and Figure 16-1 provides examples of repetitive practice of a functional task (for an overview of the OT task-oriented approach, see Chapter 34). The subsequent section provides an example of a specific TOT approach designed to remediate UE function.

Figure 16-1 Examples of task-oriented training targeting remediation of upper extremity function and postural control. **A.** Dusting a table surface. **B.** Organizing a utensil caddy.

Box 16-1

Task-Oriented Training Components

- **Functional movements:** A movement involving task execution that is not directed toward a clear ADL goal (e.g., moving blocks from one location to another).
- **Clear functional goal:** A goal that is set during everyday life activities and/or hobbies (e.g., washing dishes, grooming activity, dressing oneself, playing golf).
- **Client-centered patient goal:** Therapy goals that are set through the involvement of the patient himself or herself in the therapy goal decision process. The goals respect patients' values, preferences, and expressed needs and recognize the clients' experience and knowledge.
- **Overload:** Determined by the total time spent on therapeutic activity, the number of repetitions, the difficulty of the activity in terms of coordination, muscle activity type and resistance load, and the intensity, that is, the number of repetitions per time unit.
- **Real-life object manipulation:** Manipulation that makes use of objects that are handled in normal everyday life activities (e.g., cutlery, hairbrush).
- **Context-specific environment:** A training environment (supporting surface, objects, people, room, etc.) that equals or mimics the natural environment for a specific task execution in order to include task characteristic sensory/perceptual information, task-specific context characteristics, and cognitive processes involved.
- **Exercise progression:** Exercises with an increasing difficulty level that is in line with the increasing abilities of the patient in order to keep the demands of the exercises and challenges optimal for motor learning.
- **Exercise variety:** Various exercises are offered to support motor skill learning of a certain task because of the person experiencing different movement and context characteristics (within task variety) and problem-solving strategies.
- **Feedback:** Specific information on the patient's motor performance that enhances motor learning and positively influences patient motivation.
- **Multiple movement planes:** Movement that uses more than one degree of freedom of a joint, therefore occurring around multiple joint axes.
- **Patient-customized training load:** A training load that suits the individualized treatment targets (e.g., endurance, coordination, or strength training) as well as the patient's capabilities.
- **Total skill practice:** The skill is practiced in total, with or without preceding skill component training (e.g., via chaining).
- **Random practice:** In each practice session, the tasks are randomly order.
- **Distributed practice:** A practice schedule with relatively long rest periods.
- **Bimanual practice:** Tasks where both arms and hands are involved.

Adapted from Timmermans AA, Spooen AI, Kingma H, Seelen HA. Influence of task-oriented training content on skilled arm-hand performance in stroke: a systematic review. *Neurorehabil Neural Repair*. 2010;24(9):858–870.

Constraint-Induced Movement Therapy

Constraint-induced movement therapy (CIMT) is an example of a TOT approach designed to address arm and hand motor impairments. CIMT was originally developed for patients with hemiparesis poststroke to counteract learned nonuse, a term coined by Taub et al.⁸ in the early 1990s. This phenomenon was originally identified in animal studies and later applied to humans. Taub et al. hypothesized that the nonuse or limited use of an affected UE in individuals after a neurologic event results from a phenomenon of behavioral suppression.⁸ Hypothesized causes of learned nonuse include therapeutic interventions implemented during the acute period of neurologic suppression, an early focus on adaptations to meet functional goals, negative reinforcement experienced by a patient as he or she unsuccessfully attempts to use the affected limb, and positive reinforcement experienced by the less involved hand and/or use of successful adaptations.¹

CIMT is an intervention developed to reverse this acquired behavioral suppression. It consists of two main principles: (1) forced use of the impaired UE by restraining the less impaired UE in a sling or hand mitt for approximately 90% of waking hours and (2) massed practice (6–8 hours/day) of the impaired UE through shaping; a method of training in which a behavioral objective is approached in small successive steps that progressively increase in difficulty and standard (whole) task practice.^{8–10} In the original protocol, the training was carried out over a period of 2 weeks. Since its original development and application, several modified CIMT (mCIMT) protocols have been introduced.⁹ In mCIMT, the restraint time of the less impaired limb, the intensive training time of the impaired limb, or both the restraint and training times are reduced and/or distributed over a longer period of time.⁹ Box 16-2 provides an example of the key features of the original protocol and examples of modified protocols. Figure 16-2 illustrates the main features of the task training: shaping and standard task practice.

Figure 16-2 Constraint-induced movement therapy (CIMT). Examples of task training using the impaired hand while the unimpaired hand is restrained in a mitt. **A.** Shaping activity: multiple repetitions of flipping over cards. **B.** Standard (whole) task practice: playing a board game.

Box 16-2

Constraint-Induced Movement Therapy

Original Protocol Based on the EXCITE Trail ¹⁰	Modified Protocols
---	--------------------

Original Protocol Based on the EXCITE Trail ¹⁰	Modified Protocols
<ul style="list-style-type: none"> • Intervention length: 2 weeks. • Patients encouraged to wear a protective safety mitt on their less impaired UE for a goal of 90% of waking hours each day for a total of 14 days. • Training of the impaired limb for up to 6 hours on each week day consisting of two distinct types of task training: (1) shaping (adaptive or part-task practice—task objective is trained in small successive steps that progress in difficulty; each task is practiced in sets of individual trials of discrete movements); (2) standard task practice (functional activities [e.g., eating, writing] performed continuously for 15–20 minutes). • Behavioral techniques to enhance compliance with the program (i.e., behavioral contracts, mitt compliance device, daily practice schedule to encourage practice of two to three tasks daily at home and home diary to record task practice). 	<p>Dettmers and colleagues described the following protocol⁶³:</p> <ul style="list-style-type: none"> • Intervention length: 20 days. • Patients wore a resting hand splint on the less-affected hand on average for 9.3 hours/day, including the training sessions. • Intensive motor training of the affected UE for 3 hours/day for 20 consecutive weekdays training involved repetitive performance of daily activities (e.g., using clothes pins, picking up peas or dry berries out of a cup, opening and closing bottles). • Behavioral contract. <p>Lin and colleagues described the following protocol⁶⁴:</p> <ul style="list-style-type: none"> • Intervention length: 3 weeks. • Unaffected hand restrained in a mitt for 6 hours/day. • Intensive training of the affected arm for 2 hours/weekday; typical practice activities included: picking up marbles, flipping over cards, stacking blocks, combing hair, and writing. • Log to record the hours of mitten wearing. <p>Page and colleagues described the following protocol⁶⁵:</p> <ul style="list-style-type: none"> • Intervention length: 10 weeks. • Unaffected hand/wrist restrained in a mitt every weekday for 5 hours/day during an identified time of frequent arm use. • Individualized, ½-hour therapy sessions, 3 times/week: approximately 25 minutes of therapy focused on affected limb use during three agreed-upon daily activities (e.g., writing, brushing hair, drinking from a cup) using shaping techniques and 5 minutes of therapy was spent on more affected limb range of motion as needed. • Use of a home log to document device use and activities performed during restraint hours.

CIMT has been found to induce changes in the cortical representation of the affected UE, and the majority of evidence accumulated to date suggests that both CIMT and mCIMT reduce UE motor impairments and improve UE motor skill performance in poststroke patients with some residual motor function in the wrist and hand. These improvements, however, may not readily translate to improved performance in ADL (see the Evidence table at the end of this chapter).⁹

More recently, mCIMT has been successfully used to improve arm and hand functioning of the more involved UE in patients with multiple sclerosis (MS)^{11,12} and to improve fine and gross motor performance in patients with PD.¹³

Augmenting Task-Oriented Approaches

Approaches that combine TOT with cognitive strategies or that utilize technology to augment task training have been found to be feasible and effective for improving motor function after brain injury. In addition, several of these interventions may provide opportunities for self-directed practice outside traditional therapy sessions, or may be used with patients who have significant impairments in voluntary motor function. The following sections highlight the use of mental practice (MP), mirror therapy (MT), action observation (AO), virtual reality (VR), and robotics.

Use of Cognitive Strategies

Mental Practice

During **MP** (also called motor imagery [MI]), a patient cognitively rehearses an action in the absence of physical movements. Evidence suggests that MP activates many of the same brain regions that are activated by physical practice (PP).^{14,15} It has been proposed that MP may prime the motor system and potentiate the effects of PP. MP is typically combined with TOT and is often facilitated via audio-taped scripts that the patient either listens to before or after task training.¹⁶ MP may also be facilitated by visual prompts or verbal cues embedded into task training sessions.¹⁶ Results of several systematic reviews suggest that MP combined with task training improves motor function and ADL performance in patients after stroke.^{14,15,17}

Research investigating whether MP benefits those with other neurological diseases, such as MS or PD, is sparse. Seebachher et al.¹⁸ investigated the effect of a 4-week rhythmic-cued (metronome or music-based) MI program on walking, fatigue, and quality of life (QoL) in patients with MS. They found that compared to control participants, both forms of rhythmic-cued MI resulted in significant improvements in walking speed, distance and perception of ability, cognitive fatigue, and QoL (see the Evidence table).¹⁸

With respect to patients with PD, Tamir and colleagues¹⁹ studied the effect of a 12-week intervention that combined MP and PP of callisthenic exercises (e.g., throwing and catching a ball while in broad tandem stance, reaching in different directions) and functional activities (sit-to-stand transitions, walking) administered for 1 hour per day, 2 days per week compared to a control group that received the same PP combined with relaxation exercise. They found that the intervention group had significantly faster performance of movement sequences, greater gains on the mental and motor subsets of the Unified Parkinson's Disease Rating Scale (UPDRS), and improved performance on cognitive tests (i.e., Clock drawing and Stroop test). Both groups improved on the ADL scale of the UPDRS.¹⁹

Conversely, Braun et al.²⁰ investigated the effect of a 6-week program that embedded MP in standard therapy on mobility tasks in patients with PD. They found no effect in favor of the MP intervention on any outcome measure (i.e., Timed Up and Go, 10-Meter Walk Test, Visual Analogue Scale to measure patient/therapist perception of effect on walking performance).²⁰ Further research with these patient populations is warranted.

Mirror Therapy

Mirror therapy (MT) is an intervention based on visual stimulation, specifically the use of mirror visual feedback.²¹ During MT, a mirror is placed in approximately the midsagittal plane with the impaired limb position behind the mirror (hidden out of view). The unimpaired limb is positioned in front of the mirror, and the patient is asked to perform simple movements (e.g., opening and closing the hand, ankle dorsiflexion, plantar flexion) or simple functional tasks (e.g., grasping and releasing a washcloth, lifting a cup, stepping) while concentrating on the mirror reflection of the unimpaired limb (Fig. 16-3). This setup creates a visual illusion that the impaired limb is moving normally. During MT, patients are instructed to either keep the impaired limb in a resting position, or they are encouraged to attempt to move the impaired limb (as best as they are able) simultaneously with the unimpaired limb.²¹

Figure 16-3 Example of mirror therapy. The impaired hand is placed inside the mirror box (hidden out of view), and the patient is asked to concentrate on the mirror reflection of the unimpaired hand grasping and releasing a washcloth.

Although the precise neural mechanisms underlying the beneficial effects attributed to MT remain unclear, evidence suggests that this type of training can improve motor function when combined with standard care. For example, a recent systematic review and meta-analysis found that MT reduces motor impairments, improves motor function, and improves ADL performance in patients with stroke.²¹ MT has also been shown to improve movement speed of the more affected hand in patients with PD.²²

Action Observation

Action observation (AO) is an intervention during which a patient observes a healthy person performing a task, either in a video or real demonstration, with the intention of imitating the task performance. AO is considered a multisensory approach and is thought to promote neural reorganization via activation of the mirror neuron system.²³ Typically, after patients watch an action being performed, they are asked to duplicate the action repeatedly for a specific number of trials or minutes. For example, a patient may be instructed to watch a video of a person folding a towel and then engage in the task of towel folding (Fig. 16-4). Often, tasks are broken down into small successive steps that are strung together with increasing complexity. For example, a patient may be instructed to watch a video of a person (1) reaching her hand out to pick up a cup; (2) reaching her hand out to pick up a cup and then lifting the cup to drink from it; and (3) reaching her hand out to pick up a cup, lifting the cup to drink from it, and then returning the cup to the table.²³

Figure 16-4 Example of action observation. **A.** Patient watches a prerecorded video of a model folding a towel. **B.** Following the viewing of the video, the patient performs the task of folding a towel.

Results of a recent systematic review and meta-analysis suggest that AO is beneficial for improving UE motor function, hand function, and independence in ADL in patients after stroke.²³ There is also some emerging evidence that this intervention may improve functional mobility,²⁴ QoL,^{24,25} and ADL performance²⁵ in patients with PD (see the Evidence table).

Use of Technology

Virtual Reality

VR is a treatment approach that allows for simulated practice of functional activities in a computer-based, interactive, simulated environment designed to replicate the real-world environment.²⁶ VR systems can vary in their degree of immersion of the user from high immersion (systems in which the user is represented within the virtual environment) to low immersion (single screen projection or desktop display).²⁶ Many commercially available gaming consoles (e.g., Nintendo Wii) are considered low immersion VR systems. Researchers suggest that VR training may be advantageous for the following reasons²⁶⁻²⁸: (1) it offers the patient an opportunity to engage in goal-directed tasks in an enriched environment; this may increase saliency, feedback, and motivation, thereby promoting a greater number of repetitions and adherence to training; (2) it may allow for unsupervised practice; and (3) it may offer patients with limited motor capabilities an opportunity to engage in trial tasks that might be unsafe to practice in the real world (e.g., crossing the street or pouring a hot cup of coffee).

VR training has been used as an intervention to improve motor function in patients with stroke,²⁶ PD,²⁷ and MS.²⁸ Laver et al.²⁶ conducted a systematic review and meta-analysis to determine the efficacy of VR on UE function and activity in patients after stroke. They found that VR was not superior to conventional therapy for improving UE function. However, when it was added to usual care (providing a higher dose of therapy), there was a statistically significant difference between the groups, favoring the addition of VR. They also reported that VR had a statistically significant effect for improving ADL.²⁶ These results suggest that VR may be beneficial when added to usual care. However, the effect of VR on participation restrictions or QoL could not be determined by the study.²⁶

Dockx et al.²⁷ conducted a systematic review and meta-analysis to determine the effectiveness of VR for improving gait and balance, global motor function, ADL, QoL, cognitive function, and exercise adherence in patients with PD. The results of the review found that VR may have similar effects on gait, balance, QoL, and exercise adherence as compared to standard physiotherapy. Only one study included outcome measures related to ADL as defined in the review. No significant differences were noted between the VR group and standard care. Authors indicated that given the small number of studies conducted to date (eight studies were included in the review), generalization regarding VR effectiveness for patients with PD could not be determined.²⁷

Finally, Massetti et al.²⁸ conducted a systematic review to investigate the results shown in previous studies investigating MS and VR. Ten studies were included in the review, and results from selected studies suggest that VR may improve arm movement and control, balance, and walking abilities in patients with MS. The authors suggest that VR might serve as an alternative intervention that motivates patients above traditional motor rehabilitation. However, no attempts were made to pool data contained in the studies, and the authors cautioned that further research is needed.²⁸

Robotics

Overtime, advances in technology have led to the development of robotic training interventions for improving UE function after neurological injury. Robotic devices are specialized machines that support shoulder, elbow, or hand movements during therapy. The devices either provide passive limb movement, resist joint movements, or assist movement

of the limb at single or multiple joints depending on the device.²⁹ These devices allow progression of therapy by increasing resistance, decreasing resistance, or by varying force parameters and movement amplitudes.²⁹ Training with these devices is often coupled with VR environments and may allow for increased repetition of movements, particularly for those with severe motor impairments. Evidence suggests that this type of arm training improves function and strength of the affected arm, and ADL performance in patients after stroke.²⁹ Additionally, emerging evidence suggests that robotic training may improve UE coordination and function, as well as ADL performance in patients with MS.^{30,31} The use of robotic training devices is also being explored as a possible means for improving walking ability in patients with spinal cord injuries. Although some improvements in lower extremity motor function and activities have been reported, further studies are required to evaluate its effectiveness.³²

Figure 16-5 provides an example of a robotic device, the ReoGo™, that allows controlled movements of the elbow and wrist and a small degree of shoulder motion.

Figure 16-5 Example of a robotic device.

Management of Specific Neurological Impairments

Although TOT should be considered foundational when attempting to improve motor skill performance, it may be necessary for therapists to target the treatment of specific neurological impairments to improve engagement in occupation. The following sections highlight the clinical management of common neurological impairments: paresis and inability to fractionate movement, changes in muscle tone, deficits associated with hypokinetic (e.g., bradykinesia) and hyperkinetic (e.g., ataxia) movement disorders, and apraxia.

Intervention for Paresis and Inability to Fractionate Movement

As indicated in Chapter 15, paresis and the inability to fractionate movement are common consequences of lesions of the descending upper motor neuron system. All of the interventions discussed in the previous sections can be used to treat these impairments, but

there are some additional clinical strategies that can be employed to specifically target recruitment of paretic muscles. Electromyogram biofeedback (EMG-BFB)³³ and electrostimulation (ES)³⁴ (also called neuromuscular electrical stimulation [NMES]) are technologies that can be used to assist patients with recruiting weak muscle groups or selectively controlling certain muscles groups during TOT (also see Chapter 24). EMG-BFB is a technique that amplifies and transduces an electrical signal generated from an electromyogram into a signal that is displayed in a simplified form to the patient, for example, by hearing a change in an auditory tone or by seeing a response on an oscilloscope display (device that is used to graph an electrical signal as it varies over time).³³ EMG-BFB may help patients learn how to recruit appropriate muscles groups during task training.

ES or NMES is a technique used to elicit a muscle contraction using electrical impulses. Electrodes, controlled by a specialized unit, are placed on the skin over predetermined areas related to the muscles targeted for recruitment. An electrical current is delivered from the unit through the electrodes and delivered to the muscle, causing the muscle to contract.³⁴ Figure 16-6 shows an example of the use of ES during task training. In this case, the muscles being targeted are weak wrist and finger extensors that are needed to open the hand in preparation for grasping a piece of fruit.

Figure 16-6 Example of the use of functional electrical stimulation to recruit paretic muscles. Stimulation is placed over the wrist and finger extensors to aid in opening the hand as the patient reaches to pick up a piece of fruit.

Strengthening programs may also be utilized to address paresis. Evidence suggests that exercise and strengthening interventions improve muscle strength and function after neurological injury without causing adverse effects (e.g., increasing muscle tone)³⁵ (for details on muscle strengthening, see Chapter 14).

Intervention for Flaccidity, Spasticity, and Rigidity

Changes in muscle tone are often seen as a consequence of damage to the motor system. Thus, managing changes in muscle tone is an important component of motor control intervention. Traditionally, neurophysiological approaches, including the application of various types of sensory stimuli (e.g., tactile, thermal, vibratory), have been used to either “facilitate” (in the case of flaccidity or low muscle tone) or “inhibit” (in the case of spasticity or rigidity) muscle tone, depending on the sensory modality used and how it is applied (e.g., duration, speed, intensity) (see Chapter 35). The following list provides examples of how practitioners have used sensory stimuli to either increase or decrease

muscle tone; although it should be noted that evidence regarding their effectiveness to change muscle tone is lacking⁴:

■ **Icing:**

- Brief, rapid icing of the skin overlying a muscle belly has been used to increase muscle tone
- Prolonged icing has been used to decrease muscle tone

■ **Vibration:**

- High-frequency vibration has been used to increase muscle tone
- Low-frequency vibration had been used to decrease muscle tone

■ **Tactile stimuli:**

- Slow stroking over the skin has been used to inhibit muscle tone
- Fast stroking over the skin has been used to facilitate muscle tone

■ **Proprioceptive stimuli:**

- Joint approximation and traction have been used to facilitate muscle tone

The techniques associated with the biomechanical approach (see Chapters 14 and 32), such as muscle stretching (including casting) and passive range of motion (ROM), are frequently used to manage hypertonicity and prevent the development of contractures. However, the effectiveness of these interventions for managing increased tone is unclear.^{36,37} For example, results of a recent systematic review found that muscle stretch did not have a clinically important short-term effect on joint mobility, and it was uncertain whether stretch had clinically important short-term effects on pain or activity limitations in those with contractures.³⁷ Likewise, orthotic devices are frequently used to manage spasticity (see Chapter 22), although evidence supporting the effectiveness is lacking.^{36,38}

Changing a patient's position has also been used to modulate tone. This is based on the assumption that placement of a patient in certain positions will activate primitive reflexes that may have reemerged as a consequence of brain injury. For example, placing a patient in prone may increase flexor muscle tone, whereas placing a patient in the supine position may increase extensor tone, secondary to activation of the tonic labyrinthine reflex. Appropriate positioning is also thought to maintain muscle length, thereby preventing the development of contractures.⁴

Finally, it should also be mentioned that physicians may utilize pharmacological treatments, such as baclofen or botulinum toxin, or utilize surgical procedures (e.g., dorsal root rhizotomy, motor point blocks, placement of spinal stimulators) to manage spasticity and rigidity. Although beyond the scope of OT practice, these treatments may reduce spasticity to a sufficient level, allowing patients to engage in other motor control interventions.

Intervention for Deficits Associated with Hyperkinetic and Hypokinetic Movement Disorders

Coordination disorders can be characterized as hyperkinetic (ataxia, hemiballismus, chorea, tremor, tics) or hypokinetic (bradykinesia, Parkinsonian disorders). Both types of disorders can have a serious negative impact on occupational performance (see Chapter 15).

There is limited evidence in terms of interventions for hyperkinetic disorders, such as ataxia. Llg et al.³⁹ described an intensive coordination training program for those living with ataxia due to cerebellar degeneration. The program lasted for 4 weeks (three 1-hour sessions per week). Exercises included the following categories:

1. static balance (e.g., standing on one leg)
2. dynamic balance (e.g., sidesteps, climbing stairs)
3. whole-body movements to train trunk–limb coordination
4. steps to prevent falling and falling strategies
5. movements to treat or prevent contracture

Training improved motor performance and reduced ataxia symptoms on both impairment measures and functional outcomes. In addition, subjects achieved personally meaningful goals in everyday life as measured by goal attainment scaling.

Miyai et al.⁴⁰ randomly assigned 42 patients with pure cerebellar degeneration to an immediate or delayed-entry control group in an inpatient rehabilitation setting. Physical therapy consisted of general conditioning; ROM exercise for trunk and limbs; muscle strengthening; static and dynamic balance exercise with standing, kneeling, sitting, and quadruped; mobilizing the spine while prone and supine; walking indoors and outdoors; and climbing up and down stairs. OT consisted of improving ADLs (e.g., hygiene, dressing, writing, eating), relaxation, balance exercises, reaching, coordinative tasks of the upper limbs and trunk, and dual motor tasks such as handling objects while standing and walking. The authors' findings include⁴⁰:

- The immediate group showed significantly greater functional gains in ataxia, gait speed, and ADL than the control group.
- Improvement of truncal ataxia was more prominent than limb ataxia.
- The gains in ataxia and gait were sustained at 12 and 24 weeks, respectively.

It should be noted that many individuals living with hyperkinetic disorders have progressive diseases such as MS. Therefore, adaptive approaches are most likely to be a substantial component of intervention plans and have been recommended by various authors.⁴¹ It has been hypothesized that many of the ineffective movement patterns observed in patients can be attributed to attempts to control the degrees of freedom (see Chapter 34). Therapists need to consider this during treatment planning when choosing activities. The degrees of freedom must be controlled carefully by stabilizing or eliminating use of some of the joints to decrease the number of joints involved (e.g., supporting the distal extremity on a table or substituting flat-hand stabilization for a hand grasp). Gillen has demonstrated a variety of methods to improve task performance in clients with ataxia by manipulating the degrees of freedom via positioning, splinting, movement retraining, and equipment.^{42,43} Examples follow. See the case study of Nakai at the end of this chapter.⁴²

- **Orthotics:** The goal is to provide joint stability in order to decrease control requirements.
 - Philadelphia collar
 - Opponens orthosis
 - Wrist supports
 - Task-specific orthoses (e.g., typing, writing)
- **Environmental modifications:** Utilizing the environment for stability. Focus on stabilizing the upper/lower trunk, stabilize arms, and decrease the degrees of freedom.
 - High back chairs
 - Forearm weight bearing on work surface or wall
 - Stabilize head on wall
 - Sit at a table against wall (anterior/lateral stability)
 - Use corner of wall (anterior/lateral stability)
 - Pillows and foam for support
 - Stabilize with one arm holding a chair
- **Retrain movements:**
 - Maintain arm contact with work surface or body (slide, don't reach)
 - Move upper limbs in flexion and adduction
 - Co-contract trunk
 - Push head into back of chair
 - Break down movement pattern to change target (for a feeding example, see Case Study)
 - Experiment with slow versus quick movements

- Slide objects/tools on counter
- Avoid reach into space
- **Adaptive devices:**
 - Soap on a rope
 - Electric toothbrush/razor
 - Coated utensils
 - Cup covers
 - Long straws
 - Weights
 - Dycem
 - Basket for transport
 - Adapted cutting boards
 - Suction brushes (nail, meal preparation, dish washing)
- **Assistive technology:**
 - Tilt-in-space power base
 - Tremor-dampening electronics
 - Contoured seating
 - High back chairs with head support
 - Speaker phone/headsets, bluetooth
 - Speech-to-text technology
- **Positioning:**
 - Semi-Fowler in bed
 - Tilt-in-space wheelchair for mobility
 - High back chairs
 - Avoid unsupported sitting
 - Lean against wall for sitting/standing
 - Platform walkers for gait
- **Therapeutic exercise to increase core stability:**
 - Closed chain strengthening
 - Proximal stability (core/scapula)
 - Body weight as resistance
 - Postural alignment
 - Bridges, prone on elbow, quadruped, wall squats, kneeling, wheelchair pushups

Interventions to improve motor function for those with hypokinetic movement disorders such as PD have received more attention in the literature recently. A recent systematic review concluded the following⁴⁴:

- The majority of relevant research addresses physical performance skills.
- There is a short-term benefit of physical activity for improving or maintaining physical performance skills.
- Task-specific training (particularly in enriched environments or contexts that utilize external supports, such as rhythmic cues) may benefit the development of new performance skills.
- Improvements appear to be specific to trained skills; lack of transfer to untrained skills or generalization of performance skill improvements to improvements in ADL or broader occupational performance outcomes.

The authors suggested that occupational therapists should encourage their clients with PD to engage in regular physical activity and help them find appropriate and meaningful forms of physical activity to ensure continued engagement.⁴⁴ There is anecdotal and emerging empirical evidence that engagement in specifically structured occupations can improve function and may in fact have a neuroprotective component. These include yoga (decreased limb bradykinesia and rigidity, increased strength and power, and improved QoL were seen after 12 weeks of training)⁴⁵; boxing (improved mobility and endurance)⁴⁶; and dance (improved balance and mobility).⁴⁷

If one analyzes occupations such as boxing and dance (specifically Tango), it is clear that they require the use of high-amplitude movements. The Lee Silverman Voice Treatment Big (LSVT Big) is a protocol-driven **high-amplitude movement training** program. The program is 1 month, including four 1-hour sessions per week. The key aspects of this program include the combination of (1) an exclusive target on increasing amplitude (bigger movements in the limb motor system), (2) a focus on sensory recalibration to help patients recognize that movements with increased amplitude are within normal limits, even if they feel “too loud” or “too big”, and (3) training self-cueing and attention to action to facilitate long-term maintenance of treatment outcomes.⁴⁸

Intervention for Apraxia

Motor apraxia is a disorder of the production praxis system and may be defined as the loss of access to praxicons (motor plans) so that purposeful movement cannot be produced or achieved because of defective planning and sequencing of movements, even though idea and the purpose of task are understood.⁴⁹

The person knows what to do related to the task at hand and has the overall concept of what to do. If language is intact and the person is questioned, he or she can explain the purpose of the task at hand. Instead, he or she cannot program, plan, or produce the movements necessary to accomplish the task, despite having the sensory and motor skills to execute the task. Clinical observations related to errors during task performance may include the following^{49–52}:

- Difficulties related to motor planning in general, resulting in awkward or clumsy movements.
- Difficulties when planning movements to cross the body’s midline (e.g., difficulty adjusting the grasp on a hairbrush when moving it from one side of head to the other).
- Difficulty orienting the UE or hand to conform to objects (e.g., picking up a juice bottle with the radial side of the hand down instead of a typical cylindrical grip).
- Inflexible and static hand patterns (e.g., not being able to manipulate coins out of the palm of the hand to insert them into a vending machine).
- Difficulty sequencing movements such as the sequence to get out of bed, or sequencing complex upper limb movements such as picking up the phone and lifting it to the ear.
- Spatial orientation and spatial movement errors (e.g., moving scissors laterally instead of forward).
- Difficulty coordinating two or more joints (e.g., coupling the shoulder and elbow movements for cutting). In general, the more joints involved in the tasks, the more degraded the motor planning.
- Difficulty timing movement (e.g., delay in initiation of movement, pauses, or difficulty related to movement speed).
- Poor gesture-production ability, particularly when gesturing the use of an object (transitive gestures).
- Using a body part as an object when asked to pantomime use of an object—common diagnostic screen for motor apraxia.
- Movements are imprecise.

Recent reviews have examined the available evidence to determine the most appropriate evidence-based interventions for those living with apraxia. A systematic review by West et al.⁵³ determined that two studies that documented changes in ADL status using the Barthel Index (BI) showed a small and short-lived therapeutic effect. They determined that this change was not clinically significant and did not persist. They recommended that higher quality research be conducted.

In 2011, Cicerone et al.⁵⁴ updated their clinical recommendations for cognitive rehabilitation of people with traumatic brain injury (TBI) and stroke, based on a systematic review of the literature from 2003 through 2008.⁵⁵ Their practice standard related to apraxia

is stated as “specific gestural or strategy training is recommended for apraxia during acute rehabilitation for left hemisphere stroke.”

Similar to Cicerone et al.,⁵⁴ Gillen et al.⁵⁶ identified two potential interventions: cognitive strategy training (CST) and gesture training (GT). Both of these are described further in the sections that follow.

Cognitive Strategy Training

CST consists of teaching internal and external compensatory approaches to execute ADLs. Techniques include internal rehearsal, verbalizing actions during ADL execution, and external cueing. Building on the research of Donkervoort et al.,⁵⁷ Geusgens et al.⁵⁸ examined their data to see whether CST had a greater transfer effect to nontrained tasks than usual OT alone. Although analysis showed both treatment groups improved on trained and nontrained tasks, the CST group showed greater improvement on nontrained tasks. These data indicate a greater transfer effect in the CST condition (see the Evidence table).

van Heugten and colleagues⁵⁹ described an intervention study designed for use by occupational therapists based on teaching clients strategies to compensate for the presence of apraxia. The treatment was focused on training activities that were relevant to the individual client. The therapist and client decided on which activities to focus. Interest checklists were also used to choose activities in addition to focusing on activities that were important to carry out in the future. Every 2 weeks, other activities were chosen.

The focus of the intervention was error specific and determined by the specific problems observed during standardized ADL observations. Specifically, interventions focused on errors related to the following:

- **Initiation:** inclusive of developing a plan of action and selection of necessary and correct objects
- **Execution:** performance of the plan
- **Control:** inclusive of controlling and correcting the activity to ensure an adequate end result

Difficulties related to *initiation* were treated via specific *instructions*. Instructions were hierarchical in nature and could include verbal instructions, alerting the client with tactile or auditory cues, gesturing, pointing, handing objects, or starting the activity together. *Assistance* was the intervention provided when problems related to *execution* of the activity occurred. Also hierarchical, assistance could range from various types of verbal assist, stimulating verbalization of steps, naming the steps of the activity, to physical assistance such as guiding movements (Fig. 16-7). When having difficulty with *control* (i.e., clients do not detect or correct the errors they make during the activity), *feedback* was provided. Feedback ranged from verbal feedback related to knowledge of results to taking control of the task and controlling for errors. The specific strategy training intervention protocol is included in Box 16-3. van Heugten and Geusgens⁶⁰ have more recently described the process of CST (Box 16-4).

Figure 16-7 Example of intervention for apraxia when errors in task execution are noted. Therapist is providing physical assistance by guiding the patient's movements during the task of washing down a table surface.

Box 16-3

Cognitive Strategy Training

The specific interventions are built up in a hierarchic order, depending on the patient's level of functioning. The therapist can use instructions, assistance, and feedback.

- To direct the attention to the task at hand.
- Use gestures, mimics, and vary intonation in your speech.
- Show pictures of the proper sequence of steps in the activity.
- Physical assistance is needed:
 - By guiding the limbs.
 - In positioning the limbs.
 - To use aids to support the activity.
 - To take over until the patient starts performing.
 - To provoke movements.
- Finally, take over the task.

Feedback (for those with difficulty controlling *or* correcting errors)

Feedback can be offered in the following ways:

- No feedback is necessary because the result is adequate.
- Verbal feedback is needed in terms of the result (knowledge of results).
- Verbal feedback by telling the patient to consciously use the senses to evaluate the result tell the patient to see, hear, feel, smell, or taste.
- Physical feedback is needed in terms of the result (knowledge of results):
 - To evaluate the posture of the patient.
 - To evaluate the position of the limbs.
 - To support the limbs.
- Physical feedback is given by pointing or handing the objects to the patient.
- Verbal feedback is needed in terms of performance (knowledge of performance).

- Physical feedback is needed in terms of performance (knowledge of performance).
- Place the patient in front of a mirror.
- Make video recordings of the patient's performance and show the recordings.
- Take over the control of the task and correct possible errors.

Instructions (for those not able to initiate task performance)

The occupational therapist can give the following instructions:

- Start with a verbal instruction.
- Shift to a relevant environment for the task at hand.
- Alert the patient by:
 - Touching
 - Using the patient's name
 - Asking questions about the instruction
- Use gestures, point to the objects.
- Demonstrate (part of) the task.
- Show pictures of the activity.
- Write down the instruction.
- Place the objects near the patient, point to the objects, put the objects in the proper sequence.
- Hand the objects one at a time to the patient.
- Start the activity together with the patient one or more times.
- Adjust the task to make it easier for the patient.
- Finally, take over the task because all efforts did not lead to the desired result.

Assistance (for those with difficulties executing the task)

The following forms of assistance can be given by the therapist:

- There is no need to assist the patient during the execution of the activity.
- Verbal assistance is needed:
 - By offering rhythm and not interrupting performance.
 - To stimulate verbalization of the steps in the activity.
 - To name the steps in the activity or name the objects.

Adapted from van Heugten CM, Dekker J, Deelman BG, van Dijk AJ, Stehmann-Saris JC, Kinebanian A. Outcome of strategy training in stroke patients with apraxia: a phase II study. *Clin Rehabil.* 1998;12:294–303.

Box 16-4

Cognitive Strategy Training

Strategies for instructions to support the preparation of the performance when the client's performance deficits occur in the *orientation* phase:

- Give instructions more than once and use extra attention.
- Ask questions about the performance.
- Demonstrate the performance or its parts.
- Give a written description of the performance.
- Show pictures of the task performance.
- Show objects needed for the task.
- Hand objects to the client one by one.
- Take over performance or its parts.

Strategies for instructions to support the preparation for the performance when the client's performance deficits occur in the *execution* phase are guidance strategies:

- Show pictures.
- Guide with verbal support.
- Guide with physical support.
- Start with a slow tempo.
- Start with only one object.
- Show objects needed for the task.
- Hand objects to the client (one by one).
- Take over the performance or its parts.

Strategies for instructions to support the preparation for the performance when the client's performance deficits occur in the **control** phase are feedback strategies:

- Give verbal feedback.
- Show the result in a mirror.
- Make video recordings to show to the client.
- Ask questions about the result ("Did you put on your socks?").
- Make pictures to show to the client.

Adapted from van Heugten CM, Geusgens C. Strategies to compensate for apraxia among stroke clients. In: Söderback I, ed. *International Handbook of Occupational Therapy Interventions*. New York, NY: Springer; 2009.

Gesture Training

Smania et al.⁶¹ first described **GT** for apraxia. The authors described GT as a behavioral training program consisting of gesture-production exercises. The rehabilitation program is made up of three sections⁶¹:

1. **Transitive gestures:** (1) patient is asked to show the use of common tools (e.g., spoon), (2) patient is shown a picture illustrating a transitive gesture (e.g., using a spoon), (3) patient is required to produce the corresponding gestural pantomime, and (4) patient is then presented with a picture of a common tool (e.g., a spoon) and required to pantomime the use of that object.
2. **Intransitive-symbolic gestures:** (1) patient is shown two pictures, one illustrating a given context (e.g., a man eating a sandwich) and the other showing a symbolic gesture related to that context (e.g., the gesture of eating), after presentation; (2) patient is asked to reproduce the symbolic gesture; (3) patient is asked to produce the correct gesture (e.g., the gesture of eating) after presentation of the context picture alone (e.g., a man eating a sandwich); and (4) patient is asked to produce the correct gesture (e.g., the gesture of eating) following the presentation of a picture showing a new, but similar contextual situation (e.g., a man eating canned food with a fork).
3. **Intransitive-nonsymbolic gestures:** (1) patient is asked to imitate meaningless intransitive gestures (six proximal and six distal joint movements, half are static and half dynamic) previously shown by the examiner.

Smania et al.⁶² assessed how GT affects functional independence in ADL. The researchers completed a study with 41 left hemisphere patients after stroke. In addition to the neuropsychological test battery, they included a caregiver questionnaire regarding patient ADL independence. An additional 2-month post-training follow-up assessment was included. Results showed that the GT group's performance improved significantly on ideational, ideomotor, and gesture comprehension tests. Performance on these tests and measures of ADL independence was correlated.

CASE STUDY

Nakai is a 34-year-old Native American male who was diagnosed with MS 2 years prior to this inpatient rehabilitation admission. His initial symptoms began approximately 3 years prior to this admission and consisted of diplopia, gait impairments, and problems with upper limb coordination. Nakai was admitted to the

hospital because of worsening symptoms and an inability to complete basic self-care tasks such as feeding, grooming, dressing, and toileting. See Chapter 15 for assessment results. Based on the assessment results, two control parameters guided the development of Nakai's intervention plan⁴²:

- As the degrees of freedom (number of joints involved in the task) increased, tremors increased and functional control decreased. When the degrees of freedom were controlled (decreased) during treatment sessions, UE trajectories were smoother and resulted in an improved ability to interact with the environment and perform functional activities.
- When engaged in activities that challenged his postural stability, his tremors worsened. Observations to support this hypothesis included progressive worsening of tremors as he moved from supine to sitting to standing; improvement of tremors while seated in high back chairs and semi-reclined postures where his trunk was supported (i.e., semi-sitting position with knees flexed and supported by pillows on the bed); and worsening of tremors when Nakai became increasingly posturally insecure or when he was required to control his trunk against gravity (i.e., reaching beyond his arm span, weight shifting during ADL).

Nakai confided that he felt humiliated when staff had to assist him with feeding and oral care, thus improving independence in feeding and oral care became primary goals. To meet these goals, orthotic devices were provided in an effort to decrease motor control requirements and to stabilize the cervical spine as well as the distal UEs. A semirigid cervical collar was prescribed as well as off-the-shelf wrist supports. In addition, an electric toothbrush was provided to reduce the need for rapid alternating movements, and Dycem was used to stabilize his plate during eating. Nakai's feeding position promoted postural security and was characterized by leaning into the table in a position of forearm weight bearing to stabilize his upper trunk. In addition, his hand-to-mouth movement pattern was modified from a continuous trajectory from plate to mouth to a three-step pattern as follows:

1. Slide hand and utensil across the table and manipulate food onto the utensil.
2. Bring the hand to a point approximately 2 inches from the mouth (to decrease the effects of intention and smaller target size on worsening tremors).
3. Relax and place food in the mouth.

Likewise, Nakai's movement patterns and positioning during oral care were adapted to use the environment for UE stabilization and to minimize reaching into space. His positioning during oral care was modified to one of standing in front of a wall in a position of forearm weight bearing while simultaneously co-contracting his trunk to promote postural stability. With the electric toothbrush stabilized, Nakai was taught to systematically move his mouth around the toothbrush.

In addition, Nakai was provided with two MP CDs. One CD verbally prompted Nakai to imagine performing the task of eating using the new three-step pattern and modified positioning. The other CD verbally prompted him to imagine performing the task of brushing his teeth using the new positioning and movement pattern of moving his mouth around the stabilized toothbrush. Nakai was encouraged to use the tapes outside therapy sessions prior to task performance.

Breaking tasks down, decreasing the degrees of freedom with orthotics, increasing postural stability via positioning, the use of adaptive equipment, and supplementing the training with MP resulted in increased control of the desired movement patterns and improved task performance. Nakai was able to eat independently with utensils and perform oral care with the aid of an electric toothbrush, albeit with effort and increased time. Continued practice eventually decreased the time required to eat and perform oral care to performance levels acceptable to Nakai.

Best Evidence for Motor Control Intervention

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Action Observation ²⁵	Both groups received conventional therapy. In addition, patients in the case group were asked to observe and subsequently execute different daily actions presented via video clips. Controls observed video clips without motor content and subsequently performed the same actions as the case participant.	<i>N</i> = 15 patients with PD, ages 18–75, normal or corrected vision, normal auditory acuity, relatively cognitively intact, and the absence of depression. Case group: <i>n</i> = 7; Control group: <i>n</i> = 8. Groups did not differ statistically on any of the baseline characteristic, except for disease severity—cases were worse than controls.	Dosage information not provided in the study	Case–Control Level 2	Findings suggest AO may improve autonomy in daily living activities	Both groups improved after treatment, but change scores were higher in the cases as compared to the controls on both the UPDRS ($p = 0.004$) and the Functional Independence Measure ($p = 0.002$).
Cognitive Strategy Training ⁵⁸	Strategy training integrated into OT. The focus of training is determined by problems noted during ADL performance as they relate to initiation, execution, and control. Instruction, assistance, and feedback are used depending on the problems identified as compared to standard OT.	<i>N</i> = 113 patients with left hemispheric stroke and apraxia. Strategy training group: <i>n</i> = 56; Usual treatment group: <i>n</i> = 57. Groups did not differ statistically on any of the baseline characteristics with the exception of age: strategy training group was older.	Eight weeks of treatment according to group randomization. Experimental group had on average 25 (standard deviation [SD] = 9.8) sessions, resulting in 15 (SD = 7.7) hours of OT. Control group had on average 27 (SD = 15.6) sessions, resulting in 19 (SD = 15.0) hours of OT	Single-blind, randomized controlled trial (RCT) Level 1	Transfer effects from trained to nontrained tasks were noted for both groups, suggesting both forms of treatment resulted in transfer of training; although, the effect was larger in the group that received the strategy training intervention.	ADL change scores of nontrained task improved in both groups over time ($p = 0.00$). Change score on the ADL observations of nontrained tasks (week 8–week 0) was larger in the strategy training group than in the usual treatment group ($t = 1.78$, $p = 0.040$). No significant differences between the groups on trained tasks or on trained and untrained tasks at 5-month follow-up.

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Constraint-induced movement therapy (CIMT) and modified CIMT (mCIMT) ⁹	Forced use of the affected UE by restraining the unaffected UE with a sling or hand splint/mitt and massed practice of the affected limb via shaping and standard task practice	Forty-two RCTs were included, involving 1,453 participants who had a stroke and had some residual motor power of the paretic arm with limited pain or spasticity; more men (64%) than women; mean age range and time after stroke varied	CIMT: <i>n</i> = 9 studies mCIMT: <i>n</i> = 29 studies Restraint time of unimpaired limb, training intensity of impaired limb, and treatment duration varied across studies accordingly	Systematic review and meta-analysis Level 1	Reduces UE motor impairments and improves UE function in stroke survivors with some residual motor function in the affected UE. However, these improvements may not readily translate to improved performance of ADLs. No differences in adverse effects between CIMT and control conditions	Nonsignificant effects for disability (SMD 0.24, 95% confidence interval [CI] -0.05 to 0.52) and QoL (mean difference [MD] 6.54, 95% CI -1.2 to 14.28). Significant effects for (1) upper limb function (SMD 0.34, 95% CI 0.12–0.55); (2) perceived upper limb function (quality of use: MD 0.68, 95% CI 0.47–0.88) and amount of use (MD 0.79, 95% CI 0.50–1.08); (3) arm motor impairment (SMD 0.82, 95% CI 0.31–1.34); (4) dexterity (SMD 0.42, 95% CI 0.04–0.79)

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
MI with rhythmic cueing ¹⁸	Participants in experimental group were engaged in a 30–40-minute group (two to three people) session to get familiar with use of MI. Then, they were provided with study CDs containing verbal prompts to facilitate kinesthetic imagery of walking combined with either music or metronome and rhythmic cues used to carry out home-based MI program. Control group received standard care.	<i>N</i> = 101 patients diagnosed with mild-to-moderate MS without overt signs of cognitive impairment or depression. 85 females and 16 males; mean age was 44.1 ± 12.0 years. Groups did not differ statistically on any of the baseline characteristics.	Seventeen minute sessions per day, for 6 days/week for a total of 4 weeks. Participants recorded their practice sessions in a diary; participants practiced a median 5 (4–6) times per week	RCT Level 1	Home-based rhythmic-cued MI improves walking, fatigue, and QoL in people with mild-to-moderate MS. It appears music-cued MI may be more effective. The intervention was reported to be safe, convenient, and without adverse events.	Rhythmic-cued MI significantly improved walking speed as compared to controls ($p < 0.0001$, with a large effect size (ES) of $h^2 = 0.581$) and walking distance compared to controls ($p < 0.0001$, with a large ES of $h^2 = 0.596$). Participants walking perception improved significantly in the MI groups, and improvements were clinically meaningful in the metronome group compared to controls. Cognitive and total fatigue significantly improved in the MI groups, whereas physical fatigue improved only after music-cued MI. Psychosocial fatigue did not improve. Health-related QoL (HRQoL) significantly improved in the MI groups as compared to the control group, with greater improvements noted with music-cued MI.

Intervention	Intervention Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Power Yoga Program ⁴⁵	Yoga practice using Vinyasa style that incorporates vigorous, fitness-based positions. The program used fast transitions from one posture to another. Strength, power, flexibility, and balance were addressed by stabilizing body extremities and strengthening core muscles. Control group received usual care and three nonexercise health education classes.	N = 27 elderly (60–90) patients with PD (Hoehn & Yahr stages I–III), ambulatory (at least 50 feet); able to get up and down from floor with minimal assistance and relatively cognitively intact. Yoga group: n = 15; Control group: n = 12. Groups did not differ statistically on any of the baseline characteristics.	The yoga program was given as group class for 1 hour per session, 2 sessions per week for 12 weeks.	RCT Level 1	Yoga program reduced bradykinesia and rigidity, increased muscle strength and power, and improved QoL in older patients with PD.	Significant effects in favor of the yoga group for: (1) bradykinesia: decrease in the upper limb (UL) (4.5 points) and lower limb (LL) (2.5 points) scores, with large ES (UL: $g = -1.75$; LL: $g = -1.11$, $p < 0.001$); (2) rigidity: (decrease in 2.6 points) with a large ES ($g = -0.64$, $p = 0.001$); (3) improved muscle strength and power ($p < 0.05$) with small ($g = 0.16$, $p = 0.023$) to large ($g = 0.80$, $p < 0.001$), ES seen across various tests; (4) improved mobility ($g = -0.82$, $p = 0.025$), ADL ($g = -0.46$, $p = 0.035$) domains and the sum score ($g = -0.70$, $p = 0.016$) of Parkinson's Disease Questionnaire

Chapter 17

Balance Assessment and Intervention

Allison Chamberlain Miller

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Recognize how balance contributes to daily occupational participation and performance.
2. Describe how impaired balance contributes to occupational dysfunction.
3. Understand the neurological and physiological basis of balance.
4. Describe screening skills for balance, sit-to-stand transfers, and functional ambulation.
5. Differentiate between static and dynamic balance.
6. List standardized assessments designed to evaluate balance and fall risk.
7. Describe appropriate intervention approaches in daily occupation for balance, sit-to-stand transfers, functional ambulation, and fall prevention.
8. List evidence-based interventions for the treatment of balance.

CHAPTER OUTLINE

Balance and Impairment in Daily Occupation
Neurological and Physiological Basis of Balance
Screening of Balance Skills
Overview of Interventions for Balance Impairment
Specific Interventions for Balance Impairment
Case Study

TERMINOLOGY

Balance: an even distribution of weight enabling someone to remain upright and steady.

Base of Support (BoS): area of contact between body and support surface.

Center of Mass (CoM): anatomical point representing the mean position of total body weight; also known as *center of gravity*.

Dynamic: body positioning during active motion.

Ipsilateral: belonging to or occurring on the same side of the body.

Postural adjustments: strategic changes in body alignment that minimize changes in CoM during weight shifting in a variety of planes and directions.

Postural control: the motor act of maintaining, achieving, or restoring a state of balance during any activity.

Static: body positioning without motion.

Weight shift: transfer of body mass from one supporting limb or body part to another.

Balance and Impairment in Daily Occupation

Balance is a critical skill for participation in many daily occupations. It is required for activities performed in sitting or standing, including the ability to transition between sitting and standing and to perform functional ambulation. The *Occupational Therapy Practice Framework: Domain and Process* (3rd ed.)¹ refers to balance as both a client factor and a performance skill necessary for participation in a person's chosen occupations. Many studies have supported a correlation between sitting balance scores and occupational independence, length of stay in inpatient settings, and occupational performance after stroke.² Impaired balance not only impacts an individual's ability to perform an occupation, it is also a leading cause of falling. Falls are a major health concern in the United States because they lead to high medical costs, a

decline in quality of life, and can even be fatal. Balance deficits and falls can cause decreased levels of occupational participation and independence.³

Neurological and Physiological Basis of Balance

Achieving and maintaining balance is a complex skill that requires the coordination of musculoskeletal systems and sensorimotor neural systems.^{4,5} An individual may experience reduced sensation or motor weakness that impairs balance, and other body systems such as vision are often used to compensate for those deficits.⁶ Neurologically, balance is regulated by the sensory and motor systems, including processing of vestibular (righting and equilibrium reactions), visual, and tactile, and proprioceptive information.⁷ Cranial nerve 8, known as the vestibulocochlear nerve, is responsible for sense of balance and spatial orientation.⁸ Proprioception senses body position and movement⁸ and is one factor associated with fall risk in older adults because it declines with age and has been linked to gait disorders.⁹

This processing plays an important role in trunk or **postural control** mechanisms. Each time a person moves, his or her body's **center of mass (CoM)** changes its relationship to the **base of support (BoS)**.⁷ Postural control skills allow us to stay in balance by maintaining our body's CoM within the BoS.⁷ Individuals with asymmetric postural alignment and impaired postural control tend to be fearful of falling during **static** sitting or standing without support, and this fear increases with **dynamic** movement attempts.⁷ Control during **postural adjustments** is required for all reaching from a sitting or standing position.¹⁰ Additionally, if an individual is unable to bear or **weight shift** to one side of his or her body, caused by orthopedic or neurological deficits, balance may be impaired because of asymmetrical postural alignment and control.¹¹

Decreased trunk strength and weakness in one or both of the lower extremities can also contribute to impaired balance. Lower extremity weakness is common in older adults, as strength begins to decrease annually around the age of 50, and this weakness can increase the risk of falling.^{12,13} This is particularly true for the hip flexors, knee extensors and flexors, and ankle plantar flexors and dorsiflexors.^{4,13} Individuals with lower extremity weakness have a decreased ability to recover from balance loss, related to an increased risk of falling.¹³ There is a relationship between reduced physical activity, muscle weakness, and balance deficits in clients with chronic obstructive pulmonary disease (COPD), for example.⁴

At times, some individuals experience impaired balance because of multiple factors, such as after a stroke. For example, individuals who have experience a stroke often exhibit balance deficits related to reduced weight bearing on the affected lower extremity, increased postural sway during standing, reduced sensation, unilateral inattention, delayed equilibrium reactions, impaired postural adjustments on the affected side, and uneven weight distribution during functional movements.¹¹

Neurologically based balance disorders are those for which an individual feels unsteady or dizzy even while still or laying down and require different evaluation and treatment than those discussed in this chapter, as prescribed by a physician. Certain medications have side effects that can negatively affect balance, as well as high or low blood pressure, viral or bacterial infection in the ear, or specific change of position of the head that displaces the vestibular structures of the inner ear. There are over a dozen different balance disorders, each with different causes and treatments that should be diagnosed and prescribed by a physician. For example, benign paroxysmal positional vertigo (BPPV) can be treated by physical or occupational therapists who are trained in the Epley maneuver, a series of simple movements to help dislodge displaced vestibular structures of the inner ear that are likely causing the balance impairment.^{14,15}

Screening of Balance Skills

Balance is impaired when an individual is unable to maintain a sitting or standing position without support or assistance, whether while remaining static or during dynamic movement. Impaired balance can create skill impairment for reaching from a sitting or standing position, transferring from sitting to standing, and performing functional ambulation. This can result in a higher risk of falling as well as decreased independence in meaningful occupations.

Signs Indicating Dysfunction in Balance

Occupational therapists often work with clients who require physical assistance to maintain an upright sitting or standing posture.⁶ Signs indicating dysfunction in daily occupation can be observed by analyzing the individual's postural alignment, such as whether or not the shoulders are even, if he or she is leaning more to one side than the other, or if he or she is simply unable to maintain sitting while unsupported. This is best observed on a firm surface that requires unsupported sitting, such as on the edge of a client's bed or on a therapy mat.⁷ The ability to flex and extend the trunk can be observed to recognize signs of decreased core strength. Observation of an individual's ability to perform postural adjustments and maintain control while reaching away from the body or across midline during functional tasks can also reveal signs indicating dysfunction in daily occupation.¹⁰ Other signs or precautions include impaired righting reactions, decreased depth perception in reaching for an item, or self-report that the individual is feeling dizzy or lightheaded.

To maintain standing balance, the goal is to maintain one's CoM over the BoS during weight shifting in a variety of directions, from one leg to the other.⁷ The quality of alignment of a weight-bearing leg can be assessed by observation of the following optimal characteristics: at least 90° of ankle dorsiflexion (foot flat on an even surface), active extension at the knee (not locked), active hip extension, and neutral position of the pelvis.⁷

Possible Causes of Impairment

As discussed, there are several possible causes of impaired balance, which may occur singularly or in combination. It is important to start by understanding the client's medical history because certain diagnosis may be at a higher risk of balance impairment based on the neurological or physiological basis of the condition. It is also important to be aware that anxiety regarding falling, especially if the individual has a history of falling, can affect safety during unsupported sitting and standing tasks. Because there are several possible causes of impaired balance, multifactorial screening and assessment is recommended to determine the individualized needs of the client.

Screening Instructions

Currently, there are no studies regarding how occupational therapists assess and document sitting balance, suggesting that there is a not a commonly accepted method.² Objective, skilled documentation is of increasing importance because other health care professionals refer clients to occupational therapists for discharge recommendations² and third-party reimbursement often requires standardized, measureable data to justify intervention. It is important to record the baseline balance performance of the client at initial evaluation to measure progress throughout intervention and plan for discharge.⁶ This section offers instructions for screening for sitting and standing balance using a grading system in order to provide measurable documentation and outcome measurements. Screening for balance offers a quick option for therapists to detect and measure potential balance impairments before completing a standardized assessment of balance, which only exists for standing balance.²

Before screening an individual for balance, sit-to-stand transfers, or functional ambulation, the therapist should review the client's history and create an occupational profile. It is important to note the client's diagnoses, medications and possible side effects, any history of falling, and prior level of function. The therapist should also assess the client's blood pressure because abnormal levels can create dizziness and increase the risk of falling or injury. Ensure the client's safety at all times, starting by assessing balance in sitting (see Fig. 17-1). This means another therapist's assistance may be required to stand by the client while assessing reaching ability.

Figure 17-1 Standing in front of patient and assessing for balance deficits or complaints of dizziness before standing, for safety.

Balance can be measured by grading it to detect the severity of any balance impairments and provide objective data. Grading includes static and dynamic balance for both sitting and standing. All grades must be qualified with the assistive device being used by the client. If no device is being used, that must be stated. Balance is graded on a scale from *Normal*, to *Good*, *Fair*, and *Poor* (see Table 17-1).¹⁶ The therapist should screen static balance before dynamic balance for both sitting and standing.

Table 17-1. Balance Grades

STATIC SITTING BALANCE	
Normal (N)	Able to maintain unsupported sitting balance against maximal resistance
Good (G)	Able to maintain unsupported sitting balance against moderate resistance
Good-/Fair+ (G-/F+)	Able to maintain unsupported sitting balance against minimal resistance
Fair (F)	Able to sit unsupported without balance loss and without UE support
Fair- (F-)	Able to maintain sitting balance with UE support
Poor+ (P+)	Able to maintain sitting balance with minimum assistance from individual or chair
Poor (P)	Unable to maintain sitting balance. Requires moderate/maximum support from another individual or chair
DYNAMIC SITTING BALANCE	
Normal (N)	Able to sit unsupported, able to weight shift and cross midline maximally
Good (G)	Able to sit unsupported, able to weight shift and cross midline moderately
Good-/Fair+ (G-/F+)	Able to sit unsupported, able to weight shift and cross midline minimally
Fair (F)	Able to sit unsupported, minimal weight shift to front/ipsilateral side, difficulty crossing midline
Fair- (F-)	Able to sit unsupported, able to reach to ipsilateral side, unable to weight shift
Poor+ (P+)	Able to sit unsupported with minimal assistance and reach to ipsilateral side, unable to weight shift
Poor (P)	Able to sit supported with moderate assistance and reach to front/ipsilateral side, cannot cross midline or weight shift
STATIC STANDING BALANCE	
Normal (N)	Able to maintain unsupported standing balance against maximal resistance
Good (G)	Able to maintain unsupported standing balance against moderate resistance
Good-/Fair+ (G-/F+)	Able to maintain unsupported standing balance against minimal resistance
Fair (F)	Able to stand unsupported without UE support and without balance loss for 1–2 minutes
Fair- (F-)	Requires minimal assistance or UE support to maintain standing without balance loss
Poor+ (P+)	Requires moderate assistance and UE support to maintain standing without balance loss
Poor (P)	Requires maximum assistance and UE support to maintain standing without balance loss
DYNAMIC STANDING BALANCE	
Normal (N)	Able to stand independently unsupported, able to weight shift and cross midline maximally
Good (G)	Able to stand independently unsupported, able to weight shift and cross midline moderately
Good-/Fair+ (G-/F+)	Able to stand independently unsupported, able to weight shift and cross midline minimally

STATIC SITTING BALANCE	
Fair (F)	Able to stand independently unsupported, weight shift, and reach ipsilateral side; difficulty crossing midline without balance loss
Fair- (F-)	Able to stand with supervision and reach ipsilateral side; unable to weight shift
Poor+ (P+)	Able to stand with minimal assistance and reach ipsilateral side; unable to weight shift
Poor (P)	Able to stand with moderate assistance and minimally reach ipsilateral side; unable to cross midline

UE, upper extremity.

Adapted from: *Grading for Balance: Graded Posture Movement Ability of Individual* by Stanbridge College.

Static Sitting Balance Screening

- Determine whether the client is able to sit unsupported without balance loss and without upper extremity (UE) support.
 - If so, apply pressure with your hands to the client's trunk in the anterior, posterior, and lateral directions.
 - Determine whether the client is able to maintain balance against minimal, moderate, or maximal resistance; gradually increasing the amount of resistance to the extent that the client is able to tolerate safely and comfortably.
 - If not, determine whether the client can maintain balance with UE support or if the client requires minimum or moderate/maximum support from another individual or chair.

Dynamic Sitting Balance Screening

- If the client is able to sit unsupported, determine whether and how far he or she is able to weight shift and cross midline by asking the client to reach for an item in multiple planes including crossing midline and reaching to the contralateral, or opposite, side of the body. Make sure that the client is not using the other UE for support. Classify this as weight shifting and crossing midline minimally, moderately, or maximally.
- If the client is able to sit unsupported but has difficulty crossing midline, determine whether he or she can complete any amount of weight shifting or reaching to the **ipsilateral** side of the body (see Fig. 17-2).

Figure 17-2 Dynamic sitting balance screening.

- If the client is unable to sit unsupported, determine whether he or she needs minimal or moderate assistance to maintain sitting. This will indicate that the client is unable to reach to the ipsilateral side, weight shift, or cross midline.
- If a client requires maximum assistance to maintain sitting, you do not need to screen for dynamic balance because this indicates an absence of, or *Poor*, dynamic sitting balance.

Static Standing Balance Screening

- Determine whether the client can stand supported without UE support and without balance loss for 1 to 2 minutes.
 - If so, apply pressure with your hands to the client's trunk in the anterior, posterior, and lateral directions (see Fig. 17-3).
 - Determine whether the client is able to maintain balance against minimal, moderate, or maximal resistance; gradually increasing the amount of resistance to the extent the client is able to tolerate safely and comfortably.

Figure 17-3 Static standing balance screening.

- If not, determine whether the client can maintain standing without loss of balance with UE support and minimum, or moderate, or maximum support from another individual or assistive device.

Dynamic Standing Balance Screening (see Videos 17-1 and 17-2)

- If the client is able to stand independently unsupported, determine whether he or she is able to weight shift and reach across midline to the contralateral side minimally, moderately, or maximally. This can be accomplished by again asking the client to reach for an item and gradually increasing the distance as tolerated.
- If the client is able to stand independently unsupported, but cannot reach to the contralateral side, screen his or her ability to weight shift and reach to the ipsilateral side as well as cross midline.
- If the client is able to stand with supervision and reach to the ipsilateral side, determine whether he or she is able to weight shift.
- If the client is able to stand with minimal or moderate assistance, determine whether he or she is able to weight shift, reach to the ipsilateral side, or cross midline.
- If a client requires maximum assistance to maintain standing, you do not need to screen for dynamic balance because this indicates an absence of, or *Poor*, dynamic standing balance.

See Figures 17-4 and 17-5 for examples of a dynamic standing balance screening.

Figure 17-4 Dynamic standing balance screening.

Figure 17-5 Dynamic standing balance screening.

Another option for screening balance using a grading scale is a tool offered by Kansas University titled the *Kansas University Sitting and Standing Balance Scale (KUSSBS)*.¹⁷ This sitting balance and standing balance scale measures balance on a numerical grading scale, ranging from 0 (i.e., client performs 25% or less of sitting activity; maximum assist) to 5 (i.e., client independently moves and returns to center of gravity in all planes >2 inches). The standing balance portion has been shown to be reliable and valid in the inpatient rehabilitation setting with a small sample in one study.⁶

Assessing Impact on Daily Occupational Function

In addition to measuring the client's balance grade, it is also very important to determine the impact of balance impairments on his or her daily occupational performance. The best way to accomplish this is through skilled observation and measurement of the amount of assistance required by the client during occupational performance because there are currently no existing standardized assessments of balance that are occupation based.² Additionally, it is essential to examine the client's context and environment, including both the physical and social environment. It is also necessary to determine the client's risk for falling as well as any impact a balance deficit has on his or her occupational participation and performance. Observe the client for signs indicating dysfunction in daily occupations, as discussed earlier.

If a problem is identified through screening, an in-depth assessment should be used to better evaluate the severity of the impairment. Balance is assessed while observing the client during movement in sitting and standing, including looking in a variety of directions, reaching for items in different directions, and walking in various conditions.¹⁰ These movements require anterior movement of the pelvis, flexion of the trunk at the hips, using the lower extremities to create a BoS, and shifting body weight and CoM toward the direction of the object during reaching.¹⁰ See the Assessment table at the end of this chapter for standardized assessments that can be used to assess standing balance deficits, including fall risk.

Overview of Interventions for Balance Impairment

The therapist should create an individualized, multifactorial treatment plan that combines approaches as needed to address the cause(s) of the balance deficit(s). The approach or approaches used to address balance impairment can be determined by the underlying cause of the deficit and if there is potential to improve the deficit through remediation or if compensation and adaptation would be more appropriate. At times, it is necessary to begin with a compensatory and/or adaptive approach to increase safety and independence during the process of remediation. Remedial techniques include increasing range of motion, strength, and/or endurance where motor dysfunction has an effect on balance and fall prevention.¹⁸ Improving these motor skills may lead to an increased ability to maintain static or dynamic sitting and standing postures. Compensatory techniques introduce clients to techniques for using their UE(s) or weight shifting techniques to offset deficits that cannot be remediated or that are in the process of remediation. Adaptation techniques include several environmental options, such as adding adaptive equipment or devices to the client's environment to increase safety and independence. Some clients may benefit from a combination of all three approaches. Specific interventions are discussed next.

Specific Interventions for Balance Impairment

Remediation of Balance Impairments

If screening and assessment indicate that client factors can be improved, a remediation, or biomechanical, approach is appropriate. Exercises and occupation-based activities can be incorporated into treatment to improve core, UE, and lower extremity strength or activity tolerance, if indicated, by gradually increasing the weight and/or repetition of the activity. Preparatory methods should be used to treat edema and/or pain, such as modalities, manual techniques, and splinting or positioning, if applicable. If a client demonstrates soft-tissue stiffness causing impaired postural control or alignment, the therapist should begin with passive stretching before engaging in active balance activities.⁷ However, if the cause of impaired postural control is because of postural insecurity, the therapist can provide additional external support via physical "handling" to allow the client to safely and fully participate in the planned activity.⁷

There is a history of evidence to support the use of therapeutic exercise to increase strength and balance and reduce the risk of falling.^{19,20-22} The occupational therapist should select exercises to target any muscles that have been identified as debilitated during the assessment of strength with the use of manual muscle testing. As mentioned previously, this may include core, UE, or lower extremity muscles. Core and lower extremity muscles have a direct influence on remediating balance, whereas UE muscle strengthening may be needed for the use of compensatory and adaptive techniques for mobility and other occupations, listed in the

subsequent section. Resistive exercises to increase strength for improved balance should be incorporated with the use of functional activities to provide contextual, dynamic challenges while ensuring client safety. Other forms of exercise that have been shown to improve balance through greater strength, endurance, flexibility, and postural control include yoga,^{9,23} tai chi (see Fig. 17-6),²⁴ and repetitive task training.²¹ See the Evidence table at the end of this chapter for evidence of remediation intervention studies.

Figure 17-6 Tai chi is an exercise strategy to help restore control and balance to movement patterns.

Reaching can be improved by gradually increasing activity demands for reaching during daily occupation training or with rote exercises (see Fig. 17-7), while seated unsupported as long as safely tolerated. Balance can be improved by increasing activity demands for tasks completed in sitting or standing with the least amount of support or assistance as required to reach a higher balance grade as measured during the initial screening.

Figure 17-7 A variety of balance activities can be performed on a therapeutic ball, such as bilateral reaching.

In treating sitting balance deficits, the therapist should work to develop the client's understanding of this alignment, awareness of postural adjustments, and learning through occupation-based challenges that require active weight shifting.⁷ The therapist starts by ensuring that the client achieves optimal postural alignment for performing daily tasks in sitting. This position can be described as having the pelvis in neutral to anterior tilt with equal weight

bearing on the ischial tuberosities, the trunk extended in a midline orientation, the shoulders symmetrical and positioned anterior to the hips, the hips and knees flexed and neutrally rotated, and both feet securely on the floor and ready to accept weight (see Fig. 17-8).⁷ To help a client develop awareness of alignment and adjustments, the therapist can provide verbal and/or visual cues through the use of questions, such as “are you sitting up straight?,” and of a mirror or video recording to recognize errors and challenge the client to correct his or her posture before continuing the activity.⁷

Figure 17-8 Optimal postural alignment in sitting.

Occupation-based challenges that require active weight shifting include incorporating tasks that demand the client to move in a variety of planes, such as backward and forward, to the left and to the right, rotating the trunk to the left or right, and any combination of those movements plus upward or downward directions (see Fig. 17-9).⁷ In each direction, weight shifting is accompanied by postural adjustments. By requiring the client to shift weight in a variety of planes, he or she can improve his or her ability to look and reach for moving objects to improve balance for self-care tasks such as bathing, dressing, and grooming and household tasks such as meal preparation, laundry, and cleaning.⁷ Throughout these tasks consisting of weight shifting and reaching, core muscle strengthening occurs, further improving balance for daily occupations.⁷ Similar to sitting balance exercises, standing balance can be challenged by exercising lower extremity muscles during tasks performance that requires weight shifting by reaching for objects in a variety of planes while in standing.⁷

Figure 17-9 Laundry is placed to the left of a right-handed person to encourage reaching and development of dynamic standing balance.

Compensating for Balance Impairments

If balance skills cannot be remediated or if compensation for balance is necessary during the remediation of underlying skills, there are several options. The client can participate in education for the following:

- Safe weight shifting techniques
- Bracing with the contralateral UE
- Getting dressed lying in bed
- Learning to complete all pieces of lower body dressing in sitting and standing only one time to pull pants up around hips
- Using alternate methods of lower body dressing to decrease the need to bend toward the floor
- Performing toileting hygiene in sitting when possible
- Pulling pants up over the knees before standing from toilet to prevent pants from falling to the floor while standing
- Performing standing activities in front of a chair in case of loss of balance or the need to take a seated rest break
- Learning to position self directly in front of a workspace to avoid reaching outside the BoS during housekeeping tasks, such as cooking, unloading the dishwasher, transferring laundry, and cleaning
- Making the bed while still lying in it
- Wearing a terry cloth bathrobe to dry off after the shower instead of towel drying.

Adapting for Balance Impairments

There are several environmental adaptations that can be made to increase safety and independence for a balance impairment that cannot be improved or while the client is in the process of remediation. Many supports can be added to the home environment such as:

- Grab bars
- Stair railings
- Electronic lift chairs
- Stair lifts
- Toilet safety frames/handles
- Shower chair/bench
- Nonslip adhesive surfaces for the bathtub/shower or stairs
- Use of adaptive devices such as canes, walkers, and wheelchairs
- Use of a reacher and other long-handled items
- A pant clip for toileting clothing management
- Positioning equipment that can be added to wheelchair seating systems for postural support/alignment
- Bed rails for transfers or sitting balance
- transfer boards for lateral (seated) transfers.

Additionally, the environment can be arranged to increase safety and independence, such as:

- Setting up the environment to decrease reaching distance required to complete a task
- Setting up the environment to allow for tasks to be completed in sitting, such as a table in the kitchen for food prep
- Placing hygiene/grooming tools on the bathroom counter within reach from a chair.

The therapist should work with the client to design adaptations specific to that client's performance skills and environment.

Functional Mobility

Functional mobility training includes interventions aimed at improving a client's ability to perform bed mobility, transition between standing and sitting, and to perform daily activities while standing and walking. Balance is essential for safe, independent functional mobility. Treatment for functional mobility is similar to balance interventions, in that it provides for remediation of strength and postural adjustments to improve safety and performance of daily occupations.⁷

Standing Up and Sitting Down

Safely transitioning between standing and sitting is essential for the performance of daily occupations. Optimal performance of sit-to-stand transfer requires intact balance with the integration of adequate mobility at the pelvis and hips, postural alignment, postural adjustments, weight shifting, and strength in the core and lower extremities (see Fig. 17-10).⁷ After screening and assessment, remediation training should address any of these components that are impaired, as discussed earlier. If the limitation is suspected to be related to impaired motor planning, rather than balance, refer to Chapters 15 and 16.

Figure 17-10 Initial phase of the sit-to-stand movement involves trunk lean and horizontal weight shift to position the center of gravity over the new base of support (feet). The movement of the center of gravity in several directions is often used to study balance. BW, body weight.

When remediation of sit-to-stand transfer is not possible or safe, training should include transition to adaptation approaches. Using arm rests or grab bars to push down, reach back, pull, or steady oneself with the UE(s) is a commonly helpful and safe technique when transitioning between sitting and standing. It should be noted that this technique is not ideal for clients recovering from stroke or brain injury because these body mechanics contradict essential motor strategies.⁷ When a client is unable to achieve sit-to-stand transfer, another compensatory strategy for transferring from one surface to another is known as a squat pivot. With this approach, the client is not required to shift weight between the lower extremities. These alternative approaches are intended for clients who will not progress to walking.⁷

There are several environmental adaptations that can assist an individual with achieving sit-to-stand transfer, including raising the height of seating surface, grab bars, and using chairs with armrests. Further examples were provided in the section on Adapting for Balance Impairments.

Functional Ambulation

Walking is another essential skill for the performance of many daily occupations. Occupational therapists address walking with clients who wish to improve their performance in many functional activities that involve walking, such as bathroom, kitchen, vocational, leisure, and educational occupations. The most common risk factors for impaired functional ambulation are older age, decreased physical activity, obesity, strength or balance impairment, and chronic diseases such as diabetes or arthritis.²³ Functional ambulation training in occupational therapy often centers around safety and fall prevention while enabling a client to increase participation and independence in valued occupations. Physical therapists provide specific evaluation and treatment to prevent and reduce gait deviations. Occupational therapists work with physical therapists to maximize efficient gait patterns during occupation-based intervention for activities that require the use of the UEs while walking.⁷ Many of the occupation-based interventions for balance remediation previously described in this chapter contribute to improved functional ambulation. This includes improving stability and facilitating proper postural adjustments during activities in sitting and standing that require weight shifting and reaching in a variety of

directions⁷ and exercises to increase strength and balance. Interventions for functional ambulation should be determined based on the client's identification of valued occupations.⁷

Compensatory techniques for functional ambulation include the use of energy conservation techniques, such as walking short distances and resting often, carrying less/lighter objects while walking, walking at a slower pace, as well as holding onto furniture or other sturdy objects for balance. Many clients will independently incorporate the use of atypical body mechanics to compensate for weakness or other deficits affecting functional ambulation. The occupational therapist should work with the client to ensure compensatory strategies are safe and should not cause additional structural damage that may further impair functional ambulation.

Primary adaptive techniques for functional ambulation include the use of adaptive devices, such as canes, crutches, walkers, and wheelchairs (see Fig. 17-11). Other adaptive techniques include the use of a shopping or utility cart for balance and/or object transportation. The environment will likely need to be modified to create accessibility with adaptive devices. The occupational therapist should work with the client to devise strategies and modifications to allow the individual to continue to participate in valued occupations despite impaired or absent functional ambulation. Many individuals live full lives without participating in functional ambulation.

Figure 17-11 Walker with tray to adapt functional mobility.

Fall Prevention

Much of the research on balance interventions is related to fall prevention. Treatment of balance, sit-to-stand transfer, and functional ambulation are important components of fall prevention. However, they are only part of the picture in preventing falls because there are other risk factors. Evidence suggests that individuals with an identified risk of falling benefit from an individualized, multifactorial approach that may include a combination of the following: functional ambulation training and advice on the use of appropriate adaptive device(s), medication review and modification if necessary (especially psychotropic medications), exercise programs (with balance training as a component), treatment of postural hypotension, modification of environmental hazards, and treatment of cardiovascular disorders. For individuals living in institutional settings (i.e., assisted living and long-term care), staff education is also recommended.²⁵⁻²⁷ The therapist's role in an interdisciplinary approach to the treatment of balance and fall prevention may include functional ambulation and adaptive device training, exercise programs (including balance training), environmental assessment and modification, and staff education. There are proven benefits of exercise and balance training in preventing falls, though there is no conclusive agreement on the type, duration, or intensity of

exercise. There is also emerging evidence to support the use of virtual reality in therapy to improve balance for individuals who have had a stroke.

CASE STUDY

Patient Information

Anna is a 76-year-old woman who presented to her primary care physician with complaints of common cold symptoms and shortness of breath at rest. Her physician found that her oxygen saturation was below 90% and recommended that she be admitted to an acute care hospital. She was diagnosed with left lower lobe pneumonia and treated with intravenous antibiotics, steroids, and supplemental oxygen. Anna has a past medical history of COPD. She was discharged from the hospital to a skilled nursing facility for rehabilitation and medication management. Anna is retired, widowed, and lives alone in a single-story home. She often sleeps in the recliner because it is easier for her to breathe with her head elevated. Prior to admission, Anna was functioning at the modified independent level with activities of daily living (ADLs), requiring extra time and some compensatory strategies or adaptive equipment to complete tasks. She is inactive most of the day, outside minimal ADL and instrumental activities of daily living (IADLs) participation. Anna reports relying more on her daughter in the past few months for shopping for groceries, getting the mail, and taking out the trash. Her son-in-law mows her lawn and removes snow as needed. She does not spend much time out of the house or socializing because she reports it takes a lot of energy, she is afraid of falling in the community, and her finances are limited. She admits that she does not keep up well with housekeeping tasks and prepares simple meals. She reports falling once or twice in the past 6 months while in the bathroom and kitchen and is afraid of showering, which she reports doing about 1 to 2 times a week.

Assessment Process and Results

The occupational therapist interviewed Anna to complete an occupational profile. The evaluation was completed through observation of functional tasks and motor assessments. Her oxygen saturation was assessed at 97% oxygen at rest and 89% with activity. Anna does not appear to have any cognitive, sensory, or visual perceptual deficits. Her UE range of motion and strength are within functional limits (4/5 during manual muscle testing), however, she demonstrates weakness in her lower extremity muscles because of inactivity (3+/5 during manual muscle testing). During screening, she demonstrates Good-/Fair+ (G-/F+) static and dynamic sitting balance and Fair- (F-) static and dynamic standing balance, requiring a front-wheeled walker and standby assistance for functional ambulation resulting from impaired balance related to fatigue and lower extremity weakness. Anna participated in the Functional Reach Test, demonstrating an ability to reach 6 inches, indicating a moderate risk for falls. Anna tolerates standing 1 to 2 minutes and needs to rest after 2 to 3 minutes of total functional activity. She is able to perform upper body dressing and grooming tasks while seated with setup and standby assistance. She displays shortness of breath, and increased time is required for task completion. She requires minimal assistance for upper body bathing while seated. Anna requires moderate assistance with lower body dressing, bathing, and hygiene tasks secondary to increased shortness of breath when bending over and fatigue and impaired balance while performing tasks in standing, such as pulling pants over her hips. Anna is fearful of falling and requires minimal assistance for functional transfers and moderate assistance for tub transfers. She requires minimal assistance for toileting, clothing management, and hygiene because of fatigue and balance deficits. Anna requires minimal verbal cues to safely manage oxygen tubing for fall prevention because she is not used to performing functional tasks while on oxygen.

Occupational Therapy Problem List

- Sitting and standing balance
- General and standing activity tolerance
- Lower extremity weakness
- Setup and standby assistance needed for upper body dressing
- Moderate assistance needed for lower body dressing, bathing, and hygiene

- Setup and standby assistance needed for upper body hygiene and grooming while seated
- Minimal assistance needed for toileting
- Minimal assistance needed for functional transfers
- Moderate assistance needed for tub transfers
- Standby assistance needed for functional ambulation with a front-wheeled walker
- At risk of falling because of fatigue, balance, and oxygen tubing management
- Reduced IADL participation and performance

Occupational Therapy Goal List

Anna's goal is to return home with modified independence in ADLs and perform IADLs at her prior level of function without the use of oxygen.

- Increase safety and independence with all ADLs
- Decrease risk of falling
- Increase IADL participation and independence
- Establish a routine with increased activity as tolerated to prevent deconditioning
- Return home at highest functional level with home health therapy and support from her daughter and son-in-law as needed

Intervention

- Remediation of sitting and standing balance, activity tolerance, and lower extremity strength through exercises and occupation-based treatment activities.
- Education and incorporation of compensatory and adaptive strategies as needed to increase independence and safety with ADLs and IADLs, including energy conservation techniques, setting up the home environment to make commonly used items easy to reach, a bath bench and grab bars in the tub, compensatory strategy for tub transfers, a raised toilet safety frame with handles, a chair in her bathroom and kitchen, emergency call system in case of falls, adaptive equipment for lower body dressing and bathing, and a walker if still needed upon discharge from skilled nursing facility.
- Increased independence and decreased risk of falling with home environment assessment to incorporate identified compensatory and adaptive techniques.
- Referral to home health occupational therapist after discharge to further address performance in home environment, IADLs performance, creation of a more active routine to prevent deconditioning, such as home exercise program, and methods to increase social participation and leisure occupational participation.

Psychometric Properties of Assessments of Balance

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths And Weaknesses
--------------------------	------------------	---------------------	----------	-------------	-------------	--------------------------

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths And Weaknesses
Berg Balance Scale ²⁸	Measuring balance across 14 tasks	15–20 minutes	Concurrent validity: $r = 0.91$ with the Tinetti Balance Subscale ²⁹ ; $r = -0.81$ with Timed Up-and-Go Test (TUG) ³⁰ or $r = -0.74$ with the TUG. ³¹ Discriminant validity: discriminates among persons using various types of walking aids ²⁸	Inter-rater reliability: Intra-class correlation coefficient (ICC) = 0.98 for total scale; ICC = 0.71–0.99 for individual items. ²⁸ For total scale: ICC = 0.97 ³² and 0.95. ³³ Test–retest reliability: ICC = 0.99 for total scale. ²⁸ ICC for tests 1 week apart = 0.98 ³² and 0.96. ³⁴ Internal consistency: Cronbach's $\alpha = 0.96$ ³⁵ and 0.92–0.98 ³²	Significant changes in scores at 6 and 12 weeks poststroke. ³⁶ Minimal detectable change value = 7 points ³⁴	<i>Strengths:</i> Measures many aspects of balance; consistent reports of excellent reliability; evidence of validity. ¹⁰ <i>Weaknesses:</i> Long administration time. Has floor and ceiling effects. ³² Not predictive of falls. ^{32,33}
Functional Reach Test ³⁷	To assess the functional standing balance performance of older adults ³⁸	1–2 minutes	Concurrent validity: $r = 0.71$ with center of pressure excursion. ³⁷ Discriminant validity: Significant difference between persons with high and low risk of falls. Predictive validity: score ≤ 6 inches predictive of falls in elderly ³⁹	Inter-rater reliability: $r = 0.98$ Test–retest reliability: ICC = 0.92 ³⁷	Marginal significant change ($p = 0.07$) after physical rehabilitation, responsiveness index = 0.97 ⁴⁰	<i>Strengths:</i> Brief, functional test; excellent reliability; evidence of validity. ¹⁰ <i>Weakness:</i> Sensitivity is borderline. ¹⁰

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths And Weaknesses
Tinetti Performance Oriented Mobility Assessment (POMA) ²⁹	To measure balance and gait ⁴¹ of older adults to determine mobility status and changes over time and determine risk of fall. Individual scores are combined to form three measures: overall gait assessment score (POMA-G), overall balance assessment score (POMA-B), and a combined score (POMA-T). ⁴²	10–15 minutes	Concurrent validity with TUG -0.56 to -0.68 (all three subtests); Discriminant validity: discriminates among persons using various types of walking aids ⁴³	Inter-rater reliability $r = 0.87^{41}$; 0.80 – 0.93 (all three subtests) ⁴³ Test–retest reliability: Spearman $R = 0.72$ – 0.86 (all three subtests) ⁴³	Sensitive (0.70 with 0.52 specificity) to 1 or more falls in 225 community-dwelling elders. With a high cutoff score, 125 tested positive, but sensitivity decreased rapidly with other cutoff values. ⁴⁴	Strengths: Brief administration time; reliable and valid tool for assessing mobility status. ⁴¹ Weaknesses: The gait subtest has lower reliability and validity, limiting the ability of the POMA scale for predicting falls. ^{42,43}
Timed Up-and-Go Test (TUG) ³⁰	An objective clinical measure for assessing functional mobility, balance, and the risk of falling ⁴⁵	1–2 minutes (86 second average time including instructions) ⁴⁶	Convergent validity: Moderately or strongly correlated with Tinetti balance scores ($r = -0.55$), Tinetti gait scores ($r = -0.53$), and Tinetti walking speed ($r = 0.66$). ⁴⁶ Discriminant validity: Excellent—older adults who had experienced a fall in the previous year, used a walking aid, and suffered greater ADL disabilities required a longer time to complete the TUG. ⁴⁶	Inter-rater reliability: $ICC \geq 0.87^{47}$ Test–retest reliability: Pearson correlation coefficients ($r = 0.73$ – 0.99^{47})	Higher pooled specificity (0.73 , 95% CI, 0.51 – 0.88) than sensitivity (0.32 , 95% CI, 0.14 – 0.57) ⁴⁸	Strengths: Brief administration time; reliable and valid measure of functional mobility ³⁰ , good test–retest reliability and discriminant validity; Clients may be more willing to participate in TUG than other measures. ⁴⁶ Weaknesses: May not be accurate in predicting fall risk ^{46,48} , may be more appropriate for older persons who are frail or use mobility aids ⁴⁶ , does not address performance while performing a simultaneous motor task. ⁴⁵

Evidence Table of Remediation Intervention Studies

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance And Effect Size
Therapeutic exercise ²²	Progressive resistance and balance exercises combined with motivational group discussions (see study for details)	Community-dwelling individuals with a stroke 1–3 years prior	Twice weekly × 12 weeks	Randomized controlled trial—Level I	Significant improvement in balance	Berg Balance Scale—MD 2.5 vs. 0 points; effect size (ES), 0.72; $p < 0.01$
Yoga ²³	A yoga-based rehabilitation intervention on balance, balance self-efficacy, fear of falling (FoF), and quality of life	People with chronic stroke	Twice per week × 8 weeks. Seated, standing, and floor postures with relaxation and meditation	Prospective, randomized pilot study—Level I	Significant improvement in balance. Potential in improving multiple poststroke variables as a complement to rehabilitation in medical- and community-based settings. May be cost-effective	Balance (Berg Balance Scale)— 41.3 ± 11.7 vs. 46.3 ± 9.1 ; $p = 0.001$ FoF—51% vs. 46% with FoF; $p < 0.001$
Tai chi ²⁴	A tailored tai chi program to improve postural control	People with idiopathic Parkinson disease	Sixty minutes, twice per week × 24 weeks	Randomized, controlled trial—Level I	Reduced balance impairments in patients with mild-to-moderate Parkinson disease. Additional benefits of improved functional capacity and reduced falls	The tai chi group performed consistently better than resistance training and stretching groups (between-group difference in the change from baseline, 5.55 percentage points; 95% confidence interval [CI], 1.12–9.97; and 11.98 percentage points; 95% CI, 7.21–16.74, respectively) and in directional control (10.45 percentage points; 95% CI, 3.89–17.00; and 11.38 percentage points; 95% CI, 5.50–17.27, respectively).

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance And Effect Size
Repetitive task training ²¹	Training approaches that include performance of goal-directed, individualized tasks with frequent repetitions of task-related or task-specific movements	People with motor impairments after stroke	Nine studies included outcome measures addressing balance and mobility.	Systematic review—Level I	Seven of the nine studies reported positive effects for improving balance and mobility.	None reported

Chapter 18

Communication Assessment and Intervention

Anne Escher Sue Berger and Anne Carney

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the impact of communication impairment on occupational performance.
2. Identify conditions in adults that lead to communication impairment.
3. Understand communication impairment patterns based on diagnosis or described lesion.
4. Discuss the role of the occupational therapist in screening and evaluating occupational performance for people with communication impairment.
5. Select occupational performance assessment methods and instruments based on individual characteristics, including communication abilities.
6. Discuss strategies to adapt self-report assessments to support individuals with communication impairments to participate in collaborative goal setting, complete outcome measures, and engage in research.
7. Describe specific interventions to support communication performance.
8. Use interventions to support occupational performance for people with communication impairments.
9. Understand the role of speech language pathologists and the importance of collaboration.

CHAPTER OUTLINE

Communication Function and Impairment in Daily Occupation
Neurological and Physiological Basis of Communication
Conceptual Foundation Underlying the Role of Occupational Therapy for Communication Impairment
Communication: Disorders, Signs and Symptoms, and Causes
Communication: Assessing Impact on Occupational Performance
Specific Interventions for Communication Dysfunction
Case Study

TERMINOLOGY

- Acalculia:** acquired impairment of the ability to perform basic mathematical operations.
- Agraphia:** acquired writing impairment that frequently co-occurs with aphasia.
- Alexia:** acquired reading impairment that frequently co-occurs with aphasia.
- Anomia:** condition that refers to difficulty with word retrieval.
- Aphasia:** language disorder resulting from damage to certain areas of the brain and is characterized by difficulty with speaking, understanding, reading, or writing.
- Apraxia of speech (AoS):** motor speech disorder that limits the ability to plan and program the production of speech.
- Dysarthria:** motor speech disorder caused by weakness or difficulty controlling the muscles for speech, which may result in slurred or mumbled sounding speech.

Communication Function and Impairment in Daily Occupation

Communication imbues most daily occupations. Many activities in which people engage throughout the day involve communication, including instrumental activities of daily living (IADL), education, work, play, leisure, and social participation. Whereas some activities of daily living (ADL) may be performed independently without communication, many basic ADLs require communication when individuals need to direct caregivers for assistance.

Given that communication is such an important part of occupational performance, occupational therapists must understand and respond to clients' communication challenges. The *Occupational*

*Therapy Practice Framework: Domain and Process*¹ categorizes communication management as an IADL, defined as:

Sending, receiving, and interpreting information using a variety of systems and equipment, including writing tools, telephones (cell phones or smartphones), keyboards, audiovisual recorders, computers or tablets, communication boards, call lights, emergency systems, Braille writers, telecommunication devices for deaf people, augmentative communication systems, and personal digital assistants.

This definition focuses primarily on technology use, but communication also includes verbal and nonverbal information exchange. The American Speech-Language-Hearing Association describes functional communication skills as “forms of behavior that express needs, wants, feelings, and preferences that others can understand.”² This chapter uses a broad conceptualization of communication that includes both communication management (sending, receiving, and interpreting information from systems including other people) and functional communication (being able to express needs and wants in ways that others can understand) to address how communication influences occupational performance.

Communication influences occupational performance in multiple and complex ways. People’s quality of life and rates of psychosocial health indicators (frustration, hopelessness, depression) can all be impacted by the onset of communication challenges.^{3,4} Additionally, researchers have found that people with communication impairments have lower rates of participation in meaningful activities.³

Worrall and colleagues⁴ found that because communication impairments significantly impact relationships, people with **aphasia** (a language disorder characterized by difficulty with speaking, understanding, reading, or writing) identified social, leisure, and work participation as key rehabilitation goals. People with aphasia poststroke desire to contribute to society in meaningful ways and to practice altruism.⁴ Such meaningful goals, however, are often overlooked in rehabilitation settings. Practitioners may not recognize how best to engage clients and inadvertently fail to address clients’ self-identified occupational performance goals. Despite the fact that collaborative goal setting has been shown to increase both motivation and the likelihood of achieving goals,⁵ people with communication impairments are rarely included in the goal-setting process.⁶ Along with occupational performance impairments, limited involvement in collaborative goal setting, and difficulty participating in the rehabilitation process, clients with communication impairments are often excluded from research, unless studies specifically address communication impairment.⁷

Neurological and Physiological Basis of Communication

In 1861, Paul Broca—French anatomist, anthropologist, and neurologist—encountered a patient who lost the ability to produce meaningful speech but retained his ability to comprehend language. During autopsy of the patient, Broca observed a lesion located in the left posterior inferior frontal gyrus. Broca subsequently observed lesions in the same frontal lobe area in other patients with similar losses of spoken language. This area, which became known as Broca’s area, continues to be a region critical for speech production. More than a decade later, Carl Wernicke—a German anatomist, neurologist, and psychiatrist—observed a loss of language comprehension that he linked to lesions located in the left posterior temporal lobe. This area became known as Wernicke’s area and remains a key region for language comprehension (Fig. 18-1). Although Broca and Wernicke’s areas remain critical for the production and comprehension of language, there is an increasing body of research using neuroimaging techniques that has clarified our understanding of how the brain processes language. This rapidly evolving body of research has implicated the involvement of widespread brain networks for language processing in both the left and right hemispheres.^{8,9}

Figure 18-1 Two lateral views of the left hemisphere of the brain, which for the majority of people is the language-dominant hemisphere. Broca's area is located in the left frontal lobe and Wernicke's area in the left temporal lobe.

Neuroanatomical Structures and Functions

An overview of central and peripheral nervous system areas that possess large roles in the support of speech and language is explained in the subsequent sections (for further reading, refer to Bhatnagar,¹⁰ Duffy,¹¹ Helm-Estabrooks et al.,¹² and Seikel et al.¹³).

The Central Nervous System: Brain

The lips, tongue, and teeth are among the articulators that help us make speech sounds. The brain, however, is responsible for the planning, initiation, and coordination of the motor movements of those articulators, as well as for selecting the words, grammatical structures, and tone with which we choose to convey our needs, wants, thoughts, and feelings.

Although recent evidence indicates that language functions are supported by widespread neural networks across both hemispheres, cerebral dominance for language remains a firmly established principle.¹⁴ For most of the population—upward of 95% of right handers and 70% of left handers—the left hemisphere is dominant for language. The remaining 30% of left handers may have either bilateral dominance or right hemisphere language dominance.¹⁵ This is evidenced clinically: individuals who sustain strokes in the left hemisphere may experience the language disorder known as aphasia; whereas strokes sustained in the right hemisphere are characterized by impairments related to attention, perception, problem-solving, memory, and/or social communication (e.g., difficulty following the turn-taking rules of conversation or interpreting nonverbal communication such as facial expression or tone).

In addition to lateralization of brain functions, another key principle related to the understanding of communication is neuroplasticity, or the brain's ability to change and reorganize in response to experiences. Although the brain's plasticity is greatest during childhood, the capacity for reorganization continues throughout the life span. Adults who sustain traumatic brain injury (TBI) or stroke provide evidence for the brain's ongoing ability to reorganize itself, as observed when uninjured regions of the brain assume language functions previously associated with injured areas.¹⁶

Frontal Lobe

The frontal lobe contains the primary motor cortex or “motor strip,” which is involved in the control of voluntary motor movements on the opposite side of the body. A motor homunculus, or “little human,” serves as a neurological map, representing the region where motor processing occurs for each body part (Fig. 18-2). The homunculus is distorted because the amount of cortical space designated for each body part does not correspond to body part size, but rather to processing complexity. For example, the lips and tongue are oversized in the homunculus because the small and precise movements required to form speech sounds take up more cortical space than the less nuanced movements of the hip or knee.

Figure 18-2 A motor homunculus acts as a neurological map that indicates the location in the frontal lobe where motor activity is processed for different parts of the body.

The premotor and supplementary motor cortices of the frontal lobe are linked to the initiation and planning of motor activity. The frontal lobe of the language-dominant hemisphere also contains Broca's area, known to be important for speech production. Another critical area of the frontal lobe is the prefrontal cortex, which is linked to executive functions such as planning, problem-solving, and judgment, as well as mood, personality, and emotion. Lesions in the prefrontal region, such as those resulting from TBI, can lead to impairment in inhibition, impulse control, flexibility, and self-monitoring, which can negatively impact social communication or pragmatics.

Temporal Lobe

The temporal lobe is responsible for hearing and analyzing auditory information. Areas within the temporal lobe in the language-dominant hemisphere that transform auditory stimuli into meaning include the auditory cortex, auditory association area, and Wernicke's area. The temporal lobe is also home to the hippocampus, which is critical for memory.

Parietal Lobe

The main function of the parietal lobe is related to processing somesthetic sensations (e.g., tactile sensation and proprioception). Damage to the left (or language-dominant) parietal lobe can also result in reading impairments (**alexia**), writing impairments (**agraphia**), calculation impairments (**acalculia**), and aphasia.

The Peripheral Nervous System: Cranial Nerves

There are 12 paired cranial nerves (CNs) that relay motor and sensory information to and from the brain to parts of the head and neck, as well as to certain sensory organs and glands. CNs serve a critical role in the production of speech as well as in nonverbal communication. The CNs are numbered I through XII based on the location from which they enter and/or exit the brain or brainstem (Fig. 18-3).

Figure 18-3 A lateral view of the 12 cranial nerves.

The CN pairs that are most important for communication are CN V, CN VII, CN IX, CN X, CN XI, and CN XII. CN V, the trigeminal nerve, supports jaw movement, which is important for articulation. CN VII, the facial nerve, is responsible for facial expression and movement of the lips, which is critical for the production of labial and labiodental sounds (i.e., sounds involving the lips such as “m” and “p,” and sounds involving the lips and teeth such as “f” and “v”). CN IX, the glossopharyngeal nerve, is a smaller CN that is closely linked to CN X, the vagus nerve. CN X supports movement of the vocal folds or vocal cords, which allows for phonation or the production of sound. CN X is also responsible for movement of the soft palate, which is involved in resonance. CN XI, the spinal accessory nerve, supports gestures involving the head and shoulders that are important for nonverbal communication (e.g., shrugging shoulders and shaking head). Lastly, CN XII, the hypoglossal nerve, is responsible for tongue movement, which is a key articulator for speech production.

Anatomy and Physiology of Speech

The systems involved in speech production include respiration, phonation, articulation, and resonance. An overview of each system follows.

Respiration

Air from the lungs provides the energy source for speaking. During speech production, inhalations become shorter in duration, whereas exhalations become longer. Weaknesses or changes to the musculature in the respiratory system may contribute to hypophonia or reduced loudness.

Phonation

During speech production, the air from the lungs travels through the larynx and passes between the vocal folds (or vocal cords). Some speech sounds involve voicing, whereas others do not. For example, the vocal folds are adducted (together) during the production of the voiced “z” sound, whereas the vocal folds are abducted (apart) during the production of the voiceless “s” sound. To feel the vibration or its absence, one can place the hand on the throat, and produce and hold both

sounds for several seconds. Trauma, stroke, and other neurological diseases can weaken or paralyze the vocal folds. Paralysis of one vocal fold will still allow for phonation, but will result in a breathy quality. If both vocal folds are paralyzed, phonation can be absent.

Articulation and Resonance

The articulatory and resonance systems shape air into the sounds of speech. Once air passes between the vocal folds, the articulators interact to create the speech sounds known as phonemes. Humans have both mobile and immobile articulators. The mobile articulators include the tongue, the lower jaw, the velum or soft palate, and the lips. The immobile articulators are the alveolar ridge of the upper jaw (the ridge located just behind the upper front teeth and in front of the hard palate), the hard palate, and the teeth. Consider the action required to produce the “t” sound versus the “v” sound: the tongue makes contact with the alveolar ridge to make the “t” sound, whereas the teeth make contact with the lower lip to make the “v” sound.

Resonance is the way that airflow is modified as it passes through the oral and nasal cavities. The velum or soft palate, which is located just behind the hard palate along the roof of the mouth away from the alveolar ridge, differentiates nasal sounds from non-nasal sounds. In English, the nasal sounds are “n,” “m,” and the “ng,” the latter of which is the sound at the end of the word “sing.” To form these sounds, the velum lowers, allowing air to travel through the nasal cavity. Resonance disorders include hyponasality and hypernasality. Hyponasality occurs when inadequate air travels through the nasal cavity for the production of nasal sounds, similar to how people sound when they have a cold or congestion. Hypernasality, or nasal speech, occurs when too much air is allowed to flow through the nasal cavity during speech, such as in individuals with cleft palate. Resonance disorders can result from trauma, stroke, or neurological disease, such as amyotrophic lateral sclerosis (ALS) and multiple sclerosis.¹³

Conceptual Foundation Underlying the Role of Occupational Therapy for Communication Impairment

The *International Classification of Functioning, Disability, and Health*¹⁷ (ICF) is a framework used by health care professionals to describe, organize, and guide assessment and intervention for individuals of all ages and health conditions. The classification system provides a common language for health care professionals when discussing clients, groups, and populations. The ICF includes a section labeled *voice and speech functions* under body functions and *structures involved in voice and speech* under body structures. Within *activities and participation*, there is an entire chapter on communication with sections on *communicating-receiving*, *communicating-producing*, and *conversation and use of communication devices and techniques*. This section is separate from chapters on *domestic life*, *interpersonal interactions and relationships*, *education*, *work and employment*, and *community, social and civic life*, all activities that involve communication. The ICF section about environmental factors addresses the physical, social, and societal environments that influence one’s ability to communicate. Even personal factors, not elaborated upon in the ICF, influence communication.¹⁸ For example, people who are assertive might request others to repeat comments or slow down to facilitate understanding, whereas others may not verbalize such requests and struggle to engage in conversation. Each of these major ICF groupings (e.g., body function and environments) can be a facilitator or barrier to communication. Understanding the interaction between them can guide occupational therapy assessment and intervention.

The Participation, Environment, Occupation (PEO) model¹⁹ is another way to conceptualize communication that overlaps with the ICF. The focus of occupational therapy is to enable participation, for this chapter, focusing on communication participation. The PEO model contends that the interaction of person factors, environmental factors, and occupations—considered together—supports or limits participation. Assessing and addressing the occupational and environmental factors related to communication are within the scope of occupational therapy practice, whereas assessing and providing intervention at the body function/body structure level of the person factors related to communication are not. Rather, occupational therapists refer to speech language pathologists (SLPs) to address speech and language impairments. SLPs understand the underlying mechanisms of speech and language, and thus, much of their assessment and intervention focuses on remediating impairments, identifying compensatory strategies, and supporting goals that are meaningful to clients. Occupational therapists focus on participation and supporting clients to engage in the occupations of choice, despite communication impairments. Therefore, occupational therapists use compensatory and adaptive strategies to support occupational performance in people with communication impairments.

Most importantly, occupational therapists use an ecological approach—focusing on participation within an individual’s natural environment—when assessing how communication influences occupational performance and providing intervention to support communication participation (Fig. 18-4). For example, although an individual may perform well communicating in a private treatment room during occupational therapy, the same individual may struggle to communicate at home when the television is on in the background, or at a party while many people are talking at once. Occupational therapists consider communication in both ideal and naturalistic settings to determine supports and barriers to participation. Therapy goals focus on supporting individuals to communicate where they live, work, and play.

Figure 18-4 Playing checkers with grandchild in the home environment.

Communication: Disorders, Signs and Symptoms, and Causes

Communication disorders in adults may start in childhood or can arise due to an acquired illness or injury. The following section describes some acquired speech and language disorders seen in the adult population, including apraxia of speech (AoS), dysarthria, and aphasia.

Speech Disorders

AoS and dysarthria are considered motor speech disorders. They result from neurological injury or illness and affect an individual’s ability to plan, program, control, or execute speech production.

Apraxia of Speech

Apraxia of speech (AoS) is predominantly characterized by a reduced overall speech rate and distortions in articulation and prosody, or the rhythm of speech. In the area of articulation, sounds may be imprecise, distorted, substituted, added, or deleted. In the area of prosody, disruptions include segregating words into individual syllables and equalizing stress across syllables.¹¹ AoS is caused by illness or injury to the left or language-dominant hemisphere, most commonly after stroke. AoS frequently co-occurs with aphasia and dysarthria. TBI and neurodegenerative disease can also result in AoS.

Dysarthria

Dysarthria is a motor speech disorder resulting from muscle weakness or difficulty controlling the muscles that are used for speech and is typically caused by stroke, brain injury, tumors, or neurodegenerative disease. Dysarthria is characterized by “abnormalities in the strength, speed, range, steadiness, tone, or accuracy of movements required for the breathing, phonatory, resonatory, articulatory, or prosodic aspects of speech production.”¹¹ Individuals who have dysarthria may slur or mumble speech sounds, or may speak too slowly, quickly, softly, or loudly. There are several different types of dysarthrias that can often be associated with underlying neuropathophysiology. Parkinson disease, for example, is associated with hypokinetic dysarthria, which is characterized by variable speech rate, monopitch, monoloudness, and imprecise articulation. Individuals with ALS typically develop a mixed flaccid–spastic dysarthria, which is characterized by reduced speech rate, imprecise articulation, hypernasality, strained or strangled vocal quality, monopitch, and monoloudness.²⁰

Language Disorders

Aphasia: Definitions and Subtypes

Aphasia is a disorder resulting from damage to the brain's language areas. Because most of the population possess language centers in the left cerebral hemisphere, strokes, brain tumors, TBIs, infections, and neurodegenerative diseases that damage the left hemisphere may result in aphasia. The hallmark of aphasia is the presence of **anomia**, or difficulty with word retrieval (i.e., problems finding desired words). Additionally, varying degrees of impairment may exist in comprehension, reading (alexia), writing (agraphia), and math skills (acalculia), depending on the aphasia type and severity of damage.

One of the most common methods for differentiating aphasia subtypes is referred to as the "Boston Classification System."¹² Because all aphasias cannot be classified according to this system, and given that aphasia subtypes may evolve over time with both spontaneous recovery and treatment, a comprehensive speech and language evaluation is important to gain a complete understanding of client strengths and weaknesses with regard to speaking, listening, reading, writing, and functional communication skills. A brief description of three aphasia subtypes is provided that follows.

Broca Aphasia

Broca aphasia, also known as expressive aphasia, is the most common subtype of nonfluent aphasia. In Broca aphasia, spoken utterances can range from single words to short agrammatic phrases that contain mostly nouns and verbs, but are limited in the use of function words, such as articles, auxiliary verbs, and prepositions. Spoken communication may seem halting and effortful, which can, in turn, lead to abandoned communication attempts. Although comprehension is commonly described as good or even "intact," clients with Broca aphasia may struggle to understand complex syntax such as passive sentence structures (e.g., "the dog was chased by the bicyclist," as opposed to the active version, "the bicyclist chased the dog"). See Figure 18-5 for an example of a person with Broca aphasia, describing the "Cookie Theft" picture stimulus.

Figure 18-5 The "Cookie Theft" picture stimulus and transcriptions. (From Goodglass H, Kaplan E, Barresi B, et al. *The Boston Diagnostic Aphasia Examination: BDAE-3 Long Form Kit*. Austin, TX: Pro Ed; 2001. Used with permission from Pro-Ed.)

Wernicke Aphasia

Wernicke aphasia is a type of fluent and receptive aphasia in which auditory comprehension is impaired. Although individuals with Wernicke aphasia speak in full sentences that retain intonation and melody, they struggle to convey meaning and their spoken utterances are marked by semantic paraphasias or word substitution errors (e.g., "wife" for "son"), as well as jargon in the form of made-up words and phrases. Clients with Wernicke aphasia have variable awareness of both their expressive and receptive errors, which often results in communication breakdowns. Reading and writing are also typically impaired. See Figure 18-5 for an example of a person with Wernicke aphasia, describing the "Cookie Theft" picture stimulus.

Global Aphasia

Global aphasia is a severe form of nonfluent aphasia in which spoken output and auditory comprehension are both significantly impaired. In global aphasia, individuals have severe anomia and may produce stereotypic utterances or repeated phrases (e.g., "Yeah, right") during attempts to verbalize.

Primary Progressive Aphasia

Primary progressive aphasia (PPA) is a gradual worsening of language skills caused by progressive degeneration of nerve cells in the brain's language areas. PPA differs from aphasia in that it is a degenerative disease. PPA is typically caused by either frontotemporal lobar degeneration or Alzheimer disease.¹²

Communication: Assessing Impact on Occupational Performance

The following section focuses on assessment of occupational performance as it is impacted by communication challenges. The strategies described in the subsequent sections also support collaborative goal setting.

Screening

Occupational therapists always observe and consider client’s communication abilities as they influence occupational performance; however, occupational therapists do not screen for communication impairment. Rather, they screen for occupational performance difficulties related to communication challenges. Occupational therapists should perform chart reviews and ask family members or other health care team members about clients’ communication abilities. Occupational therapists use clinical observation skills to note whether clients appear to understand what is being said (e.g., whether client responses fit posed questions). At times, it can appear that clients understand everything while they make eye contact, nod, and smile; however, some clients are skilled at masking their communication impairment. When questioning a client’s comprehension, it is advisable to screen by providing instructions for the client to follow (such as “pick up the pen”) or posing yes/no questions to confirm marital status or living situation. If the client demonstrates communication difficulties, referral to an SLP should be made. Having both an SLP and occupational therapist involved in a client’s care will increase the client’s potential to improve both communication skills and occupational performance.

Assessing Impact on Daily Occupational Function

For clients with impaired language or speech, occupational therapists should use strategies such as adaptations and modifications to support participation in the evaluation and collaborative goal-setting process. See Table 18-1 for approaches to goal setting and assessment modification based on a review of empirical evidence, universal design principles for learning, and health literacy. For example, adapting questionnaires by placing one question per page, bolding key words, and using sans serif font can make reading easier for some people (Fig. 18-6). In addition, using photographs with simple captions may support comprehension (Fig. 18-7). When administering Likert scales, therapists should use large print and emoticon or smiley faces to denote positive and negative sides. The use of slash marks instead of scale numbers can be considered, depending on the client’s level of numeric understanding (Fig. 18-8). There is initial evidence that assessments that have been modified to support communication can still be valid and reliable.²¹

How much help do you need for each of the following?

	A lot of help	Some help	A little help	No help
Putting on shirt	1	2	3	4
Putting on pants	1	2	3	4
Putting on socks	1	2	3	4
Putting on shoes	1	2	3	4

How much help do you need to **put on your shirt?**

A lot of help	Some help	A little help	No help

Figure 18-6 The top image shows a section of a sample questionnaire regarding self-care. The bottom image shows a modified version of the sample self-care questionnaire, with the following changes made to presentation to support comprehension: one question per page, font changed to sans serif, keywords bolded, shaded row to differentiate numerical choice from word choice, and emoticons.

Figure 18-7 A to C. Examples of additional photos to use during evaluation to support collaborative goal setting.

Figure 18-8 Example of a simplified Likert scale using only slash marks, emoticons, and simple words in large font.

Table 18-1. Key Principles for Modifying Outcome Measures

PRINCIPLE	DESCRIPTION	EXAMPLE
1. Modify the presentation	Use large sans serif font; font that has extra flare is harder to read. Place one item per page to allow clients to focus on one item at a time (see Fig. 18-6).	Modify the Stroke Impact Scale ⁴⁷ to present one question per page, with larger font.
2. Use simple vocabulary and syntax	Short and clear sentences with commonly used words are best.	When asking clients to rate performance on the Canadian Occupational Performance Measure, ⁴⁸ use “How good are you at cooking?” instead of “How would you rate your performance in cooking?”
3. Use pictures	Photographs and line drawings are effective if the picture is clear without extra unnecessary details.	Use pictures, the LIV, ²² or Activity Card Sort (ACS) ⁴⁹ to support both client comprehension and expression of interest in activities (see Fig. 18-6).
4. Provide choices and simplify options	Ask close-ended or yes/no questions. Reduce number of options.	When administering the ACS, ask clients to sort into two piles instead of four to five. Ask them to first sort activity cards into “want to do/do not want to do,” then to sort cards from the “want to do” pile into “hard to do” vs. “easy to do.”
5. Provide support	Allow clients time to process questions and formulate responses. Provide scaled levels of support.	Repeat questions, restate questions, and verify responses. For example, “How good are you at cooking?” Restate as “How well are you able to make meals?” Verify as “So, you don’t cook well?”

PRINCIPLE	DESCRIPTION	EXAMPLE
6. Adapt the testing environment	Ensure quiet environments with few distractions and provide additional materials.	Provide paper, pen, and visuals (such as maps or letter boards) as needed. Ensure clients are comfortable (doesn't need to use bathroom).

Chapel Hill: University of North Carolina Department of Allied Health Sciences; 2010; Berger S, Escher A, Hildebrand M, Tabor Connor L. Modifying outcome measures to support participation for people with aphasia. *OT Pract*. 2017;22:10–13; Herbert R, Haw C, Brown C, Gregory E, Brumfitt S. Accessible information guidelines: making information accessible for people with aphasia. 2012. https://www.stroke.org.uk/sites/default/files/accessible_information_guidelines.pdf1_.pdf.

Some assessments have been developed specifically for adults with impaired communication. For example, the Life Interests and Values Cards (LIV),²² developed by an SLP and occupational therapist team, incorporates many of the strategies in Table 18-1. This measure provides visual cues and uses line drawings depicting different activities in which clients may participate. Visual cues are provided by a large green check mark and red X to facilitate client understanding of the two-pile sort system, in which clients sort activity cards into the categories of “want to do” and “don’t want to do.”

When assessing clients with communication impairments, it is imperative to assess not only their physical functioning and ADL/IADL performance but also other ways in which their communication impairment impacts their daily lives. For instance, clients with communication impairments may find themselves isolated because of their inability to converse easily with friends and family. Therapists should consider administering an assessment to understand clients’ psychosocial status, such as the Geriatric Depression Scale.²³ When administering assessments, it is important to ensure that instruments are accessible to clients by making appropriate modifications as noted earlier and using strategies listed in Table 18-1.

Instruments in the Assessment table at the end of this chapter focus on occupational performance, occupational participation, and communication participation. The Assessment table includes a sampling of instruments developed specifically for people with impaired communication, as well as other evaluations that were developed for a generic population and are user friendly or easily modified for people with communication difficulties. Many additional assessments exist that are administered by SLPs and which provide information related to the impact of communication impairment on participation and quality of life. For example, occupational therapists may encounter results from the following assessments in client charts and research studies: the ASHA Functional Assessment of Communication Skills for Adults²⁴ (a measure completed by an individual familiar with the client’s communication who rates communication independence across functional tasks), ASHA Quality of Communication Life Scale²⁵ (a self-rating scale that assesses the impact of communication impairment on relationships, communication, and participation), and the Assessment for living with aphasia²⁶ (a pictographic, self-report assessment of quality of life for individuals with aphasia).

Specific Interventions for Communication Dysfunction

The following are a sampling of evidence-based interventions that occupational therapists can use to maximize participation of clients with communication difficulties. Occupational therapists collaborate with both SLPs and clients in the selection and use of the most appropriate interventions to support participation when communication is impaired (see the Evidence table at the end of this chapter for a selection of evidence related to interventions for communication dysfunction).

Augmentative and Alternative Communication

Augmentative and alternative communication (AAC) includes low- and high-tech solutions and strategies that support communication. Augmentative strategies are used to supplement speech, whereas alternative strategies are used when speech is nonfunctional or absent. The most appropriate AAC for a client varies based on the condition, the client’s abilities and challenges, and the context. The type of AAC also depends on the client’s recovery stage and continuum.²⁷ For example, in acute care environments, focusing on communicating basic needs such as expressions of pain or thirst through picture boards may be appropriate. In later recovery stages, when functional status is more stable, the selection of high-tech solutions may be a better option.

AAC includes unaided and aided systems. Unaided systems are strategies that require only the individual and include gesturing, making facial expressions, and using body and sign language.

Although some strategies may come naturally, learning to intentionally gesture and exaggerate body language can support communication when speech is limited. Slowing the rate of speech or over articulating are strategies to improve speech intelligibility.

Aided systems require the use of a tool or device and can be as simple as pen and paper or as high tech as a computer. There is strong evidence that low- and high-tech AAC are effective to support communication in functional situations based on multiple systematic reviews.^{28,29} Using letter, word, or picture boards or books are options for many (Fig. 18-9). Personalizing these boards by including family member names or favorite foods can make communicating easier and quicker by simply pointing to words instead of spelling them out. It is important to note that word or alphabet boards may not be helpful for those with aphasia. Often clients who struggle to speak due to aphasia will also have difficulty writing and spelling. Sometimes people who struggle to speak or read, however, can point to a first letter or picture, helping the recipient of the information to make educated guesses.

Figure 18-9 Example of a picture board.

The number and variety of high-tech options to support communication has significantly increased over the past 20 years with the development of many types of computers, tablets, and cell phones, all with accessibility features (Fig. 18-10). However, while many speech generating devices allow users to designate gender, age, and language, digitized speech, although improving, does not sound like human voice.³⁰ To address this challenge, some people who anticipate the future loss of their voice, for example those with ALS, can choose to record and store their own voice through message banking.³¹

Figure 18-10 Screenshot of the general accessibility page on an iPad with two features highlighted.

Computers, tablets, and cell phones can be operated through touch technology or adapted for use with eye gaze, optical head pointers, joy sticks, or through visual or oral scanning. Because technology changes often, it can be helpful to refer clients to an AAC specialist, typically an

occupational therapist or SLP who specializes in this practice area. Some have questioned whether AAC decreases client motivation to improve natural speech skills or limits language development, but research has demonstrated otherwise.³² AAC, when used in conjunction with natural speech, can actually improve speech.

Many people abandon or stop using their AAC device even when still needed, despite possessing well-designed and appropriately chosen systems.³³ Clients abandon devices for a variety of reasons, including stigma, slow speed, equipment failure, cultural differences, inadequate training, and lack of support from family members or caregivers.³³ Therapists can help prevent AAC abandonment by assuring a good match of the device to the user's physical, cognitive, and communication abilities; providing adequate training for users, family, and caregivers; and offering realistic expectations.³⁴ Providing opportunity to practice AAC use in the client's natural environment offers meaning and motivation, is key to successful AAC use, and improves social participation.

It is critical to remember that technology is a tool. The end goal of AAC is not the use of technology, but rather increased communication participation. Focusing on this goal will help the therapist collaborate with the client to select the most appropriate technology.

Partner Training

Communication is reciprocal, and clients' ability to express themselves also involves the people who are attempting to understand what is being said. Most of the literature regarding the effectiveness of care partner training addresses the care partners of people with aphasia.^{35,36} Evidence exists, however, regarding the effectiveness of training care partners of people with social communication challenges resulting from TBI,³⁷ intellectual disability,³⁸ dementia,³⁹ and other conditions.

There are several standardized partner training protocols,^{37,40} which include a combination of the following features: education, personalized goal setting, modeling, role-play, feedback, practice, and homework. Whereas SLPs are typically the professionals who administer partner training interventions, occupational therapists can provide suggestions, strategies, and encouragement to care partners and should incorporate partner training strategies when working with clients who struggle to communicate. Strategies that care partners can use to support the expression of persons with communication difficulties include²⁷:

- Providing written choices
- Asking closed-ended (yes/no) questions
- Making available writing/drawing utensils, paper, maps, photos, objects, and technology, as appropriate (Fig. 18-11)

Figure 18-11 Use of technology (iPad and stylus) to support expression of ideas.

- Listening actively without interrupting
- Allowing extended response time
- Encouraging

Strategies that partners can use to support the comprehension of persons with communication difficulties include:

- Using multiple modalities such as pictures, calendars, maps, and gestures along with spoken words (Fig. 18-12)

Figure 18-12 Example of partner using strategy to support comprehension.

- Emphasizing keywords through tone or vocal volume
- Using short, simple sentences and familiar words
- Repeating or paraphrasing
- Using age-appropriate language and intonation
- Speaking slowly
- Limiting number of questions posed
- Keeping volume at a normal tone

Some common partner communication challenges to be aware of include (1) overcompensating by speaking very slowly or with a childish voice, (2) providing little time for the person to communicate and respond, (3) speaking for the person, (4) asking about information that is obvious or already known, and (5) preventing the influence of natural consequences (e.g., failing to demonstrate interest in topics when they are initiated).³⁷

Script Training

Script training involves teaching someone to use scripts to communicate, and evidence supports this approach for people with aphasia⁴¹ and AoS.⁴² Script training is based on both the importance of stories in everyday life and on whole task training. All people use stories, or scripts, throughout daily conversation. For example, many therapists have a set response to the question, “What is occupational therapy?” When students first enter occupational therapy school, this script may not yet have been practiced and is often said slowly, with limited confidence, and unclearly. Practice of this script takes place with peers and family members, focusing on both keywords and phrases (part task training), and explaining occupational therapy in full. With whole task training, this important “story” becomes perfected.

Script training is typically performed by SLPs, but occupational therapists can support both SLPs and clients to develop scripts in a variety of ways including:

- Collaborating with clients to determine situations in which scripts would support participation.
- Increasing technology accessibility by heightening keyboard contrast using stickers, practicing typing techniques, and exploring computer and tablet accessibility features (for clients using computers to develop scripts).
- Providing clients opportunity to practice using scripts in simulated and authentic environments.

Participation as Intervention

Improving communication skills can lead to increased participation, but as importantly, participation in meaningful occupations can improve communication. In a qualitative study of adults with aphasia, participants reported numerous benefits of volunteer activity participation including improved communication.⁴³ Volunteer experiences provided these individuals with opportunity and motivation to communicate, and increased overall confidence and self-esteem (Fig. 18-13). Dalemans and colleagues⁴⁴ discuss the importance of social participation for people with aphasia, emphasizing that social engagement provides people with voice and respect. Social participation also affords individuals who struggle to communicate the opportunity to be a part of society and to feel ordinary.

Figure 18-13 A, B. Volunteering to make first aid kits for a homeless shelter provides opportunity for communication along with increased confidence and a chance to give back to the community.

Although therapy groups often focus on improving specific skills, participants in aphasia groups reported joining groups primarily to meet other people and develop friendships.⁴⁵ Group members reported placing greater value on interactions and relationships developed during groups than on any specific skill or activity (Fig. 18-14). Although therapy groups are valuable to facilitate communication and social engagement, there is strong evidence to support the importance and positive benefits of social participation in naturally occurring environments. Engaging in motivating and authentic conversations can improve communication skills, self-confidence, and overall participation.³⁰

Figure 18-14 A, B. Collaborating with others with communication impairment to make a peach salad, using adapted recipes and visual cues.

Adaptive Strategies

The role of occupational therapy is unlimited when working with clients with communication challenges, and supporting communication and participation are key foci. Some strategies to support participation in both therapy and the home for people with decreased communication by adapting activities and/or the environment include the following:

- **Ask clients to use tablets or cell phones to photograph their home environments for therapists.** This involves clients in the assessment of and interventions for home adaptations.
- **Choose quiet environments with few distractions.** For example, when possible, therapists should communicate in private rooms instead of large clinic settings. Ask clients for permission to turn off the radio before engaging in conversation. Encourage clients to find quiet environments when socializing. Dining with one friend instead of a large group may make communicating easier.
- **Plan for emergency situations with clients.** It is important to determine whether clients have medical alert buttons or can use a phone to call 911. If clients cannot use a cell phone to verbally communicate with others, they can still obtain help by calling the 911 system, which will send help without the need for clients to speak.
- **Discourage multitasking.** Singularly focusing on the task of talking is easier than talking combined with another activity such as eating or watching television. During therapy, provide directions, ensure that clients understand all directions, and then allow clients to perform therapy activities. The avoidance of multitasking while talking is particularly important for clients with communication difficulties resulting from Parkinson disease.⁴⁶
- **Contact telephone company representatives to explore available options for clients.** For example, Speech-to-Speech (STS) services employ people who are trained in understanding a variety of speech disorders. STS communication assistants relay information to the person on the other end of the phone.²⁷
- **Support clients to advocate for themselves.** For example, develop an information card (Fig. 18-15) with clients which explains their communication difficulty. Clients can then share this card with people in stores or social environments.

Figure 18-15 Example of information card. Printed with permission from <http://aphasiaid.com>.

Finally, contextual factors are critical to consider when providing intervention for clients with impaired communication. For example, virtual contexts, such as talking on the phone, can be challenging for some people with impaired communication. Temporal contexts, such as time of day, can also influence communication due to fatigue or medication schedule. Personal contexts, such as socioeconomic status, may influence clients' ability to access AAC. Cultural contexts, as well, may support or hinder communication. For example, religious dress may limit some observable facial expressions. These are only several of the many contextual factors to consider when working with clients with communication challenges.

CASE STUDY

Patient Information

Sheng is a 69-year-old Asian American male who lives with his wife, Tuyen, in a small single-family house, 15 minutes from the city. He worked as a mail carrier until retiring at age 66. Tuyen worked as a part-time nurse but was able to leave her job to care for her husband after he experienced a stroke 1 month ago. Sheng and Tuyen have two grown children and three

grandchildren. Their daughter and two grandsons live approximately 25 minutes away; their other adult children live several hours away.

Sheng reported being a quiet, hard-working man who enjoys his family, home, and hobbies. Aside from going out to eat once or twice a week and visiting family, he stated that he keeps to himself. Tuyen, however, described herself as very social and active. They have been married for 45 years and consider themselves to be decidedly fortunate.

Prior to his stroke, Sheng and Tuyen shared very traditional roles. Tuyen completed all household tasks, including cooking, cleaning, and shopping, whereas Sheng's home responsibilities included yard work, car maintenance, and financial management. Both reported contentment with this arrangement.

Assessment Process and Results

Sheng was seen, with his wife, in an outpatient setting 4-weeks poststroke. Initial information was obtained through review of Sheng's chart. Medical notes stated that Sheng experienced a left middle cerebral artery stroke; SLP documentation reported Broca nonfluent aphasia and that Sheng had strong auditory comprehension skills and utterances of two to three words in length. The occupational therapist observed Sheng walk into the clinic (using a straight cane and ankle-foot-orthosis), take off his coat (slowly but independently), and open his water bottle by stabilizing it between his legs. From observation, it was noted that Sheng had right-sided upper extremity paresis and lower extremity weakness. Tuyen was very anxious about leaving Sheng to participate in activities alone because of his communication struggles; she expressed concern that he may become lost and unable to communicate his need for help.

After an initial informal interview with Sheng and Tuyen to gather background information, the Canadian Occupational Performance Measure (COPM) was administered to identify Sheng's self-reported, most important daily activities that had become challenging poststroke. Photo cards from the Activity Card Sort (ACS) and Life Interests and Values (LIV) were used to support Sheng's ability to share his priorities. The occupational therapist asked Sheng to perform multiple photo card sorts, each time using just two categories per sort: (1) "want to do" and "don't want to do"; and (2) "want to do" pile sorted into "do same" or "do less."

Then, using cards from the "do less" pile, the therapist asked Sheng to prioritize his most important activities and rate the performance (P) and satisfaction (S) of each activity using a Likert scale ranging from 1 to 10 (where 1 = poor performance and low satisfaction). Using an adapted scale with large font, visual icons, simplified language, and positioning the photo of each identified activity next to the rating scale, Sheng listed the following four activities as high priority:

- Using the computer (P = 2, S = 5)
- Presenting a gift to Tuyen (P = 1, S = 1)
- Using transportation independently (P = 1, S = 6)
- Fishing independently (P = 1, S = 2)

Based on evaluation findings, the therapist learned that Sheng previously completed many errands independently but now sits in the car waiting as Tuyen completes errands. Sheng enjoyed reading but is unable to read easily now; used the computer to send and answer e-mail messages, but can no longer complete this activity independently; was the family driver but no longer drives; and loved to fish both alone and with family, but now has difficulty holding the fishing pole. He shared that he is independent in self-care activities (e.g., bathing, dressing, toileting, eating) and spends much of his day watching television. Tuyen expressed that she is anxious about Sheng's independent use of paratransit and that she is unsure about how to arrange this service for him.

Occupational Therapy Problem List

- Nonfluent aphasia
- Right-sided hemiparesis
- Limited participation in self-reported desired activities
- Dependent on Tuyen to go outside the home

Occupational Therapy Goal List

By the end of 2 months, Sheng will:

1. Report that he went fishing with son and was able to independently use adapted fishing pole
2. Independently use cell phone for emergencies, and to call and answer family members
3. Use paratransit to attend therapy sessions, once arranged by wife
4. Make or purchase a surprise gift for wife

Intervention

Tuyen attended Sheng's first three occupational therapy sessions, often answering for him when questions were posed. Sheng sat quietly, appearing content for Tuyen to respond, and gesturing to her to respond when he needed help communicating. When given time, however, Sheng was able to communicate with the therapist and answer questions using gestures, words, photos, and, at times, paper and pencil. For example, he drew a picture of a boat to explain that he preferred fishing from a boat in contrast to a dock.

During these first sessions, the occupational therapist provided Tuyen with strategies to support her ability to communicate with Sheng (e.g., asking close-ended questions, listening without interrupting, allowing time for Sheng to respond) and worked with him to adapt a fishing pole holder based on his requirements and suggestions. Sheng became excited and enthusiastic for more occupational therapy sessions. Unfortunately, Tuyen fractured her ankle after falling and was unable to transport Sheng to therapy. As a result, he missed the next session and reported that Tuyen could not drive for 6 weeks. The therapist took this opportunity to address the use of paratransit. While Sheng was eager to use paratransit independently, Tuyen expressed concern. Through several phone calls, the therapist instructed Tuyen in the process of scheduling paratransit services. Tuyen followed through and arranged for Sheng to be picked up for his next therapy session. Because Tuyen could not as yet travel with him, the therapist arranged for a hospital volunteer to drive to the house and accompany Sheng on the paratransit van, to and from therapy. The therapist called Tuyen when Sheng arrived to assure her of his safety. Sheng again took paratransit in the following week, but this time alone. When he arrived at the clinic, Sheng called Tuyen, with support from the therapist, and using the cell phone that Tuyen gave him for emergencies. Sheng expressed elation to be able to attend therapy on his own and allow Tuyen time to herself. During these next sessions, the therapist worked with Sheng to practice two scripts that he developed with the SLP for telephone use: one to let his wife know that he arrived at a designated location safely, and one for emergencies (e.g., calling 911). Sheng also learned to use his phone's camera and photographed himself and his wife. In therapy, he made a collage frame, framed this photo, and wrapped it as a gift for Tuyen. To support Sheng's ability to write a card, the therapist found five possible sentences that might convey his thoughts (e.g., "Thank you for everything;" "I appreciate all you do.>"). Sheng chose one, copied the words onto the card in his writing, and signed his name.

In the final occupational therapy session, Tuyen joined him via paratransit. She was still unable to drive but enjoyed getting out of the house. During this session, the occupational therapist reinforced strategies that worked for communication and encouraged Sheng to advocate for himself (e.g., request people to speak more slowly). Because Tuyen was so impressed by Sheng's ability to call her using the phone, she planned to purchase a simple smartphone (e.g., the Jitterbug) so that he could call his children and grandchildren and gain assistance in case of emergencies. During the final session, COPM outcome measures were repeated, and Sheng's ratings improved significantly, as follows:

- Using the computer (P = 2, S = 5)
- Presenting a gift to Tuyen (P = 5, S = 8)
- Using transportation independently (P = 8, S = 6)
- Fishing independently (P = 5, S = 9)

Most Commonly Used Communication Standardized Assessments

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
--------------------------	------------------	---------------------	----------	-------------	-------------	--------------------------

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Activity Card Sort (ACS) ⁴⁹	Measures level of activity in instrumental, social, and leisure activities	~60 minutes	Concurrent validity adequate to strong; construct validity satisfactory to excellent ⁴⁹	Internal consistency generally considered strong; test-retest considered excellent ⁴⁹	Not available	Created for older adults; cards support communication; no ADL photos
Canadian Occupational Performance Measure (COPM) ⁴⁸	Measure of a client's perception of his or her performance and satisfaction of daily activities; identifies areas of difficulty in occupational performance	~15–30 minutes	Concurrent, criterion, convergent, divergent, construct, content validity all acceptable ⁴⁸	Test-retest: consistently acceptable ⁴⁸	Considered responsive to change ⁴⁸	Focus on occupational performance and challenges; encourages client-centered, occupation-based practice. Needs to be modified to be accessible to people with communication challenges.
Communicative Participation Item Bank ⁵⁰	Measures the extent to which communication impairment disrupts communicative participation	~10 minutes	Valid for use with people with aphasia ⁵¹ ; content validity strong ⁵⁰	Not available	Not available	Self-report; can be used for community-dwelling adults with different communication disorders, including MS, ALS, and Parkinson disease
Goal Attainment Scaling (GAS) ⁵²	Evaluation of intervention effectiveness based on level of individualized goal achievement	Variable	Can have strong validity when GAS intervals are precisely developed ⁵³	Considered a reliable measure with precise GAS intervals ⁵³	Sensitive to change ⁵³	Individualized, criterion referenced; predicts expected outcomes. Can be time-consuming and challenging to create five ordinal levels of goal attainment. Reliability and validity highly dependent on abilities of the person writing the GAS goals ⁵³
Life Interests and Values Cards (LIV) ²²	Developed for SLP, OT, PT to facilitate communication of client-centered interests and goal setting	~45 minutes	Considered valid instrument to elicit involvement in life activities for people with aphasia ⁵⁴	NA	NA	Facilitates communication with people with aphasia and explores their interests and goals. Not an outcome measure. Includes friends and family member questionnaire.

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Stroke Impact Scale ⁴⁷	Outcome assessment for people poststroke, measuring ADL, IADL, mobility, communication, emotion, memory and thinking, and participation	~ 15–20 minutes	High-to-adequate concurrent validity ⁵⁵	High internal consistency; good test–retest reliability ⁵⁵	Not adequate evidence ⁵⁵	Diagnosis specific—just for use poststroke; communication items along with more global items

ADL, activities of daily living; ALS, amyotrophic lateral sclerosis; IADL, instrumental activities of daily living; MS, multiple sclerosis; NA, not applicable; OT, occupational therapy; PT, physical therapist; SLP, speech language pathologist.

Evidence Table of Communication Intervention Studies

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistic Significance and Effect Size
Augmentative and Alternative Communication (AAC) for adults with decreased communication ²⁸	Use of AAC to support communication	Eighteen studies of adults aged 60+ with communication impairment (for any reason) and use AAC to support communication	Varied (and not reported in many studies)	Systematic review Level I	Technology was beneficial as an assistive communication tool. Older adults were receptive to technology. Simpler the technology, the better. Older adults, with or without disability, benefit from AAC to support communication.	No statistical analysis
AAC for people with aphasia ²⁹	Use of high-tech communication devices	Thirty articles focusing on AAC use by adults with aphasia (1989–2016)	Total of 13 different types of AAC systems were used in 30 interventions.	Systematic review Level I	People with aphasia demonstrated improvement in functional communication (communication during telephone conversations, everyday activities, written communication, and face-to-face interaction) using high-technology AAC.	No statistical analysis

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Partner training for caregivers of people with dementia ³⁹	Communication skills training for professional or nonprofessional caregivers to improve communication or interaction with people with dementia	Twelve studies focusing on communication skills training for health care professionals and lay caregivers of people with dementia in nursing homes ($n = 8$) or home ($n = 4$)	<ol style="list-style-type: none"> 1. Interventions were small groups or face-to-face trainings. 2. Hands-on practice and feedback provided. 3. Dosage varied from two sessions at 1 hour each to five sessions at 2.5 hours each. 	<ol style="list-style-type: none"> 1. Systematic review 2. Level I 	<p>Many strategies found to be effective in improving caregivers' communication skills including:</p> <ul style="list-style-type: none"> • Verbal skills including using one-step instructions, person's name, and biographical and positive statements • Nonverbal and emotional skills, including making eye contact, providing enough time, and actively listening • Attitudes toward people with dementia, including avoiding over-nurturing and increasing opportunities for pleasant events • Behavioral management skills, including using distraction and setting realistic goals • Usage of tools, including memory books and aids • Self-experiences, including reflecting on what works and what doesn't • Theoretical knowledge, including knowledge about dementia, culture, and communication 	No statistical analysis

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistic Significance and Effect Size
Partner training with people with aphasia and their care partners ³⁵	Teaching people who interact with individuals with aphasia to use strategies and resources to support communication	Twenty-five articles focusing on training partners of people with aphasia	Amount of training varied from 1.25 hours to as many as 100 hours (most common was 10–15 hours of training).	Systematic review Level I	Language impairment—less than half the studies that measured this demonstrated improvement. Communication activity/participation—more than half the studies that measured this demonstrated improvement. Psychosocial adjustment/QoL—all studies that measured this showed improvement. Communication partners—improvement noted in strategy use and psychosocial adjustment.	No statistical analysis
Script training ⁴¹	Script training for people with chronic, nonfluent aphasia	Six studies focusing on script training that explored outcomes related to rate of speech and verbal output	All studies focused on personally meaningful scripts. Intervention varied including: <ul style="list-style-type: none"> • Number of scripts practiced (from 1 to 20) • Length of intervention (from 2 to 16 weeks) 	Critical review Level V	Improvement noted in all studies for increasing rate of speech and use of script-related words in other contexts; evidence also showed increased confidence in communication and increased social participation.	No statistical analysis
Community aphasia group participation ⁴⁵	Participation in community-based group programs for people with aphasia	Individuals with severe aphasia, <i>N</i> = 7, 49–79 years old, 1–10 years after aphasia	2 months to 9 years of group participation	Qualitative study — Phenomenological approach Level V	Three themes: <ul style="list-style-type: none"> • Initially perceive community group as high risk • Benefited from structure • Opportunity for authentic interaction and chance to highlight individual strengths 	NA

NA, not applicable; QoL, quality of life.

Chapter 19

Swallowing and Eating Assessment and Intervention

Wendy Avery

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Discuss normal swallowing.
2. Define basic terminology related to dysphagia care.
3. Identify types of dysphagia and their presentation.
4. Identify diagnoses in which dysphagia is commonly seen.
5. Describe how to perform a clinical dysphagia assessment.
6. Employ basic compensatory and rehabilitative strategies to treat dysphagia.
7. Name and describe the execution of commonly used compensatory swallowing maneuvers.
8. Discuss precautions for the occupational therapist and the patient during dysphagia evaluation and intervention.
9. Describe instrumental evaluation procedures for dysphagia.
10. Describe instrumental interventions for dysphagia.

CHAPTER OUTLINE

Swallowing and Eating Function and Impairment in Daily Occupation
Neurological and Physiological Bases of Swallowing and Eating
Impaired Swallowing
Evaluation of Swallowing and Eating Skills
Conceptual Foundations Underlying Interventions for Swallowing and Eating Impairment
Compensatory and Remedial Interventions for Specific Eating and Swallowing Problems
Case Study

TERMINOLOGY

Aspiration: the entrance of food or secretions into the larynx below the level of the vocal cords.

Bolus: any food or liquid in the mouth.

Deglutition: the act of swallowing.

Direct therapy: any therapeutic technique or intervention involving ingestion of food or liquids.

Dysphagia: difficulty with any stage of swallowing.

Eating: the ingestion of food and liquid, including the preoral, oral preparatory, oral, pharyngeal, and esophageal stages.

Feeding: taking or giving nourishment.

Fiberoptic endoscopic evaluation of swallowing (FEES): the direct visualization of the swallow using a small illuminated camera at the end of a flexible tube (endoscope), which is introduced into the pharynx through the nose.

Indirect therapy: any therapeutic technique that addresses the prerequisite capacities associated with swallowing without the ingestion of food or liquid.

Instrumental evaluation: imaging and diagnostic studies to provide critical information about the unseen parts of the oral, pharyngeal, and esophageal stages of swallowing.

Mechanical dysphagia: a swallowing and eating impairment caused by the loss of oral, pharyngeal, or esophageal structures; weakness; and/or sensory deficits caused by trauma or surgery.

Modified barium swallow (MBS): moving radiographic images of swallowing structure and physiology, as recorded on DVD. It was formerly referred to and still seen in the literature as “videofluoroscopy.”

Paralytic dysphagia: lower motor neuron involvement that causes weakness and sensory impairment of oral and pharyngeal structures, including weakness or absence of the swallowing reflex.

Pseudobulbar dysphagia: upper motor neuron involvement, causing hypotonicity or hypertonicity of oral and pharyngeal structures and a slow or poorly coordinated swallowing reflex.

Swallowing: the ingestion of nourishment, beginning with introduction of food into the mouth and ending with reception of food into the stomach; it includes the preoral, oral preparatory, oral, pharyngeal, and esophageal stages.

Swallowing and Eating Function and Impairment in Daily Occupation

Normal **swallowing** and **eating** functions encompass a wide range of skills, including the sensory and motor skills related to swallowing and eating, as well as cognition and perception. Swallowing and eating are critical functions that “fuel” all other occupations and activities of daily living (ADLs). **Dysphagia**, or difficulty with any stage of swallowing, can interfere with functional independence for many recipients of occupational therapy services in multiple settings. The incidence of dysphagia is increasing as the US population is aging.¹ Dysphagia has been shown to be correlated with ADL dependence, including loss of dependent eating in rehabilitation² and nursing home populations.³ Dysphagia can lead to dehydration,⁴ pressure ulcers,⁵ and malnutrition.⁶ Malnutrition, in particular, is common in all health care settings.⁷

Dysphagia frequently causes pulmonary complications caused by **aspiration**. These complications include aspiration pneumonia,⁸ airway obstruction,⁹ and death.⁸ Impairment in eating and swallowing can lead to reduction in the ability to participate in rehabilitation as well as basic and instrumental ADLs. For most people, eating is a pleasurable daily experience and the challenges posed by dysphagia can greatly limit the enjoyment of this activity. The reduced ability to participate in social and cultural activities that include food can profoundly affect an individual.¹⁰

Neurological and Physiological Bases of Swallowing and Eating

Deglutition (the act of swallowing) is a complex process involving both volitional and nonvolitional behaviors. The cranial nerves execute the sensory and motor processes that constitute swallowing. Cortically mediated factors, including appetite, attitude, attention span, appreciation of food, and body position, influence swallowing and must be considered in evaluation and treatment. The oral, pharyngeal, and esophageal structures involved in swallowing are illustrated in Figure 19-1.

Figure 19-1 Oral, pharyngeal, and esophageal structures involved in swallowing.

The stages of swallowing include the preoral, oral preparatory, oral, pharyngeal, and esophageal stages.

Preoral Stage

In the preoral stage, food is visually and olfactorily appreciated. This stimulates salivation, and there are preparatory movements of the mouth to ready the oral cavity to receive and mobilize foods and liquids. Spontaneous upper extremity movements occur as the person reaches for and grasps utensils, cups, or finger foods and brings them into the mouth.

Oral Preparatory Stage

In the oral preparatory stage, food is received and contained by the mouth. It is then formed into a **bolus** of food and mixed with saliva. Pureed or liquid boluses require little mastication and may briefly be held centrally in the mouth by the tongue and cheek musculature. Solid food may need to be bitten off in order to be contained in the mouth. The bolus is chewed in a rotary motion and moved between the left and right molars. The buccal muscles contract to prevent food from pocketing between the cheeks and the teeth. Once masticated or formed, the bolus is brought to the center of the tongue.

Oral Stage

In the oral stage, the cheek and tongue muscles retain the bolus centrally in the mouth. The tongue squeezes the bolus against the hard palate, moving it posteriorly to the level of the faucial arches.

Pharyngeal Stage

In the pharyngeal stage, the soft palate elevates to close off the nasopharynx. The larynx and hyoid elevate and protract, minimizing the size of the laryngeal vestibule (its opening) as the epiglottis tips to cover the vestibule. Breathing stops (termed swallowing apnea), reducing the possibility of aspiration or laryngeal penetration of food or liquid. The vocal cords close. Simultaneously, the pharyngeal constrictor muscles sequentially contract to propel the bolus through the pharynx. The elevation of the larynx causes the upper esophageal sphincter (UES) to relax, allowing the bolus to pass through it.

Esophageal Stage

In the esophageal stage, the UES returns to its normal tonic state, and the bolus is transported through the esophagus via esophageal peristalsis and gravity. The lower esophageal sphincter relaxes, allowing the bolus to pass through into the stomach.

The preoral, oral preparatory, and oral stages are voluntary. The length of the oral preparatory, oral, and pharyngeal stages vary with bolus type.¹¹ Oral transit time, the length of time to accomplish the oral stage, has been assumed to be 1 to 1.5 seconds¹²; however, recent research indicates no present consensus.¹³ The pharyngeal stage is involuntary, although volitional movements can alter it. The pharyngeal stage is most effective in an upright position.¹⁴ Normal pharyngeal transit time is less than 1 second.¹¹ The esophageal stage takes 8 to 10 seconds.¹⁵ Although the patient's position may affect the esophageal stage because of the effects of gravity, this stage is involuntary.¹⁵

Impaired Swallowing

Many disease processes and trauma cause dysphagia, including those that affect the central and peripheral nervous systems, motor end plates, muscles, and other anatomical structures.

Types of Dysphagia

Dysphagia may be named by the location of its source: paralytic, pseudobulbar, and mechanical. **Paralytic dysphagia** results from lower motor neuron involvement that causes weakness and sensory impairment of oral and pharyngeal structures, including weakness or absence of the swallowing reflex. **Pseudobulbar dysphagia** results from upper motor neuron involvement, causing hypotonicity or hypertonicity of oral and pharyngeal structures and a slow or poorly coordinated swallowing reflex. **Mechanical dysphagia** is caused by loss of oral, pharyngeal, or esophageal structures; weakness; and/or sensory deficits caused by trauma or surgery, including tracheostomy. Pulmonary complications may worsen the presentation (see Boxes 19-1 and 19-2).

Figure 19-2 Tracheostomy tube. Tubes are available in different sizes and may come with or without the cuff as pictured. The pilot balloon is used to inflate the cuff with a syringe and indicates relative inflation of the cuff. The inflated cuff prevents food or secretions from falling further into the airway.

Box 19-1

Respiratory Considerations Contributing to Dysphagia

Pulmonary Concerns

Respiratory problems may contribute to dysphagia and vice versa because the respiratory and swallowing mechanisms share anatomy and physiology.

Secretion Management

The patient's airway must be clear of excessive secretions. Intermittent suctioning through the nose or tracheostomy may be needed to clear the airway. The occupational therapist should work closely with nursing and respiratory staff to assess whether airway protection and the ability to maintain oxygenation are adequate. Personnel should be available to suction the airway as necessary.

Tracheostomy

A tracheostomy tube reroutes breathing through a stoma in the neck. Tracheostomy tubes may be temporary or permanent and are used to keep the airway open (Fig. 19-2). Tracheostomies provide easy access for suctioning or ventilator use but can cause or

exacerbate dysphagia. They cause reduced smell and taste sensation because the patient is not breathing through the nose. Tracheostomy reduces the ability to clear the upper airway if laryngeal penetration occurs. It increases the risk of aspiration caused by pooling in the pharynx, delays trigger of the swallow reflex, decreases duration of vocal cord closure, and reduces laryngeal movement. An inflated tracheostomy cuff further reduces laryngeal elevation and increases the risk of silent aspiration.¹⁶ An “open” tracheostomy, in which the tube is not covered or “capped,” eliminates the subglottic pressure, reducing the force of the swallow response.¹⁷

Mechanical Ventilators

Ventilators are machines that assist patients to breathe if they cannot do so on their own. Positive-pressure ventilators may be used temporarily, to assist a patient through an acute illness, or chronically, for a patient with a long-term respiratory challenge. Positive-pressure ventilators deliver breaths to patients through a tube in the nose or mouth, or through a tracheostomy. Patients who use a ventilator to breathe via a tracheostomy may be able to eat by mouth. As breathing ceases during the swallow, a well-coordinated swallow is needed to interpose the swallow between inhalation and exhalation. Patients who have had mechanical ventilation for more than a week have been shown to have multiple swallowing deficits once the ventilator is removed.¹⁸ Patients who are ventilator dependent via tracheostomy are prone to aspiration during eating.¹⁸

Box 19-2

Clinical Dysphagia Presentation for Various Diagnostic Groups

This is not an exhaustive list of diagnoses prone to dysphagia; however, it includes those most often encountered.

Alzheimer Disease: Pseudobulbar Dysphagia

- Decreased attention span and apraxia for swallowing and self-feeding may be seen.
- Oral and pharyngeal responses are slow, and a need for physical and verbal cues to self-feed are needed.
- Difficulty with self-feeding is common, and challenges with initiating the meal may be present.¹⁹
- Agitation and behavioral challenges can hamper the eating process.¹⁹
- Clients prefer sweet-flavored and pureed foods.
- Clients are prone to aspiration²⁰ and more difficulty with self-feeding in later stages of the disease.¹⁹

Brain Injury: Pseudobulbar, Paralytic Dysphagia

- Type and severity of dysphagia in brain injury depends on the injury cause, neural location, and size of brain lesion.
- Behavioral and cognitive problems affect self-feeding and swallowing.
- There may be motor difficulty with the oral and pharyngeal phases, including aspiration.²¹
- Abnormal pathological reflexes can affect oral and pharyngeal control.
- Overall mealtime may be slow.

Cerebrovascular Accident: Pseudobulbar and Paralytic

- Pharyngeal and laryngeal sensory deficits may occur in right and left hemispheric as well as subcortical strokes.²² Reduced laryngeal closure during swallowing predisposes patients to aspiration.²³ Reduced oral sensory input from the bolus may play a role in slowing pharyngeal responses.²⁴

- Symptoms vary with lesion location and size.
- Patients with right hemispheric stroke (pseudobulbar dysphagia) display mild oral transit delays and some delay in pharyngeal trigger and laryngeal elevation. The pharyngeal stage lasts longer, and there may be penetration of the larynx and aspiration.⁸ There may be neglect or denial of swallowing problems, and sensory loss can slow motor responses to bolus presence.
- Patients with left hemispheric stroke (pseudobulbar dysphagia) display delays in initiating the oral stage and in triggering the pharyngeal stage. The pharyngeal stage takes longer. There may be apraxia for eating and swallowing.
- Patients with subcortical stroke (paralytic dysphagia) demonstrate mild oral transit delays and a delay in triggering the swallow. There is general weakness of pharyngeal swallow, as seen in reduced laryngeal elevation, reduced tongue base retraction, and unilateral pharyngeal weakness. Aspiration is common. There may also be reduced UES opening.

Developmental/Intellectual Disabilities: Pseudobulbar, Paralytic Dysphagia

- Cerebral palsy (CP) and intellectual disability, together or in isolation, may present deficits of bolus formation and transit, delayed swallow reflex, pharyngeal dysmotility, esophageal disease, and aspiration.²⁵
- Abnormal oral reflexes, and oral hyposensitivity or hypersensitivity may be observed.
- Poor postural, head, neck, and limb control can affect swallowing.
- Behaviors such as eating too quickly and putting too much food in the mouth can affect efficiency and safety of swallowing.²⁶

Head and Neck Cancer: Mechanical Dysphagia

- Swallowing problems with head and neck cancer vary with tumor type, size, and location.²⁷
- Bolus control and containment problems result from surgery to the lip.
- Resection of tumor from the floor of the mouth causes difficulty with bolus control, reduced laryngeal elevation, and its accompanying reduction in UES opening.
- Glossectomy, or removal of some or all of the tongue, causes difficult or absent bolus mobilization; a resection of the tongue base limits the elevation needed to initiate the pharyngeal swallow.
- Unilateral laryngeal cancer may require a vertical laryngectomy or hemilaryngectomy; this may cause reduced vocal cord closure, reduced posterior tongue movement, and reduced UES opening.
- Supraglottic laryngectomy reduces glottic closure, laryngeal elevation, and opening of the UES.
- Extensive cancer of the larynx necessitates a total laryngectomy, which separates the foodway and airway tracts and creates a permanent anatomical tracheostomy. Although aspiration is no longer a threat, there is reduced movement through the pharynx, remaining laryngeal tissue, and esophagus.
- Adjunctive radiation therapy causes edema in areas adjacent to the radiation field, fibrosis, and reduced salivary flow, causing dry mouth or xerostomia.
- Radiation therapy combined with chemotherapy without surgery can reduce tongue base movement, laryngeal elevation, and pharyngeal range of motion and speed.
- Radiation therapy combined with surgery can cause longer oral transit time, increased pharyngeal residue, and reduced UES opening.

Multiple Sclerosis: Pseudobulbar, Paralytic Dysphagia

- Dysphagia symptoms vary with location of plaques in the central and peripheral nervous systems. Dysphagia worsens with disease progression.²⁸

- Weakness of the oral structures and the neck muscles may be seen.²⁸
- Delayed pharyngeal swallow and weakness of pharyngeal contractions may be seen.²⁸

Neoplasms of the Brain: Pseudobulbar, Paralytic Dysphagia

- Dysphagia may be due either to a tumor or to metastasis in the brain or to medical or surgical interventions.
- Symptoms vary with the location and extent of the client's neoplasm and interventions, and symptoms may be similar to those found in clients with stroke.²⁹

Parkinson Disease: Pseudobulbar Dysphagia

- Impulsiveness and poor judgment can affect swallowing.
- Jaw rigidity, abnormal head and neck posture, impaired coordination of tongue movements and mastication. Mastication and orofacial motions are affected³⁰ along with tongue control.³¹ Alterations in the pharyngeal aspect of the swallow occur,³² including pharyngeal residue and delayed pharyngeal elevation. Abnormal head, neck, and trunk posture along with difficulty coordinating upper extremity movements for self-feeding are seen.
- Feeding and swallowing may be too slow and laborious to allow sufficient nutritional intake.
- Orofacial fatigue may make eating and swallowing more difficult as a meal progresses.³³

Evaluation of Swallowing and Eating Skills

Clinical dysphagia assessment involves two components: a clinical assessment and an **instrumental evaluation**.

Clinical Assessment

Clinical assessment of dysphagia must be thorough, with examination of all areas relevant to swallowing. It is best done using a reliable and valid tool.³⁴ A reliable and valid tool allows for accurate assessment and reassessment by different test administrators and ensures that each test item provides accurate assessment of performance components.

History, Nutrition, and Respiratory Considerations

The clinician reviews the patient's medical and surgical history, with special attention to any diagnoses and procedures that are relevant to dysphagia. The patient and caregiver also provide information about any history of swallowing disorders. Specific signs and symptoms, and modifications in behaviors relevant to mealtime are noted, as are changes in food intake and weight loss. The current nutritional sources are recorded, including the length of time the patient has been NPO (from the Latin term, *nil per os*), or not eating by mouth, if applicable. The therapist also documents any cultural and religious dietary preferences and practices. Information regarding respiratory status is gathered from the hospital chart and staff, including the presence of a tracheostomy and/or mechanical ventilation, and the level of independence with secretion management.

Assessment of Cognitive, Perceptual, and Physical Abilities

Important cognitive and perceptual considerations include the level of alertness and arousal, orientation, ability to attend to a **feeding** session or meal, ability to follow multistep commands, and any visual deficits or unilateral neglect. The clinician notes the patient's insight into his or her dysphagia and observes head, neck, trunk, and limb control and endurance for being out of bed at mealtimes. The ability to self-position and self-feed, and the need for or use of adaptive eating equipment are assessed.

Assessment of Oral and Pharyngeal Abilities

Once direct physical assessment begins, the clinician must observe universal precautions to prevent exposure to pathogens for both the clinician and the patient. The occupational therapist then assesses aspects of oral and pharyngeal control, as noted in the subsequent section. A stethoscope may be used to listen for pooling of fluid above the level of the vocal cords because pooled liquids resonate during breathing.³⁵ The therapist rates the patient's hunger and level of enthusiasm for a snack or meal.

Lip Closure

- The function of lip closure is to contain solid and liquid boluses in the mouth and to help collect the food into a bolus for swallowing.
- Signs of dysfunction include food loss through the mouth, possibly only on one side.
- Causes of impairment include oral motor weakness or muscle tone impairment.
- The impact on eating function includes the inability to keep the bolus in the mouth and initiate a swallow because pressure cannot be generated in the oral pharynx to initiate posterior bolus movement or a swallow.
- Lip closure is assessed by asking the patient to hold the lips closed over a tongue depressor. It is also assessed by observing bolus loss from the mouth during a food trial.

Bolus Containment within the Cheeks

- The cheeks function to hold the bolus within the oral cavity.
- Signs of dysfunction include food particles pocketing in the cheek or between the cheek and the teeth after the swallow.
- Causes of impairment include oral motor weakness or muscle tone impairment.
- The impact on eating function may include incomplete swallowing of the bolus, food remaining in mouth that could be aspirated later (food or secretions enter the larynx below the level of the vocal cords), and/or inability to form a cohesive bolus with more solid foods.
- To assess, observe lack of movement on the affected side or sides. Assess after the swallow by having the patient open the mouth and examine with a flashlight. Run your gloved finger inside the cheek to check for food pocketing.

Jaw Closure/Chewing

- The function of mastication (of solids) is to break down food to form a bolus.
- Signs of dysfunction include “chomping” (nonrotary chewing), or slowed or absent chewing.
- Causes of impairment include decreased muscle tone or jaw strength, neurological injury, or trauma.
- The impact of dysfunction includes the inability to break down food and form a bolus.
- To assess, have the patient open the mouth and examine with a flashlight. Large particle food remnants may be observed.

Tongue Motions

- The tongue moves food in the mouth to form a bolus and begins propulsion of the bolus to the pharynx.
- Signs of dysfunction include the inability to move the bolus side to side for chewing on either molar surface, lack of bolus formation, and/or the inability to form a bolus or propel the bolus posteriorly.
- Causes of impairment include decreased muscle tone or strength, neurological injury, or trauma.
- The impact of dysfunction is the inability to control a liquid bolus or move a bolus posteriorly.
- Assess by asking the patient to open the mouth and protrude or move the tongue from side to side.

- Dysfunction is indicated by tongue lateralization to only one side (which indicates weakness on the opposite side) and an inability to oppose the tip of the tongue outside the mouth to the left, right, superiorly, and inferiorly.

Soft Palate Function

- The function of the soft palate is to cover the nasopharynx during swallowing.
- Signs of dysfunction include nasal regurgitation (food enters the nasal cavity).
- Causes of dysfunction include decreased or altered muscle tone due to neurological injury.
- The impact of dysfunction is nasal regurgitation during swallowing, which may be associated with nasal vocal quality and aspiration.
- Assess by having the patient open the mouth, push the tongue down gently so that the uvula and soft palate are visualized, and examine uvula elevation when the patient phonates “ah.” The uvula may not elevate, or elevation may be asymmetrical. Soft palate function is most accurately visualized on **modified barium swallow (MBS)**.

Gag Reflex

- The presence of the gag reflex indicates sensitivity in the pharynx, which helps to protect the airway if food is misdirected there.
- Signs of dysfunction may be laryngeal penetration or aspiration, detectable on MBS.
- Causes of dysfunction include neurological injury or trauma from surgery.
- The impact of dysfunction is difficulty protecting the airway and lack of coughing if airway protection is challenged.
- Assess by a tongue depressor. Carefully stroke the back of the soft palate or posterior pharynx and then watch for throat clearing or cough.

Vocal Quality

- Normal vocal quality suggests good vocal cord strength, which is important as the vocal cords close during the swallow for airway protection.
- Signs of dysfunction include wet or hoarse voice or absence of voice.
- Causes of dysfunction include neurological injury, trauma, or the presence of a tracheostomy.
- The impact of dysfunction can include decreased airway protection during or in between swallows, and increased risk of laryngeal penetration or aspiration.
- Assess by listening to the quality of the patient’s voice. If wet or wet hoarse, there may be limited vocal cord ability to close during the swallow.

Volitional Cough

- Both volitional and reflexive cough help to protect the airway.
- Signs of dysfunction include lack of volitional cough. Causes of dysfunction include neurological injury, trauma from surgery, and the presence of a tracheostomy.
- The impact of dysfunction includes decreased airway protection, increased risk of laryngeal penetration, or aspiration.
- Assess by asking the patient to cough, or observe lack of cough when the airway appears challenged; may best be evaluated by MBS.

Laryngeal Elevation

- Elevation and slight anterior tipping of the larynx occurs during normal swallowing.
- Signs of dysfunction include lack of upward movement of the larynx during swallowing.
- Causes of dysfunction include neurological injury, trauma, surgery, or the presence of a tracheostomy.
- The impact of dysfunction includes the inability to effect a swallow.

- Laryngeal elevation may be palpated during bedside evaluation and assessed during MBS.

The Feeding Trial

Precautions for the therapist and patient are outlined in Box 19-3.

Box 19-3

Precautions for the Therapist and Patient

The occupational therapist is physically close to the patient during eating and is exposed to oral secretions and respirations. Likewise, the patient is exposed to pathogens on the therapist's clothing and hands and in the therapist's respiratory tract. Universal (also called standard) precautions should be used. The use of gloves is mandatory anytime the therapist touches the face, neck, or oral cavity. Use of a gown and mask may be advised.

Dysphagia patients are prone to difficulty with airway obstruction and aspiration during eating. For the safety of the patient, the swallowing therapist should be trained in suctioning of the airway, the Heimlich maneuver, and cardiopulmonary resuscitation.

Signs and Symptoms of Potential or Actual Aspiration

Although laryngeal penetration or aspiration may be silent, occurring without overt warning signs and symptoms, the following indicates that it may occur or be occurring. If observed during a dysphagia evaluation, these signs or symptoms can indicate that a feeding trial should not be initiated or should be discontinued. Specific items of concern are as follows:

1. The patient cannot remain awake for the clinical evaluation.
2. The oral and/or pharyngeal sensation and motion assessment reveal poor ability to manipulate and contain the bolus.
3. The bolus remains in the mouth, and the patient cannot initiate or complete the oral preparatory stage within a reasonable time.
4. There is excessive coughing or choking before, during, or after swallowing.
5. There is no swallow response once the oral stage is completed.
6. There is a change in voice quality, often wet, or no voice after swallowing.
7. Severe pooling or wetness is heard on auscultation or by the naked ear; secretions are poorly managed.
8. Silent aspiration is suggested by a change in the patient's color and/or respiratory rate, increased congestion on auscultation of the chest, and/or a reduction in oxygen level in the blood as recorded by pulse oximetry.

Interventions that maximize performance can be initiated before the feeding trial begins (see Figs. 19-3 to 19-5). Prior to the feeding trial portion of an evaluation (with snacks or meals), measures must be taken to optimize the patient's swallowing performance. Because these strategies do not involve ingestion of food, they are **indirect therapy** techniques.

Figure 19-3 The therapist uses a half-Nelson position to assist with head and neck control. The therapist can also assist with jaw, cheek, and lip control at the same time.

Figure 19-4 The therapist facilitates auscultation of the swallow using a stethoscope. The therapist may be able to facilitate head position and guide self-feeding while listening to the sounds of the swallow.

Figure 19-5 The therapist palpates the neck during swallowing. The first finger is under the chin, the second finger is at the base of the tongue, the third finger is over the thyroid cartilage, and the fourth finger is at the base of the throat. A very light touch should be used so as not to inhibit motion.

- The patient should be evaluated in a quiet environment to encourage concentration.
- Position the patient upright in a chair to minimize the risk of aspiration. The patient's feet should be supported, and the arms should be free for self-feeding. Patients with pseudobulbar dysphagia may need special attention to seating and positioning before eating and special positioning devices; they may need assistance to maintain head and neck alignment and facilitation to stimulate oral and pharyngeal motions prior to and during eating (see Fig. 19-3).
- Oral hygiene activities should be completed before the trial because this stimulates sensation and range of motion of oral structures.
- Present a simplified visual array of food and utensils for the patient with visual neglect and/or other visual deficits. "Anchors," colorful cues to call attention to the side of the plate, are helpful for patients with neglect.
- Present appetizing, culture-specific foods, utensils, and tableware.
- Provide adaptive equipment and/or use hand-over-hand guidance to facilitate self-feeding.
- Provide simple explanations and one-step verbal directions if necessary.
- If the patient eats too quickly or is confused by multiple food choices, present one food at a time.
- Use small-bowled utensils and verbal or manual assistance to load just a teaspoon-sized bolus. Pinch the straw to limit the amount of liquid consumed or use a covered cup with a small opening.

The safest food textures are chosen for the trial. Easy-to-manage foods and thick fluids are attempted first, especially if the patient has been NPO and/or has a diagnosis or clinical picture that suggests a high risk of aspiration. During the oral stage, the clinician observes bolus containment, formation, propulsion, and mastication. During the pharyngeal stage, the clinician assesses laryngeal elevation, voice quality after swallow, repetitive swallows, and cough reflex. The therapist should observe for signs and symptoms of laryngeal penetration

or aspiration, especially during the first feeding trial (see Fig. 19-3). The evaluation concludes with a summary, recommendations, and plan.¹⁶

Specific techniques are helpful during the feeding trial. Auscultation (listening) to the swallow with a stethoscope held lateral to the larynx (Fig. 19-4) can reveal the efficiency and safety of the oral and pharyngeal stages.³⁵ Gentle palpation of the neck (Fig. 19-5) during the swallow reveals symmetry, strength, and speed of oral pharyngeal movement and may be done simultaneously with auscultation. If the patient can self-feed, palpation and auscultation may be performed at the same time. If the patient needs help to self-feed, auscultation and guiding with hand-to-mouth efforts may be done together.

Recommendations and Plan

Once the clinical evaluation is complete, recommendations and a plan are formulated. Recommendations may include (1) whether eating by mouth is advisable, (2) whether an instrumental evaluation is advised, (3) whether a nutritional consultation with a dietitian is needed, (4) recommended diet type, (5) mealtime seating and positioning, (6) mealtime supervision, (7) adaptive equipment, and (8) type and amount of assistance. Evaluation of the patient is ongoing, and with additional information from clinical observations, instrumental evaluations, and input from other dysphagia team members, the treatment plan and goals change.

Instrumental Evaluation

Clinical assessment accompanies instrumental evaluation, which uses imaging and diagnostic studies to provide critical information about the unseen parts of the oral, pharyngeal, and esophageal stages of swallowing. Various types of instrumental evaluations for dysphagia include the following:

- **Electromyography.** Electrodes are placed either into the muscle via a small needle or on the skin over a muscle to record contractions of the muscle. Surface electrodes have been used to assess aspects of oral bolus management in neurological dysphagia patients and pharyngeal, laryngeal, and esophageal activity.³⁶
- **Fiberoptic endoscopic evaluation of swallowing.** A fiberoptic laryngoscope, a narrow flexible tube with a small camera on its tip, is introduced through the nose into the nasopharynx, where structures including the palate, pharynx, and larynx are viewed for assessment of anatomy and movement. Food is administered in different consistencies to observe posterior oral and pharyngeal function and airway protection during eating.
- **Manometry.** A catheter with transducers to measure pressure is introduced into the esophagus. The force, timing, and sequence of the esophageal contractions are measured.
- **Scintigraphy.** A radioactive isotope is mixed with food. As the bolus is swallowed, a gamma camera tracks the radioactive particles. This test measures the speed of bolus transit and can accurately measure the amount of bolus that is aspirated.
- **Ultrasonography.** An ultrasound transducer held under the chin produces images of oral and pharyngeal stages of swallow, revealing the mobility of structures and boluses swallowed.
- **Modified barium swallow.** The patient is seated between a movable camera and a fluorescent screen. Radiographic images of oral, pharyngeal, and esophageal structures are delivered to a screen from the camera as barium or barium-impregnated fluids and foods are swallowed. The images are recorded on DVD. Figure 19-6 illustrates a videofluoroscopic image of the oral, pharyngeal, and upper esophageal structures. Swallowing pathology and the effectiveness of compensatory swallowing techniques and positions can be observed. The patient may be positioned in a lateral and/or anteroposterior position to view structure and function from both perspectives. MBSs are often repeated to assess progress. A swallowing therapist is usually present to ensure that the test reproduces compensatory maneuvers and food textures being used and to ensure that it mimics real eating as accurately as possible. In some instances, the therapist may perform the MBS. Occupational therapists assisting with or performing MBS must be

expert swallowing clinicians; they must be fully trained in use of the equipment and procedures used in videofluoroscopy.

Figure 19-6 A videofluoroscopic image of the oral, pharyngeal, and esophageal structures. (Image courtesy of Bette Pomerleau, MS, SLP, and Ray Autiello, LPN, RT, of Universal Mobile Services, Haverhill, MA.)

These evaluations are usually performed by a radiologist, often together with the occupational therapist. Aspiration of food or fluid may be silent.³⁷ Imaging studies, such as MBS (see Fig. 19-6) and **fiberoptic endoscopic evaluation of swallowing (FEES)**, are needed to identify aspiration. These procedures, however, may not identify aspiration in all instances because client skills can change and the testing situation in the radiology suite may not reliably approximate an actual eating situation. Although not always able to reliably identify aspiration, these procedures do provide important information about the quality of the swallow and the efficacy of compensatory therapy techniques used during swallowing.

Conceptual Foundations Underlying Interventions for Swallowing and Eating Impairment

The intervention approach for patients with dysphagia depends on the prognosis of their illness or condition.

Remedial and Compensatory Dysphagia Therapy

Remedial, also referred to as rehabilitative treatment, focuses on restoring a more normal level of swallowing function. Potential for partial or full recovery is anticipated when goals are strictly remedial. For example, a remedial approach may be used with an acute stroke patient for whom complete or near-complete recovery is anticipated. One example is surface electromyography that provides patients with improved awareness of swallowing function, providing for better swallowing. This intervention has been shown to be useful in populations with stroke³⁸ and nonstroke disorders.³⁹ VitalStim is a specially designed

neuromuscular stimulation unit that facilitates contraction of the muscles used in swallowing, by placing surface electrodes on the neck (see Fig. 19-7).

Figure 19-7 Instrumental intervention: VitalStim. (© 2018 DJO, LLC VitalStim is a registered trademark of DJO, LLC.)

Compensatory treatment circumvents impairments with the use of alternative strategies and techniques. These techniques are used when full recovery is not anticipated, for example, for a patient with advancing Parkinson disease. Compensatory techniques may also be used to enable a safe, functional swallow prior to recovery of normal swallowing, for example, with a patient with acute pneumonia. Thus, these approaches may be used in tandem. Goals may be remedial and then change to compensatory once a plateau in function or relatively normal function is reached.

Indirect and Direct Therapy

Another consideration is the type of therapeutic techniques used. Indirect therapy addresses the prerequisite abilities or the capacity to swallow without ingestion of food or liquid. Patients who are at high risk for aspiration often begin with indirect therapy only. Indirect therapy can include range of motion, strengthening, and coordination exercises for weak or hypotonic oral and pharyngeal musculature; strengthening of pharyngeal and laryngeal structures; techniques to reduce or stimulate sensitivity of oral musculature; and techniques to improve the pharyngeal swallowing response. Indirect therapy also involves increasing the patient's level of arousal to implement treatment and manipulating the environment to optimize behaviors that affect swallowing.

Direct therapy rehabilitates prerequisite abilities or the capacity to swallow during therapeutic snacks or meals. This involves exercises and/or the use of compensatory swallowing maneuvers that include ingestion of food. Indirect therapy may continue once direct therapy has begun. An individualized treatment plan usually includes a selection of direct and indirect techniques. The complexity of interventions depends on the ability of the patient and/or caregiver to process complex information. Treatment techniques may be evaluated by MBS or FEES to assess their efficacy, especially in the pharyngeal stage where the effects of techniques are unseen. Although not discussed in depth here, optimizing self-feeding skills is an important goal to address together with swallowing goals. Although not yet supported in the literature, the sensory inputs and motor patterns used for self-feeding are likely related to those used in the partly voluntary swallow, and facilitating both skills enhances each.

Compensatory and Remedial Interventions for Specific Eating and Swallowing Problems

Specific Eating and Swallowing Problems

Swallowing Apraxia

Swallowing apraxia is difficulty or inability to swallow in the absence of motor or sensory deficits.

- **Remedial intervention:** Provide a natural mealtime setting, enhance self-feeding skills to facilitate oral skills, and provide a variety of boluses to stimulate oral movements.

Weakness of Cheeks and Lips

- **Compensatory intervention:** Provide soft solids and thick fluids for easy oral manipulation. Place food at the back and stronger side of the mouth. Tilt the head toward the stronger side. Massage the cheek to prevent pocketing. Hold the lips closed. Inspect the mouth after meals to check for residue.
- **Remedial intervention:** Use tapping, vibration, and quick stretches to stimulate movement. Provide range of motion and stretching exercises, progressing to resistive sucking and blowing exercises.

Abnormal Oral Reflexes

Oral reflexes are reflexive motions that are seen in infants and extinguished with development. They may reappear in adults with neurological injury. Rooting, biting, tongue thrust, sucking, and a hyperactive gag response are all reflexes that may be observed.

- **Compensatory intervention:** Avoid stimuli that provoke rooting, biting, tongue thrusting, sucking, or hyperactive gag reflexes. Elicit movements that are antagonistic to the undesirable reflex (e.g., encourage mouth opening to weaken the bite reflex). Seat the patient with the body well supported to minimize proximal extensor tone, which can provoke abnormal distal movements and reflexes.

Facial and Intraoral Hypersensitivity

Hypersensitivity to normal touch on the face and in the mouth can occur following neurological injury.

- **Remedial intervention:** Provide systematic desensitization to the face and intraoral area. If sensory defensiveness affects the whole body, a program of graded sensory stimulation to the body should precede stimulation to the oral area, followed by careful introduction of food. Use systematic desensitization with guided imagery to reduce muscle tone and anxiety regarding eating and mouth sensitivity.

Oral Hyposensitivity

Oral hyposensitivity can occur following neurological injury and involves reduced sensation of the oral cavity to contact from a bolus or liquid.

- **Compensatory intervention:** Place the bolus on areas of the mouth that are more sensitive. Use warmer or colder boluses, flavorful food, and heavy or viscous boluses to stimulate sensation.^{36,40}
- **Remedial and compensatory intervention:** Use a sensory diet that provides heightened tactile and proprioceptive input to the intraoral structures to stimulate sensation and movement before and during a meal or snack.

Reduced Lingual Control

Reduced lingual (tongue) control occurs when neurological injury has affected coordinated tongue motions required for speech and swallowing.

- **Compensatory intervention:** Introduce a diet requiring little oral manipulation, including soft solids and thick fluids. Use a posterior and/or lateral placement of food on the stronger side. Inspect the mouth for residue after meals.
- **Remedial intervention:** Introduce active and passive tongue range of motion exercises and activities. Provide quick stretches to the tongue with a tongue depressor or gloved fingers. Provide articulation and tongue strengthening exercises.

Slow Oral Transit Time

Slow oral transit time is slowed oral propulsion and manipulation of the bolus due to weakness or neurological injury.

- **Compensatory intervention:** Use cold boluses to hasten oral transit time (be cautious that they do not melt into a difficult-to-manage liquid). Sour boluses, such as those infused with lemon juice, can speed oral manipulation.

Delayed Swallow

A delayed swallow occurs when the oral and pharyngeal stages of the swallow do not occur in a timely way. As noted earlier in the chapter, the normal oral phase takes 1 to 1.5 seconds and the pharyngeal phase takes less than 1 second.

- **Compensatory intervention:** Use highly flavored boluses to reduce swallowing delays.³⁶ Use chin tuck to enhance airway protection.⁴¹ Increase bolus volume and viscosity to reduce pharyngeal delay time.
- **Remedial intervention:** Try thermal-tactile stimulation: stroke the anterior faucial arches with an iced laryngeal mirror (Fig. 19-8), which hastens initiation and overall speed of swallowing immediately after application.⁴²

Figure 19-8 Thermal-tactile stimulation of swallow. An iced laryngeal mirror is used to stroke the faucial arches to elicit or improve strength of the swallowing reflex.

Reduced Laryngeal Elevation

Laryngeal elevation is the (normal) elevation of the larynx that occurs during the swallow; it accompanies a slight forward tipping of the larynx.

- **Compensatory intervention:** Use the Mendelsohn maneuver to prolong elevation of the larynx⁴³ or a chin tuck to elevate the larynx.⁴¹ Use a supraglottic or super-supraglottic swallow to clear or minimize any material in airway. These swallow procedures are used by patients to close the larynx during the swallow to prevent food and liquids from entering the lungs.
- **Remedial intervention:** Use Shaker exercises (a program of neck flexion exercises) to strengthen suprahyoid musculature and prolong opening of the UES.⁴¹

Reduced Laryngeal Closure

During the swallow, the larynx (which includes the vocal cords) closes to protect the airway from penetration by food or liquid.

- **Compensatory intervention:** Use a supraglottic or super-supraglottic swallow to enhance airway protection, or use a chin tuck to elevate and close off the larynx.
- **Remedial intervention:** Introduce vocal cord adduction exercises.

Tracheostomy

Occlusion of a tracheostomy tube minimizes aspiration and improves swallow biomechanics.⁴⁴ Use of a one-way speaking valve, usually a Passy-Muir valve, can decrease frequency of aspiration.⁴⁵ Dysphagia often improves with decannulation (removal of tracheostomy).⁴⁶

Compensatory Swallowing Maneuvers

Compensatory swallowing maneuvers use volitional movement to improve the quality of the swallow. Most of them are complex and require the patient to possess a good attention span and the ability to follow complex directions.

The occupational therapist typically must try different interventions, whether remedial or compensatory, preferably with the assistance of MBS, to assess which techniques work most effectively. Clinicians should work under the guidance of an experienced occupational therapist when using a technique that is new to them.

Chin Tuck

This maneuver moves the base of the tongue back and narrows the opening to the larynx, thus protecting the airway.⁴⁷ Have the patient tuck the chin down toward the chest while swallowing.

Effortful Swallow

An effortful swallow helps to elevate the base of the tongue during swallowing.⁴⁸ The patient squeezes hard with the throat muscles while swallowing.

Mendelsohn Maneuver

This technique prolongs opening of the UES.⁴³ The patient pushes the tongue into the roof of mouth and attempts to keep the Adam's apple up while swallowing.

Head/Neck Rotation

Head/neck rotation closes the weaker side of the pharynx and uses the stronger intact musculature in cases of unilateral weakness of the pharynx and/or vocal folds. Head/neck rotation also improves the quality of the swallow.⁴⁹ The patient turns the head to the weaker side while swallowing.

Supraglottic Swallow

Named for use with supraglottic laryngectomy patients, the supraglottic swallow compensates for weak vocal cord closure and reduces penetration of food into the larynx during swallowing by closing the vocal cords.⁴⁹ The patient swallows while holding the breath and then coughs. The volitional cough that is done after swallowing helps to ensure that anything in the airway returns to the pharynx to be reswallowed.

Super-Supraglottic Swallow

This technique reduces penetration of food into the larynx during swallowing by narrowing the opening to the airway.⁴⁹ The patient holds the breath and bears down. The patient should be instructed to maintain the breath-hold and bearing down while swallowing. Afterward, the patient volitionally coughs.

Progression of Diet with Swallowing Therapy

The occupational therapist typically must try different interventions, whether remedial or compensatory, preferably with the assistance of MBS, to assess which techniques work most effectively. Clinicians should work under the guidance of an experienced occupational therapist when using a technique that is new to them.

As indirect therapy begins, some patients may receive all nutrition, hydration, and medication via a nonoral source, such as intravenous or gastrostomy tube feedings. As the patient recovers the ability to swallow without laryngeal penetration or aspiration, direct therapy with the therapist present begins during snacks and progresses to meals. As improvement continues and the patient learns compensatory techniques, he or she may

progress to eating under the supervision of nursing personnel and trained significant others and then progress to eating independently. Calorie counts are initiated by the dietitian to assess the adequacy of oral intake. Once food intake improves and calories are consistently sufficient, nonoral feeding sources may be used only for hydration and/or medication. Finally, as the patient improves and fluids and medications are safely ingested by mouth, the use of nonoral feeding sources can be discontinued. Diet textures are upgraded as skills develop. Depending on the diagnosis and potential for recovery, patients may level off at any point in the described progression.

Dysphagia Diets

Dysphagia diets are designed to provide stepwise gradation of food and fluid textures that are matched to the patient's improving oral and pharyngeal skills. A diet of mechanical soft foods (foods that have been chopped or ground) that form a moist, cohesive bolus, and thickened fluids may reduce the incidence of aspiration compared with pureed foods and thin fluids.³⁶ Specific textures and stronger flavors can stimulate optimal oral and pharyngeal motion; for example, stronger and spicy flavors may stimulate swallowing responses.^{36,40} Patients may have strong preferences; those with dementias may prefer sweet flavors and reject foods that require chewing. Dysphagia diets for most patients follow this general progression:

1. Thick purees, such as pudding and applesauce
2. Very soft moist chewables, such as soft cooked vegetables, fruits, and soft pastas
3. Drier chewables, such as cookies and breads
4. Foods requiring biting, firmer chewables such as meats, and mixed textures like cereals and milk or pills and water.

The progression of fluids advances as follows:

1. No fluids at all
2. Honey-thick fluids
3. Nectar-thick fluids
4. Thin, flavored fluids
5. Water

Fluids are easily thickened with commercial thickeners, which can be mixed with hot or cold beverages. Unthickened or "free" water is sometimes provided to dysphagia clients on the assumption that consuming small amounts of water creates little risk of pneumonia and can improve hydration.⁵⁰ This may best be assessed by FEES as opposed to MBS because the latter uses barium or barium-infused food or liquid that may change the swallowing ability.

Because bacterial pathogens in the mouth may be aspirated into the lungs, meticulous oral hygiene before and after meals is needed with any oral intake to reduce the risk of pneumonia.⁵¹ It is important that all caregivers know and understand an individual patient's diet so that no foods or fluids are provided that are contraindicated.

Patient and Caregiver Training

Although the occupational therapist alone may carry out treatment, the plan for intervention also includes education of the patient, nursing staff, and caregivers. The patient and family should understand the cause and prognosis of the patient's dysphagia and the importance of strategies to be carried out at home. It may be helpful to have the patient view the MBS or FEES to fully comprehend his or her condition and the benefits of compensatory techniques. Mealtime seating, adaptive equipment, and the type and amount of assistance must be taught to caregivers. Meal preparation practice and community outings can reinforce diet modifications, enhance patient and family education in various settings, and motivate the patient.

As the emphasis on evidence-based practice and rehabilitation advances, clinicians must keep abreast of new knowledge. The author encourages the reader to explore further learning and expertise in dysphagia care. Early discharge from acute care and rehabilitation hospitals, and minimized staffing in health care facilities, create situations in which competence in dysphagia intervention has become a mandatory skill for occupational therapists. Occupational therapists, with their background in the many abilities and capacities that influence eating and swallowing, make logical primary swallowing therapists.

Acknowledgments

The author thanks Janice P. Alden and Cheryl A. McCarthy for their assistance with photographs used in this chapter. Thanks also to Bette Pomerleau, MS, SLP, and Ray Autiello, LPN, RT, formerly of Universal Mobile Services in Haverhill, Massachusetts, for their assistance with the modified barium swallow image reproduced in this chapter.

CASE STUDY

Patient Information

Dominick is a 73-year-old Italian American male with a left hemispheric cerebrovascular accident (CVA). He was admitted to an acute care hospital with aphasia and right upper extremity weakness, with a prior history of hypertension, transient ischemic attacks (TIAs) with aphasia, and chronic heart failure.

Assessment Process and Results

A dysphagia evaluation was performed using a standardized dysphagia assessment. The evaluation revealed that Dominick had hypotonicity and reduced control of his lips, cheek, and tongue on the right side. Decreased airway protection skills were evidenced by his inability to phonate because of vocal cord weakness, inability to cough volitionally, and reduced laryngeal elevation as palpated during swallowing. He was not aphasic. Dominick was able to swallow foods from a beginning level dysphagia diet, including foods with soft, moist textures, such as pudding and applesauce, with mild food spillage out of the right side of his mouth because of poor lip control, delayed formation and propulsion of the bolus, and delayed initiation of the swallow. He had difficulty grasping utensils and cups because of hypotonicity of his dominant right hand.

Occupational Therapy Problem List

- Dominick showed hypotonicity of oral, pharyngeal, and laryngeal structures, resulting in a delay in and reduced coordination of bolus control both in the mouth and in propelling the bolus posteriorly to initiate a swallow.
- He also demonstrated a delay in initiation of the swallow.
- His reduced upper extremity control resulted in awkward use of his dominant arm to self-feed.

Occupational Therapy Goal List

- Dominick will tolerate a more advanced dysphagia diet, adding soft chewables such as cooked fruit and soft pasta.
- Dominick will tolerate these textures without clinical signs of aspiration.
- Dominick will be independent in vocal cord adduction exercises.
- Dominick will support the right side of his lower lip and massage the right cheek during the oral preparatory stage to prevent food spillage and pocketing in his right cheek.
- Dominick will feed himself with his right hand with built-up utensils and an adapted cup while weight bearing on his right elbow.

Intervention

Dominick was seen daily for occupational therapy during 1 week as a hospital inpatient. Constant supervision at mealtime was accomplished, and all meals and snacks took place with him seated upright in a chair. Occupational therapy intervention addressed exercises and positioning to enhance tone and control of oral motor skills, laryngeal exercises to strengthen his vocal cords and improve laryngeal elevation, and facilitation of tone and movement in his hypotonic right upper extremity to improve self-feeding skills. Dominick and his caregiver were educated and given handouts on the nature of his dysphagia, exercises, and mealtime procedures and precautions.

Dominick was discharged from the hospital to home in the company of his wife. He and his wife were taught to thicken fluids with commercial thickeners at home. As his vocal cord strength returned, his volitional cough became stronger, and he gradually became able to speak in a loud whisper; vocal cord strengthening exercises continued. Dominick was able to discontinue use of external lip control strategies as oral motor control returned. He continued use of built-up utensils and weight bearing at the elbow while self-feeding. He continued with outpatient occupational therapy and speech-language pathology to address voice issues for 4 more weeks.

Most Commonly Used Standardized Assessments for Dysphagia

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Mann Assessment of Swallowing Ability ⁵²	Evaluation of swallowing function	15–20 minutes	Validity was tested to determine 71% sensitivity.	Inter-rater reliability testing determined 82% for agreement on the presence of dysphagia; 75% for the presence of aspiration.	Accuracy of diagnosing dysphagia 72%	Standardized in hospital and inpatient rehabilitation setting, standardized for CVA patients
Dysphagia Outcome and Severity Scale ⁵³	Rating of dysphagia severity	5–10 minutes	Not tested	Inter-rater 90% and intra-rater 93%	Not tested	Parameters are not defined; thus, clinician's expertise is needed; it can be completed regardless of patient's cognition and language status; an MBS must be completed for scoring.
Dysphagia Evaluation Protocol ⁵⁴	Evaluation for dysphagia in acute and rehabilitation patients with acute and chronic dysphagia	30–45 minutes including feeding trial	Determined by experts to possess face validity	Inter-rater 89%; overall agreement on test items; Intra-rater 93%	Accuracy of predicting aspiration, penetration, or pooling, 60%	Comprehensive evaluation that helps to development a comprehensive eating and swallowing treatment plan

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
McGill Ingestive Skills Assessment ⁵⁵	Evaluation of feeding and swallowing skills in the elderly with various conditions, not including trauma or head and neck cancer	The length of a meal: 20–30 minutes	Construct validity determined in comparison with two ADL scales (The Functional Independence Measure and the Modified Mini-Mental State Exam) at 0.45 and 0.25, respectively, $p < 0.05$	Inter-rater reliability > 0.80 for most subscales	Known groups validity determined for those with dentures at 0.01 with $p < 0.05$	For use in tertiary care nursing facilities in those with neurogenic dysphagia

Best Evidence for Dysphagia Interventions Used in Occupational Therapy

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Immediate effects of thermal-tactile stimulation on timing of swallow in idiopathic Parkinson disease ⁵⁶	Effect of thermal-tactile stimulation as assessed prestimulation and poststimulation by videofluoroscopy	Thirteen patients with Parkinson disease and dysphagia	Thermal-tactile stimulation applied to faucial pillars in pharynx	Pre–post nonexperimental design Level III	Median pharyngeal transit time for swallowing both fluid and paste textures was improved. Oral transit time was unaffected with both textures.	Pharyngeal transit time for fluids: $p < 0.004$; for paste: $p < 0.01$
A randomized study of three interventions for aspiration of thin liquids in patients with dementia or Parkinson disease ⁵⁷	Comparison of three interventions for aspiration in patients with dementia and/or Parkinson disease: chin-down posture, nectar-thickened liquids, and honey-thickened liquids	711 patients who aspirated on thin liquids assessed with videofluoroscopy	1. Chin-down posture 2. Nectar-thickened liquids 3. Honey-thickened liquids	Randomized controlled study Level I	Honey-thickened fluids were more effective than nectar-thickened fluids to eliminate aspiration, and both were more effective than chin-down position with thin fluids.	1. Chin down vs. nectar thickened, $p < 0.001$ 2. Chin down vs. honey thickened, $p < 0.0001$ 3. Nectar thickened vs. honey thickened, $p < 0.0001$

Chapter 20

Cranial Nerve Assessment

Sharon A. Gutman and Dawn M. Nilsen

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the 12 paired cranial nerves with regard to function, neuroanatomical location, and motor/sensory transmission.
2. Demonstrate appropriate screening procedures to assess the function of all 12 cranial nerves.
3. Predict distinct lesion symptoms based on specific cranial nerve damage.
4. Describe how specific cranial nerve damage will likely impair patient function in daily life activities.
5. Correctly interpret the results of a cranial nerve screening examination.

CHAPTER OUTLINE

Cranial Nerve Function and Impairment in Daily Occupation
Neurological and Physiological Basis of Cranial Nerve Function
Cranial Nerve Screening Procedures
Case Study

TERMINOLOGY

- Ageusia:** a sensory disorder involving loss of taste; may result from olfactory, facial, or glossopharyngeal nerve damage.
- Anesthesia:** a sensory disorder involving insensitivity to all sensation; may result from trigeminal nerve damage.
- Anosmia:** a sensory disorder involving loss of smell; may result from olfactory nerve damage.
- Bitemporal hemianopia:** an ocular condition in which vision has been lost in the temporal field halves of both eyes; results from optic chiasm damage.
- Contralateral homonymous hemianopia:** an ocular condition in which vision has been lost in the same field halves of both eyes; results from optic tract lesions.
- Dysarthria:** a speech disorder in which words are slurred; may result from glossopharyngeal, vagus, and hypoglossal nerve impairment.
- Dysphagia:** an eating disorder involving difficulty manipulating and transporting solids/liquids from the oral cavity to the pharynx; can result from damage to the following cranial nerves: trigeminal, facial, glossopharyngeal, vagus, accessory, and hypoglossal nerves.
- Dysphonia:** a speech disorder involving decreased vocal volume or hoarseness; may result from glossopharyngeal and vagus nerve impairment.
- Dyspnea:** a respiratory disorder involving difficulty breathing; may result from glossopharyngeal and vagus nerve impairment (in this case, dyspnea results from rapid heartbeat causing shortness of breath).
- Hemianopia:** an ocular condition in which vision has been lost in one-half of a visual field; results from damage to the optic tract.

Homonymous quadrantanopia: an ocular condition in which vision has been lost in a specific visual field quadrant; results from optic pathway lesions.

Near triad: an extraoculomotor response in which three ocular changes occur that allow a visual target to be brought into focus: convergence, lens accommodation, and pupillary constriction.

Nystagmus: an ocular condition in which both eyeballs involuntarily oscillate when moved to a visual field extreme; may result from impairment of the vestibulocochlear nerve.

Strabismus: an ocular condition involving deviation of one eyeball as it sits in the orbital socket; may result from extraocular cranial nerve impairment.

Cranial Nerve Function and Impairment in Daily Occupation

The cranial nerves (CNs) are 12 pairs of peripheral nerves located in or near the brainstem and carry sensory and motor information to and from the structures of the head, face, and neck. Five CNs (olfactory, optic, facial, vestibulocochlear, and glossopharyngeal nerves) are responsible for the special sense functions of vision, audition (hearing), olfaction (smell), and gustation (taste).¹⁻⁴ Damage to these CNs can cause impairment of the special senses associated with them. Unilateral blindness, or loss of vision in one eye, can result in a failure to attend to objects in that lost visual field, creating significant safety risks. For example, patients may bump into furniture or walls, trip over items on the floor, fail to identify oncoming traffic while crossing the street, or miss needed items in a handbag such as one's keys. Hearing loss can impair one's ability to identify safety signals in the environment, such as smoke alarms, ambulance sirens, or automobile horns. When smell is lost, patients may fail to identify food burning on a stove or the presence of gas or mold in the home environment. Because of the neuroanatomical organization of the pathways connecting olfaction and gustation, lost smell is commonly accompanied by suppressed taste.⁵ When both smell and taste are compromised, patients may experience decreased appetite (critical in the frail elderly) and are at risk for food poisoning if left to prepare meals independently.¹⁻⁴

The extraocular CNs (oculomotor, trochlear, and abducens nerves) are responsible for eyeball movements up, down, medially, and laterally. When one or more of these nerves are damaged, vision remains but is impacted by **strabismus** (deviation of one eyeball as it sits in the orbital socket), diplopia (double vision), or lost pupillary reflex (pupil constriction in response to light).¹⁻⁴ These conditions can severely impair a patient's safe negotiation of the environment. The presence of a strabismus can impact one's ability to safely traverse steps, curb cuts, and uneven surfaces (sand, gravel, dirt), placing the patient at risk for falls. Patients with diplopia, whose vision is doubled, may become unsafe drivers, unable to determine the true location of other cars and pedestrians. Such patients, who may also fail to correctly grasp objects such as pot handles and drinking glasses, often drop items of daily living, resulting in possible safety incidents. When patients are engaged in hot meal preparation, they are at increased risk for scalds if hot food and drinks are spilled.

The vestibulocochlear nerve mediates equilibrium, or balance. When this CN is damaged, a patient's balance and protective responses become impaired, placing the patient at risk for falls and injury.¹⁻⁴ Environments in which transitional movements are required (negotiating steps, ramps, and curb cuts; getting in and out of a car; getting on and off of a toilet; rising from bed) can pose a fall risk.

Six CNs have roles in swallowing (trigeminal, facial, glossopharyngeal, vagus, accessory, and hypoglossal nerves) and, if impaired, can result in **dysphagia**, choking, and food aspiration. Aspiration of oropharyngeal contents into the lungs can result in

lower respiratory tract infections. In the frail elderly with compromised immunity, such infections can fatally lead to aspiration pneumonia.¹⁻⁴

Neurological and Physiological Basis of Cranial Nerve Function

The 12 paired CNs predominantly originate from the brainstem and exit the brain between the midbrain and the medulla (see Fig. 20-1). Each CN is named and numbered from rostral (toward the head) to caudal (toward the tail or posterior body), and collectively, the CNs are considered to be part of the peripheral nervous system. This means that damage to a CN has the potential to resolve similarly to other peripheral nerve structures. It should be noted, however, that CN cell bodies, or nuclei, are located directly within the brainstem, or within the central nervous system. When CN cell bodies are destroyed as a result of disease or injury, resolution is not possible and the lost CNs function will not be recovered.¹⁻⁴

Figure 20-1 The 12 paired cranial nerves.

When CN impairment occurs, ipsilateral (same side as the lesion) symptoms commonly result because most nerves do not cross midline. As noted earlier, several CNs carry sensory information that mediate the special sense functions of olfaction, vision, audition, and gustation. Several CNs carry somatic motor components that innervate the skeletal muscles of the head and neck. Other CNs carry somatic sensory components that transmit sensory messages between the brain and the skin of the face and head. Some CNs transmit visceral motor and sensory signals (responsible for innervation of cardiac muscle, smooth muscle, and glands located throughout the body) and are considered to be part of the parasympathetic division of the autonomic nervous system (ANS). The ANS is responsible for our vegetative or critical life functions, such as respiration, heart rate, temperature, and blood pressure. The parasympathetic nervous system is the division of the ANS responsible for slowing heart rate, respiration, and metabolism and promoting digestion. Several CNs are mixed nerves that carry combinations of the abovementioned components, allowing them to serve multiple functions.¹⁻⁴

This chapter describes each CN with regard to (1) function, (2) neuroanatomical location, (3) type of sensory and/or motor information transmitted, (4) screening

procedures, and (5) signs indicating dysfunction in daily occupation. The intervention of specific CN impairments is not described in this section but can be found in Chapters 8, 12, 14, 17, and 19, addressing the intervention of visual, sensory, motor, balance, and swallowing disorders.

Cranial Nerve Screening Procedures

Cranial Nerve I: Olfactory Nerve

CN I is a special sensory nerve that mediates olfaction, or smell. The olfactory nerve's sensory receptors are chemoreceptors located in the olfactory epithelium in close proximity to the nasal mucosa. Chemoreceptors in the nose convey olfactory signal to the olfactory bulb located in the inferior frontal lobes. Olfactory messages then travel to the areas of the brain concerned with the processing, interpretation, integration, and storage of olfactory information. For example, olfactory messages travel to the hippocampal formation in the temporal lobes, a structure responsible for long-term memory storage, including memories associated with scent and odor. The storage of odor memories in the hippocampus accounts for why specific scents can elicit long-term memories more efficiently than any other sense. Olfactory messages are then sent to the hypothalamus, thalamus, and, finally, to the orbitofrontal cortex, where they are interpreted and integrated with gustatory information. This is why lesions of the olfactory nerve can impact taste sensation in addition to smell.⁵⁻⁷

If an olfactory nerve lesion is unilateral—in other words, if only one olfactory nerve is impaired and the other is preserved—no symptoms will be observed because the preserved nerve will compensate for the one that is lost. Bilateral lesions—lesions that obliterate the function of both olfactory nerves—result in **anosmia**, or loss of smell. Anosmia commonly occurs as a result of traumatic brain injury. When patients present with loss of smell, **ageusia** (loss of taste) occurs as well.⁵⁻⁸

Screening Procedures

 Olfactory nerve function is assessed by testing the patient's sense of smell using the screening procedures outlined as follows (see Fig. 20-2 and Video 20-1)^{6,7,9}:

Figure 20-2 Olfactory nerve screening.

- The patient should be seated with vision occluded.
- Each olfactory nerve should be screened separately by presenting scents to one nostril at a time.
- Ask the patient to block one nostril; the therapist should screen the opposite nostril by presenting one odor stimulus at a time.

- Use four scents that are familiar to the patient (peppermint, cinnamon, coffee, and vanilla). Avoid pungent odors (ammonia and acetic acid) that can stimulate nerve endings in the mucosal lining, which is innervated by the trigeminal nerve. Stimulation of the trigeminal nerve may cause patients to believe that they can smell the odor stimulus, thus giving a false-positive result.
- Ask whether the patient smells the odor stimulus. The ability to smell the odor is more important than the actual identification of the specific stimulus.
- Provide the patient with a verbal choice of specific odors if he or she has word-finding difficulties or cannot identify each specific odor, but can smell them.

Assessing Impact on Daily Function

To determine how olfactory nerve impairment may impact daily function, ask the following questions. It is beneficial to have a close family member corroborate the patient's answers, particularly if the patient is elderly with memory problems or has a head injury. If possible, observe the patient in the home environment.

- Do you have difficulty smelling foods cooking on the stove?
- Have you ever burned food (on the stove, in the oven, or in the toaster) because you didn't smell it?
- Have you ever mistakenly eaten spoiled food because you didn't notice through smell or taste that it had perished?
- Do you have any problems tasting your food? Have you experienced a decrease in appetite because food doesn't seem to have a taste anymore?

If possible, the therapist should prepare toast or coffee while the patient is seated nearby but with body turned to prevent visual cues. Ask whether and when the patient can identify the smell of the selected stimulus. Patients who cannot identify the stimulus scent may be at risk for the abovementioned safety incidents and should receive an in-depth evaluation.

Cranial Nerve II: Optic Nerve

CN II is a special sensory nerve responsible for visual acuity, or the accuracy of sight rather than the interpretation of a visual stimulus. The optic nerve mediates the afferent limb of the pupillary light reflex, in which the pupil constricts when exposed to direct light. When photoreceptors (rods and cones) of the retina are stimulated by light, they send visual information through the optic nerves to the optic chiasm. The optic chiasm is the point at which some optic fibers cross over to the opposite side, whereas others remain uncrossed. These crossed and uncrossed fibers then exit the chiasm, forming the optic tracts. Visual messages travel from the optic tracts to several locations, including the thalamus (a primary relay center for visual information), hypothalamus (involved in circadian rhythm regulation), and midbrain (responsible for visual reflexes and the unconscious detection of visual information). Visual messages then travel to the occipital lobes for visual detection and interpretation.^{1-4,10,11}

Screening Procedures

Optic nerve function is assessed by screening the patient's visual acuity and visual fields. It should be noted that while therapists perform visual acuity and visual field tests, ophthalmologists perform fundoscopic examinations in which the retina and optic head are inspected. Visual acuity and visual field function are assessed using the screening procedures outlined in the subsequent section.⁹⁻¹¹

Visual Acuity Test (Snellen Eye Chart)

-  The patient should be seated at a distance of 20 feet from the chart (see Fig. 20-3 and Video 20-2).

Figure 20-3 Screening visual acuity: Optic nerve screening.

- First, screen each eye separately (monocular vision). If the patient wears corrective lenses, test the patient with lenses on.
- Then, screen both eyes together (binocular vision). Patients should wear their prescribed corrective lenses.
- Ask the patient to read the top line from left to right.
- Then, instruct the patient to read each successive line below the top line, if possible.
- The number listed beside each letter line indicates the number of feet at which that line can be read by an individual with normal vision. Note the last line for which the patient correctly identified more than 50% of letters.
- Document the patient's score for the tested eye as the distance at which the patient could read the letters (20 feet), over the number listed on the chart next to the last line read (in which the patient could correctly identify more than 50% of letters).
- Record the number of letters missed by the patient in the last line read. For example, a score of 20/40–1 indicates that the patient could read at a distance of 20 feet all but one of the letters in the line that a normally functioning eye can read at 40 feet.
- If the patient scored 20/40 or lower, an ophthalmology referral should be made.

Visual Field Test (Confrontation Testing)

An examination of visual fields provides important information about the functioning of the visual pathway from the optic nerve to the visual cortex; the most common method of visual field testing is called confrontation testing. The eye's visual field encompasses the area of central to peripheral vision when the eye focuses straight ahead. Visual fields are assessed by identifying the point at which patients are first able to detect a visual stimulus along each peripheral perimeter. Visual fields are screened in the vertical and horizontal planes in four quadrants: (1) superior (upper) and (2) inferior (lower) nasal fields, and (3) upper and (4) lower temporal quadrants. When a patient gazes straight ahead, a stimulus positioned directly in front of him or her is considered to be at 0°. A stimulus positioned directly over the patient's head is considered to be at 90°. A stimulus positioned directly in line with the ears and held about 1.5 feet away from the head is also said to be at 90°.^{9–11}

-  The therapist should be positioned in front of the seated patient (see Fig. 20-4 and Video 20-3).

Figure 20-4 Screening visual fields (confrontation): Optic nerve screening.

- Screen one eye at a time.
- Occlude the opposite eye by asking the patient to cover that eye with the palm of the hand or by holding an occluder over the eye.
- Ask the patient to gaze directly ahead at the therapist's nose. Move the visual stimulus in the horizontal plane from the 90° position to the 0° position. Instruct the patient to verbally indicate when he or she first sees the visual stimulus (finger or pen cap).
- Document the horizontal plane position at which the patient first identified vision of the stimulus.
- Repeat these procedures in the vertical plane.

Normal horizontal peripheral vision is 85°; normal peripheral vertical vision is 45°. Therapists should suspect the presence of a visual field deficit if a patient scores more than 5° below these norms. A field deficit may also be indicated if one of the peripheral fields is abnormally small; referral to a specialist for further testing should be made. Visual pathway lesions cause specific types of visual deficits. For example, if a patient reports the presence of a blind spot within a visual field, retinal damage is indicated. Unilateral blindness (loss of vision in one eye, but not the other) suggests an optic nerve lesion. **Hemianopia** is a condition in which vision has been lost in half of a field of one eye. A **contralateral homonymous hemianopia** occurs when vision has been lost in the same field halves of both eyes, indicating a lesion of the optic tract. **Bitemporal hemianopia** is a condition in which vision is lost in the temporal field halves of both eyes and usually results from damage to the optic chiasm. Loss of a specific visual field quadrant is called a **homonymous quadrantanopia** and commonly results from lesions of the optic pathways as they project from the lateral geniculate bodies to the primary visual cortex.⁹⁻¹¹

Assessing Impact on Daily Function

To determine whether visual acuity problems have impacted daily function, provide reading materials (book or magazine) and observe the patient while reading. If the patient squints while reading or attempts to move the reading material closer to or further from the eyes (normal reading material should be held at a distance of ~1.5 feet), visual acuity may be impaired.

- Ask whether the patient can easily identify coins held at arm's length.
- Ask the patient if reading fine print (such as a magazine or phone book) is difficult.

- Ask the patient to demonstrate a fine motor activity (such as threading a needle, tying a fishing pole hook, or texting on a smartphone) to determine whether squinting occurs or if the patient attempts to reposition the object closer to or further from the eyes.

To determine whether and how a visual field deficit has impacted daily function, again observe the patient while reading. If the patient moves the reading material horizontally to maintain its view within his or her visual field, instead of fluidly scanning the lines, a visual field deficit may be indicated.

Allow the patient to participate in a simple cold meal preparation activity, such as making a sandwich. Place all items on a table in a 3-foot span. Observe whether the patient ignores items falling within the range of one particular visual field, or moves the head or body unusually in order to see objects in all visual field ranges. When patients ignore items falling within a visual field, or move the head/body unusually in order to see all objects, a possible field deficit may be indicated.

Ask whether the patient has recently tripped or fallen because he or she didn't see steps or objects on the ground. Ask whether the patient has bumped into furniture or walls while ambulating. Such experiences may indicate possible field deficits.

Cranial Nerve III: Oculomotor Nerve

Three CNs are collectively referred to as the extraoculomotor nerves: CN III, CN IV, and CN VI. CN III consists of both somatic and visceral motor components and mediates eye movements, pupillary constriction, and lens accommodation—all important for the coordination of eye and head movements. The oculomotor nerve originates in the midbrain and exits the superior orbital fissure to reach both somatic and visceral motor targets located in the eye. The somatic motor components of CN III originate in the oculomotor nucleus of the midbrain and ipsilaterally innervate four of the six extraocular muscles: superior rectus (upward and medial eye movements), inferior rectus (downward and medial eye movements), medial rectus (medial eye movements), and inferior oblique (upward and lateral eye movements), as well as the levator palpebrae muscle that lifts the upper eyelid.^{1-4,12}

The visceral motor components of the oculomotor nerve originate in the Edinger-Westphal preganglionic nucleus of the midbrain. Axons of these neurons ipsilaterally innervate the sphincter pupillae and ciliary muscles, which are responsible for pupillary constriction and lens accommodation, respectively.^{1-4,12}

As noted earlier, CN II mediates the afferent limb of the pupillary light reflex, whereas CN III mediates the efferent limb. The pupillary reflex occurs when light is shined into the eye and the pupil receiving the light constricts (referred to as the direct response). At the same time, the pupil of the opposite eye constricts (referred to as the consensual response).^{9,12}

CN III is also involved in the **near triad** or near response. This response involves activation of both somatic and visceral motor components. When gazing from a distant target to a closer one, three ocular changes occur that allow the visual target to be brought into focus. In the first change, referred to as convergence, both eyes move medially (through the somatic motor activation of the medial rectus muscles) to align the eyes with the closer target. Simultaneously, lens curvature increases. This visceral motor response is referred to as lens accommodation and increases the lens' refractive power. Pupillary constriction is the third change (visceral motor) and increases the eyes' field depth.^{9,12}

Screening Procedures

CN III is assessed conjointly with the other extraocular motor nerves (CN IV and CN VI) by examining ocular alignment and range of motion, pupillary light reflex, and convergence.^{9,12}

Ocular Alignment

- The patient should be seated and instructed to gaze straight ahead. Note any abnormalities in ocular alignment:
 - **Esotropia:** Medial or internal strabismus; one eye is inwardly misaligned.¹³
 - **Exotropia:** Lateral or external strabismus; one eye is outwardly misaligned.¹³
 - **Hypertropia:** Vertical strabismus; one eye sits higher than the other.¹³
 - **Hypotropia:** Vertical strabismus; one eye sits lower than the other.¹³
- Dim the lighting and shine a pen light at the bridge of the patient's nose. Note symmetrical corneal reflection. If corneal reflection appears asymmetrical, strabismus is indicated.

Ocular Range of Motion

-  The patient should be seated with the therapist positioned in front (see Fig. 20-5 and Video 20-4).

Figure 20-5 Screening ocular range of motion: Oculomotor nerve screening.

- Test one eye at a time.
- Occlude vision of the eye not being tested by asking the patient to cover the eye with the palm or using an occluder.
- Instruct the patient to maintain the head in a fixed position and visually scan a moving stimulus (finger or pen cap) presented by the therapist.
- Move the visual stimulus slowly in the shape of an H. Note any impairment in ocular range of motion (inability to move the eye up, down, medially, or laterally).

Pupillary Light Reflex: Direct Response

- The patient should be seated and instructed to gaze straight ahead. Note any asymmetry of pupil size.
- Dim the room lighting to increase the patient's pupil size.
- Shine a penlight into one eye for ~2 seconds. Note whether the pupil constricts quickly or sluggishly. Impairment is indicated if pupil constriction is sluggish or fails to occur.

- Repeat the procedure for the opposite eye.
- Using a penlight, shine light into both eyes at the same time allowing equal amounts of light to fall on both eyes. Turn the penlight on and off, and observe whether both pupils dilate and constrict at the same time and to the same degree. Impairment is indicated if both pupils do not dilate and constrict simultaneously and to the same degree.

Pupillary Light Reflex: Consensual Response

- In a dimly lit room, place one hand on the patient's nose between the eyes to limit light exposure to the eye being tested.
- Shine a penlight into one eye and observe the pupillary reflex in the opposite eye (both eyes should constrict).
- Document whether the pupil of the unstimulated eye fails to constrict simultaneously with the pupil of the illuminated eye. Impairment is indicated if the pupil of the unstimulated eye does not constrict at the same time and to the same degree as the pupil of the opposite eye.

Convergence

-  The patient should be seated with the therapist positioned in front (see Fig. 20-6 and Video 20-5).

Figure 20-6 Screening convergence: Oculomotor nerve screening.

- Hold a pencil (or similar visual stimulus) in front of the patient (~18 inches away from the nose), and instruct the patient to visually fixate on the pencil.
- Slowly move the pencil toward the patient's nose in a straight line. Instruct the patient to maintain gaze fixated on the pencil as it is moved closer to the nose.
- Observe for simultaneous medial movement of both eyes. Record the distance at which convergence was broken (when the patient could no longer medially invert both eyes). Convergence is normally broken at ~3 to 4 inches from the nose.
- Note any asymmetry in eye movements or pupillary constriction. Impairment is indicated if asymmetrical eye movements occur or if the pupils fail to constrict as the eyes converge.

CN III lesions (oculomotor nerve palsy) will result in paralysis of the ipsilateral extraocular muscles (superior rectus, inferior rectus, medial rectus, and inferior oblique). The patient will be unable to move the eye upward, downward, or inward; the eye will

assume a downward lateral strabismus in the orbit because of the unopposed actions of the lateral rectus and superior oblique muscles (see Fig. 20-7). Partial or complete ptosis (drooping of the upper eyelid) may also occur. The affected eye's pupil will be dilated with impairment of the pupillary light reflex. Convergence will also be impaired because of weakness of the medial rectus muscle, and as a result, the patient may complain of diplopia or blurred vision, particularly when viewing objects at close range.^{9,12}

Figure 20-7 Downward lateral strabismus: Oculomotor nerve dysfunction.

Assessing Impact on Daily Function

To determine whether extraoculomotor nerve impairment has impacted daily function, therapists should observe for the presence of strabismus, diplopia, or blurred vision because these conditions can severely affect one's ability to negotiate the physical environment.

- Ask whether the patient has tripped or experienced any recent falls at home or in the community.
- Ask whether the patient has difficulty safely traversing steps, curb cuts, and uneven surfaces such as gravel driveways and uneven sidewalks.

The presence of diplopia and blurred vision can severely affect driving, meal preparation, and any activity involving reading such as phone use.

- Ask whether the patient has difficulty driving as a result of diplopia or blurred vision, and ever experiences difficulty determining the true location of cars and pedestrians.
- Ask whether the patient has recently experienced any safety incidents in the kitchen as a result of diplopia or blurred vision, such as misperceiving the location of and failing to accurately grasp pot handles, drinking glasses, stove knobs, and plates. Has the patient scalded himself or herself by dropping hot food or drinks because of diplopia or blurred vision?
- Ask whether the patient has difficulty using a smartphone as a result of diplopia or blurred vision. Allow the patient to demonstrate use of a smartphone to observe possible deficits.

Cranial Nerve IV: Trochlear Nerve

CN IV is an extraoculomotor nerve, along with CN III and CN VI. The trochlear nerve is a somatic motor nerve that innervates the contralateral superior oblique eye muscle, which is responsible for depression (downward eyeball movement), abduction (lateral eyeball movement), and intorsion (inward eyeball rotation) movements of the eye. The trochlear nerve nucleus is located in the caudal midbrain and yields axons that decussate before exiting the midbrain, making it the only motor CN that crosses midline. CN IV exits the skull through the superior orbital fissure, where it enters the orbit to reach its target.¹⁻⁴

The function of CN IV is assessed conjointly with the other two extraoculomotor nerves (CN III and CN VI) through examination of ocular alignment and range of motion. A

trochlear nerve lesion will result in paralysis of the contralateral superior oblique muscle, causing the patient to experience difficulty moving the contralateral eyeball downward and laterally. This occurs because of the unopposed action of the medial and superior rectus muscles, which pull the eyeball upward and inward. As a result, a vertical medial strabismus may be apparent (see Fig. 20-8), and the patient may complain of diplopia at both far and near distances.^{1-4,14,15}

Figure 20-8 Vertical medial strabismus: Trochlear nerve dysfunction.

For screening procedures and assessment of daily functional impact, see CN III.

Cranial Nerve V: Trigeminal Nerve

CN V is a mixed nerve with both somatic motor and sensory components. The nerve originates in the pons and divides into three branches (ophthalmic, maxillary, mandibular) before exiting the skull. The ophthalmic and maxillary branches only carry sensory information; the mandibular branch carries both motor and sensory information. Along with CN III, CN IV, and CN VI, the ophthalmic branch exits the skull through the superior orbital fissure. The maxillary and mandibular branches exit the skull through the foramen rotundum and foramen ovale, respectively.¹⁻⁴

The motor nucleus of CN V is located at the mid-pontine brainstem and yields axons that ipsilaterally innervate the muscles of mastication, the anterior belly of the digastric muscle, the tensor veli palatini, and the tensor tympani. This branch of the trigeminal nerve also mediates the efferent limb of the masseter reflex.¹⁻⁴

The somatic sensory components of the trigeminal nerve ipsilaterally innervate the face, head, cornea, and conjunctiva of the eye; the mucosa of the nasal cavity and sinuses; and the inner oral cavity, including the teeth and anterior two-thirds of the tongue. The ophthalmic branch of the trigeminal nerve mediates the afferent limb of the corneal reflex.¹⁻⁴

Screening Procedures

CN V is assessed by examining motor function of the jaw, testing facial sensation, and eliciting the corneal and masseter reflexes.^{9,16}

Motor Function

Assess the muscles of mastication for strength and symmetry.

- The patient should be in a seated position with the therapist positioned in front.
-  Instruct the patient to open the mouth. Note any jaw deviation to one side or asymmetry of the opened mouth (see Video 20-6).
- Instruct the patient to move the jaw from side to side. Note any asymmetry of jaw movement.
- Instruct the patient to bite down on a tongue depressor. Gently attempt to pull the tongue depressor, and ask the patient to resist your attempts to remove it. Note any asymmetry between right and left jaw strength.

Sensory Function

Assess sensation on the patient's face, head, and inner oral cavity. Evaluate the intact side prior to the suspected involved side.

- The patient should be seated with vision occluded.
- Use a cotton swab applicator to stroke the inner oral cavity.
- 📺 Use a cotton swab to stroke the patient's forehead, cheek, jaw, and chin (see Fig. 20-9 and Video 20-7).

Figure 20-9 Screening sensory function of the trigeminal nerve.

- Ask the patient to verbally identify the facial area being touched. Note any areas of **anesthesia** (insensitivity to sensation). If areas of anesthesia are detected, repeat the procedure using the bare wooden end of a cotton swab applicator to assess sensation of sharp items. If sensory deficits are found for sharp items, repeat the procedure using test tubes of hot and cold water to assess temperature detection.

Reflexes

EXAMPLE: CORNEAL REFLEX (BLINK REFLEX)

- Gently touch the patient's cornea using a sterile cotton swab.
- The stimulated eye should close (direct response) along with simultaneous closure of the opposite eye (consensual response).

MASSETER REFLEX

- 📺 Using a reflex hammer, gently tap the chin (see Video 20-8).
- The masseter muscle should contract.

CN V lesions will result in ipsilateral paralysis of the jaw muscles and ipsilateral sensory loss of the face, head, and inner oral cavity. The patient will present with jaw weakness, difficulty opening the mouth, difficulty chewing, and jaw deviation to the affected side. The patient will also present with an absent corneal and masseter reflex on the affected side.¹⁶

Assessing Impact on Daily Function

When CN V is damaged, patients will have difficulty chewing food, may unknowingly pocket food in the inner oral cavity, and may drool or allow food and liquids to escape from the mouth area on the affected side. Therapists should ask patients if they have

difficulty chewing food and should check for the above conditions by observing the patient during eating and drinking.

Male patients may be at risk for razor cuts during shaving on the affected side of the face; all patients may be at risk for undetected abrasions to the affected side of the head resulting from minor accidents and falls. Therapists should ask patients and their family members if such events have recently occurred.

An absent corneal reflex may increase the risk of eye irritation, infection, or injury, and therapists should ask patients and family members if such ocular problems have recently occurred.

Cranial Nerve VI: Abducens Nerve

CN VI is one of the extraoculomotor nerves, along with CN III and CN IV. Like the trochlear nerve (CN IV), CN VI is a somatic motor nerve that innervates the ipsilateral lateral rectus eye muscle (responsible for lateral eye movements). The nucleus of CN VI is located in the caudal pons and yields axons that exit the brainstem at the pons–medullary junction. Along with CN III and CN IV, CN VI exits the skull through the superior orbital fissure, where it enters the orbit to reach its target.¹⁻⁴

CN VI is assessed conjointly with the other two extraoculomotor nerves by examining ocular alignment and range of motion. When CN VI is damaged, paralysis of the ipsilateral lateral rectus muscle occurs, and the patient will have difficulty moving the affected eyeball laterally. This condition occurs because the medial rectus muscle, which pulls the eyeball medially, is working unopposed and a medial strabismus may be apparent. Such patients will be unable to move the eye past midline and may experience diplopia and blurred vision.^{9,17}

For screening procedures and assessment of daily functional impact, see CN III.

Cranial Nerve VII: Facial Nerve

CN VII is a mixed nerve that contains both somatic and visceral sensory and motor components. The sensory portion of the nerve innervates the taste receptors on the anterior tongue, whereas the motor portion innervates the muscles of facial expression, the stapedius muscle (located in the middle ear), posterior belly of the digastric muscle, and the efferent limb of the corneal reflex. Axons of the visceral motor neurons are responsible for ipsilateral innervation of the lacrimal gland (for tear production) and the submandibular and sublingual salivary glands (for saliva production).¹⁻⁴

CN VII originates at the pons–medullary junction, enters the temporal bone through the internal acoustic meatus, and exits the temporal bone through the stylomastoid foramen. Although CN VII is referred to as one nerve, it actually consists of two comingled nerves: the nerve proper and the intermediate nerve.¹⁻⁴

Screening Procedures

CN VII is assessed through an examination of the motor function of the muscles of facial expression, taste sensation on the anterior tongue, and the corneal reflex.^{9,18,19}

Motor Function

The muscles of facial expression should be evaluated for strength and symmetry.

- The patient should be seated with the therapist positioned in front.
- Instruct the patient to smile, frown, and pucker the lips. Note any asymmetry between both sides of the face during these facial movements.
-  Ask the patient to blow the cheeks up with air. Gently push on the patient's cheeks while instructing him or her to resist your manual pressure. Note any asymmetry between cheek strength (see Fig. 20-10 and Video 20-9).

Figure 20-10 Screening motor function of the facial nerve.

- Instruct the patient to elevate the eyebrows and forehead. Preserved ability to wrinkle the forehead with lower facial muscle weakness indicates an upper motor neuron lesion (commonly resulting from stroke). Ipsilateral paralysis of both the forehead and facial expression muscles indicates a lower motor neuron lesion (commonly resulting from CN damage).

Sensory Function

Taste sensation on the anterior aspect of the tongue should be evaluated. Always assess the intact side prior to the suspected involved side.

- The patient should be seated with vision occluded.
- One at a time, present sweet, salty, and sour solutions to the anterior tongue (senses sweet) and middle and lateral tongue (senses sour and salty). Ask whether the patient can taste and identify each substance type.

Corneal Reflex

See section on Screening Procedures for CN V.

A lesion to CN VII will result in ipsilateral paralysis of the muscles of facial expression, lost taste sensation on the anterior two-thirds of the tongue, changes in tear and saliva production, and an absent corneal reflex. Because the facial nerve gives off branches that innervate the stapedius muscle, patients with CN VII lesions may complain of ipsilateral hyperacusis, or increased sound sensitivity.^{9,18,19}

Assessing Impact on Daily Function

To assess whether and to what extent a CN VII lesion has impacted a patient's daily function, determine the following. Corroborate patient responses with close family members.

- Ask whether the patient has experienced changes in appetite because food no longer tastes appealing or the same. Determine whether weight loss has occurred and if nutritional intake has been impacted.
- Because patients may pocket food in the mouth as a result of oral muscular weakness, observe patients while eating and drinking.

- Ask whether the patient has withdrawn from social participation because of asymmetrical facial control and movement.
- Ask the patient if increased or decreased tear and saliva production have interfered with daily life activities such as reading, eating/drinking, and driving. Over production may cause blurred vision and an inability to control drooling. Underproduction may cause dry eye and mouth.
- If the corneal reflex is absent, the patient may be more susceptible to eye irritations, infection, and injury. Ask if any of these have recently occurred.
- Ask whether the patient has been bothered by loud noises and, as a result, has changed routines relating to social participation, entertainment, and phone use.

Cranial Nerve VIII: Vestibulocochlear Nerve

CN VIII is a special sensory nerve responsible for audition and balance. The nerve originates in the pons–medullary junction and exits the skull to enter the inner ear through the internal acoustic meatus. CN VIII consists of two branches: cochlear and vestibular. The cochlear branch mediates the function of audition by transmitting sensory signals (sound waves) originating from fluid movement in the cochlea to the brain. The vestibular branch mediates balance/equilibrium by transmitting sensory signals about body and head position that originated from fluid movement in the vestibular apparatus (semicircular canals and otolith organs) to the cortex and cerebellum.¹⁻⁴

The vestibulocochlear nerve is assessed by examining the special sensory functions of hearing and balance and by screening for the presence of **nystagmus** (rapid eye movements that result from activation of the vestibulo-ocular reflex).

Auditory Branch of the Vestibulocochlear Nerve

Assessing the auditory branch involves screening the function of hearing. Auditory screens are usually performed by an audiologist to distinguish between conductive and sensorineural hearing^{9,20-22}:

- Conductive hearing loss results from impairment of the outer and middle ear structures.^{20,21}
- Sensorineural hearing loss results from impairment to the inner ear structures, vestibulocochlear nerve, and/or temporal lobe.^{20,21}

Two tests are commonly used to distinguish between conductive and sensorineural hearing loss: Weber Test and Rinne Test.²² Both ears are tested.

-  **Weber Test:** Strike a tuning fork and place it against the middle of the patient's forehead. Sound is heard through bone conduction and should be heard equally in both ears. If sound is heard louder in one ear, a conductive hearing loss in that ear is indicated (see Fig. 20-11 and Video 20-10).

Figure 20-11 Weber test: Vestibulocochlear nerve.

- **Rinne Test:** Strike a tuning fork and place it against the mastoid bone. When the patient indicates no longer being able to hear the sound, move the tuning fork next to the auditory canal (see Fig. 20-12 and Video 20-11). Sound heard through air conduction is usually twice as long as bone conduction. If the patient no longer hears the sound when the tuning fork is moved to the auditory canal, conductive hearing loss is indicated. If sensorineural hearing loss has occurred, both bone conduction and air conduction will be impaired, and sound will be heard louder in the opposite ear.

Figure 20-12 Rinne test: Vestibulocochlear nerve.

Vestibular Branch of the Vestibulocochlear Nerve

Assessing the vestibular branch involves screening for the presence of nystagmus and evaluating balance and equilibrium responses.^{9,20}

Nystagmus Screening

- The patient should be seated with the therapist positioned in front.
- Instruct the patient to maintain the head in a fixed position while visually tracking a moving object (finger or pen cap) held at a distance of ~15 inches from the patient's

nose.

- Move the visual stimulus in an H and X pattern.

Romberg Test (To Test Balance and the Presence of Protective Responses)

- 🎧 Ask the patient to stand with feet together while holding arms next to or crossed in front of the body (shoes should be removed). Stand close to the patient to prevent possible falls (see Video 20-12).
- Instruct the patient to first stand with eyes open and then with eyes closed. Observe for increased sway or loss of balance.
- Gently displace the patient's balance and check for protective responses.

CN VIII lesions can result in ipsilateral sensorineural hearing loss and/or tinnitus (ringing in the ears), vertigo (dizziness), nystagmus, and impaired balance and equilibrium responses.²⁰⁻²²

Assessing Impact on Daily Function

To assess whether and to what extent a CN VIII lesion has impacted a patient's daily function, determine the following. Corroborate patient responses with close family members.

- Ask whether the patient has problems with hearing during conversation (in-person or via phone use), television viewing, or driving; misses information as a result; or has withdrawn from social participation.
- Ask whether the patient has recently experienced dizziness (with or without nausea) for periods of time that has impacted the ability to participate in daily activities. Patients with vestibular neuritis may require vestibular rehabilitation to retrain the brain's response to motion-induced vertigo.
- Ask whether the patient has recently experienced falls or feels unsteady on his or her feet in daily activities such as bathing and dressing. Observe the patient as he or she attempts to reach above to retrieve items in high cabinets and bends to reach items in low cabinets.

Cranial Nerve IX: Glossopharyngeal Nerve

CN IX is a mixed nerve that contains both somatic and visceral sensory and motor components. CN IX originates in the medulla at the level of the postolivary sulcus and exits the skull through the jugular foramen. The nerve's motor components mediate swallowing (along with CN X, vagus nerve) and secretion of the parotid gland. The sensory components of CN IX are responsible for (a) taste sensation on the posterior tongue region; (b) sensation (pain, temperature, touch) of the external auditory meatus and posterior tongue region; and (c) visceral sensation of the pharynx, parotid gland, and carotid body and sinus. CN IX and CN X conjointly play primary roles in the gag and swallowing reflexes.¹⁻⁴

Screening Procedures

CN IX and CN X functions are screened together.^{9,23}

Sensory Function

See section on Screening Procedures for evaluating taste sensation for CN VII, facial nerve. Use the same procedures, but instead apply bitter substances to the posterior region of the tongue.

Motor Function

The gag and swallow reflexes are assessed.

GAG REFLEX

Swipe a tongue depressor or cotton swab applicator at the back of the patient's throat and observe for immediate contraction of the pharyngeal muscles and elevation of the palate.

SWALLOW REFLEX

Present the patient with different foods of varying textures and viscosities (solids, pureed, thick and thin liquids) one at a time. Observe the patient's ability to swallow, noting signs of food aspiration, coughing, throat clearing, or wet vocal quality (indicating food pocketing in the larynx).

Assessing Impact on Daily Function

To assess whether and to what extent CN IX impairment has impacted the patient's daily activities, determine the following. Corroborate patient responses with close family members.

- Ask whether the patient has recently experienced difficulty swallowing solid food and/or liquids, including coughing and choking.
- If the patient indicates the presence of swallowing difficulties, determine which types of foods/liquids are most problematic.
- Ask whether swallowing difficulties have altered the patient's food intake (has the patient begun to eat less or lost weight), nutritional intake (is the patient eating a sufficient amount and array of food for adequate nutrition), and social eating with others (does the patient avoid eating with others).

Cranial Nerve X: Vagus Nerve

Similar to CN IX, CN X is a mixed nerve that contains both (a) somatic and visceral motor components and (b) somatic and visceral sensory components. Along with CN IX, CN X originates in the medulla at the level of the postolivary sulcus (caudal to CN IX) and exits the skull through the jugular foramen.¹⁻⁴

CN X's motor components mediate swallowing, speaking, digestion, and cardiorespiratory processes. The nerve's sensory components are responsible for (a) sensation of the skin at the external auditory meatus, the external ear, and the dura of the posterior cranial fossa; (b) taste at the epiglottis and base of the tongue; and (c) visceral sensation from the larynx, pharynx, heart, aortic arch, lungs, and gastrointestinal tract. As mentioned previously, both CN IX and CN X conjointly mediate the gag and swallowing reflexes.¹⁻⁴

Screening Procedures

When evaluating the gag and swallowing reflexes, CN IX and CN X are assessed together (see section on Screening Procedures for CN IX). The vagus nerve is additionally assessed by evaluating the function of the palatal muscles, voice quality, and breathing using the following screening procedures.^{9,24,25}

- The patient should be seated with the therapist positioned in front.
- Instruct the patient to say "ah" while observing the soft palate and uvula to detect whether the uvula is maintained in midline. Weakened palatal muscles on one side will cause the uvula to be pulled toward the opposite side.
- Observe the patient's articulation of speech. Check for the presence of dysarthria (slurred speech) and **dysphonia** (decreased vocal volume or hoarseness).
- Observe the patient's respiratory status and check for the presence of **dyspnea** (difficulty breathing).

In addition to swallowing and speaking difficulties, impairment of the vagus nerve may also result in dyspnea and changes in heart rate, such as tachycardia (rapid heart rate at resting).⁹

Assessing Impact on Daily Function

To assess whether and to what extent CN X impairment has impacted the patient's daily activities, determine the following. Corroborate patient responses with close family members.

- Ask whether the patient experiences difficulty clearly and audibly articulating speech in conversation, has difficulty communicating through speech in-person or by phone, and/or has withdrawn from social participation because of speech difficulties.
- Ask whether the patient experiences rapid heart rate at rest and if this interferes with any daily life activities, such as eating, sleeping, reading, or television viewing.

Cranial Nerve XI: Accessory Nerve

CN XI is considered to be a somatic motor nerve that ipsilaterally innervates two muscles: the sternocleidomastoid (SCM) and trapezius muscles. The SCM is responsible for (a) head lateral flexion to the same side and (b) head rotation to the opposite side. The trapezius muscle mediates the scapular movements of elevation, depression, rotation, and retraction.¹⁻⁴

CN XI has two nerve roots: spinal and cranial. The spinal nerve root originates from motor neurons in the cervical segments of the spinal cord (C1–C6). These motor neurons yield axons that ascend the cervical segments and enter the cranial cavity through the foramen magnum. The spinal root, along with CN IX and CN X, exits the skull via the jugular foramen to reach its motor targets. The CN root originates in the caudal medulla from motor neurons located in the nucleus ambiguus and dorsal motor vagal nucleus. The cranial root exits the skull via the jugular foramen and immediately combines with CN X.^{26,27}

Screening Procedures

CN XI is primarily assessed by evaluating the function of the spinal nerve root as it innervates the SCM and trapezius muscles.^{9,27}

Sternocleidomastoid Muscle

- The patient should be seated with the therapist positioned in front.
- Assess the uninvolved side first, followed by the involved side.
-  Instruct the patient to flex the head laterally (toward the same side) and rotate the head to the opposite side (see Video 20-13).
- Ask the patient to resist your attempts to gently return the head toward a neutral midline position.
- Note asymmetry of movement and strength, and check for atrophy of the affected SCM muscle.

Trapezius Muscle

- Instruct the patient to shrug both shoulders toward the ears and maintain that position.
-  Ask the patient to resist your attempts to gently depress the shoulders (see Fig. 20-13 and Video 20-14).

Figure 20-13 Screening trapezius muscle function: Accessory nerve.

- Note asymmetry of movement and strength, and check for atrophy of the affected upper trapezius muscle.

A CN XI lesion will result in paralysis or weakness of the SCM and trapezius muscles. As a result, the patient will have difficulty rotating the head to the opposite side (of the lesion) and will present with drooping of the affected shoulder. The patient may also experience swallowing difficulties (dysphagia) resulting from weakened laryngeal muscles innervated by the CN root.^{9,27}

Assessing Impact on Daily Function

To assess whether and to what extent CN XI impairment has impacted the patient's daily activities, determine the following. Corroborate patient responses with close family members.

- Ask whether the patient has difficulty turning his or her head while driving, bathing, grooming, dressing, and in response to noise or someone's voice. Observe the patient's ability to rotate the head directly within these activities.
- Ask whether the patient has difficulty reaching above his or her head to retrieve items from overhead cabinets, putting on a coat or over-the-head sweater, or brushing one's hair. Observe the patient during these activities.
- If swallowing difficulties are noted, use the screening procedures outlined in the sections addressing CN V, CN VII, CN IX, and CN X to determine how such impairment has impacted daily life function.

Cranial Nerve XII: Hypoglossal Nerve

CN XII is a somatic motor nerve that innervates ipsilateral tongue muscles and is responsible for tongue movements required in swallowing (oral stage) and speaking. The nerve originates in the hypoglossal nucleus located within the caudal medulla, yields motor axons that exit the medulla at the preolivary sulcus, and exits the skull through the hypoglossal canal.¹⁻⁴

Screening Procedures

CN XII function is assessed by examining tongue movement.^{9,28,29}

- The patient should be seated with the therapist positioned in front.

- Instruct the patient to protrude the tongue. Observe whether the tongue deviates toward the ipsilateral side. Also note the presence of unilateral or bilateral fasciculations (muscle twitches or fast, involuntary muscle contractions) and/or atrophy of the tongue muscles.
- Instruct the patient to move the tongue from side to side. Observe any asymmetry in tongue movement.
- Instruct the patient to push the tongue against the right cheek, then the left.
- Ask the patient to resist your attempts to depress each cheek as he or she pushes the cheek outward. Note any asymmetry in tongue strength.

CN XII lesions result in ipsilateral tongue muscle paralysis. Such patients present with ipsilateral weakness and atrophy of tongue muscles, deviation of the protruded tongue to the affected side, and possible fasciculations in the ipsilateral tongue muscles. Patients commonly experience dysphagia resulting from an inability to use tongue muscles to manipulate food into a bolus that can be transported to the pharynx. **Dysarthria** (slurred speech) may also occur secondary to an inability to use the tongue to produce sound and enunciate words.^{9,25,28,29}

Assessing Impact on Daily Function

To assess whether and to what extent CN XII impairment has impacted the patient's daily activities, determine the following. Corroborate patient responses with close family members.

- Ask whether the patient has recently experienced difficulty swallowing solid food, including coughing and choking.
- Ask whether swallowing difficulties have altered the patient's food intake (has the patient begun to eat less or lost weight), nutritional intake (is the patient eating a sufficient amount and array of food for adequate nutrition), and social eating with others (does the patient avoid eating with others).
- Ask whether the patient experiences difficulty clearly articulating speech in conversation, has difficulty communicating through speech in-person or by phone, and/or has withdrawn from social participation because of speech difficulties.

CASE STUDY

Patient Information

Mateo is a 63-year-old retired Hispanic man who reports facial weakness, diminished taste, persistent tearing, and increased aural sensitivity, all present on the right side only. He reports that symptoms occurred suddenly 2 weeks ago and were noticeable upon waking. No other unusual health events were reported other than a viral infection that fully cleared 2 weeks prior to the reported symptoms.

Assessment Process

Because the therapist suspected CN VII, facial nerve damage, Mateo was screened for the following: (1) bilateral strength and symmetry of the muscles of facial expression, (2) taste sensation on the anterior aspect of the tongue, and (3) corneal reflex function.

Assessment Results

Mateo was observed to have asymmetry and weakness of the facial muscles on the right side including his forehead muscles, indicating lower motor neuron impairment (found in CN damage) as opposed to upper motor neuron involvement (found in stroke). Taste sensation, particularly sweet and salty, were absent on the anterior two-thirds of the tongue. In response to stimulation of the right cornea, it was noted that the corneal reflex was absent on that side. During evaluation, it was observed that

Mateo’s right eye teared continuously and he repeatedly wiped saliva from the right corner of his mouth. He stated that eye tearing often caused blurred vision, which interfered with reading and television viewing. He reported using cotton balls in his right ear to reduce sound sensitivity that had recently developed and was aggravated by television viewing, phone use, and street sounds such as police sirens. Although Mateo reported no change in eating and dietary habits, his daughter, who was present at the evaluation, mentioned that her father was eating less and now preferred to eat alone in his room rather than with family. In response, Mateo stated that he was experiencing difficulty containing food and fluid in his mouth and that foods didn’t taste as good as they used to. Bell’s palsy,³⁰ impairment of CN VII, was suspected, and referral made for a full neurological evaluation.

Occupational Therapy Problem List

- Weakness and asymmetry of right-sided facial muscles with apparent difficulty handling foods and liquids. The patient appears to be withdrawing from social participation as a result. An in-depth dysphagia evaluation is warranted.
- Increased right-sided tear and saliva production causing blurred vision in daily occupations such as reading and phone use.
- Increased right-sided sound sensitivity that appears to be interfering with daily occupations, such as phone use, television viewing, and community participation.
- Reduced taste sensation on the anterior two-thirds of the tongue, causing decreased appetite. An in-depth nutritional evaluation should be made.

Commonly Used Standardized Assessments in Cranial Nerve Evaluation

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Berg Balance Scale (BBS) ³¹	Performance-based assessment of balance in the elderly	15 minutes	Concurrent validity was established with Barthel Index ($r = 0.67$), Timed Up-and-Go ($r = 0.76$), and Tinnetti Balance Test ($r = 0.91$).	Inter-rater reliability = 0.98. Internal consistency = 0.96	BBS was able to identify fallers with 100% accuracy.	Strengths: Short administration time, high reliability and moderate-to-high validity, and high sensitivity. Weaknesses: Test activities are not based in daily occupational activities.
Dysphagia Evaluation Protocol ³²	Observation-based assessment of swallowing difficulties for adults	30 minutes	Face and content validity reported to be high based on a panel of experts.	Inter-rater reliability ranged from 0.85 to 1.00. Test-retest reliability ranged from 0.83 to 1.00.	Not established	Strengths: Developed for use by occupational therapists, high validity and reliability, and short administration time. Weaknesses: Sensitivity not established.

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Full Range Test of Visual-Motor Integration ³³	Paper-and-pencil test of visual motor skills for children and adults	10–30 minutes	Content validity reported to be high based on a panel of experts. Concurrent validity with Developmental Test of Visual-Motor Integration ($r = 0.85$).	Internal consistency = 0.91. Test–retest reliability = 0.85. Inter-rater reliability = 0.96	Not established	Strengths: High reliability and validity, short administration time Weaknesses: Paper-and-pencil test that is not ecologically valid (based in daily occupation), instrument is expensive.

Chapter 21

Environmental Assessment and Modification: Home, Work, and Community

Tracy Van Oss Martha J. Sanders and Pamela Hewitt

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Identify common environmental modification assessments used in the home, workplace, and community.
2. Understand the purpose and processes of conducting home, workplace, and community environmental assessments.
3. Determine how to ensure that individuals and populations fit living spaces.
4. Incorporate universal design principles into the planning of living spaces.
5. Understand common modifications to enhance safety and functional performance of clients with disabilities in the home, workplace, and community.

CHAPTER OUTLINE

Environmental Assessment and Modification
Universal Design
Measuring for Fit: Understanding Anthropometrics
Purposes for Environmental Assessments
Home Environment Assessment and Modification
Workplace Environmental Assessment
Interventions for Work Environments
Community Environmental Assessment and Modification
Case Study

TERMINOLOGY

Accessibility: the ease with which the physical environment may be reached, entered, and used by all individuals.

Aging in place: the idea that environments can be modified to support changes in functional performance as a result of aging, thus ensuring continued residence in one's own home.

Anthropometrics: the science of measuring body size and proportions and applying measurements to the design of equipment and spaces.

Environmental modification: alteration of physical environments to improve safety and occupational performance.

Ergonomics: a set of principles to improve worker efficiency and comfort and to decrease injury risk by designing workplaces, equipment, and work processes that fit workers.

Physical environment: the features of a person's surroundings that are built or exist in nature.

Universal design: a set of principles for the built environment that enhance optimal function and convenience for all individuals, regardless of ability.

Visitability: the concept that homes can be accessible for persons in wheelchairs to visit.

Environmental Assessment and Modification

The environment influences human behavior and provides the context within which all occupational roles are performed. Numerous stakeholders including clients, family, contractors, designers, physicians, and employers are interested in promoting healthy and safe environments for clients. Occupational therapists uniquely focus on clients' occupations within the location in which they are performed. Therapists consider how the environment supports and optimizes

clients' safe engagement in chosen occupations in the present and future. Thus, therapists are well suited to perform environmental assessments and modifications in the home, workplace, and community. **Environmental modifications** are defined as adaptations applied to the **physical environment** to promote safety and full participation. The American Occupational Therapy Association (AOTA) has developed evidence-based practice guidelines for home modification interventions.¹ Federal, state, and local regulations impact environmental modifications relative to building codes, accessibility, and safety.

History and Legislative Standards

Occupational therapists' role in environmental modifications at home, work, and in the community has been shaped by legislation that supports the rights of individuals with disabilities to full societal participation. **Accessibility** to public buildings, employment settings, and housing choices is fundamental to individuals' safety and meaningful community participation. The following section outlines key legislation impacting environmental modifications.

American National Standards Institute

Founded in 1918, the American National Standards Institute (ANSI) develops standards to ensure the safety and health of US consumers as well as the protection of the environment.² ANSI develops building and design standards to allow for accessibility in conjunction with the Americans with Disability Act (ADA), the US Department of Housing and Urban Development (HUD), and Fair Housing Accessibility Guidelines. For example, ANSI determined specifications for the turning radius needed for a standard wheelchair to enter and exit a room. These specifications are used as a guide for both public spaces and private remodelers designing bathroom modifications for wheelchair users.

Fair Housing

The Fair Housing Act Accessibility Guidelines (FHAAG), established in 1968, mandated accessibility in multifamily housing and ensured rights for people with disabilities for equal access to housing options. According to this law, individuals cannot be denied the opportunity to modify a rented home to meet their needs for accessibility; however, renters endure modification costs.³ Specific accessibility requirements have been established to ensure that the design and construction of public residential buildings comply with the Fair Housing Act (e.g., buildings must have accessible entrances or routes).

Americans with Disabilities Act

The Americans with Disabilities Act (ADA)⁴ extended equal rights protection to individuals with disabilities. The ADA outlined three areas in which state and local government became responsible for providing reasonable accommodations that ensured access to employment, public services, facilities, transportation, accommodations, and telecommunications. Title I mandated that employers accommodate individuals in hiring and employment who are qualified and who meet disability criteria. Titles II and III mandated accessibility to private and public facilities, recreational facilities, state and local government buildings including businesses and schools, and public transportation. Many buildings and spaces constructed prior to 1990 may still contain accessibility barriers.

The ADA was revised in 2008 (Amendments Act 2008) to expand its application to a larger group.⁵ The definition of "disability" was revised to include impairments that substantially limit participation in major life activities, such as work. The 2010 ADA Standards for Accessible Design outline how both public-sector and private-sector services, programs, and facilities should comply with and implement accessibility requirements.⁶

Building Standards

Building standards support accessibility by providing specific architectural dimensions and building guidelines for applicable private and public facilities. In 2004, the US Access Board released the updated ADA-ABA (Architectural Board Act) Accessibility Guidelines for new or altered buildings, which provide accessibility requirements for public and private facilities.⁷ The specifications in these guidelines are based on adult and child dimensions and anthropometrics, and are applied during the design, construction, or alteration of buildings and facilities covered by ADA titles II and III. Specifications are provided for most aspects of the built environment,

including the space required for maneuvering wheelchairs in corridors and rooms, washrooms, building entrances, and parking lots.

Standards for Specific Environments

Building accessibility standards apply to public and private businesses with public access; however, additional standards are often developed for specific environments, such as workplaces, playgrounds, and daycare centers. Occupational Safety and Health Administration (OSHA) standards are aimed at creating safe environments for workers. Although these legislative acts do not mandate involvement by health care professionals, occupational therapists are well suited to ensure that legislative requirements are met, clients are aware of available services, and planned environmental modifications meet clients' identified current and future needs.

Universal Design

In 1997, a group of American advocates developed the principles of **universal design** that have been commonly adopted in a variety of nations. Universal design principles highlight strategies to promote accessibility, inclusive design, and safety in activities available to a wide range of people. Universal design is based on the idea that all environments, products, and communication systems—not only those serving people with disabilities—should be developed to facilitate ease of use, safety, and optimal function. Because most existing environments have not been built using universal design principles, environmental modifications are commonly needed to increase accessibility. The following principles summarize key universal design principles.⁸

Equitable Use

Equitable use refers to design that is useful and marketable for all users. For example, automatically opening doors decrease the need for strength, and motor and cognitive skills. In addition to being useful for people with functional limitations, automatic doors are helpful to any worker carrying packages through doorways. Automatically opening doors and curb cuts are useful for people using scooters and wheelchairs, as well as parents with strollers. Furniture with adjustable chair and table heights are similarly useful for all people.

Flexibility in Use

Flexibility in use refers to design that accommodates a wide range of individual preferences and abilities. Seats or benches placed in public places, such as parks or malls, allow people of all ages to rest and those with pulmonary issues to conserve energy. A no-step entrance and a curbless shower are also examples of universal design features in the home.

Simple and Intuitive Use

Simple and intuitive use addresses multiple ways to present information. Products that are designed for use by everyone should use simple language and universally recognized symbols, such as red faucet labeling for hot water and blue for cold. Other examples include product assembly instructions that use diagrams instead of language. Similarly, international retailers use diagram labeling for products having an international audience.

Perceptible Information

Perceptible information refers to design that communicates necessary information effectively to users, regardless of environmental conditions or users' sensory abilities. An example includes interior automobile gas cap labels displaying the location of the car side on which the gas cap is located. Another example includes home fire alarms that have visual and auditory signals and large dial displays. Also in this category are products or devices that provide verbal, written, and tactile information regarding use.

Tolerance for Error

Tolerance for error refers to design that minimizes hazards and the possibility of adverse consequences from accidental or unintended actions. Examples are red light indicators on stoves to alert users that surfaces are still hot, and refrigerator signals that alert users when doors are left ajar. Staircases that have two railing levels at differing heights to accommodate shorter and taller individuals to enhance safety is another example.

Low Physical Effort

Low physical effort refers to design that can be used effectively, comfortably, and with minimal fatigue. When traveling, moving sidewalks allow passengers to reduce energy expenditure, especially with luggage in tow. Useful products may include lever door handles and rocker switches for people with poor hand strength or loss of fine motor abilities. Groceries can become heavy at any life stage, and the installation of a package shelf can be beneficial when entering the home. Long-handled equipment such as reachers can reduce bending to retrieve items from the floor and aid in lower body dressing. The use of built-up utensils can reduce fatigue when preparing meals requiring repetitive movements such as stirring, peeling, and cutting. Also included in this category are devices and products that are touch-activated, such as can openers and faucets.

Size and Space for Approach and Use

This refers to design that promotes approach, reach, manipulation, and use, regardless of the user's body size, posture, or mobility. Examples include raised kitchen appliances such as dishwashers to reduce bending, microwaves located in pullout drawers to reduce reaching, and sink faucets positioned in counter fronts for easier access. Additional examples include push-button door openers located at appropriate heights for all users, and entryways that accommodate wheelchair maneuverability.

Measuring for Fit: Understanding Anthropometrics

Anthropometrics is the study of human body dimensions such as height, weight, leg length, and body segment length as applied to living and working spaces, furniture, and equipment. Anthropometrics is the basis for designing spaces that “fit” an individual or group in the home, workplace, or community. Because human dimensions vary with population, age, ethnicity, and clinical conditions, it is important to understand how anthropometric measurements are applied to space planning. For general space planning, occupational therapists, designers, and architects depend on tables of body sizes in order to design spaces that “fit” the majority of individuals (i.e., 95% of the largest and 5% of the smallest users). Individuals, however, who are unique, at the extremes of size, who are pregnant, or who have disabilities, may require individual measurement to ensure a proper “fit” for their space.⁹ The following steps for measuring a person or population to ensure “fit” applies to home, work, and community settings.

Steps to Use Anthropometric Measurements to Design Space

1. Identify the target user population.
2. Identify the criteria that are important to the user (e.g., comfort, use, clearance through an area).
3. Identify important body dimensions (e.g., thigh length for a chair seat).
4. Determine whether the space is being designed for one person or for a population (consider averages and extremes).
5. Measure body parts or find data from anthropometric data tables. Measure length of body segments between joints using a measuring tape or calipers.
6. Consider other factors impacting use of space (e.g., wearing heavy clothing in cold temperatures may impact fit, and use of walkers or wheelchairs).
7. Create a mock-up or virtual model that can be tested with a user.

Purposes for Environmental Assessments

Occupational therapists perform home, work, and/or community assessments to improve clients' or populations' occupational performance. Therapists need to clearly identify the purposes of such assessments in order to select evaluation instruments that can gather the most appropriate information.

Overall Independence

Occupational therapists are consulted to promote independence for individuals with disabilities that limit engagement and mobility as a result of chronic or short-term (e.g., postoperative) conditions. Each condition may require a slightly different evaluation focus. For example, clients in wheelchairs will need identification of environmental modifications to accommodate

wheelchair use; clients with visual impairment may need modifications to enhance visual function (e.g., increased lighting, color contrast, and low-tech aids); and clients with dementia may need modifications to compensate for memory and wayfinding problems. Each client's medical history and daily life needs should be clearly identified at the onset of the evaluation.

Home Safety and Fall Prevention

Fall prevention refers to strategies and modifications designed to minimize fall risk in the home and other environments. For older adults, falls can have devastating consequences, including long-term disability, the potential need for extended care, loss of confidence, depression, social isolation, and even premature death. Research on the effectiveness of home interventions provided by occupational therapists indicates that environmental modifications can effectively reduce falls in older adults.¹⁰ Fall prevention interventions address such environmental features as physical structure, furniture, rugs, lighting, and stairs. Home safety evaluations address additional hazards such as overloaded electrical outlets and tangled cords placed in walking paths, unsafe use of appliances and stoves leaking gas, and chemical (radon, carbon monoxide detectors) and biological hazards (mold, dust mites). Whereas therapists may detect such hazards during home safety evaluations, other consultants will perform chemical and biological testing.

Aging in Place

According to the American Association of Retired Persons (AARP), 89% of people aged 50 years and older who are considering options for housing express preferences for remaining at home, within familiar settings and communities, and with family and friends.¹¹ Adults 50+ define successful aging as taking care of oneself, independently making choices, participating in community activities, and pursuing desired hobbies and interests.¹² Additional considerations that promote **aging in place** are the high cost of nursing homes and assisted living facilities, which lead older adults to remain in their homes with supportive services, environmental modifications, and/or renovations. Occupational therapists identify clients' current needs and anticipate potential future needs to promote safe aging in place, such as relocating a master bedroom and bath downstairs (to avoid stair use), and building an accessible house entrance.

Community Livability

Livability addresses the structure, accessibility, services, and enhancements that promote quality of life for all community inhabitants. **Visitability** is the incorporation of basic features into the homes of persons using mobility devices to facilitate ease of entrance, exit, visit, or stay, for any length of time.¹³ The advocacy group, Concrete Change, developed by Eleanor Smith, asserts that all home environments should be designed to improve livability and visitability for home inhabitants and visitors.¹⁴ For example, basic home features that should be incorporated into all homes and that enhance accessibility of visitors using wheelchairs include no-step entrances, wide doorways of 32 inches, and access to first-floor bathrooms.

Injury Prevention and Productivity

Workplaces must meet ADA standards to promote equal access to job opportunities and public spaces for individuals with disabilities. A workplace evaluation may have the additional foci of preventing injuries and improving productivity. Although injury prevention programs include analyses of job tasks and worker body mechanics, work environments are evaluated to examine conditions that promote safety and health, while reducing injury risk. Environmental conditions, such as workstation design, noise, and lighting, impact productivity by affecting ease-of-task completion.

Home Environment Assessment and Modification

Understanding the Client: The Occupational Profile

Occupational therapists seek to understand how people interact with their environments to engage in desired occupations. Using occupational profiles, the client-therapist interaction begins by determining the client's previous roles and occupations, and present desires and expectations for activity participation. Therapists obtain important client characteristics, including age, height, weight, medical conditions, hospitalizations, and past medical history. Therapists also obtain information about client performance patterns, activity demands,

ambulation modes, and current or anticipated future use of assistive devices and adaptive equipment. Additional questions and use of standardized assessments and observation allow therapists to assess visual impairment, balance and coordination, cognition, and safety awareness.

Evidence suggests that home environment interventions are most effective when they consider the specific needs of individual clients rather than generically addressing a checklist of common home safety concerns.^{15,16} The need for home modifications will vary among individuals occupying similar spaces, depending on factors such as health status, cognitive and visual-perceptual function, physical mobility, financial resources, and whether clients live alone or with others. For example, a home evaluation for a client with dementia may focus on the need for memory cues, wayfinding strategies, and safety systems, whereas a home evaluation for a client with spinal cord injury (SCI) may focus on the home's physical structural characteristics that require modification to promote occupational participation. Therapists identify barriers to participation and make personalized recommendations for environmental modifications that ensure optimal independence and safety for each client.

Team Approach: Including a Variety of Stakeholders

Throughout the assessment process, occupational therapists collaborate with caregivers to ensure that recommendations for adaptations support caregiving activities. Therapists also work collaboratively with other professionals to plan and complete modifications. Building professionals—such as contractors, designers, architects, and building code officials—are not part of typical health care teams, but provide important structural, zoning, and financial information related to environmental interventions. To effectively achieve desired outcomes, interprofessional team members must similarly perceive client goals and engage in collaborative problem-solving.

Funding Options

Funding options vary greatly by region, health insurer, and needed environmental modifications. Possible funding and resources for assistance with modifications may include Rebuilding Together, Area Agencies on Aging, Centers for Independent Living, and the Bureau of Rehabilitation Services. Many individuals without sufficient financial resources or assistance, however, will often need to “pay out of pocket.” Employers may fund workplace accommodations for employees with disabilities and are required to accommodate ADA-specific issues that are financially feasible. Some insurers may subsidize home and/or workplace accommodations. Community organizations with grant funds may also financially sponsor services that improve community and home accessibility.

Creating the Problem List

Once assessments have been completed, occupational therapists should compile a list of areas in which client occupational roles cannot be met because of environmental conditions. This list should be specific and co-created by clients, therapists, and community stakeholders. The problem list should include criteria to promote the desired goal, which may, in turn, yield a number of solutions. Each client problem list is unique to the individual, and therapists create personalized intervention plans that address all identified needs. Examples of problems may include cognitive challenges effecting safe meal preparation, balance impairments limiting safe tub transfers, and visual-perceptual deficits impacting reading medication labels.

The Process of Home Assessment and Modification

Once a home assessment referral is made, therapists should plan to bring writing instruments (e.g., laptop or pad), tape measures, and cameras. The reason for a home safety evaluation should be clear regarding the client's safety needs and desires for role resumption. For example, some clients will require a home modification evaluation because they have begun permanently using a wheelchair, whereas others may desire to age in place. Most referrals will require evaluation of both the exterior and interior home environments. The following provides guidelines for assessment and modification of home environments.

Entryways, Ramps, and Home Exteriors

Therapists begin home assessments by examining the home's entryway. Pathways leading to front or back doors should be well lit with gentle slopes and textured surfaces that are even throughout all walkways. Trees or shrubs should be well maintained to prevent fallen berries or leaves from creating slippery conditions. Access to stairs should be clutter free with slip-resistant surfaces and adequate handrails. Universal design features such as a package shelf outside the door, or an overhang above the door, can mitigate unnecessary struggling and risk. Thresholds into the home should be flush with the floor or no higher than 0.5 inches to prevent tripping. A 5 3 5 foot space (1.5 3 1.5 meters) both outside and inside the doorway should be present to provide an adequate turning radius for wheelchair users. Use of appropriate lighting is one of the most important features, as well as a doorbell that is lit or has a vibrating device/alarm or amplification. Finally, use of a keyless entry system can be installed for ease of access into the home. If entering via the garage, a garage door remote control and inside light are needed to minimize safety hazards. Box 21-1 provides minimum illuminance levels for both exterior and interior spaces based on recommendations from the Illuminating Engineering Society of North America.^{17,18}

Box 21-1

Recommended Minimal Lighting Levels

Compiled from Illuminating Engineering Society of North America. *The Lighting Handbook*. 10th ed. New York, NY: Illuminating Engineering Society of North America; 2011.

After assessing the home entrance and analyzing the information gained from the client's evaluation, therapists apply skilled judgment to select appropriate ramp types. Portable ramps offer flexibility in time and installation and are often used for temporary health conditions (Fig. 21-1). Permanent ramps are recommended for clients who have health conditions that will not improve or will worsen over time resulting in the necessity of a wheelchair for functional mobility. In this case, it is recommended that the therapist work with a Certified Aging in Place Specialist (CAPS) builder to accurately measure slope, run, and direction changes based on the topography of the entrance's approach. If a ramp is present or needed, it should comply with ADA standards. Each landing must be at least 60 3 60 inches (1.5 3 1.5 meters), and the slope of the ramp should be a maximum of 1 foot (30.48 cm) of rise for each 12 feet (3.65 meters) of run.² Ramps should also possess handrails on each side and can be located inside the garage if warranted.

Figure 21-1 Portable ramp. (Reprinted with permission from Gregg Frank.)

Exterior Stairs, Elevators, and Lifts

Whereas ramps are one option for creating a step-free entrance, lifts may be another alternative. An aesthetically pleasing option is the use of soil and ground covering to create a gradual sloping feature called an earth berm (Fig. 21-2). Elevators also allow accessibility to all home levels (see Fig. 21-3). Stair lifts are another alternative for persons to safely move from one home level to another. Cognition should be assessed for safety when navigating stair lifts as part of the clinical reasoning process. If clients have short-term memory deficits, display inability to process new directions, or have dementia or Alzheimer disease, an alternative to a stair lift may be necessary because neurocognitive deficits will impact client safety, especially when exiting the chair at the top of the stairs (Fig. 21-4).

Figure 21-3 Vertical platform elevator for wheelchair users.

Figure 21-4 Outdoor stair lift. (Reprinted with permission from Justin Oakley.)

Stairs: Exterior and Interior

Stairs throughout the home must be well lit with a light switch at the top and bottom of each staircase. The flat part of the steps, or the treads, should be 11 to 12 feet (~28 to 30 cm) deep and 36 inches (~91 cm) wide. Treads should have a nonslip surface, have color contrast between risers and steps for clients with low vision, and be clutter free. A landing at every 10 steps is helpful for older adults who need to stop and rest because of limited endurance.

Use of a bilateral, sturdy handrail is another important component to keep clients safe while climbing or descending stairs. Handrails should be about 34 inches (~86 cm) from the floor, 1.5 inches (~4 cm) from the wall, and extend 1 to 2 inches (~2 to 5 cm) beyond the top and bottom steps. Handrails should be tightly secured to wall studs and support the appropriate weight of all users.²

Doors

There are many door styles, including sliding doors, barn doors, bifold doors, and pocket doors, and clients may choose one for multiple purposes, including wheelchair accessibility. The client and therapist will consider the door style as well as hardware (e.g., hinges and doorknobs), the width of the open door clearance, the threshold height, and the door weight. Ideally, to prevent

injury to hands propelling a wheelchair, an opening of 36 inches (~91 cm) is recommended. Standard doors can be adapted by removing the door hardware to gain additional open space. Replacing standard hinges with swing-clear offset hinges allows doors to swing open and out of the way of the door frame. This action provides an additional 2 inches (~5 cm) clearance (on the door side of the frame) for people using wheelchairs and walkers. Door knobs should be replaced with lever-style handles to enhance ease of use, particularly for clients with limited hand mobility secondary to injury or disease. A keyless entry and peephole can be considered, as well as their ideal height for users.²

When assessing doorway thresholds for potential trip hazards or for wheelchair propulsion, a zero threshold is ideal. In the home interior, the threshold can be removed and filled with a replacement surface that is level with the floor. If the occupational therapist is assessing the entire home for functional mobility safety, recommendations can be made to install the same flooring throughout the house so that zero thresholds exist between doorways and rooms.

When assessing exterior doors, it is important to note that although exterior door thresholds cannot be removed, they can be replaced with lower height thresholds to allow easier wheelchair mobility and reduce fall risk. Also, note that exterior doors are heavier and can be difficult to open. In this case, therapists may recommend power door openers similar to those used in public dwellings.

As with all home modification recommendations, collaboration with the client and caregiver is most important in determining a list of priorities for safety, functional mobility, and cost. Although standards are set by ANSI 117.1 for accessible doorways and entrances in public dwellings, occupational therapists can customize doorways for individual clients in private homes.

Lighting and Outlets

Utilization of natural light by opening curtains or shades is a simple suggestion for improving lighting. Care must be taken, however, to avoid glare or even overlighting at midday (a problem for those with macular degeneration or aging eyes). Repositioning furniture near clean windows might offset the need for electrical lights, particularly during the day. Use of automatically lighting nightlights in bedrooms, bathrooms, and hallways is important for older adults and persons with low vision to prevent unintentional injuries in the evening and in darkly lit home areas. A seemingly simple act such as requesting family members or friends to occasionally change light bulbs can eliminate unnecessary climbing that may precipitate a fall.

A light switch should be located at each room's entrance and connected to a light source for that specific room. Touch control table lamps, remote controls, and multiple light switch styles are available, including motion activated and sound- or voice-sensor switches, depending on the client's individual preference and needs. Light-up rocker and slider switches can be installed to help clients easily detect light switch location in the dark to reduce fall risk. The color of furniture, appliances, and walls should contrast with floors and countertops to enhance visual detection. Electrical outlets are often low to the floor, making them difficult to reach; however, extension cords should be used sparingly and should be tacked to the wall to ensure clear walking paths (for recommended minimal lighting levels in the home, see Box 21-1).^{17,18}

Interior Floors, Hallways, Doorways, and Windows

Interior floor surfaces should be smooth and slip resistant and can include low pile carpeting or nonglare, nonslip surfaces such as sand-finished tile or hardwood floors with a satin, low-shine finish. Area rugs, throw rugs, and runners without nonslip rubber backing should be discouraged because of their potential to cause tripping and falls. Therapists, however, must acknowledge clients' desire to keep rugs, and in this case, rugs can be made less hazardous by placing nonslip rubber mats underneath or using double-sided tape to secure them in place.

Doorways and hallways throughout the home should be well lit and clutter free to prevent falls. Use of neutral color paint that contrasts with the floor is optimal to promote visual performance and safety. Hallways should be at least 36 inches (~91 cm) wide to accommodate wheelchairs, and thresholds between rooms should be eliminated or maintained at 0.5 inches (~1 cm) or lower. A clear space in front of and behind doorways with at least 60 inches (~1.5 meters) of space is optimal for all users. If doorways to rooms along the hallway are narrow,

adjustments can be made to remove some of the mechanisms within the door to increase the doorframe width for wheelchair clearance. Additionally, by adding swing-clear offset hinges to interior doors, a 34-inch (~86 cm) opening can be achieved with minimal reconstruction by the builder. Also, lever handles set no higher than 44 inches (~1 meter) from the floor create easy-to-open doors and can facilitate improved use of the home for all. It is important to remove or repair flooring that is warped, worn, or buckled for safety purposes. Additionally, electrical outlets should be within reach and not overloaded.²

Finally, recommendations for windows and window treatments should consider the client's ability. Some windows are electronically operated and open and close with ease; other windows rely on remote controls to open and close blinds for safety and privacy; and others are simply manual. Windows should not be overlooked because they may be the only exit in home fires. Therapists should assess the client's ability to both open and close windows, as well as access to windows. Furniture and clutter preventing window access should be removed.

Bathrooms

There are several features that can be modified in the bathroom to make activities of daily living (ADLs) more manageable, comfortable, and safe. Bathroom recommendations may include a door that is at least 32 inches (~81 cm) wide, one that swings out, or a pocket door that slides within the wall. There should be sufficient floor space in the bathroom for safe transfers from a wheelchair for toileting or bathing. The use of grounded fault circuit indicator (GFCI) outlets (i.e., grounded outlet to minimize short circuit and fire risk), rubber-backed bathmats to reduce slipping, anti-scald detectors to maintain water temperature below 120°, and the provision of bathroom phone access are preventive recommendations to promote bathroom safety.

Numerous toilet options exist relative to height, color, and capabilities. A typical toilet can be purchased with a 17 to 19 inch-height (~43 to 48 cm) height with varying types of seating options. Toilet heights can be increased or lifts added to make sitting and standing easier. Other options include light-up toilet seats for night use or bidet toilet seats to wash, dry, and keep perineal areas clean (Fig. 21-5). Automatic options with remotes or flush sensors exist. There should be at least 18 inches (~46 cm) of free space in front of the toilet and 42 inches (~1 meter) of space on one side for adequate transfers from another seated position if needed. Open-ended toilet paper holders should be within easy reach. An added toilet paper/grab bar option may also be considered.²

Figure 21-5 Bidet toilet seat and suspended sink. (Reprinted with permission from Gregg Frank.)

The sink and counter should be 34 inches (~86 cm) from the floor, with knee space beneath for persons needing to sit to perform self-care activities. Counters should be rounded and clutter free, with daily used items placed within easy reach. There should also be one lever handle located in the sink front to control hot and cold water temperature. A mirror that is adjustable or tilts downward will benefit persons who are seated.

The bathtub–shower combination should have a nonslip surface and temperature water controls that can be easily reached from outside the tub. Positioning soaps and towels nearby can eliminate reaching and possible balance loss. Bottled soaps are less likely to drop to tub floors and cause potential falls compared to handheld soaps. Use of handheld showers and tub seats or benches are frequent recommendations, particularly for clients with balance problems,

low endurance, and lower extremity mobility limitations. There are, however, cut-out tubs that allow clients to use a small opening to walk in and out of the bathtub (Fig. 21-6). Finally, for clients who bathe in tubs but may have difficulty rising, there are hydraulic bathtub lifts.

Figure 21-6 A and B, Cut-out bathtub. (Reprinted with permission from Justin Oakley.)

One needed modification may be to replace bathtubs with curbless showers to facilitate bathing from a wheelchair (Fig. 21-7). Curbless or roll-in showers can be uniquely created through collaboration between occupational therapists, clients, and contractors. Use of smaller floor tiles that are mildew resistant may reduce slipping and potential mold exposure. Placement of seating options, faucets, and shower heads should be aligned with user and/or caregiver needs in mind. Rolling shower chairs should be able to easily glide over shower dams if necessary. Another consideration may be a shower bay, which is a portable shower system with a shower chair that attaches to a sink.

Figure 21-7 Shower and walk-in soaking tub. (Reprinted with permission from Gregg Frank.)

Walk-in shower stalls should also have nonslip surfaces and easy-to-reach soaps, towels, and water controls. The use of fold down seats with handheld shower heads offers the option of sitting in the shower for persons with limited endurance or balance. Grab bars in the shower provide extra security for persons requiring stability or assistance with transfers. Walk-in showers without thresholds can be beneficial for persons with decreased balance or who use roll-in shower chairs.

Inside the shower itself, adaptations can be installed that can fit the needs for all. Shower pumps for shampoos, conditioners, and body soaps allow for easy use of these regularly used items. Therapists may provide adaptive equipment for shower use, including bath mitts, long-

handled sponges, or suction-cupped foot scrubbers. Shower seats or benches with backs/rails (some swivel) or tub slide shower chairs may be recommended to promote safe tub entrance and exit. Handheld showers and shower combos with on/off switches to control water while seated, or adjustable height showerheads, allow all persons to sit or stand while bathing. If bathmats are troublesome for some to use on a daily basis, therapists can replace mats with nonskid mildew-resistant bath strips that adhere to floor surfaces. The safest shower doors are made of tempered, laminate safety glass and should be recommended if clients have needed financial resources. Otherwise, shower curtains with bottom weights should be recommended. If there is no light source in the shower area, the shower curtain should be made of clear mildew-resistant plastic to allow light from the main bathroom light fixture (usually at the ceiling or sink). Finally, there may be need for a visual display to identify water temperature to prevent scalding.

Pedestal sinks or vanities with under-cabinet leg room can be used with clients using a wheelchair or seat for self-care activities. Lever faucets, touch control faucets, or auto turn-off faucets can be useful depending on client needs. Sinks can have faucet handles offset to the side or front for ease of use. Mirrors with tilt options are helpful for those who sit at the sink. Therapists should be certain that all necessary items are positioned on the countertop within easy reach and that cabinets have C- or D-shaped handles if hand function is limited.

Grab bars can be obtained in a variety of lengths, circumferences, and textures and can be purchased from the local pharmacy, home center store, or online. The type and style of grab bar can be chosen by the homeowner and therapist for appropriate weight capacity and functional use. Therapists will also make recommendations for grab bar location based on a user's current and predicted future abilities. It is important to make sure that clients never use towel racks, soap dishes, or sinks from which to push or pull, because these items will not withstand excessive pressure. Installers should collaborate with clients and therapists to meet recommended requirements for specific users. Grab bars must be installed by licensed contractors for optimal safety and sealed with silicone on shower walls to prevent leaks. Use of grab bars next to toilets, and in and around shower stalls and tubs, can support clients needing assistance or stability with transfers.

When renovating bathrooms, nonglare bathroom surfaces and lighting should be selected, with color contrast between floor and wall tiles. Task lighting positioned at the top and sides of sink mirrors, and on shower ceilings, best promote safe function. Nightlights are useful for safe entry in the dark, and heat lamps should be considered to control temperature variation and increase drying time (thereby decreasing rushing and potential accidents).

Bathroom storage should be considered for catheter, oxygen tank, and colostomy equipment and supplies. When working with bariatric clients, special equipment should be considered to accommodate weight for tub benches, roll-in shower commode chairs, and toilet commodes placed over existing toilets (to increase height and provide safety rails). When clients use caregiver assistance, therapists must consider how the environment will be used by a dyad.

Kitchen

The kitchen is a common area that can become dangerous as a result of utensil use and hot surfaces. Using effective task lighting, light-up utensil drawers, or natural light for mealtime prep and eating can eliminate potential kitchen injuries. Phones and fire extinguishers should be easily accessible in case of emergencies. Doorways should be wide enough with low thresholds to allow easy and safe access to kitchens.

Several styles of refrigerators with adjustable shelves, a variety of door arrangements, and options including water and ice dispensers exist. Refrigerator door openings vary and include side by side, freezer on bottom or top, and combinations and can be selected based on client preference and function. Dishwashers at least 8 inches off the ground reduce reaching demands; it is also important to make sure that sufficient space exists to allow wheelchair users to be positioned next to the dishwasher. Many dishwashers are now designed with waist height drawers for convenience and safety.²

Wall-mounted ovens with pull-down or side-swinging doors at convenient heights can make cooking easier. Use of push-button controls at the stove front instead of back limits excessive reaching and reduces burn risk. Use of tilted or angled mirrors above stoves allows seated users to view inside pots. Cooktops also have a variety of options available to meet client needs and

preferences. Burners should be staggered and sit below smooth, glass tops for easy cleaning and safety. Stove knobs should be located at stove fronts to prevent potential burns when reaching over hot burners. Cooktops should also sit atop counters that allow sufficient knee space for seated users. Stovetops should have indicator lights to alert homeowners that burners may still be hot. Clutter-free, nonglare, heat-resistant counters with rounded edges and smooth surfaces promote safe and efficient use of this potentially dangerous area.

Microwaves are used frequently by older persons who receive “Meals on Wheels” or who heat leftover food provided by family, friends, or neighbors. Microwaves should have a shelf nearby, touchpad controls with tactile cues as needed, and be located at an adequate height from the floor appropriate for the user. Microwaves can also be installed as drawer options. There should be a clear path and safe method to transfer hot items to and from the stove, microwave, or cooktop. This may include utility cart use or sliding items on the counter rather than lifting them.

Multiple or adjustable counter heights can be suitable for many users. Storing frequently used items on the counter can also reduce reaching or bending. There are multiple storage options with pullout drawers, electronic adjustable counters and shelving, rollout shelves, and mixer lifts for those who use this heavy appliance. Use of D- or C-shaped handles on shelves or cabinets are useful for all users. Dishes, glassware, and utensils should be within reach for easy access, whereas heavy pots and pans can be stored below counters in slide-out drawers. Upper cabinets can be easily reached at 48 inches from the floor and lower cabinets at 6 inches for seated users. Use of Lazy-Susans on deep shelves or in corner cabinets can improve access and limit unnecessary reaching. It is important for therapists to assess clients’ ability to access upper and lower cabinets, and reposition supplies to enhance safe meal preparation.

Kitchen sinks are easily accessible from seated positions at 34 inches (~86 cm) from the floor with no more than 6.5-inch (16.5 cm) deep basins.² Use of single lever handle faucets, instead of individual knobs, allows control of hot and cold water with one handle. Retractable spray hoses, anti-scald devices, and lever handles located near the counter front best support kitchen safety. Knee space beneath counters and sink benefits wheelchair users or persons needing to sit. Insulation or panels placed in front of pipes should be added to protect legs from potential burns. Placement of garbage disposal switches, if present, should be within easy reach. Finally, placement of trash cans, compactors, and/or recycling bins should be assessed and positioned for easy and frequent use (Fig. 21-8).

Figure 21-8 Kitchen with raised dishwasher and adjustable stove, oven, and cabinets.

Living and Dining Rooms

Living and dining room areas are common spaces in which people spend considerable time each day. The placement of cordless phones in these areas is important should emergencies arise requiring calls for assistance. Central vacuum system use can eliminate the need to lift and carry a vacuum cleaner. It is important to assess how well clients are able to sit down onto and rise from furniture, particularly low and armless chairs. Recommendations for persons having

difficulty with sit-to-stand transfers may include use of firm cushions for increased support, chairs with bilateral arms, adding risers or leg extenders to furniture to increase seat height, or power lift chair use. It is additionally important to make sure that clear walking paths exist to reduce fall risk. Recommendations may be made to reduce obstacles, clutter, and glare and enhance mobility with the rearrangement of furniture and strategic lighting placement. This may include painting walls light colors that provide contrast to furniture; using touch control table lamps, task lighting, and motion-, sound-, or voice-sensor switches; and using remote controlled, rocker, slider light, or light-up light switches that can be easily located in the dark. Windows should be easy to open, and sheer curtains that cover entire windows should be used to allow natural light without glare or shadows commonly occurring from vertical and horizontal blinds (which can increase fall risk). Easy-to-read or preprogrammed thermostats are also needed in this space.

Bedrooms

Bedrooms can be individualized for the person(s) occupying this space. Beds should be specific to client height, weight, and health condition. It is important to assess how well clients are able to sit down onto and rise from their beds. Recommendations to increase bed mobility may include risers up to 4 inches (~10 cm) to increase bed height or adjustable beds that raise and lower electronically. Programmed vibrating beds can also be recommended to serve as morning alarms and alert clients of ringing doorbells or the presence of smoke or fire (such beds can be connected to smoke alarms). When clients require assistance to get out of bed, simple bed rails, floor-to-ceiling poles, trapeze bars, or ceiling lifts may be necessary. Clients should be instructed to keep flashlights and phones near the bed, use automatically lighting nightlights, and remove clutter to enhance safety and reduce fall risk. Recommendations for bedroom furniture should consider client mobility needs and wheelchair use relative to furniture height and layout. Chairs with armrests are useful to assist with transfers and dressing, and bedside commodes with absorption pads in the basin can limit nighttime ambulation (further reducing fall risk).

Closets

Closets should be assessed for ease of access and item retrieval relative to client mobility limitations. There are many closet space configurations. Sliding doors may limit a client's ability to perceive and access all closet items at once, whereas bifold doors may impede a seated user's access when attempting to reach inside. Some clients may prefer to remove closet doors completely to increase easier access to items inside. Shelving and double-hung rods should be adjusted to a client's height and reaching limitations; pull-down closet rods that lower clothing within a client's reach may be beneficial. Hanging shoe bags and racks maintain these items' accessibility and reduce clutter. For persons with visual impairments, stick-on wall lights and tagging clothes to identify colors may be helpful. Closet lighting should be of sufficient intensity to allow searching for and matching clothing colors.

Home Safety Technologies

Assistive technology can greatly improve clients' quality of life and should be considered when making recommendations for modification of the home or daily routine. Some technologies are appropriate for caregiving, whereas others are designed for client use to enhance occupational participation. Therapists must determine the need for technology based on clients' objectives and wishes, nature of their health condition (e.g., progressive and worsening or temporary such as postsurgical recovery), and cognitive functional level. Therapists will additionally need to collaborate with caregivers and family to determine budgets for technology because financial status will influence decision-making.

Choices for home modification technology are dependent on training needs as well as device complexity. According to Georgia's Assistive Technology Act Program, assistive technology can be categorized into three main categories based on use and needed training.¹⁹

Low Technology

Low-technology items are devices or equipment that require minimal training by the occupational therapist, may be less expensive, and do not have complex or mechanical features.¹⁹ Examples for the home include under-cabinet jar openers, lever-style handles for doors and faucets, C-shaped cabinet handles, rocker light switches, and double-sided carpet

tape. Examples of low-technology items used in daily activities include reachers, long-handled shoe horns, dressing sticks, and built-up handled utensils.

Medium Technology

Medium-technology items are devices or equipment that require moderate training by the therapist, may have some complex features, and may be electronic or battery operated. Medium-technology items are more expensive than low-technology devices and are primarily adaptations to the home.¹⁹ Some examples include hot water regulators to prevent scalding, tub benches and seats, grab bars, handheld shower heads, raised toilet seats, versa frames, and large button telephones.

High Technology

High technology refers to the most complex devices or equipment that likely require maximal training by the therapist, have digital or electronic components, and may be computerized. As a result of these factors, such items can be costly.¹⁹ It is imperative that therapists determine the need and potential successful use of these technologies prior to obtaining them for clients. Examples of such technology include stair lifts; walk-in tubs; tub hydraulic lift seating systems; electronic transfer ceiling track systems; power door openers; wheelchair elevator systems; adjustable height kitchen counters, cabinets, and appliances; power stand assist chairs; electronic adjustable beds; life alert systems; and electronic medication management devices.

Home Safety Technologies

These can be categorized separately as advanced systems that can be installed directly in the home to enhance client safety. Many of these technologies would be recommended by the therapist when working with clients with low vision or hearing loss. Examples of smart home technology command centers for phone and alarm systems include vibrating beds that awaken clients when smoke or fire is detected and flashing lights or audible alarms that alert clients to emergencies and ringing phones.

Safety in the kitchen is of particular concern for clients with dementia. To prevent burns and fires resulting from short-term memory loss, electronic home technologies that sense motion can be installed in the kitchen. Such systems can provide audio cues to remind clients to return to the stove if the system detects lack of motion after a set time. The system can also be programmed to automatically turn off the stove in this situation. Sensor systems and webcams are additionally recommended to monitor client whereabouts within and exiting the home, as in the case of sun downing and nighttime wandering seen in late-stage dementia.

Workplace Environmental Assessment

Purpose of Conducting a Workplace Assessment

The purpose of workplace environmental assessments is to prevent injuries and promote comfort, safety, and productivity for employees and workgroups. Workplace environmental assessments may be conducted along with **ergonomic** job analyses that identify the sequences of job tasks, body motions and postures, time spent in specific postures, and risk factors for musculoskeletal disorders. Workplace environmental assessments may be requested by (1) the worker's physician or insurance company to promote safe return to work, (2) the company safety department to promote injury prevention, or (3) human resources for ADA issues. In all cases, input from workers, supervisors, and employers are critical to understand worker challenges, personal and organizational resources, company expectations, and productivity standards. If a worksite assessment is for an individual worker, therapists will collect information through the occupational profile about the worker's medical history, pattern of discomfort, and current functional limitations.

Preparing for the Worksite Visit

Prior to assessing a worksite environment, therapists should contact the company to clearly identify the reason for the visit, request a job description, and set a visit date. A job description identifies the primary job function and duties that are considered essential to the job. The job description will typically include qualifications such as education, needed experience, skills, and work conditions (hours, location). Therapists can verify this information with the company contact person and client. This will help therapists identify worker priorities for the assessment.

Therapists will then identify the specific tasks, task sequences, physical and cognitive demands, and worker positions needed to accomplish the job.

Therapists should consult relevant workplace standards, guidelines, and resources from OSHA, National Institute for Occupational Safety and Health (NIOSH), and professional organizations for a particular workplace. For example, lighting guidelines from the Illuminating Engineering Society (IES) provide recommendations for various job tasks (see Box 21-1).¹⁷ Assessment supplies will be determined by the nature of the worksite visit. Typical supplies for office and industry visits may include personal protective equipment (PPE) as required by the workplace (e.g., steel-toed footwear and protective glasses), assessment recording tools (e.g., forms, computer), measuring tape, force strain gauges (e.g., Chatillon gauges, handheld force gauges), stopwatches, light meters and thermometers, and cameras (with video recording capacity).

Components of an Environmental Assessment

Similar to the home assessment, therapists should observe a worker or representative perform required job tasks in order to understand how the workstation supports the job. Features of the work environment that impact job task performance are addressed here. All workstations address reach and clearance, which are two important considerations in a worker's ability to access the task being performed and "fit" into the workspace provided. The size of the worker (see section on Measuring for Fit: Understanding Anthropometrics, p. 407) is critical for determining the appropriate reach, clearance, heights, and workstation design.

- **Clearance** refers to sufficient headroom, legroom, and elbowroom in the work area. Clearances should always be designed for the largest user (95th percentile). The therapist will observe, measure, and determine whether clients have adequate legroom, armroom, and headroom (if in cramped spaces).
- **Reach** refers to the location of controls and materials accessed to perform a task. Usual manual work should be conducted close to one's body (14 inches [~ 35 cm]). The tools, staplers, phones, and calculators may be located within about 24 inches (~ 61 cm) of the individual to minimize awkward postures. Reach should be designed for the smallest user (5th percentile) to minimize awkward postures⁹ (Fig. 21-9).

Figure 21-9 Reach envelope. The primary work zone for table top work is within about 10 to 14 inches (~ 25 to 35 cm) of the elbow. This zone should include frequently used work equipment such as the keyboard and primary equipment. The secondary work zone, within about 20 inches (~ 21 cm) of the elbow, includes items such as phones, calculators, and less frequently used tools.³⁴ Document in the public domain and may be freely copied.

Therapists should consult normative data for anthropometric information related to sitting, standing, and reaching relative to hand tool and equipment design. These are measured when workers are sitting and then again standing depending on the workstation.

Task Requirements and Workstation Design

The task requirements of the job dictate worker posture and body motions. Therapists should note the visual requirements of the job (e.g., location of visual cues, objects to manipulate, or information) because these will determine worker head position. Visual information that is positioned directly in a worker's line of sight will promote an upright head/neck posture. Visual information that is placed lower (such as a laptop monitor) will require workers to flex their

neck and trunk to view images. Computer screens placed far from the body (beyond arm's length) and low (below head height) will cause workers to flex the neck and trunk forward to view the screen.

Similarly, worker posture also results from placement of workstation equipment. If work surfaces and equipment are placed too high, workers must reach for objects, prompting shoulder flexion and fatigue. If work surfaces are too low, workers must bend their trunks, contributing to low back discomfort. The working areas of desks or benches should be close to the body and unobstructed.^{20,21}

Seated Workstations

Seated work is common in offices, call centers, laboratories, dental offices, and seated assembly workstations. Well-designed seated workstations can minimize discomfort from prolonged sitting. Discomfort arising from low back, neck, or shoulder pain reduces work efficiency and may contribute to musculoskeletal disorders over time if awkward postures are sustained.

Computer workstations are examples of seated stations that include a chair, computer (desktop or laptop) with keyboard and monitor, desk (traditional or standing), input device (mouse, trackball), lights, and other office equipment such as document holders and calculators. In laboratories or assembly environments, task-specific equipment will replace computers, such as microscopes or micrometers. The following workstation components should be assessed for workers using seated or standing computer workstations (Fig. 21-10).

Proper Posture

- | | | | |
|-----------------------------------|--------------------------|---------------------------------|--------------------------|
| Head/neck upright, facing forward | <input type="checkbox"/> | Hips perpendicular to floor | <input type="checkbox"/> |
| Shoulders at one's side | <input type="checkbox"/> | Low and mid back supported back | <input type="checkbox"/> |
| Elbows bent to about 90° | <input type="checkbox"/> | Knees bent to 90° | <input type="checkbox"/> |
| Wrists straight | <input type="checkbox"/> | Feet flat on floor or footrest | <input type="checkbox"/> |

Figure 21-10 Seated and standing computer workstation checklist. (Developed by Martha Sanders, 2018.)

Computer Workstation Components

Ergonomic Chair

Well-fitting ergonomic chairs can minimize the risk of long-term neck, back, and even leg problems when fit properly.

- **Height adjustment:** Elbows should be aligned with the desk, keyboard, or working surface. Feet should be flat on the floor or on a footrest.
- **Lumbar and thoracic support:** The worker's back should be in contact with the backrest and comfortably fit the lumbar curve.
- **Seat pan length:** Seat pan length should support the thighs yet allow workers to fully bend the knees to 90° (chair seat should extend to about 2 inches (~5 cm) behind the knees). Seat edges should be rounded and upholstered.
- **Seat angle:** Seat angle should be 100° to 110° and allow the worker to access the desk, as well as allow movement backward by 5° to relax the spine.
- **Footrest:** Footrests should support the feet if workers are unable to reach the floor. Footrests also promote upright posture in chairs and relieve pressure on thighs and low back.
- **Armrest:** Armrests should barely reach the elbows when flexed at 90°. Perspectives differ with regard to armrest use when typing. Armrests are customarily used when relaxing; however, if used while typing, care should be taken to ensure that posture is upright and the trunk is not flexed forward.

Desk or Surface

- Desk height should be about same as elbow height when flexed to 90° to access keyboards. Chairs must be height adjusted if desks are not adjustable.
- Desk surfaces should have rounded edges or wrist rests.

Keyboard

- Keyboards may be placed close to desk edges or on keyboard trays below desk surfaces.
- Keyboards should be flat or positioned at a negative tilt.
- Keyboard width should be approximately shoulder width to minimize internal rotation of the arms.

Computer Monitor

- Workers should face the monitor directly (and should not rotate the trunk or neck).
- Monitors should be positioned at about arm's length away from the body.
- Monitors should be positioned perpendicular to the window to avoid sun glare.
- Screen tops should be at eye level or slightly lower.
- Laptop stands are needed to attain the correct height of laptop monitors.

Input Device Mouse or Input Device

- Mouses should be positioned close to the keyboard.
- Traditional mouses should fit the transverse arch of hand.
- Various mouse and input device options include vertical mouses (forearm positioned in neutral), handshoe mouses (contours to fingers and thumb), trackballs, touchpads, and styluses.

Laptop computers are heavily used for personal and workplace use but present challenges for optimal setup. When laptop computers are used on desk surfaces, monitors are too low; when laptops are placed on raised surfaces to improve monitor placement, keyboards are too high, causing excessive reach.

Standing Workstations

Standing workstations are common in industrial settings for assembly tasks, warehousing, and manual materials handlings. Standing for long periods without breaks, particularly on hard surfaces, can be associated with leg, low back, and foot pain (such as plantar fasciitis). Work surfaces that are low create the need for excessive neck flexion, as shown in Figure 21-11. Standing workstations must be evaluated to determine the optimal work surface height, reach, clearance, and posture needed for essential tasks. Additional considerations are flooring, the

presence of ergonomic mats, rest areas (chairs), and the duration of time spent in standing, walking, and carrying tasks.

Figure 21-11 Standing workstation. Worker standing at a laser machine. Note flexion of neck and extension of elbows resulting from low height of working surface. Worker would benefit from an ergonomic mat for prolonged standing.

Lifting Workstations

Frequent lifting of heavy loads in awkward positions contributes to the development of low back pain. Therapists should determine the safe lifting limits for workers and the workstation factors that promote safe lifting and decrease low back pain risk. The NIOSH Lifting Equation is based on the assumption that a healthy person can lift 51 lb (~23 kg) when an object is located at the ideal height for the person, lifted close to the body, carried a reasonable distance, and possesses good handholds. When workstation design conditions change requiring greater bending and reaching, the load that a worker can safely carry decreases.

Standardized tests such as the NIOSH Lifting Equation and the Liberty Mutual Tables can be consulted to guide therapists in (a) identifying key variables that impact workers' ability to lift and (b) providing the level or risk in the current workstation.

Lighting

Lighting is most commonly assessed at the location where the task is performed using a light meter. This measure of light, *illuminance*, refers to the light intensity on the surface where work is performed. Additionally, therapists can use a lighting checklist to gather information about the worker's perceived ease in completing tasks based on current lighting conditions.²²

Noise

Noise-induced hearing loss can occur when workers are exposed to high intensities of noise over 85 to 90 dB. Companies in which workers are exposed to continuous noise are required to determine noise level, provide audiometric testing for workers, and institute a hearing

conservation program for workers exposed to 85 dB per day. Noise-related testing is typically performed by occupational safety and health personnel according to OSHA standards.²⁰

Temperature

Most indoor environments are temperature controlled at 70 to 73 (~21 to 23 Celsius). Extreme considerations such as workers' regular exposure to high heat, humidity, or cold, for example, should be reported. Such temperature extremes may be particularly detrimental for individuals with arthritis or Raynaud phenomenon.^{22,23}

Flooring

Floor surfaces are important considerations in workplace fall prevention, ease of moving equipment, and standing workstation comfort. Although therapists may not be involved in the initial floor selection, they can make recommendations for individual workstation safety and comfort. In general, slip-resistance surfaces are recommended, particularly where moisture or wet floors may occur. This type of coating, however, creates increased friction for pushing carts or equipment. Companies must determine flooring based on safety and tasks performed. In general, ergonomic mats are recommended for standing workstations to reduce leg and foot fatigue. All mats and rugs should be secured to the floor to prevent tripping hazards.²¹

Interventions for Work Environments

Workstation design influences a worker's postures, work patterns, workflow, and, ultimately, comfort and productivity throughout the day. Therapists should ensure that workstation layout—including the location of objects, surface heights, and visual displays—is well organized.²¹ Therapists must keep in mind that workstation equipment recommendations alone do not ensure clients' appropriate equipment use and adjustment. Therapists must educate workers about proper postures and body mechanics, train them in workstation adjustments, and follow up to ensure that recommended practices are carried out.^{23,24}

Workplace Layout

Workspaces should be organized in a logical manner to minimize wasted effort. The location of frequently used items, task sequences, and workflow should all be considered. Personalized items (e.g., family and pet photos) should be placed away from the direct working area. Several key principles, also emphasized in universal design principles, help determine optimal item placement²¹:

- **Importance principle:** Place the most important items in the most easily accessible location.
- **Frequency-of-use principle:** Place the most frequently used items in convenient, close-to-reach locations.
- **Function principle:** Place items with similar functions together (staples, paper clips, scissors).
- **Sequence-of-use principle:** Lay out items in the same sequence in which they are used.

Because workspace is at a premium, only frequently used items should be placed in the worker's reachable distance (Fig. 21-9).

Workstation Design

Workstations should be designed specific to the tasks performed and promote a worker's neutral posture. A neutral posture is a biomechanically advantageous position that allows the body to efficiently use its muscles. A neutral posture is achieved when the head is upright and the neck is slightly flexed, the shoulders are at the sides and flexed less than 20° to 25°, the elbows are flexed to about 90°, and the wrists are in 0° of flexion. Positions that deviate from a neutral posture require more energy to sustain. Workstations should incorporate adjustability to accommodate changes in the tasks performed and other workers occupying the workspace.

In general, work equipment or controls that are regularly used should be located within a worker's "reach envelope." This refers to a semicircular shell in front of workers that allows them to easily access work tasks when the elbows are flexed to 90° and objects are within 14 inches of the body. Items located outside the primary zone should be accessed less frequently.

Figure 21-9 illustrates the reach envelope. The worker should not reach above shoulder height or behind the back on a frequent basis.

Seated Workstation Adjustments

Seated work requires little physiological effort and provides stability for precise work. Prolonged sitting, however, increases spinal compression forces and the potential for static loading on the neck and shoulders; careful readjustment is critical for employees assuming seated positions for much of the day.²¹ Although some offices or seated workstations have adjustable furniture and equipment, workers may not be familiar with proper computer workstation setup and sometimes use equipment “right out of the box” (e.g., on the lowest chair setting). Many valuable online resources and videos demonstrate proper computer setup.²⁵ The following are steps to examine worker posture and adjust equipment to promote a neutral posture (Fig. 21-12).

Figure 21-12 Seated workstation.

Computer Workstation Adjustment Process

1. Observe the worker regularly performing work tasks and record each body part's posture in the evaluation process.
2. Position clients in a neutral sitting posture. Align the elbows and wrists with the keyboard so that the fingers can access the middle row with the wrists straight.
3. Move the keyboard to the location for best access.
4. Move the mouse close to the keyboard to minimize reach.
5. Check that the palms are not resting on the hard edges of the computer or desk.
6. Adjust chair height (up if shoulders are flexed when reaching for the keyboard; down if elbows are extended when reaching for the keyboard). Ensure that elbows, wrists, and keyboard are aligned in a neutral wrist position (straight).
7. Adjust chair features. Seat pans should fully support the thighs. Seat pans that are too deep (long) cause users to sit forward and lose contact with the backrest. Seat pans that are too

- short create increased pressure under the thighs and potential instability. Lower the chair arms if they touch the desk directly. Adjust the lumbar support up or down.
8. Determine the need for a footrest (if person's feet do not touch ground).
 9. Ensure that clients face the monitor. Identify head/neck position in relation to the monitor. Adjust the monitor height or determine the need for a laptop stand.

Laptop computers should make use of a laptop stand to raise the monitor height and a peripheral keyboard placed on the desk to ensure that workers are keying without excessive reaching. Therapists should demonstrate several optimal positions that workers should assume throughout the day to promote movement and position change.

Standing Workstation Adjustments

Standing workstations are common in assembly, warehousing, and machining tasks. The same principles exist relative to working in a neutral position of the upper extremity; however, hip and lower extremity posture need to be addressed along with concerns for prolonged standing.

Workers should stand with hips midway between an anterior and posterior pelvic tilt. Foot rails or a low stool can be used for intermittent foot placement both to relieve stress on the low back (as it promotes a neutral pelvis) and to change leg position. Anti-fatigue mats promote small postural changes to stimulate venous pump to the legs and should be placed on hard floor surfaces to minimize leg, feet, and low back discomfort. The following guidelines consider the position of the body during a task to leverage stability or force.²¹

- Precise work requires a higher work surface to provide proximal stabilization (2 to 4 inches [~5-10 cm] above the elbow for drafting work or precise assembly).
- For light assembly work, the work surface can be 2 to 4 inches (~5-10 cm) below the elbow to best utilize upper extremity musculature forces.
- Heavy work requires a lower work surface (about 4-5 inches [~10-25 cm] below the elbow) to leverage body and trunk strength. Heavier work requires a lower work surface to increase available muscle forces.

All work surface edges should be rounded or padded to avoid compression of soft-tissue structures.

Lifting Workstation Adjustments

Modification of lifting workstations can minimize injury risk. Principles rely on the use of mechanical assists and proper heights relative to the worker.²⁰ Adjustability is key for multiple individuals using the same workstation (Fig. 21-13).

Figure 21-13 Lifting workstation. **A.** Improper lifting with a flexed trunk and load far from body. **B.** Proper straight back and load.

- Use mechanical assists to transfer loads between surfaces.

- Use adjustable surfaces to lift loads at waist height.
- Reduce the size of containers lifted to minimize awkward reaches.
- Design handles, hooks, or handholds to promote firm object grasp.
- Change jobs from pulling to pushing.

Sit–Stand Workstations and Physical Activity

Sit–stand workstations are increasingly recognized as beneficial in promoting changes in body position for sedentary workers.²⁶ Sedentary or seated work has been associated with the development of chronic disease, cancers, obesity, and increased mortality.²⁷ Much effort has been undertaken to promote movement and overall increased activity in the workplace.

Hedge^{25,28} promotes a combination of sit–stand–move routines for office workers (sit 20 minutes, stand 8 minutes, move 2 minutes), noting that simply moving from a prolonged sitting to a prolonged standing position is not beneficial. Sit–stand workstations are one way to promote postural changes that may decrease musculoskeletal strain from either position alone (Fig. 21-14). Although training is required for all ergonomic modifications, the use of sit–stand workstations in particular requires education regarding the duration of time for each posture, proper workstation height, and continued importance of movement. Research suggests that sit–stand stations can decrease musculoskeletal discomfort and fatigue and improve mood without jeopardizing productivity. Such gains, however, were not realized in research studies unless ergonomic training accompanied equipment use.²⁴

Figure 21-14 Sit–stand workstation.

Sit–Stand Options

Numerous options now exist for sit–stand workstations. Decisions about which sit–stand equipment to adopt depend on factors such as space allotment, cost, ease of surface adjustment up or down, and the amount of workspace needed around the keyboard. Ideas for creating sit-and-stand areas or buying dedicated sit–stand equipment are provided as follows:

- Different work areas can be designated for sitting and standing work. Create a separate work area at a desk; then move to another location for standing work.
- Desktop sit–stand equipment. An adjustable surface is placed on top of a desk and manually raised and lowered. The equipment may have one or multiple levels for placement of a monitor and keyboard. Limited work area exists around the keyboard (Fig. 21-14).
- Adjustable desks (crank or electric) allow the entire desk surface to raise to standing or lower to sitting. Ample workspace around the keyboard is available.

Community Environmental Assessment and Modification

Occupational therapists promote environments that enable clients to participate in community roles with the same opportunities and dignity as that of individuals without disabilities. For example, it is not acceptable for wheelchair users to be forced to use freight elevators at the back of buildings, endure safety risks to maneuver sidewalk curbs, or require others to lift them over even a few steps to enter buildings. In order for persons with physical disabilities to fully engage in and feel included in community life, they should experience easy, convenient, and safe access to desired places, services, and programs. ADA legislations and universal design principles are now applied in mainstream design approaches to promote access across most community settings.²⁹

Community Environmental Assessment

A number of instruments are available to assess community environments. Some assessments target the person–environment fit and enable clients to identify aspects of the home and community environments that hinder desired occupational participation (e.g., physical characteristics and social attitudes) (see Boxes 21-2 and 21-3). Other community assessments, such as online livability indices, rank environmental areas, services, and amenities that most impact life: housing affordability and access; safe and convenient transportation; neighborhoods that provide access to life, work, and play; environments with clean air and water; access to health services; civic and social involvement opportunities; and inclusiveness and diversity (Box 21-3). Therapists can work with clients to examine communities that best fit their needs as they transition from one life stage to another. Other instruments measure built environmental features associated with physical activity and walking, including architectural, traffic, transportation, and aesthetic features as well as proximity to services and retailers. These features can have a positive impact on the ability of persons with disabilities to access their neighborhood community.

Box 21-2

Descriptions of Home Environmental Assessments

Assessment and Description

Cougar Home Safety Assessment³⁵: Identifies potential safety issues in residences.

I-HOPE¹⁵: Home assessment for older adults (<https://starklab.wustl.edu/i-hope-kit/>).

Home Environment Lighting Assessment (HELA)³⁶: Near-task home lighting assessment for older adults with low vision.

Home Environmental Assessment Protocol (HEAP)³⁷: Environmental hazards specific to individuals with dementia.

Home Falls and Accidents Screening Tool (HOMEFAST)³⁸: Preventive health assessment to determine fall risk of older persons in the home.

Home for Life Design, Home Assessment App, and Solution: Mobile platform to conduct home assessments efficiently (www.homeforlifedesign.com).

Housing Enabler³⁹: Predicts problems arising as a consequence of a client’s functional limitations and barriers in the home.

Safety Assessment of Function and the Environment for Rehabilitation Health Outcome Measurement and Evaluation (SAFER-HOME), Version 3⁴⁰: Used to evaluate

change over time of clients' functional abilities and task completion in the home.

TVO Bathroom Assessment⁴¹: A bathroom assessment of both environmental and functional aspects to promote safety, reduce falls, and encourage aging in place.

Westmead Home Safety Assessment (WeHSA)⁴²: Identifies and prioritizes home hazards with client input specific to falls in older adults.

Box 21-3

Descriptions of Community Environmental Assessments

Assessment and Description

Livability Index⁴³: Ranks seven areas of environment, services, amenities that are important to community life.

Senior Walking Environmental Assessment Tool–Revised (SWEAT-R)⁴⁴: Addresses built environment features related to physical activity for older adults.

Neighborhood Walkability Scale (NEWS)⁴⁵: Used to assess the perception of neighbor design features by area residents.

Irvine Minnesota Inventory (IMI): Focuses on the built environment related to physical activity, specifically walking, in the community.

Community Environmental Modification

Client-Specific Modifications

The impetus for community environmental modifications can be generated from a specific client's needs or those of an entire community. When therapists serve clients for whom occupational participation is impeded because of community environmental barriers, therapists should work with community stakeholders (e.g., city officials and planners, and business owners) to present a client's case and strategize feasible solutions that benefit not only the client but all community members. Examples may include the incorporation of benches in public areas (e.g., public gardens, malls, museums) for clients who fatigue easily as a result of disease or injury; the availability of ATM machine screen magnification for clients with visual deficits; the provision of simple pictorial instructions for clients with cognitive deficits who use kiosk machines to purchase subway and bus transportation cards; the addition of grocery store aisle signage using food photos for clients with visual or literacy deficits; and the installation of appropriately timed pedestrian walk signals displaying timed, street crossing countdowns for clients with mobility or cognitive impairment. In these instances, therapists can present possible solutions and work with community planners and business owners to strategize implementation.

Population-Based Modifications

Occupational therapists can also serve as consultants for populations or groups desiring community modifications that benefit all members. When considering population-based modifications for communities, therapists will work as a member of a collaborative team with municipal officials, city planners, ADA specialists, business owners, and community members. For example, when working to build a new accessible recreational center and park for a school or town, it is imperative to work with city officials to determine and comply with zoning requirements and budgets. Therapists should seek community residents' input when evaluating how well a community promotes walking, socializing, safety, and intellectual stimulation; identification of barriers, such as inaccessible transportation, should also be made. Once identified, therapists can generate recommendations, based on client and community priorities, to create spaces and plans with local municipalities. Ideally, solutions should benefit all community members through inclusive and universal design concepts. Funding for projects may be secured through grants, fundraising, or other community sources.

In general, paths and surfaces should accommodate a wide range of people, including users of scooters and wheeled mobility devices, parents with strollers, and two people in wheelchairs strolling together or in tandem.³⁰ Surfaces should be level, and transitions from one level to another should be achieved with ramps, earth berms, and lifts. Options for handrails and seating

benefit persons with limited endurance and balance problems. Indoor seating areas should be strategically placed in large walking areas, such as shopping malls, home center stores, supermarkets, schools, and parks. Signage should be simple, contain symbols or illustrations, and have limited printed text to accommodate persons with visual or cognitive impairment, or poor literacy. Lighting should enhance safety, provide clear vision of paths and walkways, be evenly distributed across a space but also minimize glare, and should highlight task-specific activities such as kiosk use (Fig. 21-15).

CASE STUDY

Patient Information

Dyani is a 19-year-old Native American female with a recent C-7 complete SCI resulting from a motor vehicle collision. After a short acute care hospitalization and rehabilitation center stay, Dyani was discharged home. The occupational therapist at the rehab center made recommendations for a custom wheelchair; there are plans for a portable ramp to enter the family home and a drop-arm bedside commode. Dyani received training for and is now independent in transfers and ADLs. She plans to continue therapy in the home.

Reason for Occupational Therapy Referral

The family has requested a home assessment for additional recommendations regarding bathroom modifications to increase self-care independence. Dyani's insurance company has agreed to provide homecare assessment and services.

Assessment Process and Results

The therapist met with Dyani and her family to learn about the existing bathroom environment, concerns regarding bathroom use, and plans for ADL routines. Dyani prefers to shower each evening and perform bowel and bladder routines in the morning. The current bathroom has a standard toilet, bath/shower combination, sink, and large closet. The therapist observed Dyani's current bathroom area use and used the TVO Bathroom assessment to document environmental enablers and hindrances in this space (Box 21-4). Although Dyani was taught to safely use a tub bench with supervision while in rehab, she is elated to learn that the bathroom can be modified to allow her to complete ADLs independently and alone.

Occupational Therapy Problem List

- Decreased independence in self-care and basic ADLs
- Difficulty with sink and shower water controls
- Difficulty transferring to the tub bench without assistance from caregivers
- Unable to reach the toilet paper located behind the toilet
- Unable to see herself in the mirror for grooming

Occupational Therapy Goal List

(All within 2 weeks after modifications)

- Dyani will perform toilet hygiene with modified independence and adaptive toilet seat controls.
- Dyani will use a rolling shower seat for transfers in and out of the roll-in shower with modified independence.
- Dyani will perform grooming tasks independently.
- Dyani will independently control water temperature with one-touch lever handles.

Intervention

The family was willing and able to make modifications to the bathroom to allow Dyani to perform self-care and ADLs as independently as possible. The use of a toilet seat bidet with remote facilitated hygiene while seated allowed Dyani the dignity to perform this task without assistance. Partial closet space was used to build a roll-in shower, and with the use of a roll-in shower chair, Dyani was able to bathe on her own. Additional modifications that increased independent bathing were a handheld shower with control, touchless soap/shampoo dispensers, and lever handles to control water temperature at the sink and the shower. Additionally, a roll-under sink, mirror at sink height, and adequate lighting assisted Dyani to perform grooming tasks. A closet portion was maintained for medical supplies and storage.

Once the above modifications were completed, Dyani was seen again by the occupational therapist. The results of the post-TVO assessment showed no further areas to modify. Dyani was able to use the bathroom without assistance to perform self-care and ADLs safety and independently.

Box 21-4

Sample from TVO Bathroom Assessment

Primary Bathroom

ADEQUATE LIGHTING # of Lights _____ Accessibility of Switches: _____ Yes _____ No • # of Lights: Identify the number of light fixtures in the bathroom, <i>not</i> the number of bulbs • Accessibility of Switches: Can all users use switch appropriately? Can all users reach light switch? COMMENTS: If users cannot reach switch, identify the reason why (i.e., height, location of switch). Also note the type of switch (i.e., rocker, flip, knob, motion sensor, dimmer)
SINK/VANITY Height of Sink: _____ Height: Measurement should be taken from top surface of sink to floor (~34 inches or 86 cm) Water Control Type/Style _____ Able to manipulate: _____ Yes _____ No Water Control: Identify if it is a handle, knob, motion activated Accessible Mirror: _____ Yes _____ No Accessible Mirror: Is the mirror located at an eye level for all users? Storage Access _____ Storage: Identify location (i.e., above or below sink). COMMENTS:
TOILET <i>*When assessing this area of the bathroom: Ask client to demonstrate ability to properly get on and off toilet. Also ask for client to reach for toilet paper when sitting on the toilet and toilet handle.</i> Height _____ Height: Measure from floor to top of seat (standard height: 17 inches or 43 cm). Toilet Handle Able to Manipulate: _____ Yes _____ No Toilet Paper Dispenser: Location _____ Distance from Toilet _____ Able to Use: _____ Yes _____ No Distance of toilet paper dispenser: Measure from edge of toilet to dispenser. COMMENTS: Identify client's functional capabilities.

Selected Assessments for Home Environments

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
The Housing Enabler ³⁹	Questionnaire to assess the congruence or fit between an individual with a functional impairment and the home environment. Measures functional limitations (15 items) and physical environmental barriers (188 items).	Up to 2 hours depending of functional limitations and physical environment	Content item selection based on literature review and expert opinion; adjusted after pilot studies	Inter-rater: Studies report excellent results ranging from 81% to 100% agreement; test-retest: interclass correlation (ICC) range —0.92–0.98.	Person–environment fit scores captured significant differences between baseline and follow-up by means of signs and McNemars’s tests.	Strengths: Meticulous development and testing. Up-to-date website. Widely used in Europe. Useful for both clinical and research purposes. Weaknesses: Rating training more difficult to arrange outside Europe. Time-consuming to administer.
Home Falls and Accident Screening Tool (HOME FAST) ³⁸	Health care provider completed questionnaire; designed to identify risk of falls as a result of home hazards; may be used as an outcome measure to evaluate interventions for improving function in the home environment.	20–30 minutes	Content: Based on the literature; field testing with 83 older adults; review of content and field testing data by an expert panel; reduced number of items; content further examined in a cross national validation (Australia, Canada, the United Kingdom) where occupational therapists, physiotherapists, and nurses responded to a survey regarding the content and weighting of items.	Inter-rater: Evaluated ($n = 40$) using k for individual items and weighted k for the total number of hazards; overall weighted k was 0.56 (considered fair-to-good agreement); k values for individual items indicated 4 items had excellent reliability, 20 items had fair-to-good reliability, and 1 item (hazardous outside paths) had poor reliability.	Sensitivity shown by comparison of expert ratings and second ratings of home hazards; 68.6% agreement (95% confidence interval [CI] 63.4–73.6) ($n = 844$ sample ratings)	Strengths: Can be quickly administered as a screening assessment. Research has been conducted in various countries. Initial psychometric research is positive. Initial evidence suggests may be useful as an outcome measure. Weaknesses: Further examination of the predictive validity, responsiveness, and test-retest reliability would strengthen our understanding of the measure.

Instrument and Reference	Intended Purpose	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Safety Assessment of Function and the Environment for Rehabilitation Health Outcome Measurement (SAFER-HOME) Version 3 ⁴⁰	SAFER-HOME based on SAFER tool: Designed to measure intervention effectiveness and changes in safety intervention over time (12 domains: living situation, mobility, environmental hazards, kitchen, household, eating, personal care, bathroom and toilet, medication, addiction and abuse, leisure, communication and scheduling, and wandering)	45–90 minutes	Content: For both the SAFER and the SAFER-HOME established through review by experts and clinicians as well as statistical analysis of completed measures	Internal consistency: Cronbach's for total scores = 0.8593; subscales ranged from 0.539 to 0.789	No formal studies have directly examined sensitivity to detect change; preliminary investigations show promising results; occupational therapists ($n = 95$) administered the SAFER-HOME V1 twice; 76% indicated the assessment measured changes in the client.	Strengths: Comprehensive coverage of home safety. Developed and tested rigorously. Comprehensive training manual provided. Weaknesses: Length of administration may be problematic in some clinical situations. Further research on responsiveness to change needed.
Westmead Home Safety Assessment (WeHSA) ⁴²	Assessment to identify fall hazards in the home environments of older adults	One home visit	Content: Established through content analysis of the literature and a rigorous expert review process	Inter-rater: Tested in a sample of 21 clients' homes; c values of >0.75 for 34 items and between 0.4 and 0.75 for 31 items; k could not be calculated for some items.	Not established	Strengths: Comprehensive and systematic assessment of home hazards specific to falls in older adults. Manual is helpful and provides operational definitions for key hazards. Weaknesses: Does not address home hazards besides falls. Further psychometric testing required.
Work Environment Impact Scale (WEIS) ⁴⁶	Worker capacities and perceptions A worker's perception of impact of work environment on performance, satisfaction, and physical, social, and emotional well-being	30 minutes	Content validity good to moderately good; internal consistency satisfactory (0.72)	Test–retest good-to-moderate at 0.35–0.78 (median 0.61)	Discriminates levels of work environment among subjects; targets impact of environment on users	Strengths: Short administration time, moderate-to-good validity, and reliability. Weaknesses: Scores based on observation; not norm-referenced; costs to purchase

Evidence Table of Intervention Studies for Home Environmental Modifications

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Home modification by an occupational therapist ³¹	Steps to living environment modifications: (1) comprehensive assessment (interRAI HC instrument), (2) identify the needs and wishes of clients, (3) home visits to provide counseling and plan the modifications, (4) after modifications occupational therapist teach clients how to correctly use the new materials	All participants were at least 65 years old and frail. Frailty was assessed by the Edmonton Frailty Scale.	From four to five visits	Quasi-experimental design Comparison between three groups of intervention (home modifications by occupational therapist; home modifications by occupational therapist with a case management component; other interventions without home modifications) and a control group Level II	Home modifications by an occupational therapist showed a significant reduction of falls at 6 months combined or not with a case management component (the sample consisted of 1,565 people).	Clients receiving home modifications by an occupational therapist had a lower chance of falling in the next 6 months (odds ratio [OR] = 0.46). Similar results for interventions combining case management and home modifications (OR = 0.39). No impact from projects providing other types of interventions than home modification (OR = 1.20).
Comparison of environmental assessment and modification provided by an occupational therapist vs. an unqualified trained assessor ³²	Westmead Home Safety Assessment and strategies to address hazards	Community-dwelling adults aged 70 years and older with a recent history of falls (controls $n = 78$; occupational therapist assessor, $n = 87$; trained assessor $n = 73$)	1.5- to 2-hour home assessment and two follow-up phone calls	Randomized controlled trial Level I	Participants in the group had significantly fewer falls at 12-month follow-up; no change in fall rate for those in trained assessor group (controls).	Occupational therapist group: Incident rate ratio (IRR) = 0.54; confidence interval (CI) = 0.36–0.83, $p = 0.005$ Trained assessor group: IRR = 0.78; CI = 0.51–1.12; $p = 0.34$

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Ergonomic prevention programs to improve positioning and workstation design for microscope workers ²³	Two intervention groups: One group education-only (handouts, information); second group education + training (slide presentation, handouts, discussion), and onsite adjustment of workstation	Fifty-one laboratory workers randomized into three groups: education-only = 16; education and training = 24; control group = 11.	Education + training delivered as a 1-hour slideshow presentation and handouts followed by onsite workstation adjustment for 15 minutes	Three groups, randomized, control group Level I	Workers showed improved position, workstation design, and work behaviors following intervention as measured by the Laboratory Assessment Checklist.	Education-only ($p = 0.002$) and education + training ($p = 0.000$) showed significantly improved scores as compared to control group. Education + training showed stronger gain than education-only group. Within-group effect size: Control group—0.71; Education-only group—1.02; education-training group—2.09.
Computer ergonomics program to improve postural comfort in university workers using computers ³³	Ergonomics interview, group ergonomics educational session, and individual consult in workers' offices	Healthy university employees (25); females = 22, males = 3	Intervention delivered in one session: 15 minutes intake, 45 minutes educational session, 15 minutes onsite consult; postural discomfort scale (1–10) completed each week for 6 weeks.	Single subject Level 4	Improvements in workstation adjustment and decreased discomfort	Highest discomfort levels reported in the neck (14/25 reported pain above 5); 21 (84%) of 25 participants reported less discomfort on discomfort rating scale. Most common area of adjustment was the chair.

Section 3 Rehabilitation Technology

Chapter 22

Upper Extremity Orthoses

Nancy S. Hock and Lori DeMott

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Define and discuss key concepts and terms related to orthoses.
2. Identify major purposes for using orthoses.
3. Explain general precautions relative to the use of orthoses.
4. Identify key factors to consider when selecting the most appropriate orthosis.
5. Given a photograph or illustration, identify the orthosis and a clinical problem for which it may be used.
6. Select an appropriate orthosis for a given diagnosis based on a specific clinical need.
7. Identify additional methods of support for the upper extremity.

CHAPTER OUTLINE

Introduction
Classification of Orthoses
Orthosis Selection
Theoretical Foundations for the Use of Orthoses as a Therapeutic Intervention
Purposes of Orthoses
Efficacy and Outcomes
Case Study

TERMINOLOGY

- Arm sling:** a fabric orthosis that supports the proximal upper extremity to restrict motion, reduce pain, or prevent or reduce shoulder subluxation.
- Arm trough:** an upper extremity positioning device that supports the lower arm and is attached to a wheelchair armrest.
- Dynamic orthosis:** a device that applies a mobile force using rubber bands or springs; primarily used to regain joint mobility or facilitate function.
- Lapboard:** a portable tabletop that is applied to a wheelchair to provide a working surface or support one or both upper extremities; also known as a lap tray.
- Mobile arm support (MAS):** a device that supports and facilitates arm movement by compensating for gravitational forces and may be used for remediation in clinical intervention or compensation during occupations such as self-feeding; also known as a dynamic arm support.
- Orthosis:** any externally applied device added to a person's body to support, align, position, immobilize, prevent or correct deformities, assist weak muscles, allow tissue proliferation and remodeling, or improve function.
- Serial casting:** applying casts at routine intervals as range of motion improves, with the goal of restoring joint mobility or increasing soft-tissue length.
- Serial static orthosis:** remolding or fabricating new static orthoses as range of motion improves, with the goal of restoring joint mobility or increasing soft-tissue length.
- Static orthosis:** a device that has no moving parts; primarily used to support, stabilize, protect, or immobilize.

Static progressive orthosis: orthosis that uses nondynamic forces to elongate soft tissue to decrease contractures through the application of incrementally adjusted static force to promote lengthening of contracted tissues.

Introduction

Orthoses are often an integral component of occupational therapy for patients with physical dysfunction. Orthotics entails prescription, selection, design, fabrication, testing, and training in the use of these special devices.

Successful use of an orthosis is made possible only through an integrated team approach including the patient, his or her significant others, and health care providers. Several rehabilitation professionals may bring their expertise to different aspects of the orthotic process. The physician typically prescribes the device. The certified orthotist is an expert in the design and fabrication of high-temperature thermoplastic orthoses, especially complicated spinal, lower extremity, and upper extremity orthoses used to restore function. The rehabilitation engineer is an expert in technical problem-solving involving mechanical and/or electrical solutions to unique needs of patients.

The occupational therapist, as an expert in adapting the upper extremities for use in occupational performance tasks, has the major responsibility for the recommendation of appropriate orthoses, the design and fabrication of custom thermoplastic orthoses, and the testing and training in the use of orthoses. Occupational therapists often collaborate with orthotists and rehabilitation engineers to solve problems encountered by patients in performing their occupations and activities of daily life. The therapist presents the parameters of the problem to these professionals in terms of the patient's abilities and limitations and the functional and psychological goals that the prescribed device should meet or allow. The orthotist or engineer then proposes technical solutions, and together they apply them to the patient and evaluate the outcome.

Finally, and possibly most importantly, the patient and caregivers bring key physical, psychological, social, and functional characteristics to the orthotic process and should be considered the primary members of the team. For the orthosis to be successful, all team members must work in close collaboration.

Classification of Orthoses

The numerous kinds of upper extremity orthoses vary according to the body parts they include, their mechanical properties, and whether they are custom-made, custom-fit, or prefabricated.

According to the Centers for Medicare and Medicaid, an **orthosis** is an externally applied device used to support a weak upper extremity, or to restrict or eliminate motion. The term splint refers to casts or strapping for reduction of fractures or dislocations.¹ Historically, the term splint has been used to describe what we now call an orthosis. This can be confusing for students and novice therapists, as well as referral sources and payers. The term splint should not be used by therapists when describing or documenting the fabrication or recommendation of an orthosis. A therapist can incorporate an orthosis into a patient's treatment plan without a prescription, but in order to obtain reimbursement, a prescription from a physician is required, or a certificate of medical necessity must be signed by a physician.

Basic Types of Orthoses

Orthosis fall into four categories: static, serial static, static progressive, and dynamic. The **static orthosis** (Fig. 22-1), which has no moving parts, is used primarily to provide support, stabilization, protection, or immobilization. Static orthoses can either be prefabricated (Fig. 22-2) or custom fabricated. **Serial static orthoses** can be used to lengthen tissues and regain passive range of motion (ROM) by placing tissues in an elongated position for prolonged periods.^{2,3} With this process, orthoses are remolded as tissue remodeling occurs, and ROM increases. Serial static orthoses are typically custom

fabricated. Because immobilization causes such unwanted effects as atrophy and stiffness, a static orthosis should never be used longer than physiologically required and should never unnecessarily include joints other than those being treated. The benefits of orthosis use must outweigh the problems associated with its use.

Figure 22-1 Custom-fabricated static forearm-based resting hand orthosis with wrist in slight extension, thumb palmarly abducted, and metacarpal and interphalangeal joints in slight flexion.

Figure 22-2 Prefabricated neoprene hand-based thumb support.

Static progressive orthoses use nondynamic components, such as Velcro, hinges, screws, or turnbuckles, to create a mobilizing force to regain motion. This type of orthosis, termed inelastic mobilization, offers benefits not available with serial static or dynamic orthosis use, because the same orthosis can be used without remolding, and adjustments can be made more easily as motion improves.⁴ Static progressive orthoses can either be custom fabricated or prefabricated.

Dynamic orthoses use moving parts to permit, control, or restore movement. They are primarily used to apply an intermittent, gentle force with the goal of lengthening tissues to restore passive motion. Forces may be generated by springs, rubber bands, or elastic cords. This type of orthosis use is termed elastic mobilization.⁴ Dynamic orthoses can be either custom fabricated or prefabricated.

When using a dynamic, serial static, or static progressive orthosis to increase ROM to address soft-tissue contracture, two concepts are critical. The first is that the force must be gentle and applied over a long time.^{4,5} Safe force must be determined based on tissue tolerances, which will vary between patients. Providing excessive force can result in an undesirable inflammatory response, which could lead to tissue damage or microtrauma.⁶

The second concept is that, to be effective and prevent skin problems, the line of pull must be at a 90° angle to the segment being mobilized.⁷ To ensure this, forces are directed by an outrigger, a structure extending outward from the orthosis. Violating this principle could result in either distal or proximal migration of components of the orthosis, which would limit gains in passive ROM.

Outriggers may be high profile or low profile (Fig. 22-3). Each design has distinct advantages and disadvantages. Selection of outrigger design must be based on the specific patient's needs and abilities. High-profile outriggers are inherently more stable and mechanically efficient, require fewer adjustments to maintain a 90° angle of pull, and require less effort for the patient to move against the dynamic force. Low-profile outriggers are less bulky but require more frequent adjustments and greater strength to move against the dynamic force.^{4,7}

Figure 22-3 Outriggers directing proper 90° line of pull. A. High profile. B. Low profile. (Adapted with permission from Hunter JM, Mackin EJ, & Callahan AD, eds. *Rehabilitation of the Hand: Surgery and Therapy*. 4th ed. St Louis, MO: Mosby; 1995.)

When deciding between using a serial static, dynamic, or static progressive orthosis to improve passive joint motion or to increase tissue length through tissue remodeling, therapists must consider the current stage of healing to provide the appropriate amount of tension. Figure 22-4 demonstrates the appropriate type of orthosis recommended across the continuum of healing.^{4,8}

ACUTE 3–11 days	PROLIFERATIVE 21 days to 12 weeks	CHRONIC 12 weeks to 6 months
Static orthosis		
Dynamic orthosis		
Static progress orthosis		
Serial-static orthosis		
Fragile Disrupted tissue	Immature collagen fibers	Stiffness/Brittle Mature tissue

Figure 22-4 Mobilization orthosis based on the stage of healing. (From Fess EE, Gettle KS, Phillips CA, Janson JR. *Hand and Upper Extremity Splinting: Principles and Methods*. 3rd ed. St Louis, MO: Mosby; 2005; Glasgow C, Tooth LR, Fleming J, Peters S. Dynamic splinting for the stiff hand after trauma: predictors of contracture resolution. *J Hand Ther*. 2011;24(3):195–206. doi:10.1016/j.jht.2011.03.001.)

In addition to functioning as a mobilization orthosis, dynamic orthoses can also be used to assist weak or paralyzed muscles. These dynamic orthoses may be intrinsically powered by another body part or by electrical stimulation of the patient's muscles and typically support the patient's return to functional use of the upper quadrant.

Orthosis Terminology

One challenge when discussing orthoses is the lack of uniform terminology in the medical literature, which makes it difficult to compare and contrast features and outcomes when a single orthosis may be known by many names. There are names of orthoses that are sometimes misunderstood by referring physicians and therapists, such as wrist cock-up, resting hand, and finger gutter. There is an international coding system (ICS) that is currently used for reimbursement.⁹ Descriptions are based on body parts that the orthosis crosses. For example, a forearm-based resting hand orthosis would instead be called a **Wrist Hand Finger Orthosis (WHFO)**. A Healthcare Common Procedural Coding System (HCPCS) is used to code orthoses using L codes. For example, a **Hand Finger Orthosis (HFO)** would be coded using L3913 for reimbursement.⁹ These codes identify the correct reimbursement, but do not inform the payer the purpose of the custom orthosis.

To simplify, organize, and describe a standardized professional nomenclature, the American Society of Hand Therapists (ASHT) developed the Expanded Splint/Orthosis Classification System (ESCS). It classifies orthoses based on the following six criteria:

1. Articular/nonarticular
2. Anatomic focus
3. Kinematic direction
4. Purpose
5. Number of secondary joints included
6. Number of joints included.⁷

According to this system, a wrist cock-up orthosis is a wrist extension immobilization, type 0, because no other joints are affected. Although the intent was to serve as a universal language for referral, reimbursement, communication, and research, the system has not been widely used outside the hand therapy community. Table 22-1 provides descriptions of the common term for orthoses used in clinical discussions, the ICS, and also the ESCS.

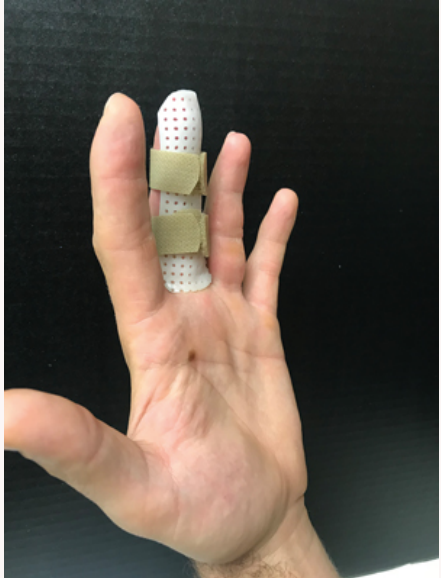

Table 22-1. Orthoses Terminology

COMMON CLINICAL TERMINOLOGY	INTERNATIONAL CODING SYSTEM ¹⁰	ASHT SCIENTIFIC CLASSIFICATION ECSC ⁴
<p>Wrist control orthosis</p> 	<p>(WHO) Wrist hand immobilization orthosis (wrist 20° extension)</p>	<p>Wrist extension mobilization; type 0 [1]</p>

COMMON CLINICAL TERMINOLOGY	INTERNATIONAL CODING SYSTEM ¹⁰	ASHT SCIENTIFIC CLASSIFICATION ECSC ⁴
<p>Ulnar gutter orthosis</p> 	<p>(WHFO) Wrist hand finger immobilization orthosis (wrist 30° extension, RF-SF MP joint 60° flexion, RF-SF IP joint full extension)</p>	<p>Wrist extension immobilization; type 1 [5]</p>
<p>Dorsal blocking orthosis</p> 	<p>(WHFO) Wrist hand finger dorsal blocking orthosis (wrist 30° flexion, MP joint 70° flexion, IF-SF IP joint full extension)</p>	<p>IF-SF extension restriction orthosis, type 1 [13]</p>
<p>Long opponens orthosis</p> 	<p>(WHFO) Wrist hand finger orthosis: thumb immobilization (wrist 30° extension, thumb CMC joint palmar ABD, MP joint 20° flexion, IP joint free)</p>	<p>Wrist radial deviation immobilization; type 2 [3]</p>

COMMON CLINICAL TERMINOLOGY	INTERNATIONAL CODING SYSTEM ¹⁰	ASHT SCIENTIFIC CLASSIFICATION ECSC ⁴
<p>Short opponens</p> 	<p>(HFO) Hand finger orthosis (thumb CMC joint 30° flexion and palmar ABD, MP joint 10° flexion)</p>	<p>Thumb CMC joint abduction immobilization; type 1 [2]</p>
<p>Clam shell</p> 	<p>(WHFO) Wrist hand finger orthosis: circumferential (wrist 30° extension, thumb palmarly abducted)</p>	<p>Wrist extension mobilization; type 0 [1]</p>
<p>Yoke orthosis</p> 	<p>(FO) Finger orthosis: limits MF flexion</p>	<p>MF metacarpal joint extension transmission; type 1 [3]</p>

COMMON CLINICAL TERMINOLOGY	INTERNATIONAL CODING SYSTEM ¹⁰	ASHT SCIENTIFIC CLASSIFICATION ECSC ⁴
<p>Sugar tong</p> 	<p>(EWHO) Elbow wrist hand orthosis: distal radioulnar joint immobilization orthosis (forearm neutral and wrist 30° extension)</p>	<p>Wrist neutral immobilization; type 1 [2]</p>
<p>Mallet finger orthosis</p> 	<p>(FO) Finger orthosis: DIP joint immobilization</p>	<p>Index finger DIP extension immobilization; type 0 [1]</p>
<p>Long arm orthosis</p> 	<p>(EO) Elbow orthosis (elbow -60° extension)</p>	<p>Elbow flexion immobilization; type 0 [1]</p>

COMMON CLINICAL TERMINOLOGY	INTERNATIONAL CODING SYSTEM ¹⁰	ASHT SCIENTIFIC CLASSIFICATION ECSC ⁴
Finger gutter orthosis 	PIP/DIP joint extension immobilization (FO) Finger orthosis (0° extension)	Middle finger pip joint extension immobilization; type 1 [0]

Examples are inclusive, not exclusive.

ABD, abduction; CMC, carpal metacarpal; DIP, distal interphalangeal; IF, index finger; IP, interphalangeal joint; MF, middle finger; MP, metacarpal; PIP, proximal interphalangeal; RF, ring finger; SF, small finger.

Orthosis Selection

Orthosis provision is a beneficial intervention strategy available to therapists when used correctly and appropriately. The end goal of orthosis use should always relate to the patient's return to function (Figs. 22-5 to 22-7). The diagnosis of the patient directs the purpose of the orthosis—whether to immobilize, lengthen soft tissue, or substitute for nerve loss. The therapists must consider not only the anatomic and physiological needs for proper orthosis design but also a holistic approach when determining the correct orthosis to also promote function.¹¹ Additionally, the orthosis must also provide aesthetic appeal and comfort.¹² Otherwise, the orthosis may be recommended and fabricated, but the patient may choose to not use it. Therefore, the therapist must think critically and often creatively with careful consideration of each patient's unique physical and psychosocial needs, as well as personal factors and contexts.^{11,13}

Figure 22-5 Yoke orthosis to limit middle finger metacarpal flexion to allow return to computer use.

Figure 22-6 Anticlaw orthosis to allow return to writing.

Figure 22-7 Orthosis for combined ulnar and median nerve pathology. Orthosis prevents clawing and supports thumb in a position of opposition for use with pinch tasks.

The therapist's multifaceted role is to evaluate the need for an orthosis clinically and functionally; to select the most appropriate orthosis (custom fabricated or prefabricated); to provide or fabricate the orthosis; to assess the fit of the orthosis; to teach the patient and caregivers the purpose, care, and use of the orthosis; and to provide related training as needed. The therapist must take a leadership role to ensure that the treatment team, including the patient and caregivers, work collaboratively in every phase of the orthotic process. A patient-centered, occupation-based approach empowers the patient and caregivers to participate actively. This also positions them as the experts in the patient's

occupations, lifestyle, values, image, and activity contexts, which complements the expertise that the health care professionals bring. The therapist should clearly explain rationales, make clinically sound recommendations, and offer choices to the patient whenever possible. This helps establish each team member's accountability and increases the likelihood that the patient will actually use the orthosis as instructed.

When deciding to incorporate an orthosis into a treatment plan, the following key questions should be considered:

- What is the primary clinical or functional problem?
- What are the indications for and goals of orthosis use?
- How will the orthosis affect the problem and the patient's overall function?
- What benefits will the orthosis provide?
- What limitations will the orthosis impose?
- What evidence is available related to the orthosis use?

Based on these considerations, the therapist must select or design the most appropriate orthosis. In some cases, the best choice is no orthosis at all.

The growing array of commercial products has led to a greater number of choices. The first choice to be made is whether the orthosis should be custom fabricated or prefabricated. Materials must also be considered. The therapist must be familiar with properties, benefits, and drawbacks of each. Options abound, with rigid, semi-rigid, and soft materials available (see Chapter 23).

When making an orthosis selection, several key factors must be carefully weighed:

- Among the orthosis-related factors are type, design, purpose, fit, comfort, cosmetic appearance, cost to purchase or fabricate, weight, ease of care, durability, ease of donning and doffing, effect on uninvolved joints, and impact on function.
- Patient-related factors include clinical and functional status, attitude, lifestyle, preference, occupational roles, living and working environments, social support, issues related to safety and precautions, ability to understand and follow through, and financial or insurance status.

Orthosis Adherence

Previous literature suggested that patient education on orthosis use and a wearing schedule, the comfort of the orthosis, and involving the patient in the preference of orthosis and family support all improve compliance with use of an orthosis. However, a more recent systematic review of adherence to orthosis wear in adults with acute upper limb injuries found little published scientific evidence and concluded that existing studies were of varied quality. Authors suggested future research is needed to examine the relationship between orthosis adherence and socioeconomic status as well as other patient characteristics.¹⁴ Additional review of the literature concluded there is limited evidence to correlate orthosis material selection with adherence, but indicated some evidence to support the use of behavioral approaches with orthosis adherence.¹⁵ With the relatively small base of literature on orthoses, therapists must continue to put their clinical judgments and experience to the test and strive to develop evidence-based practice related to observed outcomes and factors that influence successful use of orthoses as an intervention.

The therapist must consider, carefully monitor, and teach both the patient and caregiver to report any of these problems that may be related to orthotic use:

- Impaired skin integrity (pressure areas, blisters, maceration, dermatological reactions)
- Pain
- Swelling
- Stiffness
- Sensory disturbances/numbness

- Increased stress on uninvolved joints
- Functional limitations

Should problems with orthosis wear arise, the therapist should examine both the orthosis and the wearing schedule. The orthosis itself may not fit properly or comfortably. The patient's functional demands may outweigh the benefits of orthosis wearing, or the wearing schedule may be too complex. Actively engaging the patient in the problem-solving process is likely to improve the outcome. Although it is important to strive for the ideal, therapists must remain realistic in the scope of the patient's daily life.

Theoretical Foundations for the Use of Orthoses as a Therapeutic Intervention

There are remedial, compensatory, and adaptive approaches when incorporating an orthosis as part of an intervention plan. Using the Biomechanical Frame of Reference, remediation integrates an orthosis to improve ROM, strength, or endurance.¹⁶ For example, following a distal radius fracture, patients may demonstrate extreme digit stiffness preventing them from holding small objects such as coins and medication, or even grasping a fork or toothbrush. Use of a mobilization orthosis to increase digit flexion allows the patient to be able to make a fist and to increase their functional performance. Remediation involves regaining a skill that was present prior to the onset of an injury or disease.¹⁷ Return to grasping coins, medication, and a toothbrush are all examples of skills regained through remedial use of an orthosis as an intervention.

In contrast, the Rehabilitative Frame of Reference promotes the use of compensatory strategies and adaptations to increase functional performance.¹⁶ For example, patients with C4–C5 spinal cord injuries with tetraplegia can use **mobile arm support (MAS)** to perform activities they otherwise could not. These patients will exhibit weak deltoid and biceps muscles, limiting their functional performance. The use of MAS can allow these patients to participate in self-feeding, driving a power wheelchair, playing games, writing, using electronic devices, and performing grooming tasks.¹⁸

Compensatory strategies may be recommended along with adaptive techniques. Thermoplastic material used for custom orthoses fabrication can be molded to create adaptive handles to promote participation in activities of daily living. When working with patients following C4–C5 spinal cord injury, the MAS may allow the patients to bring their hand to their face for self-feeding, and adaptations to eating utensils and cups may allow the patients to use their distal extremities for functional use.

Purposes of Orthoses

Orthoses are categorized according to several purposes, including:

- Support a painful joint
- Immobilize for healing
- Protect tissues
- Provide stability
- Restrict unwanted motion
- Restore mobility
- Substitute for weak or absent muscles
- Prevent contractures
- Modify tone

Although a specific orthosis is discussed under the category for which it is most commonly used, that purpose may not be its only one. Also, a single orthosis may fulfill several functions simultaneously. The orthoses presented here are by no means an exhaustive list but a representative sampling of commonly used or historically significant orthoses. Inclusion of specific orthoses should not be interpreted as an endorsement of one

type over another. Whenever possible, published evidence-based data have been included. Because the intent of this chapter is to provide an overview of orthoses, the reader is encouraged to explore the references and resources for more detailed information.

Immobilization to Support a Painful Joint

Pain in a joint or soft tissues can result from a wide variety of causes, including acute trauma (such as sprains and strains), nerve irritation (such as carpal tunnel syndrome and cubital tunnel), inflammatory conditions (such as tendonitis and rheumatoid arthritis [RA]), and joint instability (such as degenerative arthritis, ligamentous laxity, and shoulder subluxation). When resting a joint is indicated to relieve pain, protect joint integrity, and/or decrease inflammation, supportive orthoses can be used. These orthoses are often worn all day or all night or both to provide the maximum benefit, or they may be worn only during selected activities. Unless contraindicated, the orthosis should be removed at least once a day for skin hygiene and gentle ROM exercises to prevent loss of joint mobility. The following are common examples of orthoses used for pain relief.

Supporting a Painful Shoulder

Subluxation occurs secondary to weakness of the rotator cuff muscles and the weight of the dependent arm, resulting in inferior displacement of the humeral head from the glenoid fossa.¹⁹ There are many factors that contribute to glenohumeral joint subluxation. These may include improper positioning, a lack of support when in the upright position, as well as pulling on the hemiplegic arm during transfers.²⁰ **Arm slings** have been developed to prevent or correct shoulder subluxation or reduce pain in patients who have subluxation caused by brachial plexus injuries, hemiplegia, or central cord syndrome injuries. Sling designs are numerous, with some commercially available and others fabricated by the therapist.

Certain slings support and immobilize the whole arm. These slings, such as the standard pouch and the double arm cuff sling, restrict motion by keeping the humerus in adduction and internal rotation and the elbow in flexion. Although these slings may take some of the weight off of the affected shoulder, these supports typically facilitate an increase in flexor tone in the synergy pattern, decrease arm swing during ambulation, impact body image, and restrain function that could limit recovery (Fig. 22-8).²⁰ Other sling designs support the shoulder but leave the rest of the arm free for function, such as a humeral cuff sling, GivMohr and OmoNeurexa sling (Figs. 22-9 and 22-10).

Figure 22-8 Sling that facilitates increased flexor tone in a synergy pattern and does not promote functional use of upper quadrant. **A**, Front View; **B**, Rear View.

Figure 22-9 GivMohr sling that provides distal support, but holds upper quadrant to the side of the body instead of a flexor synergy pattern. **A**, Front view; **B**, Rear view; **C**, Side view.

Figure 22-10 OmoNeurexa sling. **A**, Front view; **B**, Rear view.

The use of supports in reducing shoulder subluxation remains controversial and lacks empirical evidence. A systematic review by Ada et al. found no evidence to conclude that supportive devices are effective in preventing or reducing subluxation or in decreasing pain after stroke.²¹ A systematic review by Nadler and Pauls concluded that application of slings to an already subluxed shoulder resulted in a decrease in vertical subluxation during use, but these changes were not maintained when the orthosis was removed.¹⁹ Authors also concluded that slings with support to the proximal humerus were less effective than those that supported the upper extremity with a distal attachment. Previous literature suggest the benefits of supporting the forearm and elbow in flexion using slings such as the Hemi sling, Harris sling, or Triangular sling to decrease subluxation. More recent evaluation of the GivMohr and OmoNeurexa identified these slings as effective in decreasing subluxation during use, but the benefit to these products is that they allow elbow motion and also hold the upper extremity in a more neutral extended position at the side of the body.¹⁹ This review also provided some support for the use of a sling for 4 weeks to decrease pain at the glenohumeral joint following stroke.¹⁹

The patient's acceptance of the sling also must be considered. Relative ease of donning and doffing the sling is imperative so the limb is not damaged further from improper wearing. More definitive research on the effectiveness of slings and orthoses in the management of the flaccid or subluxed shoulder is needed, and therapists should carefully consider all options before recommending slings.

Arm troughs, lapboards, and half-lapboards are also used to support the painful shoulder when the patient is seated in a wheelchair and also have been demonstrated to decrease glenohumeral joint subluxation during use.²⁰ It is important to remember that these supports lack the constant relationship between the patient and the support as exists with slings.

Lapboards are generally indicated for patients with poor trunk control or visual field deficits and for those who require greater variability of upper extremity positioning or a work surface. Arm troughs and half-lapboards are used for patients who need a device that does not interfere with wheelchair propulsion or transfer activities (Fig. 22-11). Full and

half-lapboards can be purchased commercially or custom fabricated from acrylic or wood. Some designs allow the half-lapboard to be rotated up and out of the way, instead of having to be removed from the wheelchair when the patient needs to transfer. Arm troughs are also commercially available or can be custom-made. Lap boards and arm troughs keep the upper extremity abducted and externally rotated to prevent contractures. These allow for positional changes, but do not always provide consistent proper positioning.²²

Figure 22-11 Lap board (A) and arm troughs (B) to support the upper extremity.

Supporting a Painful Elbow

The treatment of lateral and medial epicondylitis often entails the use of orthoses to relieve pain and prevent further stress to affected tissues. In both conditions, pain reduces grip strength and function. Counterforce braces (Fig. 22-12), of which there are several commercial models, are wide, nonelastic bands designed to limit full expansion of the forearm extensor or flexor muscle masses during contraction.²³ These braces can also be custom fabricated from thermoplastic or strapping materials. The literature reports wide variation in the success of braces.²⁴ Instruct the patient that complications can result from the brace being applied too tightly, including nerve compression syndromes. The patient must be carefully taught accordingly.

Figure 22-12 Counterforce strap used to limit muscle contraction of the wrist extensors and decrease pain in the lateral elbow region.

A wrist orthosis placing the wrist in 35° to 40° of extension and worn alone or in conjunction with a counterforce brace is often prescribed to rest the forearm musculature.²³ A study by Jafarian et al. found that use of a counterforce brace resulted in immediate increase in pain-free grip strength, whereas a wrist orthosis did not.²⁵ Conversely, Garg et al. found that pain relief was significantly better with a wrist orthosis than with a counterforce brace.²⁶ However, Sadeghi-Demneh and Jafarian found a greater reduction in pain with the use of a counterforce strap as compared to a wrist orthosis.²⁷ The prescription of orthoses must be based on the patient's symptoms. It is vital that the cause of the problem and the biomechanics of loading forearm musculature are also addressed in relation to all activity demands.

Supporting a Painful Wrist or Hand

Resting hand orthoses are used to support the wrist, fingers, and thumb. The normal resting position of the hand is determined anatomically by the bony architecture, capsular length, and resting tone of the wrist and hand muscles. This is typically 0° to 20° of wrist extension, 20° to 30° of metacarpophalangeal (MCP) joint flexion, 10° to 30° of proximal interphalangeal (PIP) joint flexion, and slight distal interphalangeal (DIP) joint flexion, the thumb carpometacarpal (CMC) in slight extension and abduction, and the thumb MP and IP in slight flexion (see Fig. 22-1).⁴

A resting hand orthosis is commonly prescribed for patients with RA. A randomized controlled trial found that in addition to pain relief, nighttime use of resting hand orthoses improved hand strength and functional status.²⁸ With RA, the orthosis should be in a position of comfort, regardless of whether this is the ideal anatomical position.⁴ During an acute exacerbation of the disease, orthoses are generally worn at night and during most of

the day and removed at least once for hygiene and gentle ROM exercises. It is recommended that orthosis use continue for at least several weeks after the pain and swelling have subsided.⁴

Wrist extension, or cock-up, orthoses are probably the most commonly prescribed type of orthosis for the upper extremity. Indications for use include sprains, strains, tendonitis, arthritis, carpal tunnel syndrome, following cast removal of wrist fractures, and other conditions that cause pain. A wrist orthosis typically positions the wrist in 10° to 30° of extension, which is thought to be the best position for hand function.⁴ A well-fitting orthosis is one that clears the distal palmar and thenar creases to allow for unrestricted mobility of the fingers and thumb and that conforms to the palm to support the arches of the hand. Wrist orthoses may be volar (Fig. 22-13), dorsal, or circumferential and can be custom fabricated or prefabricated. Because these orthoses are intended to provide wrist support while allowing functional use of the hand, fit and comfort are crucial.

Figure 22-13 Volar wrist immobilization orthosis.

A growing variety of prefabricated orthoses are available, with designs and materials offering a range of soft to rigid support. Elasticized wrist orthoses with an adjustable metal stay that slides into a volar pocket (Fig. 22-14) are commonly used because they are cost-effective and readily available. The drawbacks of these orthoses are that they do not fully support the palmar arches, they do not completely clear the palmar and thenar creases, and the metal stay is often prepositioned at a 35° to 45° angle of extension. Therefore, it is critical to fit and adjust the stay to the desired angle before issuing the orthosis. Other commercial products are made of wire-foam, neoprene, leather, canvas, and other fabric blends, all of which offer features having distinct advantages and disadvantages.

Figure 22-14 Prefabricated wrist support.

Orthoses vary in the amount of motion they allow or restrict. Collier and Thomas compared ROM at the wrist with three commercial supports and a custom-made volar thermoplastic orthosis.²⁹ The prefabricated orthoses allowed the same amount of motion (wrist flexion to about neutral and wrist extension to about 26°–31°). In contrast, the custom-fabricated thermoplastic orthosis allowed less wrist flexion (not past 14° of wrist extension) and more wrist extension (about 40°). This suggests a custom-fabricated thermoplastic orthosis may be more appropriate for conditions where limited wrist flexion is desired.

Another common indication for a wrist orthosis is carpal tunnel syndrome, a condition caused by median nerve compression, resulting in symptoms including pain, sensory disturbances, muscle weakness, swelling, stiffness, and frequent dropping of items. Symptoms often are worse at night or with repetitive activity involving wrist flexion. For pain and related symptoms caused by carpal tunnel syndrome, conservative or postoperative treatment often uses wrist orthoses to prevent the elevation of carpal tunnel pressure by restricting wrist motion.³⁰ A neutral position (Fig. 22-13) is recommended, avoiding wrist extension.³¹

There is a consensus that prefabricated wrist orthoses, which often place the wrist in excessive extension, may not be of any benefit unless they are modified to a less extended position. A systematic review of orthosis use for carpal tunnel syndrome showed benefits from various orthosis types and wrist angles, with evidence suggesting that custom-fabricated orthoses and full-time orthosis wear promote better results.³² Orthosis use is most effective when initiated early after symptom onset. Control of wrist position alone may be insufficient, and blocking the MPs in slight flexion may also be needed to decrease intratunnel pressure.³⁰

A long opponens orthosis (Fig. 22-15), also known as a long thumb spica, can relieve pain from wrist and thumb arthritis or from de Quervain tenosynovitis of the abductor pollicis longus and extensor pollicis brevis. This orthosis is typically based on the volar or radial aspect of the forearm and extends distally to immobilize the thumb CMC and MP joints. The wrist is generally positioned in slight extension, with the thumb in slight flexion and palmar abduction to enable opposition to the index and middle fingers.³³ If the thumb IP joint or the extensor pollicis longus tendon is involved, the IP joint can be included in the orthosis as well. Prefabricated orthoses often provide a softer support and are easier to use for function, whereas custom-made thermoplastic orthoses give more rigid immobilization.

Figure 22-15 Long opponens orthosis/forearm-based wrist and thumb orthosis.

A thumb CMC stabilization orthosis, or a hand-based thumb orthosis, is a static orthosis that encompasses the first metacarpal to provide stability, reduce pain, and increase hand function. It restricts motion of the CMC and MP joints but leaves the wrist relatively mobile and the thumb IP free. A static thumb MP orthosis allows for CMC and IP motion and can be used when the disorder is localized to the MP joint alone.

Indications for hand-based thumb spica include RA or osteoarthritis (OA) of the thumb CMC or MP joints or trauma to soft tissues, such as the ulnar collateral ligament of the MP. The thumb is generally positioned to enable opposition to the fingers for function while in the orthosis. When used with arthritis, the orthosis is worn during functional activities and at night. If ligament damage is suspected, the orthosis is worn at all times.

For a precise fit and rigid support, orthoses can be custom fabricated from thermoplastic materials (Fig. 22-16). Newer commercial products made of soft, breathable elastic material have moldable thermoplastic stays to enable a custom-fit, combining comfort and

ease of fabrication with the required individualized rigid support. Rigid support may not always be needed. In comparing a custom-made thermoplastic orthosis and a soft neoprene support for OA of the thumb CMC joint, Weiss et al. found that the prefabricated neoprene orthosis (Fig. 22-2) provided greater pain relief and function and was preferred over the custom thermoplastic orthosis by 72% of the subjects.³⁴ Sillem et al. similarly found that patients preferred a soft prefabricated orthosis even though a more rigid custom orthosis provided greater pain reductions.³⁵ Bani et al. found a greater reduction in pain with a custom thermoplastic orthosis than with a neoprene-prefabricated orthosis.³⁶ Systematic reviews found evidence for the effectiveness of orthosis use to relieve pain and improve function in CMC OA, found evidence of varying patient orthosis preferences, but found no evidence of orthosis design superiority.^{37,38}

Figure 22-16 Custom-fabricated hand-based thumb carpal metacarpal orthosis or short opponens orthosis.

If the thumb or finger IP joints are painful from trauma or arthritis, lateral, dorsal, or volar gutter orthoses may be used for pain relief. Silicone-lined sleeves (Fig. 22-17) or pads can protect painful joint nodules from external trauma.

Figure 22-17 Digit sleeve.

Pain, volar subluxation, and ulnar deviation of the MCPs are common sequelae of RA. MCP ulnar deviation supports may be used to provide stability, realign joints, reduce joint stress, and relieve pain. They may delay the progression of deformity, but do not correct or prevent it.³⁹ These supports may be worn alone or incorporated into a resting hand orthosis.

Prefabricated and custom-designed orthoses with dividers or straps to align the digits include dynamic and static and soft and rigid. However, rigid static orthoses (Fig. 22-18) used to achieve passive correction of deformity can create focal pressure points on the digits. The prime indicator for use and selection of an MCP ulnar deviation support should be the patient's preference.⁴⁰

Figure 22-18 Custom-fabricated ulnar drift orthosis used to reduce ulnar drift of the digits, which is seen with individuals with rheumatoid arthritis.

Immobilize for Healing or to Protect Tissues

Many of the orthoses previously discussed for pain relief can also be used to immobilize for healing or protection following injury or surgery. For example, a type of sling used to relieve traction pain associated with a brachial plexus injury can also protect the nerve structures from overstretching during the healing phase. A thumb MP orthosis that relieves pain from arthritis may also be used while an acutely injured collateral ligament heals.

Immobilize or Protect the Shoulder, Upper Arm, or Elbow

The sling is the simplest and most commonly used device for the upper extremity when there is a need to limit motion of the shoulder yet allow for some motion of the arm on the thorax. The basic arm sling (Fig. 22-19) consists of a forearm pouch or cuffs, a strap, and a mechanism for adjusting and securing the strap. To adjust a sling for patient use:

Figure 22-19 Basic sling for immobilization.

- Place the patient upright.
- Ensure the elbow is flexed to 90° and is seated properly in the sling, with the hand and wrist also supported as the design allows.
- Adjust the strap or straps so the arm is comfortably supported.
- Check for comfort.
- Teach both the patient and caregiver how to properly don and doff the sling.
- Monitor the axilla and areas where sling straps cross the body for signs of moisture and skin breakdown.
- Monitor for signs of edema and joint stiffness.

To further limit mobility, shoulder immobilizers (Fig. 22-20) can be used. These devices, which relatively immobilize the shoulder and elbow, are typically used following shoulder surgical reconstructions, arthroplasty, and rotator cuff repair. Immobilizers are more complex than slings, involving strapping that wraps the body to stabilize the arm against the trunk. Several commercial designs are available.

Figure 22-20 Shoulder immobilizers commonly used following to protect a rotator cuff repair. A, Front view; B, Side view; C, Rear view.

Foam abduction pillows or wedges may be used to maintain the arm at a certain elevation from the body. Abduction braces, sometimes called airplane orthoses, are commercially available or custom fabricated from thermoplastics. These devices are based on the trunk and can position the shoulder in varying degrees of abduction or rotation and the elbow in varying degrees of flexion or extension. Commercial braces offer ease of adjustability with the use of wrenches but may need extra padding to prevent skin breakdown. Indications for use include postoperative shoulder rotator cuff repairs, burns, and skin grafts to the axillary region.

The treatment of humeral shaft fractures often involves functional fracture bracing. A humeral fracture brace provides external stabilization and alignment of the fracture by compressing surrounding soft tissues while allowing for early mobilization of the shoulder and elbow. These braces may be prefabricated or custom fabricated by the therapist from low-temperature thermoplastics. They are circumferential in design, with D-ring or Velcro straps to allow for a secure closure and size adjustments as edema subsides. They should be lightweight and made of a perforated material for ventilation. Excellent results with the use of functional fracture bracing of the humerus have been reported.⁴¹ A Sarmiento brace (Fig. 22-21) is the typical prefabricated choice for conservative treatment of humeral shaft fractures.⁴² Whether the brace is prefabricated or custom fabricated, the therapist should ensure that its distal end does not block elbow flexion motion and that its proximal end does not unnecessarily limit shoulder motion.

Figure 22-21 Sarmiento brace—humeral fracture brace to immobilize humeral shaft fracture. (Courtesy of BraceAbility.)

Casts, orthoses, and hinged braces can be used to immobilize and protect the elbow following fractures, burns, ligamentous injuries, or other surgical procedures. Casts offer rigid immobilization and may be made according to a circumferential, posterior, or anteroposterior bivalve design that allows the cast to be removed for wound care or ROM. Hinged braces are frequently used to protect healing ligaments by limiting certain amounts of motion of the elbow. Thermoplastic orthoses may be anterior or posterior and may be secured by Velcro straps or an elastic wrap. Anterior elbow extension orthoses (Fig. 22-22) are most commonly used to immobilize and position the elbow following skin grafting.

Figure 22-22 Elbow extension orthosis.

Immobilize or Protect the Wrist or Hand

The maintenance of normal hand function requires strong tissue repair with free gliding between adjacent structures. Proper positioning of the wrist and hand is critical to prevent complications due to injury, edema, and tissue healing. Orthosis use in the early stages of healing can counteract the typical joint contractures of the injured hand that produce common deformities of wrist flexion, MCP extension, IP flexion, and thumb adduction. It is essential to position joints correctly and keep uninvolved joints moving so that they will not stiffen.⁴³ Incorrect application of an orthosis or improper positioning while in an orthosis may lead to both joint limitations and tissue damage.

Unless specifically contraindicated, the antideformity, or safe, position of immobilization for most hand conditions is with the wrist in 10° to 30° of extension, the MCPs in 70° to 90° of flexion, the IPs in 0° to 15° of flexion, and the thumb in palmar abduction.^{4,43} This position may also be referred to as intrinsic plus and is most often accomplished through a volar custom-fabricated low-temperature thermoplastic orthosis (Fig. 22-23). If edema is present, the orthosis should be secured by an elastic wrap or gauze wrap to avoid a tourniquet effect from straps. It is crucial never to force joints into the ideal position but to position joints as closely as possible to the ideal and serially revise the orthosis until the optimal position is realized.

Figure 22-23 Forearm-based immobilization orthosis in an intrinsic plus position.

Antideformity orthoses are integral to the treatment of acute dorsal hand burns because even a small burn can lead to significant deformity or contracture.⁴⁴ The most commonly recommended positions for joints is with the wrist in 15° to 30° of extension, the MCPs in 50° to 70° of flexion, the IPs in full extension, (Fig. 22-23), and the thumb in palmar abduction or midway between palmar and radial abduction with the MP and IP in slight flexion to full extension to prevent common burn-related contractures.⁴⁵ Custom-fabricated orthoses, preferably of a perforated material, ensure the best fit. Orthoses may have to be adjusted daily for optimal fit and maintenance of proper joint positioning. For the grafting and rehabilitation phases of burn treatment, orthosis design varies with the positions necessary to counteract the contractile forces of the scars.

Wrist orthoses, as discussed in the previous section, may be used for protection or immobilization of wrists following cast removal or to treat soft-tissue injuries. Athletic injuries to the wrist and hand, such as contusions, sprains, strains, fractures, and joint dislocations, often require the use of protective orthoses to enable the patient to continue participation in sports. As with other orthoses, selection of material and design should be carefully tailored to the patient's needs. Materials may be thermoplastic, fiberglass, or neoprene. Selection should be based on the degree of immobilization required, material durability and breathability, the player's sport position, governing rules of the sport, and the safety of other players.

Treatment of tendon injuries and repairs may involve static positioning to immobilize the tendon for healing using a dynamic orthosis to protect the tendon while allowing controlled motion to increase tendon repair strength and gliding. Flexor tendon repair protocols vary, but a protective dorsal blocking orthosis (Fig. 22-24) positioning the wrist and MCPs in flexion and blocking the IP joints at 0° of extension is typically used. Rubber band traction may be added to hold the digits in a flexed position or to enable resistive extension and passive flexion exercises. The orthosis is custom fabricated from low-temperature thermoplastic and is often worn for as long as 6 weeks.⁴⁶

Figure 22-24 Dorsal blocking orthosis used to protect a repair of a digit flexor tendon.

Treatment and orthoses for extensor tendon injuries are based on the level of injury. For injuries at the DIP level that may result in a mallet finger deformity, the DIP is immobilized for 6–8 continuous weeks in a slightly hyperextended position.⁴⁷ The PIP joint is left free. The orthosis used may be volar, dorsal, or circumferential and is typically custom fabricated for the best results. Thermoplastics, Quick Cast, or Orficast may be used for fabrication. Excellent results for the treatment of mallet finger (Fig. 22-25) have been reported with various orthoses.⁴⁸ For injuries at the PIP level, treatment includes Quick Cast (Fig. 22-26) or thermoplastic immobilization with the PIP in absolute 0° of extension for 6 to 8 continuous weeks to prevent boutonniere deformity. For more proximal tendon injuries, orthoses may involve static positioning, dynamic assists, or both.⁴⁷

Figure 22-25 Use of Quick Cast to protect terminal extensor tendon (Mallet finger).

Figure 22-26 Use of Quick Cast to hold proximal interphalangeal joint in extension following central slip injury.

Relative motion orthoses are sometimes used following a more proximal extensor tendon laceration to limit MCP flexion. This is sometimes referred to as a yoke orthosis (Fig. 22-6). The position of the bar fabricated out of thermoplastics or Orficast material limits MCP flexion, therefore minimizing the extensor tendon glide.⁴⁹

Orthosis fabrication is an integral part of postoperative MCP arthroplasty treatment. Early positioning and motion following arthroplasty often uses a dynamic MCP extension assist (Fig. 22-27) to support the wrist, control MCP position and alignment, allow guided motion, and assist with extensor power. This controlled stress allows for joint capsule remodeling over time.⁵⁰ Dynamic MCP extension assists may use high-profile or low-profile outrigger designs. They have slings to support the MCPs in neutral extension and deviation and to provide rotatory alignment. Outrigger kits are commercially available, or the outrigger may be hand fabricated. The dynamic extension orthosis may be supplemented by a static positioning orthosis at night.^{4,50}

Figure 22-27 Forearm-based dynamic metacarpophalangeal extension orthosis.

To protect digits but allow for stabilization or controlled motion of the MCP, PIP, or DIP joints following injury or surgery, buddy straps (Fig. 22-28) that connect an injured finger to an adjacent finger, can be used. Common indications for these include stable fractures, PIP joint dislocations, collateral ligament injuries, and staged flexor tendon reconstructions.^{4,39}

Figure 22-28 A, Buddy straps using an adjacent digit to support an injured digit. B, Can also be used to encourage movement of an injured finger by strapping it to the adjacent digit.

Provide Stability or Restrict Unwanted Motion

Orthoses can be helpful in stabilizing joints when their integrity has been compromised by an acute injury or a chronic disease such as arthritis. Stabilization or restriction of motion can often greatly facilitate functional use of a limb.

Stabilize or Restrict Motion of the Shoulder or Elbow

In addition to the purposes previously described, slings, and hinged elbow orthoses can also be used to provide proximal stability that may enable improved distal function.

Stabilize or Restrict Motion of the Wrist or Hand

It is essential to determine the position in which a joint needs to be supported relative to hand dominance and task requirements because specific functional demands vary greatly among individual patients. The wrist is considered by many to be the key to ultimate hand function, and therefore wrist orthoses are commonly prescribed to provide stability. Dorsal wrist orthoses allow for the greatest palmar sensation but are least supportive, volar wrist orthoses are most commonly prescribed and provide a moderate amount of stability, and circumferential wrist orthoses provide the greatest amount of stability.⁵¹ For optimum mechanical advantage to support the weight of the hand, the forearm portion of the orthosis should be two-thirds the length of the forearm.^{4,51}

A lumbrical bar is a hand-based orthosis that extends over the dorsal aspect of the proximal phalanges to restrict unwanted hyperextension of the MCPs that can result from an ulnar nerve or combined median and ulnar nerve injury. By blocking this motion, IP flexion contractures can be prevented and functional hand opening can be improved as the power of the long finger extensors is transferred to the IPs for extension. Custom-fabricated thermoplastic orthoses (Fig. 22-29) provide for an intimate and streamlined fit.⁵²

Figure 22-29 Lumbrical bar orthosis for anticlaw.

This same principle of restricting undesired motion is used in a PIP hyperextension block, also known as a swan-neck orthosis. Swan-neck deformities are common sequelae of RA and a possible complication following an extensor tendon injury or repair. These deformities often cause difficulty with hand closure, as PIP tendons and ligaments can catch during motion, and the finger flexors have less of a mechanical advantage to initiate flexion when the PIP is hyperextended. By blocking the PIP in a slightly flexed position, the patient can flex the PIP more quickly and easily.^{39,40}

For short-term use or for trial purposes, custom-fabricated thermoplastic swan-neck orthoses (Fig. 22-30) may suffice. For long-term use or for use on adjacent digits, commercial swan-neck orthoses are often recommended because they are more durable, less bulky, more easily cleaned, and more cosmetically appealing. Custom-ordered ring splints made of silver or gold are attractive, durable, streamlined, and adjustable for variations in joint swelling, but they are more costly. Silver splints have also been shown to improve dexterity.⁵³ Prefabricated splints made of polypropylene (Fig. 22-31), also available commercially, offer some of the benefits of silver splints with less cost. In a study comparing commercial silver and polypropylene splints, both were equally effective and acceptable to patients.⁵⁴ Heavy-duty metal splints, such as Murphy ring splints, may benefit patients who use their hands in highly demanding tasks. Swan-neck splints can also be used to provide lateral stability to unstable IP joints of the fingers or thumb.

Figure 22-30 Custom-fabricated orthosis to block proximal interphalangeal joint hyperextension and to prevent swan-neck deformity.

Figure 22-31 3 Point Products Oval 8 orthosis to prevent swan-neck or boutonniere deformity. **A**, Support and stability; **B**, Mobility; **C**, Alignment.

Flexible boutonniere deformities may benefit from immobilization to block the PIP in a more extended position to allow for greater functional hand opening. These orthoses may be custom-made by the therapist or custom ordered from the companies that fabricate swan-neck splints. Because there is direct pressure over the PIP, the dorsal skin must be carefully monitored for signs of breakdown.

Thumb stability is a requirement for almost all prehensile activities, so support of unstable thumb joints may have a particular value for function.⁴ Instability of the CMC often requires a long thumb orthosis that crosses the wrist because shorter hand-based orthoses may not adequately support the CMC. Short thumb immobilization orthosis (see Fig. 22-16) also known as a short opponens orthosis, can provide MP stability and a stable post for pinching. Although a circumferential design is commonly used, problems with marked MP deformity can make donning and doffing of the orthosis difficult, and direct pressure over the MP may lead to a breakdown of fragile skin.

Restore Mobility

Orthoses play an integral role in the restoration of mobility by lengthening soft tissue or impacting joint contractures that can occur as a result of poor positioning, trauma, scarring, or increased muscle tone.⁵⁵ As described earlier in this chapter, custom-fabricated serial static, dynamic, or static progressive orthoses may be used to provide a low load of pressure over a prolonged period of time to impact contracture management. This can also be used in the management of tone following neurological pathology.

A therapist implementing an orthosis program to regain motion must understand how orthoses work to affect positive change. ROM is gained not by tissue stretching but by actual tissue elongation from new cell growth.^{4,5} Inelastic mobilization applies constant forces needed to remodel tissues and is the most effective means for gaining motion in chronically stiff joints. Elastic mobilization is most indicated for acute joint stiffness or more supple joints because forces can be more easily controlled and fine adjustments made.⁴ The forces used must be gentle and carefully applied, and the tissue must be closely monitored for signs of excessive stress, such as redness and inflammation, which are indicators of tissue damage or microtrauma.⁶

Fixed contractures and chronically stiff joints often respond best to inelastic mobilization from serial casting. Casting material is ideal because it conforms intimately and is more rigid than thermoplastics. Casts are changed as motion gains are achieved. In a systematic review of upper extremity casting in central nervous system disorders, however, there was insufficient high-quality evidence on the long-term benefits from casting, and there was high variability in casting protocols.⁵⁶ Therefore, it is not possible to make specific recommendations for practice.

Dynamic mobilization orthoses are more effective when used for early contractures.⁸ Orthoses can be removed for hygiene and function and are worn at night so as not to interfere with use of the extremity. This decrease in wearing time, however, means that tissues are not kept under constant tension, which may result in less rapid gains. The amount and direction of force must be carefully monitored and adjusted as joint angles change. Static progressive mobilization orthosis use is often indicated for fixed or chronic contractures. However, static progressive force should more commonly be used with extension mobilization programs as patients may not tolerate a prolonged position in maximum flexion.³

Restore Mobility of the Shoulder, Elbow, or Forearm

A serial static abduction orthosis can be used to apply pressure to and elongate burn scars in the axilla. The benefits of wearing this type of orthosis must be carefully weighed against the complete lack of function that it imposes. For flexion contractures of the elbow, thermoplastic anterior elbow extension orthoses (see Fig. 22-22), serial casts or dropout casts, and dynamic elbow extension or static progressive elbow extension (Fig. 22-32) orthoses can be used.

Figure 22-32 Static progressive elbow extension orthosis.

Serial casting, which typically entails changing the cast weekly, can safely reposition joints without providing undue stress to tissues.^{2,3} Contractures that develop as a result of increased tone, such as in the patient with a brain injury, casting is often used in conjunction with nerve blocks, Botox injections, or other surgical procedures. Great care must be taken with casting in the presence of severe tone, because pressure areas may develop.

Loss of forearm rotation, often seen following spinal cord injury, peripheral nerve injury, or fracture, can be treated with a dynamic or static progressive forearm orthosis. Orthoses can be custom fabricated⁴ or obtained commercially as a preformed product or kit (Fig. 22-33). Altering the direction of force when using these orthoses can produce supination or pronation.

Figure 22-33 Static progressive forearm orthosis. (Courtesy of Joint Active Systems.)

Restore Mobility of the Wrist or Hand

Serial static thermoplastic wrist orthoses, dynamic wrist orthoses, and static progressive wrist orthoses can be used for limitations in wrist flexion or extension. These may be custom fabricated or preformed. Dynamic or static progressive component kits can also be purchased commercially. This allows the therapist to custom mold the orthosis base while more easily assembling force units.

Lack of MCP flexion can devastate hand function. Many dynamic orthosis designs to regain MCP motion are available. Custom-fabricated thermoplastic orthoses use individual finger loops over the proximal phalanx (Fig. 22-34). When using dynamic force, these loops are attached to rubber bands or springs that provide the needed force for sustained tension. When using static progressive force, the loops are attached to nylon cord or Velcro straps for tension. An outrigger is used to direct the line of pull at 90°. It is important to clear the distal palmar crease so as not to block full flexion ROM. These orthoses may be forearm based or hand based, depending on the mechanical advantage needed, degree of stiffness, and the patient's wrist strength and stability.⁴

Figure 22-34 A. Forearm-based static progressive metacarpophalangeal flexion orthosis. B. Forearm-based static progressive orthosis for three joint flexion.

Limited PIP flexion makes grasp difficult, and limited PIP extension interferes with the ability to open the hand in preparation for grasp or to release objects. PIP flexion contractures are a frequent complication of trauma or poor positioning and extension contractures can be seen following dorsal hand burns or prolonged immobilization for fracture management.

To address these contractures, forearm or hand-based dynamic thermoplastic orthoses similar to those designed for MCP flexion and extension can be used. A hand-based prefabricated dynamic PIP extension orthoses or prefabricated static progressive orthosis (Fig. 22-35) can be used to isolate PIP extension. Static progressive force can be applied for flexion to the MP or the IP joints (Fig. 22-36) using a custom-fabricated orthosis. Glasgow et al. also found the duration of dynamic orthotic is a key factor in PIP joint contracture resolution, with flexion motion obtained more quickly than extension.⁵⁷ Securing the MCP joint in flexion using a custom hand-based orthosis can also assist in promoting PIP extension (Fig. 22-37).

Figure 22-35 Prefabricated hand-based static progressive proximal interphalangeal extension orthosis.

Figure 22-36 Dynamic PIP extension orthosis.

Figure 22-37 Hand-based dorsal metacarpophalangeal flexion orthosis to promote proximal interphalangeal extension.

Thermoplastic gutter (Fig. 22-38), circumferential orthoses, and dynamic mobilization orthoses are useful in the treatment of mild contractures, whereas serial digital casting (Fig. 22-39) has been advocated for moderate to severe contractures.² Casting offers the advantages of intimate conformity, rigidity, breathability, and uniform distribution of pressure. Casting requires the patient's cooperation in keeping the cast dry, and casts have the disadvantage of not being removable for function or motion. For most effective results, casts should be left on continually and changed at least twice per week,² or sooner if they become loose or wet. The DIP joint may be left free if its motion is not limited. It may be beneficial to involve the DIP in the cast if increased mechanical advantage is desired for PIP extension.

Figure 22-38 Custom-fabricated thermoplastic digit extension/gutter orthosis.

Figure 22-39 Quick Cast digit extension orthosis.

Adduction contractures of the thumb, which are commonly seen in burns and median nerve injuries, are most often treated with serial static thumb abduction orthoses, which conform to the first web space (Fig. 22-40). It is important to ensure that abduction forces are directed to the CMC joint by involving as much of the distal aspect of the first metacarpal as possible.⁴ Strapping must be designed to apply pressure in the proper direction and to prevent distal migration of the orthosis. This often requires a strap that crosses the wrist.

Figure 22-40 Web spacer orthosis.

Substitute for Weak or Absent Muscles

Orthoses are commonly used to assist patients in maximizing the functional use of an affected upper extremity. Orthoses may be used temporarily, as in the case of recovering nerve injuries or neurological diseases such as Guillain-Barré, or they may be prescribed for long-term use, such as in complete spinal cord injury or progressive neuromuscular conditions like amyotrophic lateral sclerosis. They are generally worn only during the day or for specific functional tasks. An orthosis that is successful in improving the ability to function is often much more accepted and appreciated by the patients than orthoses prescribed for other purposes.

Substitute for Weak or Absent Shoulder or Elbow Muscles

A MAS (Fig. 22-41) can support the shoulder and forearm to encourage motion of weak proximal musculature, allow for distal function against gravity, and enable occupational performance as well as prevent loss of motion and provide pain relief. Contraindications to use include glenohumeral joint instability, and care must be taken to ensure that the humeral head does not sublux or impinge on the supraspinatus when the arm is in the device.

Figure 22-41 Mobile arm supports: In order of low to high complexity, the arm supports are listed left to right, top to bottom: A. Ergorest arm support. B. Jaeco nonelevating mobile arm support. C. Saebomas mobile arm support, typically used in clinical sessions for remediation. D. 0540 powered arm support, mounted on the person's power wheelchair in place of the armrest for consistent support. (Courtesy of Cara E. Masselink, MS, OTR/L, ATP.)

A MAS is a mechanical device that supports the weight of the arm and provides assistance to shoulder and elbow motions through a linkage of ball-bearing joints.⁵⁸ The MAS is either powered or nonpowered and is typically mounted to a patient's wheelchair, but it can also be attached to a tabletop or even a floor stand for trial use. The mechanical principles are threefold: (1) use of gravity to assist weak muscles, (2) support of the arm to reduce the load on weak muscles, and (3) reduction of friction by ball-bearing joints. The MAS may be nonelevating or elevating and may be used in clinical intervention or compensation during occupations. Criteria for use include:

- A defined functional need
- An adequate source of power from the neck, trunk, shoulder girdle, or elbow muscles
- Adequate motor control such that the patient can contract and relax functioning muscles
- Sufficient passive joint ROM, with 0° to 90° of shoulder flexion and abduction, 0° to 30° of external rotation, full internal rotation and elbow flexion, and 0° to 80° of pronation preferred
- Stable trunk positioning
- A motivated patient
- A supportive environment that provides the patient with the opportunity and assistance to use the device

Patients who may benefit include those with cervical spinal cord injury,¹⁸ muscular dystrophy, Guillain-Barré syndrome, amyotrophic lateral sclerosis, poliomyelitis, and polymyositis. The benefits of MASs include^{18,59}:

- Opportunity for movement and decreased risk of joint contractures

- Supported use of upper quadrant to improve available strength
- Improved posture
- Decreased compensatory movements
- Increased independence in many activities of daily living
- Increased social participation
- Improved confidence

It is also important to note the psychological factors impacted by the use of a MAS. Patients report improved independence and confidence as a result of performing additional activities. Patients also report improved performance of intimate tasks such as hugging or shaking hands.⁵⁹

Selection of MAS components, assembly of parts, and balance and adjustment of the MAS generally require additional training. Therefore, to fit and educate a patient on the use of a MAS, either additional training or consultation with an experienced therapist to ensure the best possible fit to provide the patient with the maximal mechanical advantage is needed.

Substitute for Weak or Absent Wrist or Hand Muscles

The combination of sensory loss and motor imbalance due to a peripheral nerve injury greatly impairs normal hand function. It is impossible to build an external device that can substitute for the intricately balanced muscles that an orthosis attempts to replace.³ In supporting nerve palsies with an orthosis, the key concept is to understand the patient's condition and neuromuscular status so as to prescribe or design an appropriate orthosis to increase function. Orthoses should keep areas of intact sensibility free if possible, should be as simple as possible, and should not immobilize joints unnecessarily. The orthosis program must be closely monitored and altered in response to nerve recovery as the patient's muscle status changes. In a study to assess factors that influenced orthosis wear in peripheral nerve lesions, the only significant variable was a positive effect as perceived by the patient; 52% of patients reported terminating wear because the orthosis hindered their daily life and 23% reported terminating wear because the orthosis had not been of any use. Interestingly, the highest effectiveness score was for day orthoses for the dominant hand aimed at replacing function.⁶⁰

Radial nerve palsy, commonly associated with humeral fractures, can result in the complete loss or partial weakness of wrist, finger, and thumb extensors and weakness of forearm supination and thumb abduction. The loss of wrist extensor strength devastates hand grasp. Not only is the patient unable to position the hand properly, but the inability to stabilize the wrist in extension impairs normal function of the long finger flexors. Loss of extrinsic finger extension is much less of a functional problem because the unaffected intrinsic muscles can actively extend the IPs. Supporting the wrist in extension is the primary goal of an orthosis for radial nerve palsy, and the use of a simple static wrist orthosis may suffice in improving hand function.⁴

There are many prefabricated radial nerve orthoses as well as custom orthosis designs available to dynamically extend the wrist, MCPs, and thumb (Fig. 22-27). It is usually preferable not to include the thumb because of the limitation in intrinsic motion it imposes and the danger of stressing the MP collateral ligament through poorly directed forces. Caution should be used when prescribing a dynamic orthosis because strong unopposed flexors may easily overcome the dynamic forces trying to hold the wrist and hand in extension, negating functional benefits.

A custom-fabricated radial nerve orthosis, also known as a Colditz orthosis, is designed to allow for partial wrist and full finger motion and a facsimile of a normal tenodesis effect. This orthosis consists of a low-profile outrigger attached to a dorsal forearm base. Nonelastic cords connect the orthosis base to finger loops. The cord length is adjusted so that, when the MCPs actively flex, the wrist is brought into extension. Conversely, when the wrist flexes, the cord tension causes the MCPs to extend. Minimal training is required

for the patient to be able to use the orthosis functionally, and grasp and release of objects is greatly enhanced. Further advantages of this orthosis are the maintenance of normal hand arches, the absence of thermoplastic material covering the palm, the low-profile design, and the facilitation of wrist extensor strength as return of nerve function occurs.³ Prefabricated orthoses and outrigger kits are commercially available.

Orthosis use following median nerve palsy is geared toward substituting for weak or absent thenar muscles that render the thumb unable to pull away from the palm and oppose to the fingers. This is most often accomplished through a custom-fabricated thermoplastic opponens orthosis that stabilizes the thumb in a position of abduction and opposition to enable pulp-to-pulp pinch (Fig. 22-16). Although such an orthosis often greatly improves fine motor prehension, this must be individually assessed because substitution patterns from unaffected thumb muscles may provide sufficient thumb function.^{3,4} Patients may choose to wear an orthosis for opposition for selected activities only.

In the presence of ulnar nerve palsy, the hand assumes a claw position, or intrinsic-minus position, with ring and small finger hyperextension of the MCPs and flexion of the IPs. This is a result of weakness or loss of lumbrical and interossei muscles, which are responsible for MCP flexion and IP extension. The prime objective of an orthosis is to assist in grasp and release of objects by preventing the claw position. This is accomplished by an anticlaw orthosis, which blocks the MCPs in slight flexion, allowing the force of the unaffected long finger extensors to extend the IPs.

Dynamic orthoses, such as prefabricated spring wire orthoses, do not work well because the spring tension is usually not sufficient to hold the MCPs in flexion when the patient actively opens the hand. Thus, the MCPs hyperextend against the force, which actually strengthens the long extensors and encourages deformity.³

A static custom-fabricated thermoplastic orthosis is advocated as the best solution. It should be nonbulky, carefully molded to distribute pressure evenly over the dorsum of the proximal phalanges, and designed so as not to obstruct full flexion of all joints.^{3,4} The orthosis may include just the affected ring and small fingers (Fig. 22-6) or may include all fingers to distribute pressure more effectively and comfortably. An orthosis is also used in the treatment of combined median and ulnar nerve injuries, resulting in the clawing of all four fingers and limitations in thumb abduction (Fig. 22-7).

Static orthoses, which allow passive holding of functional implements such as utensils or pens, may also be used in the presence of wrist or hand weakness. A hand-based universal cuff (Fig. 22-42), a wrist support with a universal cuff, and a short or long design Wanchik Writer orthosis are examples of these orthoses.

Figure 22-42 Hand-based universal cuff used to secure fork for self-feeding.

Orthoses may also be used to facilitate distal motion and motor reeducation in neurologically impaired upper extremities. The SaebFlex (Fig. 22-43) dynamic orthosis uses a fixed wrist support and a finger/thumb spring system that assists with opening the hand during grasp-and-release activities. The Ness H200 Hand Rehabilitation System (Fig. 22-44) supports the wrist in a functional position and uses low-level electrical stimulation to assist finger and thumb motion. Specialty training in fitting and use of these devices is required, and evidence of their efficacy is limited, pending more independent studies.^{61,62}

Figure 22-43 SaeboFlex orthosis—Uses dynamic forces to assist with release with allowing grasp to enable return to purposeful activities.

Figure 22-44 Ness H200—Device uses a low-level electrical stimulation to activate weak or paralyzed muscles within the forearm to improve hand function.

Prevent Contractures or Modify Tone

Careful attention to positioning in the presence of wound healing, muscle imbalance, abnormal muscle tone due to stroke or brain injury, or motor disorders such as cerebral palsy is critical in the prevention of loss of ROM, which can lead to functional or skin hygiene problems. Many of the static orthoses and casts previously mentioned for immobilization, stabilization, or substitution can be used for this purpose. Examples of these orthoses include acute burn immobilization orthosis to prevent wrist and digital contractures, wrist extension orthoses to prevent contractures caused by wrist drop, thumb abduction orthoses to prevent thumb adduction contractures, and anti-claw orthoses to prevent MCP hyperextension and IP flexion contractures. Lapboards, arm troughs, and suspension arm slings can help to position the upper extremities properly. Bivalved plaster casts or anteroposterior orthoses can be used to maintain ROM, especially in the presence of increased tone. Care must be taken to avoid pressure problems by ensuring that casts are properly padded and that the skin is closely monitored.

Ideally, these orthoses should not limit function, exert excessive stress on soft tissues, or interfere with movement of uninvolved joints. If orthoses are not required for functional use, it is often possible for patients to wear static immobilization orthoses at night only. In addition to the prevention of contractures, orthoses may be used to prevent shortening of the muscle–tendon unit. For example, a volar thermoplastic orthosis worn at night to position the wrist and fingers in maximum composite extension can help to prevent extrinsic tightness of the long finger flexors.²

The use of orthoses in the modification of tone in the wrist and hand continues to be controversial in the literature and in practice. Opponents of orthosis use argue that an orthosis may lead to increased muscle tone, joint stiffness, and muscle atrophy and may interfere with treatment aimed at facilitation and functional use. Proponents of orthosis use contend that an orthosis can reduce tone and prevent joint contracture. In a systematic review of hand orthosis use to prevent contracture and reduce spasticity following stroke, Lannin and Herbert found insufficient evidence to either support or refute its effectiveness.⁶³ Tyson and Kent concluded from their systematic review that current evidence suggests orthosis use does not improve function, motion, or pain following stroke.⁶⁴ Garros et al. also studied a volar dorsal orthosis worn by patients with wrist and hand spasticity poststroke.⁶⁵ The results showed an increase in patient-rated occupational performance at 3 months, but no long-term follow-up was done.

Common static orthosis designs include resting pan orthoses, finger spreaders or abduction orthoses, and cone orthoses.¹³ Several prefabricated orthoses are commercially available, but no clinical studies have been done to establish their fit and effectiveness.

Efficacy and Outcomes

Although the use of upper extremity orthoses is an accepted practice with much clinical and intuitive support, the state of best evidence about upper extremity orthoses is limited (see the Evidence table at the end of this chapter). Good, valid studies of current practice are needed to enhance our knowledge of orthosis use efficacy and variables that lead to optimum outcomes.

CASE STUDY

Patient Information

Tom, a 25-year-old full-time graduate student, has sustained a shaft fracture of his left dominant hand small finger metacarpal (MCP) following a fall on the ice when walking his dog. The fracture is 10 days old and stable. His performance patters include the roles of a full-time graduate student, a part-time employee as a server at a local restaurant, a son, and a brother. His leisure activities include bike riding, snowboarding, reading, and playing guitar. Tom lives with two other students in a small campus apartment. Tom was referred to occupational therapy for custom orthosis fabrication and treatment to address limits in active ROM and edema.

Initial Assessment

The Disabilities of Arm Shoulder and Hand Questionnaire (DASH) was administered to identify patient factors impacted by the injury. The DASH is a 30-item self-report questionnaire used to measure symptom and function in people with musculoskeletal disorders.⁶⁶ Tom's score indicated that he was 65% disabled for activity and participation. The DASH prompted discussion regarding several functional activities that are limited and are important to him. He complained of difficulty writing, using the keyboard for school tasks, grasping plates and cups for work tasks, preparing meal, and playing the guitar. At the time of the initial occupational therapy evaluation, the fracture healing is in the primary callus formation state of osteoblastic activity and that pain-free active ROM out of orthosis is allowed. Active ROM was assessed, and limitations were noted at the wrist in all planes, the MCP, PIP, and DIP joints of the long, ring, and small fingers. Total active motion (TAM) for the long finger was 210°, 195° for the ring finger and 185° for the small finger. The patient demonstrated 35° of wrist extension, 30° of wrist flexion, 15° of radial deviation, and 15° of ulnar deviation. Edema was noted at the dorsum of the hand and also in the digits. Measurements were taken with a tape measure to objectively assess edema. Fine motor coordination was assessed using the 9 Hole Peg test with limitations noted in speed—requiring 20.90 seconds for the left dominant involved hand and only 17.83 seconds for the right hand. The thumb, index finger, and middle finger can be used for nonresistive pinch activities. Resistive activities are restricted until there is evidence of bone healing. Therefore, hand strength was not assessed during the initial evaluation. Patient complains of a pain level of 6/10 at the fracture site.

Occupational Therapy Problem List

- Tom requires increased time to complete school-related tasks, such as typing and writing.
- Tom is unable to perform the required work tasks of a server and is currently working seating customers instead.
- Tom requires increased time to complete basic activities of daily living and is unable to squeeze a shampoo bottle and fasten his pants.
- Tom complains of difficulty sleeping secondary to hand pain.
- Tom is unable to play the guitar secondary to restrictions.
- Tom requires minimal assistance for meal preparation tasks to open jars, cut meat and vegetables, and lift pots and pans.

Occupational Therapy Goals

- Tom will be independent with donning and doffing orthosis in 1 week.
- Tom will demonstrate at least 240° TAM including three joint flexion of long, ring, and small fingers for use to hold small objects in his palm within 4 weeks.
- Tom will report a pain level of no greater than 2/10 to be able to sleep through the night within 2 weeks.
- Tom will perform meal preparation with modified independence within 6 weeks.
- Tom will return to work part time as a server within 8 weeks.
- With increased strength and ROM, Tom will independently squeeze shampoo bottle within 8 weeks.

Occupational Therapy Intervention

The occupational therapist fabricated a wrist hand finger immobilization orthosis (Fig. 22-45) to include the ring and small finger. This forearm-based orthosis protects the site of the fracture with support to both the palmar and dorsal aspects of the hand with the wrist in 20° to 30° of extension, the MCP joints in 70° of flexion, and the IP joints in full extension. Tom was educated in the care of the orthosis and how to don and doff the orthosis. At this time, Tom is required to wear the orthosis for all activities and while

sleeping. Tom can remove the orthosis five times per day to perform recommended exercises. During treatment, the orthosis is monitored for correct fit because adjustments will be needed as dorsal hand edema subsides. Occupation-based interventions are directed to improve his performance to return to his activities of daily living, work, school, and leisure tasks.

Figure 22-45 Forearm-based immobilization orthosis for metacarpal fracture. **A, B.** Wrist is in slight extension, and ring and small fingers are immobilized in metacarpophalangeal (MCP) flexion and interphalangeal (IP) full extension to protect fracture for approximately 4 weeks. **C, D.** Hand-based immobilization orthosis with MCP in flexion and IP joints to ring and small fingers in full extension to protect fracture for 4 to 8 weeks dependent on activity.

Tom is provided a home exercise program that includes tendon gliding exercises and active ROM for his wrist. These exercises should assist in decreasing edema, but Tom is also educated in edema management techniques such as elevation and the use of a compression glove.

Owing to precautions related to fracture healing, Tom’s performance of functional tasks is restricted. Most activities will be performed using his uninvolved, nondominant extremity. Tom is able to use his involved, dominant extremity for nonresistive tasks using his thumb, index, and long fingers. Adaptive occupation is addressed through the use of assisted devices or modifications.

Progress

Because there is physiological evidence of callus formation that usually occurs between 4 and 6 weeks, Tom’s orthosis is modified from forearm based to hand based. Bone callus formation indicates bone maturation and strength, and with this information, there is a corresponding change in the expectation of use and the patient’s occupational capacity is increased. Tom is able to remove the orthosis for light activities of daily living, including showering, keyboard use, cell phone use, and light dressing tasks.

Active ROM was assessed to monitor progress. TAM of digits increased to 230° of the long finger, 215° of the ring, and 208° of the small. Wrist flexion increased to 45°, extension increased to 42°, radial deviation increased to 22°, and ulnar deviation increased to 25°. Tom also demonstrates a decrease in edema, a decrease in reports of pain to 3/10, and improved fine motor coordination with a decrease in time required to complete the 9 Hole Peg test in 18.65 seconds.

Following evidence of clinical union confirmed by x-ray (usually 6–8 weeks following fracture), Tom’s hand strength can be assessed, and he can begin to use his dominant hand for resistive tasks. The orthosis is typically discontinued at this time. Tom is able to return to work as a server and all other resistive functional tasks such as playing the guitar, riding his bike, and preparing meals.

Best Evidence for Use of Orthotics as Intervention

Intervention	Description of Intervention	Participants	Dosage	Level of Evidence	Benefit	Statistical Probability and Effect Size

Intervention	Description of Intervention	Participants	Dosage	Level of Evidence	Benefit	Statistical Probability and Effect Size
Immobilization orthosis for thumb OA ⁶⁷	Different types of orthosis and designs	Fourteen publications including a total of 580 subjects	At least 2 weeks of orthosis use was recommended.	Systematic review; Level I evidence	Immobilization of the CMC joint is effective regardless of design and reduces pain and improves function.	Impact of orthosis use on hand strength was inconclusive. Significant effect was noted with reduction in pain and improved hand function. Analysis of results was not reported secondary to variances in studies.
Treatment strategies for treatment of thumb OA ⁶⁸	OA treatment strategies: joint protection, CMC immobilization orthosis, thumb isometric exercises	Sixty subjects	6-Week treatment program, including orthosis use, exercises, assistive device education, and joint protection education	Pre-post design; Level II evidence	Statistical and clinical differences were noted in pain, ROM, and functional use.	80% power established with sample size. Significant improvements in pain ($p < 0.0001$), active motion (right $p = 0.003$, left $p = 0.0001$), and Canadian Occupational Performance Measure (COPM) ($p = 0.0001$).
Wrist orthosis and patient education as treatment for carpal tunnel syndrome ⁶⁹	Effects of wearing a wrist support orthosis and receiving education on activities, which increase pressure in the carpal tunnel	Random assignment: 30 in treatment and 24 in control group	Intervention group: 8 weeks orthosis use and patient education (150 minutes of treatment time)	Randomized controlled trial; Level I evidence	Benefits were noted with improved grip strength, decreased pain, improved sensation, and improved function.	Power and effect sizes were not reported. Significant differences found in post-test of intervention group with the Boston Carpal Tunnel Questionnaire ($p = 0.001$), visual analog scale (VAS) ($p = 0.001$), Phalen's test ($p = 0.031$), grip strength ($p = 0.020$), Purdue Pegboard ($p = 0.021$), and monofilament test ($p < 0.001$).

Intervention	Description of Intervention	Participants	Dosage	Level of Evidence	Benefit	Statistical Probability and Effect Size
Orthosis intervention for thumb OA thumb CMC ³⁸	Effectiveness of custom-fabricated orthosis and prefabricated orthoses to reduce pain	469 subjects in 12 studies	Orthotic wear for 2 weeks up to 7 years, various wearing schedules	Systematic review of 12 studies published in 2000 or later; Level I evidence	Significant decrease in pain at short term (≤ 45 days) and long term (≥ 3 months)	Significantly reduction in hand pain at short-term (< 3 months) and long-term (≥ 3 months) follow-up, with a standardized mean difference of 0.37 (95% confidence interval [95% CI] 0.03, 0.71) and 0.80 (95% CI 0.45, 1.15). Unable to determine effects size because of lack of homogeneity of study design, methods, and orthosis design.
Orthosis intervention and therapy for thumb CMC OA ⁷⁰	Hand orthosis and therapy benefits over time; baseline, 6 weeks, 3 months, and 12 months	122 subjects	Subjects were provided an orthosis for use and therapy to include a home exercise program and education in appropriate pinch patterns. Specific dosage varied between subjects. Subjects were treated for up to 12 weeks, 2 times per week.	Prospective observation cohort; longitudinal; Level II evidence	Improvement in pain and function. Fifteen percent of subjects eventually sought surgical intervention after 2.2 years.	Reports of pain in last week decreased from 49 to 36 over 12 months on a VAS, $p < 0.05$. Reports of pain with activity decreased from 60 to 21 over 12 months, $p < 0.05$. Michigan Hand Questionnaire (MHQ) scores decreased from 65 to 69 ($p < 0.05$), which was not clinically relevant.

Chapter 23

Upper Extremity Orthoses Fabrication

Nancy S. Hock

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe the anatomical, biomechanical, and mechanical principles applied to the construction of custom-fabricated orthoses.
2. List the primary reasons to use orthoses as a therapeutic intervention.
3. Recognize factors affecting compliance with orthoses.
4. Explain design, pattern-making, and construction for three custom-fabricated orthoses.
5. Describe the orthosis fabrication process.

CHAPTER OUTLINE

Orthosis Fabrication Introduction
Anatomical and Biomechanical Considerations When Fabricating Custom Orthoses
Patient Considerations When Choosing to Incorporate Orthoses into the Treatment Plan
Considerations Regarding Thermoplastic Orthoses Construction
Custom Orthosis Construction
Case Study

TERMINOLOGY

- Custom-fabricated orthosis:** an individually made device for a specific patient that is based on clinically determined measurements or tracings and involves the use of basic materials such as plastic, metal, leather, or cloth in uncut or unshaped sheets.
- Custom-fit orthosis:** a prefabricated device that is not manufactured for an individual and may need assembly, fitting, trimming, or molding.
- Dynamic orthosis:** a device that applies a mobile force with rubber bands or springs in one direction while allowing active motion in the opposite direction.
- Fibroblastic phase:** a stage of wound healing that follows the inflammatory phase, during which fibroblasts proliferate and initiate collagen production in the healing of tissues.
- Inflammatory phase:** a stage of wound healing immediately following injury or surgery, characterized by edema and infiltration of leukocytes and macrophages to begin healing tissue.
- Maturation phase:** a stage of wound healing that follows the fibroblastic phase, characterized by wound contraction, remodeling, and maturation of the healed tissues.
- Orthosis:** a device that is applied to the body to provide immobilization, avoid deformity, correct deformity, protect healing structures, limit motion, or to allow tissue proliferation and remodeling for the upper extremity.
- Prefabricated orthosis:** a device that is obtained off the shelf, but may require adjustment.

Splint: casts or strapping that are used to reduce fractures or dislocations; this term is used primarily by physicians or clinicians applying a cast.

Static progressive orthosis: a device designed to elongate soft tissue to decrease contractures through the application of incrementally adjusted static force to promote lengthening of contracted tissues.

Orthosis Fabrication Introduction

To effectively construct a hand **orthosis**, one must appreciate the significance, biomechanics, and anatomy of the human hand. Mary Reilly described the significance of hand function in her 1961 Eleanor Clarke Slagle lecture when she suggested, “That man, through the use of his hands as they are energized by mind and will, can influence the state of his own health.”^{1(p88)} Others have suggested that hands are among the features that distinguish human beings from other living creatures. Hands are most certainly important to occupational performance.

Pathology of the upper extremity can result in impairments of many client factors including limitations in joint mobility or muscle strength, swelling, sensory impairment, and pain. Occupational therapists often address these impairments by incorporating an orthosis into a patient’s intervention plan to enhance performance skills and occupational performance.

In this chapter, we introduce the biomechanical and anatomical structures of the hand that occupational therapists consider when fabricating an orthosis. We then provide basic information about the construction of orthoses, appreciating that practice and further training are required to develop expertise in this area. A **splint** refers to casts or strapping used to reduce fractures or dislocations. The word splint/splinting should not be used when documenting orthosis fabrication.²

Anatomical and Biomechanical Considerations When Fabricating Custom Orthoses

A functional understanding of the human body requires the appreciation of three major areas of scientific study: musculoskeletal anatomy, neuromuscular physiology, and biomechanics.³ Recovery of hand function following disease or injury may be optimized when the abovementioned scientific study are combined with an understanding of function in occupation and orthosis fabrication.

Anatomy

The anatomy of the hand informs the concept, design, and construction of custom-fabricated or custom-fit hand orthoses. Such consideration requires a basic review of the macrostructure of tissues and component structures that contribute to functional interaction with the environment.

Anatomic Principles Applied to Custom Orthosis Fabrication

- Bones create structural support and arches of the hand. Orthoses conform to structure and arches to create dual obliquity and support a functional position.
- Joints create levers for movement. The more stable a joint, the less motion; the more actual degrees or planes of motion, the less stable.
- Muscles create movement of joints. Orthosis design is intervention specific, encouraging motion, stability, or immobilization of tissue and joints.
- Neuromuscular physiology is the organ system that drives function. Orthosis design must allow neuron to muscle fiber communication in order to be a beneficial intervention.
- The integumentary system encapsulates the body. Understanding the relationship of skin creases to joints is important for orthosis design and construction.

The metacarpals vary in length and height. Metacarpals of the radial fingers are longer than the ulnar fingers of the hand. The metacarpal heads on the radial side of the hand are higher than those on the ulnar side of the hand, an effect more pronounced when the hand is closed. The therapist must apply this concept of dual obliquity to the construction of an orthosis. That is, the orthosis must be longer and higher on the radial side of the hand⁴ (Fig. 23-1).

Figure 23-1 Concept of dual obliquity applied to orthosis fabrication.

Bone

The specific functions of bone that must be considered for orthosis fabrication include structural support, levers for body movement, and protection of underlying structures. Bones are categorized according to shape and size. Long bones have a shaft that acts as a rigid tube; each end of the shaft is expanded, creating a basic component of a joint. Short bones are cube shaped, as long as they are wide. Flat bones are broad and thin with flat or curved surfaces, and sesamoid bones are round.⁵ The three primary arches of the hand are assured by the structural anatomy of the bones. An orthosis must conform to these concave arches to support a functional position of the hand (see Fig. 23-2). The distal transverse arch is formed by the metacarpal heads of the index, long, ring, and small fingers. The longitudinal arch extends from the wrist to the long or index finger. The oblique arch is formed through opposition of the thumb and small finger.⁶ It is important to maintain these arches throughout the fabrication process. Otherwise, collapse or flattening of these arches may result in decreased functional return of the hand.⁷

Figure 23-2 Arches of the hand must be supported in orthosis fabrication.

Joint

A joint can be defined according to structure or function. Structurally, it is a place where two or more bones are joined to one another by soft tissue. The major function of a joint is to allow movement. The hand consists of joints that have space between the articulating bones that allow for movement. Joints surfaces create bony prominences that should be considered during orthosis fabrication as they can be pressure areas. Adequate orthosis design requires conformity to bony prominences, assuring proper fit and reduced risk of pressure points from orthosis use (Fig. 23-3). Joints are constructed to allow for a balance between mobility and stability.⁵ The motion available at joints within the hand is variable. The more mobile a joint, the less stable it is. When a joint has inherently less stability, it is at higher risk for injury. It is important to note there is increased joint mobility on the ulnar side of the hand as compared to the radial side, and this should be considered during orthosis fabrication.⁷ Additionally, there is basically no motion allowed at the carpometacarpal (CMC) joints of the index and long fingers and only a small amount of motion that occurs at the CMC joints of the ring and small.⁸ The concepts of joint stability and mobility must be considered in custom orthosis design and construction to assure the orthosis is safe and performs as intended.

Figure 23-3 Bony prominences can lead to pressure points, especially over the back of the hand. Careful contouring of the thermoplastic material can minimize this problem.

Muscle

Most skeletal muscles have attachments to two bones: the origin, where it begins, and the insertion, where it ends. Musculotendinous structure crosses a joint or joints located between the origin and insertion. When a muscle contracts, it shortens toward its center; when the contraction force is sufficient, one or both of the bones to which the muscle is attached will be pulled toward the center of the muscle.⁵ The joint or joints between the muscle's origin and insertion function to allow movement. Understanding the action of a joint caused by the forces applied by muscle and other generated forces is critical to orthosis design.

Integumentary System

As the largest organ system of the human body, skin completely encapsulates the body and permits unrestricted mobility.⁹ Dorsal hand skin is relatively thin with creases directly over articulations. Volar skin is fibrous and thick with more defined creases. As with dorsal digital creases, the volar digital creases directly correlate with joint location. The palmar creases are often used as landmarks for orthosis fabrication.¹⁰ For example, the distal palmar crease is a landmark for the distal aspect of a volar-based orthosis to allow motion at the metacarpophalangeal (MCP) joints. The thenar crease should also be considered during orthosis fabrication to allow full movement of the thumb. The wrist crease should be clear for hand-based orthoses to allow full wrist flexion¹⁰ (see Fig. 23-4).

Figure 23-4 Creases of the hand provide landmarks for the distal ends of the orthosis. For a wrist support orthosis, the distal end of the orthosis should not block the thenar eminence or distal palmar crease.

Biomechanical Principles Applied to Custom Orthosis Fabrication

When wearing an orthosis, external forces are applied, thus requiring a basic knowledge of anatomy and biomechanics to ensure proper fit of the orthosis and appropriate outcomes. An orthosis with poor fit can result in skin breakdown and poor compliance.

Proper Position with Custom Orthosis Fabrication

Proper positioning of the extremity in an orthosis is vital to minimize the risk of joint contracture following injury to the hand.

- The intrinsic plus position is the appropriate position for immobilization. Dobson et al. recommend the 0–30° of wrist extension, the MCP joints in 70–90° of flexion, and the interphalangeal (IP) joints in full extension. This position creates tension on the collateral ligaments, preventing the development of joint stiffness or contracture¹¹ (Fig. 23-5).

Figure 23-5 Position of safe immobilization or intrinsic plus position.

- Natural hand postures impact function. When the forearm is supinated, the wrist is in neutral to slight radial deviation, and when the forearm is pronated, the wrist has increased ulnar deviation. An orthosis fabricated in supination, for a patient whose

occupations are primarily done in pronation, will likely result in poor fit and compliance.

- The normal biomechanics of digit flexion result in convergence toward the scaphoid bone. This must be taken into account when fabricating a dynamic or static progressive orthosis to address passive digit flexion and provide the appropriate direction of force (Fig. 23-6).

Figure 23-6 Digits flex toward the scaphoid.

Mechanical Principles Applied to Orthosis Construction

90° Angle for Dynamic or Static Progressive Orthosis Fabrication

Orthoses using outriggers with springs, nylon lines, or elastic bands/cords should be fabricated by considering the line of the force as well as the degree of the pull.

- In dynamic or **static progressive orthoses**, the line of pull (force) must be at a 90° angle to the joint at which motion is intended (see Fig. 23-7). Maintaining this angle allows the force to be correctly applied to the joint to improve passive motion. This also prevents compression or distraction of the articulating surfaces.¹²

Figure 23-7 Demonstrating correct angle of pull from outrigger.

- The magnitude of force applied through dynamic traction can be measured using a Haldex gauge.¹³ However, it can also be determined through experience. The clinician should look not only at blanching of the skin but also at patient tolerance of the orthosis and outcomes. If the patient has tolerated an orthosis for a long period of time, but no gains were made, force could be increased. If the patient was only able to tolerate the orthosis for a short period of time and no gains were made, force should be decreased.

The therapist risks putting excessive pressure to the joints and soft tissues if the force delivered by either side of the joint axis is not in balance with the other side of the orthosis.¹⁴ Unbalanced mechanical advantage can create problems such as skin breakdown or joint compression.

Torque

Torque (moment of force) is a result a force multiplied by a lever arm.¹⁵ The distance that is perpendicular to the force is known to be the moment arm of that force.¹⁶ The moment arm multiplied by the force produces the torque force.⁷ A mechanical advantage is created by the ratio between the lever length from which the force is applied and the length of the lever arm where the force is delivered.¹² Clinicians must consider Newton's Third Law when determining forces to deliver with the use of an orthosis, as with every action, there is an equal and opposite reaction.¹⁶ Excessive force, despite a satisfactory level arm, could result in migration of the orthosis, causing skin irritation or breakdown, pain, and poor compliance impacting desired outcomes.

Levers

Mechanical advantage occurs when a lever system is efficient.⁷ The more efficient the lever system, the less force is needed to create a change. Upper extremity anatomy consists of several basic lever systems. The first-class lever system is the basis of mechanical principles for immobilizing the hand (Fig. 23-8). First-class levers provide forces on opposite sides of the axis, similar to a seesaw. Second-class levers have an axis at one end of a rigid lever, and the resistance is between the axis and the force, such as a wheelbarrow. Third-class levers are commonly found in the musculoskeletal system and have an axis at one end, while the force is provided through a long moment arm.⁷ Second-class levers have greater efficiency than third-class levers. Most orthoses have a first-class lever system.¹⁷

Figure 23-8 The orthosis as a class 1 lever system.

With constant resistance, the force in the lever system can be decreased by increasing the length of the force arm. In the case of a wrist support orthosis, the forearm trough is the force arm, and the metacarpal bar serves as the resistance arm. The longer the forearm trough, the less pressure is transferred from the weight of the hand to any one part of the forearm in contact with the orthosis or strap. Using this principle, the forearm trough should be designed as long as possible without interfering with elbow motion, approximately two-thirds the length of the forearm.

Stress/Force

Force occurs when there is a push or pull created by two objects having contact. Compressive and shear forces can occur with orthosis use.¹⁶ Compressive forces act in directions toward each other, and shear forces act parallel to one another, but in opposite directions.⁷ Clinicians can control this force by increasing the area where force is applied, as pressure is created by the force divided by the area where it is created.¹² Otherwise, these forces can lead to tissue breakdown. When designing and constructing an orthosis, these principles must be considered for optimal outcomes. This means that a wide, long orthosis applies less pressure in any one area than a narrow, short orthosis. A forearm-based orthosis should cover at least two-thirds the length of the forearm to avoid sheering. A contoured orthosis requires more material and surface area contact than an uneven or point-pressured design over a prominence. Padding may actually increase pressure to the hand if the orthosis is not well molded.

Three Points of Pressure

To immobilize or mobilize a joint using an orthosis, three points of pressure are used. These forces guide orthosis design and direct strap placement to ensure proper force application. Three linear forces are created using a middle force that pulls in an opposite direction from the other two forces.¹⁰

Add Strength through Contouring Tensile Characteristics

The response a material has to stress and the degree of strain produced in an elastic body is described in Hooke's law of elasticity. This law suggests that if the same material is curved, the level of energy stored is greater, and the material can more effectively withstand force.¹⁸ This means that contour mechanically increases a material's strength. Therefore, orthoses should be constructed with contour and extend midway around the part being immobilized to create increased strength and maximum comfort.⁴ Curved and contoured edges are preferred over square edges.

Patient Considerations When Choosing to Incorporate Orthoses into the Treatment Plan

As with any intervention, the clinician considers many patient factors in determining the appropriateness of an orthosis.

- The clinician should evaluate the patient's neurovascular status (sensation and blood supply), mobility, motor function, edema, tone, and cognition prior to orthosis design and construction.
- Sensory deficits in the hand are concerning because the patient may be unable to feel pressure points or areas of irritation from the orthosis. This may lead to skin breakdown or injury.
- In the case of hypersensitivity, wearing an orthosis can protect the fingertip or hand from unpleasant stimuli.
- Edema may also indicate the need for close monitoring of orthosis fit and comfort. As edema diminishes, the orthosis will require modification or remolding to maintain proper fit.
- Changes in range of motion (ROM) and edema may occur during the course of dynamic or static progressive orthosis intervention, thus requiring frequent modifications to ensure proper biomechanics. Changes in tone may warrant modification to a serial static orthosis. Therefore, ongoing assessment is required when using an orthosis in a treatment plan to ensure fit, proper biomechanics, and comfort to ensure appropriate outcomes.

When designing an orthosis, it is important to maintain the thumb in a functional position to ensure prehension to the index and long fingers. Typically, the thumb is held

in palmar abduction and opposition to these fingers for effective prehension, unless thumb movement is contraindicated following a postoperative protocol. While forming the orthosis, the clinician may have the patient grasp a pen or other object to test the thumb motion needed to achieve functional prehension. When designing a splint for the patient with carpal tunnel syndrome, the clinician should be aware of a wrist position that results in the lowest pressure in the carpal canal. Cha recommends a neutral position, avoiding wrist extension.¹⁹ Fufa et al. recommend an intrinsic plus position for contracture prevention following hand burns with the wrist in 20–30° of extension, MCP joints in 70–90° of flexion, IP joints in full extension, and thumb palmarly abducted.²⁰

Considerations for Designing an Orthosis

The following questions should be taken into account when determining the appropriate orthosis design:

- What is the patient's provisional diagnosis?
- Is there a good reason to fabricate an orthosis? If so, what does the orthosis need to accomplish?
- Does the benefit of using an orthosis outweigh the benefits of not using an orthosis?
- Does the clinical evaluation support the provisional diagnosis and orthosis intervention?
- What are the implications of an orthosis on various anatomical factors (e.g., affected structures, number of joints)?
- Biomechanically, should the orthosis be static, static progressive, or dynamic?
- What are the mechanical considerations? Forearm or hand based? Volar or dorsal design?
- Can the treatment goals be achieved with a **prefabricated orthosis**?
- Does the patient understand the purpose and benefits of the orthosis?
- Can the patient don and doff the orthosis as required?
- What can be done to support patient adherence to wearing the orthosis?

Theoretical Foundations for the Use of Orthoses as a Therapeutic Intervention

There are many reasons to introduce an orthosis into a patient's therapeutic program. An orthosis can be used as a method of remediation as well as compensation. Using the biomechanical frame of reference, remediation allows patients to restore ROM, strength, and endurance.²¹ For example, a patient who has experienced radial nerve compression following a midshaft humeral fracture will demonstrate limitations in wrist, digit, and thumb extension, causing the extremity to have significant limitations in functional performance. Use of a forearm-based dynamic extension orthosis will significantly improve function of the upper extremity. This increase in functional use will improve ROM at the glenohumeral joint, improve the strength of digit flexors, and increase endurance for occupation. This is especially important, given the length of time required for nerve regeneration.

Using the rehabilitative frame of reference, compensation allows patients to return to function despite limitations.²¹ An orthosis can be used as compensatory because it can substitute for motor loss or a lack of stability. For example, following prolonged median nerve compression at the carpal tunnel, patients may lose the ability to oppose the thumb to digits. This presents as a significant functional challenge when attempting to grasp items. Using a hand-based thumb orthosis that holds the thumb in palmar abduction will allow compensation for this limitation in motion. The use of this orthosis may also prevent contracture of the thumb in adduction because this is many times associated with distal median nerve pathology.

Adaptation is many times needed to alter or change how a task is completed to increase a patient's ability to complete meaningful tasks. Thermoplastic material can be used to improve occupational performance by softening scraps of the material to enlarge handles, alter grip-and-pinch patterns, and create loops to grasp items needed for function. For example, thermoplastic material can be twisted with loops to create an apparatus for a patient suffering from a C6 spinal cord injury to don pants, it can be added to a key to improve the ability for it to be grasped, and it can be added to eating utensils to improve use.

Phases of Tissue Healing

Fess reported that an orthosis can be used to limit motion following a sprain/strain, nerve or vessel repair, or fracture.²² Therefore, clinicians must have at least basic knowledge of the several phases of wound healing when incorporating an orthosis in a treatment plan. The first phase of wound healing is the **inflammatory phase**, also called the exudative stage. During this stage, there is a clearing of debris to prepare for tissue repair.²³ During the inflammatory phase, the therapist may use a static orthosis to immobilize and protect the healing tissues in the hand and wrist. An orthosis in the position of safe immobilization is also known as the intrinsic plus position, with the wrist slightly extended, MCPs flexed, and IP joints fully extended (see Fig. 23-5). Incorporating an orthosis in the functional position may be considered in the latter two phases of tissue healing (Fig. 23-9). This places the wrist in slight extension as in the intrinsic plus orthosis, and MCP joints and IP joints in slight flexion while placing the thumb in palmar abduction.

Figure 23-9 Functional position of the hand.

The second phase of healing is the **fibroblastic phase**, also called the reparative stage. During this phase, an orthosis may be used to mobilize healing tissues while still protecting them. As the strength of the healing tissue increases, the third stage of healing, the **maturation phase** or remodeling phase, occurs.²³ Low-load force may be applied through use of a **static progressive orthosis** or a **dynamic orthosis**, designed to lengthen contracted tissues through application of incrementally adjusted static force. As maturation progresses, the tissues can tolerate an increased amount of stress.²⁴

It is important to provide the appropriate amount of stress to tissue during the healing process. The speed at which tissue healing and maturation occurs varies among individuals.²⁵ Providing high levels of force through an orthosis at the incorrect time in the healing process may lead to tissue damage or microtrauma.²⁶ Understanding of the healing process allows therapists to better identify the orthosis needs of their patients. Initially, a dynamic orthosis will address limitations in joint stiffness, which are not resolved with passive mobilization. If the tissue matures and a hard end-feel is noted during passive range of motion (PROM), a serial static or static progressive orthosis will likely be required.²⁵

Reasons to Use Orthoses

There are many reasons to include an orthosis as part of an intervention plan. These include²²:

- Improve function
- Avoid deformity
- Correct deformity
- Protect healing structures
- Limit motion
- Allow tissue proliferation and remodeling

Influence of Orthosis Use on Tissue Remodeling

An orthosis can be incorporated into a treatment plan to promote tissue proliferation and remodeling.²² Total end range time (TERT) is described as the total time a stiff joint is held at its passive end range with tension provided by an orthosis.²⁶ Flowers reported temporarily elongating tissue with a stretch technique is not effective because of the viscoelastic properties of soft tissue.²⁷ Instead, using an orthosis to hold a joint at its end range for a long period of time to promote a growth response, actually lengthens tissue. Ideal tissue remodeling occurs with gentle elongation of tissues.²⁸ There is a direct relationship between the length of time a dynamic orthosis is used to provide tension and improved passive motion.²⁹ Glasgow et al. recommend orthosis intervention to impact contracture resolution within 1–2 months postinjury.³⁰ A 6-hour daily wearing time is identified as optimal at TERT.^{29,31}

Patient Adherence to Orthosis Use

Patient adherence profoundly influences the effectiveness of any intervention. Even the most expertly designed and constructed orthosis will not benefit the patient if it is not worn. Adherence to a therapeutic program is influenced by intrinsic and extrinsic factors. Intrinsic factors are derived from the patient's perception of hand function, the seriousness of the injury, and the perceived efficacy of the treatment or rehabilitation.³² The clinician must understand that a patient's perception of the effectiveness of the orthosis in achieving the goals of rehabilitation can influence his or her willingness to wear an orthosis.^{15,33} An informed patient takes ownership and adheres to orthosis use.

Extrinsic factors likely to influence adherence include time restriction, discomfort or pain, forgetting to perform the home program or orthosis application, interference with family or social activities, and a lack of positive feedback.³² Cole et al. recommend applying behavioral approaches, such as providing feedback and encouragement, to promote self-efficacy and improve adherence to treatment plan.³⁴ In the interest of being client centered, it is helpful to collaborate with the patient to identify effective options that are also acceptable to the patient.

Strategies to Promote Orthosis Compliance

- Incorporate the patient's preferences (as able) in orthosis design.
- When possible, educate family members of the importance of orthosis use.
- Educate the patient on benefits of orthosis use and possible outcomes if it is not used.
- Instruct in proper orthosis wear and care, including orthosis hygiene.
- Make sure the orthosis fits properly and feels comfortable.
- Incorporate aesthetics into the orthosis design for improved cosmesis.
- If possible, offer options (custom-fabricated or prefabricated) to the patient.
- Provide for easy application and removal of the orthosis.
- If feasible, collaborate with the patient on a wearing schedule.

Considerations Regarding Thermoplastic Orthosis Construction

Material Properties

Low-temperature thermoplastic material is typically used with custom orthosis fabrication. This material becomes moldable at a low temperature of 140–170°, allowing

molding of the orthosis directly on the patient's skin versus high-temperature thermoplastic, which requires a temperature of 210°.35 There are several things to consider when selecting thermoplastic material. First is the resistance to stretch, which is how much resistance there is to pulling or stretching when the material is heated or softened. Material with a high resistance to stretch will tolerate firm handling and is typically used for larger orthoses and when working with patients with spasticity. Material with a low resistance to stretch is more appropriate for smaller orthoses, but can be challenging for the novice therapist. The drapability of the material should also be considered. Drapability impacts the material's ability to conform to the skin surface, providing good fit with minimal handling.36 Some material has memory, allowing the material to return to its original shape when reheated. This material turns clear when heated, to indicate it is ready to be molded.37 This feature is important when an orthosis requires frequent modifications, as with serial static orthoses.

It is important to base material selection on the type of orthosis you are fabricating, the experience level of the therapist, and characteristics of the patient. Properties of various thermoplastic materials are outlined in Table 23-1. For example, a novice therapist using a material with minimal resistance to stretch may have difficulty overstretching the material and should instead allow gravity to do much of the work instead of stroking or pulling on the material. Material with a low resistance to stretch may also show fingerprints and/or nail marks if held too firmly, impacting aesthetics of the orthosis and potentially patient wearing compliance.

Table 23-1. Properties of Various Thermoplastic Materials

THERMOPLASTIC MATERIAL	PROPERTIES	DISTRIBUTERS/MATERIALS
Minimum resistance to stretch	Comfortable Drapability Avoid heavy handling Not for the novice fabricator Hand-forearm-based orthoses	<i>Performance Health</i> • RolyanPolyform <i>North Coast Medical</i> • Clinic <i>Orfit</i> • OrfitFlex NS
Moderate resistance to stretch	Drapability (good balance) Tolerates greater handling For novice and experienced Various orthosis sizes	<i>Performance Health</i> • TailorSplint <i>North Coast Medical</i> • Preferred <i>Orfit</i> • Orflight
Maximum resistance to stretch (with memory)	Translucent when heated Tolerates repeated heating Can use with spasticity Tolerates firm handling Larger orthoses	<i>Performance Health</i> • AquaplastResilient <i>North Coast Medical</i> • Encore <i>Orfit</i> • Tecnofit
Maximum resistance to stretch (without memory)	Resistant to stretching/fingerprints Rigidity Tolerates firm handling Larger orthoses	<i>Performance Health</i> • Synergy <i>North Coast Medical</i> • Solaris <i>Orfit</i> • Orfibrace NS

There are several other considerations for selecting thermoplastic material. Material comes in various thicknesses, such as 1/16", 1/12", 3/32", or 1/8". A thicker material is suitable for orthoses that require firm support, when working with patients with spasticity or abnormal tone, or with fracture bracing. A thinner material is appropriate when fabricating finger- or hand-based orthoses or when working with children.38 Material can also be purchased with various levels of perforation to provide greater ventilation and for fabricating circumferential orthoses.38 These features are important when placing an orthosis over a wound dressing or when there is skin maceration.

A material's self-adherence or bonding ability must be considered when the orthosis design requires attaching two or more pieces of material together. An example is attaching an outrigger to an orthosis. Polyform (Performance Health) is one example of a material that has a coating, or laminate, on the surface that resists self-adherence until it is modified.³⁹ This coating must be removed before attaching straps or other permanent attachments using a solvent or scraping the surface. Uncoated material provides effective bonding if pressed together when heated.³⁸ This technique can be challenging for the novice therapist if the material is accidentally folded onto itself during handling.

Material is available in multiple colors. Purchasing several colors, however, may not be feasible or cost-effective if working in a small clinic environment. Many adult patients prefer a material that matches their skin tone to avoid drawing attention to their injury or limitation. It is important to note that darker colors show less wear and tear and look cleaner. However, when working with older adults and those with low vision, contrasting colors may aid with strap application and prevent the orthosis from getting lost or mixed into laundry.⁴⁰

Technological advances have allowed incorporation of an antimicrobial agent into several thermoplastic materials. This is important because orthoses are often worn continuously against the skin, and a moist environment can lead to bacteria build-up and an unpleasant smell. Antimicrobial protection may make the orthosis easier to clean.

High-temperature thermoplastics are also available for rigid immobilization. They require use of a band saw for cutting and an oven for heating.⁴ These high-temperature thermoplastics have high-impact strength, but do not contour well, making them unsuitable for orthosis fabrication.

Material can be purchased from various companies. An employer may have established contracts with certain suppliers, thus limiting thermoplastic material and supplies. To that end, it is important to be familiar with the basic properties of material to best select certain thermoplastics from each supplier.

Thermoplastic material can be purchased in individual sheets or in a case of 4. To prevent waste, these sheets need to be cut into smaller pieces with a utility knife. Material can also be purchased in precut patterns, thus eliminating cutting prior to heating, a time saver in orthosis fabrication (see Fig. 23-10).

Figure 23-10 Precut thermoplastic material. **A**, Wrist immobilization orthosis; **B**, Hand-based thumb immobilization orthosis; **C**, Forearm-based wrist and thumb immobilization orthosis.

Soft lightweight materials, such as neoprene or thickened closed cell foam, are also available to support the hand and wrist. These materials provide light restriction, which may be desirable for patients who do not tolerate hard thermoplastic orthoses. A prefabricated orthosis requires less time and effort to prepare on the part of the therapist; however, evidence suggests custom-fabricated orthoses are preferred over prefabricated for some diagnoses.³⁷ The clinician should consider the patient's tolerance to any material being used when recommending prefabricated orthoses or custom-made orthoses.

Necessary Basic Equipment for Orthosis Fabrication

Fabricating a custom orthosis requires many supplies beyond thermoplastic material. An electric fry pan, splint pan, or hydrocollator is required to soften thermoplastic material. A utility knife and extra blades are needed to cut sheets of material into smaller pieces to fit within the splint pan, and heavy-duty chrome-plated scissors are needed to cut material after it is softened. Many experienced therapists use Gingher scissors for this task. An all-purpose pair of scissors is needed to cut Velcro loop strapping and Velcro hook. A heat gun is needed for spot-heating areas of the orthosis. A pair of needle-nosed pliers is useful for removing Velcro hook. If more complicated orthoses, such as dynamic or static progressive, will be fabricated, additional equipment will be required, including a hole punch to insert a rubber band post. Outrigger wire, wire benders, wire cutters, and bonding solvent are necessary to attach an outrigger to the orthosis. Finger loops, nail hooks, elastic bands/cords, springs, nylon outrigger line, super glue, and D-ring attachments or safety pins are all needed to attach the outrigger to the hand. Moleskin or close cell foam can also be used to reduce friction or stress to the skin.

Custom Orthosis Construction

Orthosis Design

As previously discussed, the primary determination of orthosis design is identified by the provisional diagnosis. The design process is multifactorial, incorporating not only the clinical condition that led to the need for the orthosis, but also taking into account the client factors identified in a thorough assessment of the patient and his or her performance skills, occupations, and performance patterns. Design decisions are also informed through review of the evidence and knowledge of the biomechanical and physiological factors relevant to the orthosis design. It is also important to consider the cost of the orthosis because thermoplastic material is expensive and orthosis fabrication can be time-consuming, both of which impact potential cost to the patient. If a prefabricated orthosis that provides the same purpose is available, it may be a more cost-effective option than a **custom-fabricated orthosis**. Examples of orthoses are shown in Figure 23-11.

Figure 23-11 A. Resting orthosis. B. Hand-based thumb orthosis. C. Dorsal wrist orthosis. IP, interphalangeal; MCP, metacarpophalangeal.

Thermoplastic Material Selection

To reiterate, in order to select the material that best meets the patient's needs and aligns with the purpose of the orthosis, the therapists should be familiar with the properties of

various thermoplastics.

Steps in Custom Orthosis Fabrication

1. Design orthosis.
2. Select appropriate material.
3. Make a pattern/Check on patient.
4. Cut thermoplastic material using utility knife.
5. Heat thermoplastic material.
6. Score material outlining pattern with scissors.
7. Cut outlined softened material with scissors.
8. Form orthosis.
9. Finish edges.
10. Apply straps, padding, and attachments.
11. Evaluate the orthosis for fit, function, and comfort.

Making a Proper Pattern

After establishing the orthosis design, a proper pattern must be created. This is a critical step in custom orthosis fabrication because a well-designed pattern results in an orthosis with appropriate support, function, and fit. Moving forward without a proper pattern could result in waste of thermoplastic material and a waste of the patient and therapist's time. Three common splint patterns are illustrated in Figure 23-11. Paper towels provide an excellent moldable pattern, but any type of paper can be used for the pattern. Place the patient's hand directly on the paper and mark the anatomical landmarks according to the design of the orthosis (see Fig. 23-12).

Figure 23-12 Drawing a pattern for a resting hand orthosis on a patient.

The pattern must extend beyond the lateral borders of the hand and forearm to allow the splint to form a trough, which will extend halfway around the surface being immobilized to provide adequate support. This is critical to prevent sheering or pressure from the orthosis. When creating a forearm-based orthosis that is either dorsal, volar, or lateral, extend the forearm trough two-thirds the length of the forearm. Once the pattern is drawn, cut it out and then place it on the patient to assure appropriate fit (see Fig. 23-13, and also look ahead at Figs. 23-23 and 23-26).

Figure 23-13 Fitting the pattern on the patient.

Modifications are easily achieved by reducing the pattern, adding paper for extra length or width, as needed. If the patient is unable to lay the hand flat for pattern drawing due to deformity or spasticity, use the uninvolved hand for pattern-making and flip the pattern over for the contralateral side. A pattern can be adjusted for edema or other variations before transferring the pattern to the thermoplastic material. When the pattern fits as designed, use scissors to score it onto heated thermoplastic material. The pattern can be cut out using heavy-duty scissors.

Cutting Thermoplastic Material

Thermoplastic material can be purchased in either 18 × 24 or 24 × 36 inches sheets. Cut the full sheet with a utility knife by scoring and bending it (Fig. 23-14); place the bent material over the edge of a firm table to cut the pieces completely apart (see Fig. 23-15). Doing so also results in a manageable sheet of thermoplastic that is likely to fit in a splint pan and reduces waste. Heat the thermoplastic and score the outline of the pattern using scissors (see Fig. 23-16). Do not use a pen or marker to trace the pattern on your material because it is difficult to completely remove and impacts the aesthetics of the orthosis. After ensuring the material is soft, and to avoid cut marks, cut out the pattern using long strokes with sharp, heavy-duty straight-edged scissors (see Fig. 23-17).

Figure 23-14 Scoring thermoplastic material with a utility knife.

Figure 23-15 Cutting thermoplastic material with a utility knife.

Figure 23-16 Scoring heated material with scissors to outline pattern.

Figure 23-17 Cutting the thermoplastic material.

Cutting the material after heating eliminates rough edges, reduces stress to therapists' hands, and saves time in the finishing step. Minimize fingerprinting by maintaining the material on the work surface, not on a terry cloth towel, and handling it by sliding your flattened hand under the material, lifting as little as possible, and retaining the material horizontally while cutting to avoid stretching.

Heating Thermoplastic Material

Electric fry pans, splint pans, and hydrocollators are typically used to heat thermoplastic materials (Fig. 23-18). If using a hydrocollator, prevent material from stretching or dropping to the bottom using a heat pan liners to cradle the material. Water temperature is usually kept at 150°F to 160°F for most materials, but the recommended temperature varies between materials. Always consult the manufacturer's recommendations for specific materials. Keep a thermometer in the water to ensure consistent temperature. Typical heating time for most materials is about 1 minute. Check the material to ensure that it is heated uniformly before forming the orthosis on the patient. The working time for thermoplastic material varies from 1 to 6 minutes, depending on the material properties. Thin materials cool more rapidly than thick. Heat guns do not uniformly soften thermoplastic material, hence are recommended only for spot heating when attachments are required, minor adjustment, and edge finishing.

Figure 23-18 Heating cut-out thermoplastic material.

Forming the Material into an Orthosis

Once the entire piece of material is heated, use tongs or a spatula to remove the material from the water by holding the edge, allowing you to grab the material with your fingers, taking caution not to stretch the pattern. Be mindful to not to put your fingers in the hot water. At this point, the entire piece of thermoplastic material should feel soft and easily moldable. Lay the material on a towel to briefly dry. If the material is too hot, let it cool slightly before placing it on the patient to assure tolerance and comfort. A rule of thumb is that if you cannot comfortably hold the material on your own arm, you should allow it to cool prior to placing it on your patient. As a reminder, when using a material with draping qualities, it is best to let gravity assist the positioning.

Proper Patient Positioning during Orthosis Fabrication

Ideally, your patient should be seated during orthosis fabrication. This enables the extremity to remain in a relaxed position. This positioning allows the therapist to respect the biomechanical principles of the hand, such as the palmar arch. To that end, the therapist must also find a position that the patient can comfortably maintain. This may

require some creativity, such as using a plinth so that the patient can be in supine if he or she exhibits restricted shoulder or elbow motion.

Proper upper extremity positioning during orthosis construction can make the difference between use and noncompliance. For example, if the orthosis is formed with the patient's forearm in supination, the orthosis trough may impose undue forearm pressure when it is moved toward the more common functional pronation position. The problem is reduced when the orthosis is formed in neutral, creating enhanced comfort during functional use. To assist with fabrication, place the extremity in a position to allow gravity to assist with molding. This reduces the amount of handling required from the therapist. After placing the patient's hand and forearm in the desired position, apply the heated thermoplastic material. Avoid gripping or squeezing the material (Fig. 23-19).

Figure 23-19 Forming the forearm-based resting hand orthosis on the patient.

Finishing Edges of the Orthosis

Smooth edges are important to prevent pressure points. Cutting the material at the required temperature allows the edges to seal smoothly without requiring additional work (Fig. 23-20).

Figure 23-20 Trimming the orthosis to improve fit.

When using some perforated materials or rough-cut thermoplastics, it may be necessary to smooth the edges by dipping the edge of the orthosis into the hot water and cutting it to produce a smooth edge or alternatively, smooth it lightly with fingertip pressure. Flare the proximal portion of forearm-based orthoses to finish the edge to avoid pinching during full elbow flexion.

A heat gun produces a very hot stream of dry heat. It should never be directed toward the patient's skin. To avoid damage to the motor, set the heat gun on a cool setting before turning it off.

Applying the Straps

Straps attach the orthosis to the patient. Their location must be carefully planned to achieve optimal surface contact for pressure dispersion and positional stability. Apply adhesive-hook Velcro to the orthosis and use loop or foam strapping material to hold the orthosis securely on the patient. Hook Velcro adheres well to the orthosis if the surface is prepared for the bond. This is done by removing the nonstick finish on the thermoplastic. Use a heat gun to spot heat the part of the orthosis that will receive the Velcro hook and press a cotton towel into the material. Then spot heat the sticky side of the Velcro with a heat gun before applying it to the thermoplastic (Fig. 23-21).

Figure 23-21 Heating Velcro hook to attach to orthosis.

Other preparation techniques include applying a solvent or scraping the plastic with the sharp edge of a scissor blade. There are also variations that may be used to apply Velcro hook. A full piece of sticky-back Velcro should be applied on the forearm portion of the orthosis to prevent it from falling off when the orthosis is donned or doffed. Two pieces on the edge of the orthosis can be applied on the hand portion of the orthosis.

Beyond Velcro, other strapping options include durable foam, neoprene, and elastic strapping, which are all available in a variety of widths. Applying clinical reasoning to determine the proper strapping material is critical. Two-inch straps should always be used when securing an orthosis over the forearm. One-inch straps can be used in the hand. Foam strapping may be more appropriate when using an orthosis on fragile skin. Strap placement should also be considered when fabricating an orthosis over a nerve or vessel graft, skin graft, or when there is compromised skin integrity. It is best to round the corners of the strapping material to improve aesthetics and comfort. Straps should also be an hourglass shaped when crossing a web space.

The finished forearm-based resting hand orthosis constructed in Figures 23-12 through 23-21 is shown in Figure 23-22.

Figure 23-22 Finished forearm-based resting hand orthosis on the patient.

Figures 23-23 through 23-25 depict the process of making a hand-based thumb orthosis, and Figures 23-26 through 23-29 depict the process of making a dynamic extension orthosis.

Figure 23-29 Applying moleskin to the distal aspect of the orthosis.

Outrigger Attachments

Outriggers and pulleys can be attached to a dynamic or static progressive orthosis after its base is complete. An outrigger is best considered as an extension to the orthosis base, providing the desired angle to direct a static progressive or dynamic force. Outriggers can be created by bending wire. Outriggers can also be made by rolling or pressing softened thermoplastic into shape.⁴¹ Alternatively, commercial outriggers can be purchased (see Fig. 23-30 commercially available outriggers). The therapist should consider the requirements of the outrigger, determining whether it is to be high or low profile, single or multiple finger, static progressive, or dynamic.⁴² If the outrigger requirements are of a very specific or complex application, it is best to purchase custom kits, which increases orthosis fabrication costs.

Figure 23-30 Commercially available outriggers. **A.** The Base 2 Multi-Digit MP Extension Kit through North Coast Medical. (Courtesy of North Coast Medical.) **B.** Phoenix Outrigger Kit. (Courtesy of Human Factors Engineering.).

Process for Creating a Custom Outrigger

A technique to create a custom outrigger with thermoplastic material such as Polyform is described in the following. It is best to use the same material used for the splint base.

1. Heat a piece of material and place it on a cotton towel.
2. Cover the material on all surfaces with the towel and press the towel into the material.
3. The impression of the towel indicates the removal of laminate from the material.
4. Remove the material from the towel and press the warm material into the shape of a solid tube.
5. The material can be reheated in the splint pan as needed and rolled into a tube and then flattened.
6. Reheat the material to allow flexibility to conform it to the hand for precise construction.

If you elect to add any type of outrigger or pulley, prepare the orthosis surface for optimal bond. Use a heat gun to spot heat the material to receive the outrigger or pulley and press a cotton towel into the material to remove the laminate. Spot heat the post or area of the outrigger that will contact the base and attach it to the base while both pieces are heated.

Bonding solvent or scraping the surface of the base can also remove the laminate. The outrigger or pulley attachment points should be treated similarly. Use a heat gun as described earlier and press them together. To increase the material bond, gently pull and push the base and outrigger enough to stress the material, gradually forcing them tighter together, but not enough to separate or shift the position of attachment. As the material cools, hold the pieces together for adequate bonding. They can be cooled with cool water or a cold spray before starting the next attachment.

The described technique will omit the need for additional reinforcement. If an alternate technique is used, heat another piece of thermoplastic and apply it over the outrigger base attachment. Always prepare surfaces with dry heat for effective bonding. Dynamic splints may be prone to slide distally because of the force or pull on the orthosis base. You can control this migration with appropriate strap placement and a friction-enhanced material that is in contact with the skin. Silicone gel or Microfoam tape (available through Performance Health) provides light friction to keep the orthosis base in place. Rubber bands, coil springs, or elastic thread provide the tension to a dynamic orthosis. They can be attached to the orthosis base with a thermoplastic hook, Velcro tabs, or thumbscrews placed proximal to the outrigger on the orthosis base. Pulleys or line guides such as Velcro hook and loop can redirect the line of pull as needed for dynamic or static progressive flexion orthoses. Monofilament (fishing line)

attached to the rubber band creates a smooth excursion for the rubber band tension as it pulls over the outrigger or under the pulley (see Fig. 23-28).

The monofilament attaches to a finger sling, fingernail hook, or tab to provide the appropriate tension and angle of pull. Dynamic orthoses may incorporate commercially available hinges, which provide a movable axis at a joint. Static progressive orthoses use locking hinges and various types of inelastic components such as Velcro strips, monofilament line, MERiT components, and Click Strips.⁴³ Hinges and turn screws may also be used for static progressive orthoses to provide adjustable positioning of stiff joints in the optimal position tolerated by the patient. These components allow for adjustments as the patient achieves increased mobility.²⁴

The Use of Padding

When padding an orthosis, allow extra space in the design and molding phases to contour over a bony prominence, to avoid additional pressure in this area. Some padding can be applied before forming the orthosis. When applying the padding after orthosis construction, ensure that the material padding is measured to fit only the material enlarged to accept padding (see Fig. 23-29). To reduce scissor damage, cut the padding before removing the pad backing. Then, place padding over the thermoplastic area in need of padding, assuring proper placement. Remove the backing and apply padding to the orthosis (see Fig. 23-29).

If padding is applied to the thermoplastic before heating, the excess water should be squeezed out before applying the orthosis to the patient. Stockinette liners can be used instead of padding for light protection, and sticky-back moleskin is also available as a thin, soft padding material. Please note that padding should never substitute for a well-fitting orthosis.

Evaluating Fit and Comfort

Once orthosis fabrication is complete, the therapist performs a checkout to verify its fit and comfort and to ensure that the patient understands its use and care (see Figs. 23-22, 23-25, and 23-28).

Training and Education

Patients must understand the goal and purpose of orthosis use. It may also be helpful to inform them of the consequences of failing to comply with orthosis wear. This information should be provided in written and verbal form. If the patient has a cognitive deficit, provide instructions to a caregiver. Patients or caregivers also need to receive instructions to watch for pressure points, edema, and excessive dynamic tension, and on how to adjust the orthosis, if feasible. Ensure that patients know how to clean their orthosis and to keep thermoplastic orthoses away from heat so they do not lose their shape. Schedule a follow-up visit if you anticipate needing to modify the orthosis, and always provide a method for patients or caregivers to contact you with questions or concerns about their orthosis.

Orthosis Checkout

After fabrication is complete, ask the patient to wear the orthosis for about 20 minutes and then remove it. This can be done while providing the patient with instructions for orthosis use or when reviewing a home program. During this time, if redness or blanching is identified and does not readily resolve, it may be an indication of a pressure area.¹³ Modify the orthosis if signs of excessive pressure are present and then reevaluate fit and comfort. This is critical to ensure proper use, prevent skin breakdown, and avoid unnecessary trips to return to the clinic for modifications.

Prior to sending the orthosis home with the patient, consider the following questions:

- Does the orthosis achieve the purpose?
- Does the orthosis maintain proper position at rest and perform as required with stress?
- Does the orthosis contour to and fit the hand considering arches and bony prominences?
- Does the orthosis extend beyond necessary structures causing undue restrictions?
- Is the orthosis long enough to support immobilized structures?
- Is the orthosis finished with smooth edges and resolved pressure points?
- Can the patient apply and remove the orthosis independently?
- Does the patient understand wear and care instructions?

In summary, orthotic intervention requires a client-centered approach by a skilled therapist. This requires practice and mentorship. Custom orthosis fabrication is an important component in a holistic rehabilitation process to meet the occupational performance goals of the patient and should not be considered as just the application of a device. By combining applicable knowledge, principles of orthosis fabrication, skill, and creativity with the patient's needs, the therapist can meet the challenges imposed on the patient to meet the goals of rehabilitation.

Acknowledgments

The authors have no financial connections with the named products in this chapter.

Collectively, we would like to thank Charles Quick and Priscillia Bejarano for providing a strong foundation from the seventh edition of this text.—N.S.H.

I would like to thank Sommer Groendyke for assisting with photography. I would also like to thank my amazing family and friends who have offered support during the development of this chapter.—N.S.H.

CASE STUDY

Patient Information

Sarah is a 62-year-old, right-hand-dominant female who has been diagnosed with osteoarthritis of the CMC joint of the thumb of her right hand. Sarah was referred to outpatient occupational therapy for conservative management to reduce hand pain and improve function.

Sarah reports she lives with her husband of 30 years in a one-story home. Her performance patterns include the roles of a part-time employee as a librarian, a wife, and a mother of three and grandmother of eight. Her leisure occupations include reading, baking, and gardening. Client factors that affected include independence in all functional mobility and modified independence for most basic activities of daily living (ADL) because of increased time for buttoning, tying shoes, zippers, and fasteners. She complains of difficulty with tasks, such as turning a key, grasping books, writing, opening jars and bottles, performing cooking tasks, and using gardening tools due to pain, limited strength, and decreased mobility. She complains of swelling and redness at the base of her right thumb after prolonged use and reports a pain level of 2/10 at rest and 7/10 with activity on the visual analog scale.

Assessment Results

During the assessment, Sarah demonstrated limitations in grip-and-pinch strength as compared to her contralateral hand. She also demonstrated decreased thumb palmar and radial abduction and localized edema at the CMC joint of the thumb and the proximal phalanx. Sarah also demonstrated increased time when completing the 9 Hole Peg Test as compared to her nondominant hand, thus demonstrating decreased fine motor coordination. Ligament stress testing revealed slight joint instability and

tenderness with palpation at her right thumb CMC joint. Sarah's sensation was intact, and no redness or inflammation present. Right-digit and wrist active range of motion (AROM) was within functional limits.⁴⁴

Occupational Therapy Problem List

- Sarah requires increased time to complete ADL tasks, such as buttoning, tying shoes, and zippers secondary to poor fine motor coordination; decreased AROM in thumb abduction; and decreased pinch strength.
- Sarah demonstrates difficulty completing baking tasks, secondary to difficulty stirring and lifting pans.
- Sarah reports difficulty pulling weeds and digging with hand trowel.
- Sarah complains of difficulty sleeping, secondary to hand pain.
- Sarah is unable to open jars and bottles, secondary to decreased grip-and-pinch strength.

Occupational Therapy Goal List

- Sarah will demonstrate decreased time required to complete the 9 Hole Peg Test to be equal to nondominant hand to perform buttoning tasks independently.
- Sarah will demonstrate increased grip strength by 6 lb to lift baking pans with modified independence with use of a custom-fabricated hand-based orthosis.
- Sarah will sleep through the night with use of a custom-fabricated hand-based orthosis.
- Sarah will demonstrate increased pinch strength by 4 lb to independently open pop bottles.

Intervention

Sarah was fitted with a custom-fabricated hand-based thumb orthosis made from a 1/16-inch thermoplastic material with the thumb placed in palmar abduction and the IP joint free. She received instruction on her program of orthosis wear and care, pain-free strengthening to thumb extensors and abductors, wrist strengthening, and AROM exercises.⁴⁵ Sarah was also educated to perform strengthening exercises to her first dorsal interosseous muscles to reduce subluxation at the thumb CMC joint.⁴⁶ Joint protection, energy conservation, and the benefits of adaptive equipment use were introduced.⁴⁷ Sarah stated that her orthosis felt comfortable and that she was able to don and doff it without difficulty. A follow-up appointment was scheduled for an orthosis check, review of all instructions, and options for adaptive equipment.

Progress

At follow-up, Sarah reported tolerating the orthosis well and wearing it at night time and as needed during the day. She is able to work and garden with the orthosis on. Sarah reported speaking with her supervisor at work and that they agreed to have her spend a greater amount of her work shift at the checkout counter and less time shelving books to help lessen pain. She reported compliance with her home exercise program and has integrated joint protection strategies and adaptive equipment into her daily routine. Sarah purchased an electronic reading device to avoid the prolonged pinch required to hold open a book. She now uses a potato peeler with an enlarged grip, and has a pouring stand for pots and pans. Sarah also reported using home paraffin baths to help alleviate joint pain.

Best Evidence for Orthotic Interventions Used in Occupational Therapy

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Dynamic orthosis to address proximal interphalangeal (PIP) joint contracture ²⁹	Determine the relationship between PIP joint contracture resolution and weeks of treatment using dynamic orthosis	Forty-one subjects with a total of 48 stiff PIP joints	Flexion deficits maximized gains after 12 weeks of orthosis use and extension deficits continued to demonstrate gains after 17 weeks of orthosis use.	Prospective cohort study; Level II evidence	Improvements in flexion noted on average 1.77° per week and improvements in extension noted on average 77° per week of orthosis use.	$p < 0.001$ for both flexion and extension when examining the relationship between duration of orthosis use and gains in AROM. No effect size was described.
Orthosis intervention for hand osteoarthritis ⁴⁵	Effectiveness of custom-fabricated orthosis and prefabricated orthoses to reduce pain	Four hundred and sixty-nine subjects in 12 studies	Orthotic wear for 2 weeks up to 7 years, various wearing schedules	Systematic review of 12 studies published in 2000 or later; Level I evidence	Significant decrease in pain at short term (≤ 45 days) and long term (≥ 3 months)	Significantly reduction in hand pain at short-term (< 3 months) and long-term (≥ 3 months) follow-up, with a standardized mean difference of 0.37 (95% confidence interval [95% CI] 0.03, 0.71) and 0.80 (95% CI 0.45, 1.15). Unable to determine effects size owing to lack of homogeneity of study design, methods, and orthosis design.
Mobilizing orthoses ³¹	Assess the time of orthosis use in a 24-hour period using TERT and gain in PROM	Forty-three subjects randomly assigned to two groups. Thirty-two subjects completed the intervention for 4 weeks. Following exclusion, a final sample of 11 participants was obtained.	Use of a mobilizing orthosis either < 6 hours per day or 6–12 hours per day	Prospective sequential clinical trial with random assignment; Level I evidence	Daily TERT of > 6 hours resulted in faster contracture resolution as compared to daily TERT of < 6 hours per day over a 4-week treatment period.	The only statistically significant predictor was group assignment ($p = 0.005$). Pretreatment joint stiffness ($p = 0.162$) and joint type ($p = 0.463$) were not significant.

Intervention	Description	Participants	Dosage	Research Design and Evidence Level	Benefit	Statistical Significance and Effect Size
Tested the validity of TERT theory ²⁶	Assessed the theory if an increase in PROM is directly related to the amount of time a stiff joint is held at its end range	Fifteen subjects with 20 PIP flexion contractures between 15° and 60°	Group A was casted for 6 days in end range extension and then casted 3 days in end range extension. Group B was casted for 3 days in end range extension and then 6 days in end range extension.	Experimental with random assignment; Level I evidence	Total gains in PROM following 3 days of continuous casting was 60° and total gains in PROM following 6 days of continuous casting was 106°.	$p < 0.005$ indicating TERT was a valid theory.

Physical Agent Modalities and Biofeedback

Alfred G. Bracciano

LEARNING OBJECTIVES

This chapter will allow the reader to:

1. Describe a theoretical framework for the use of physical agents within occupational therapy.
2. Describe types of physical agents, their classification, and mechanism of action.
3. Discuss professional, ethical, and regulatory issues related to physical agent use.
4. Discuss sources of evidence and the clinical use of physical agents.
5. Identify the phases of healing and the biophysiological impact of physical agent modalities (PAMs) on the process.
6. Define pain, pain theory, and the influence of PAMs on pain modulation.
7. Compare the primary classifications of PAMs: thermal agents, electrotherapeutic agents, and mechanical devices.
8. Describe the biophysiological effects of thermal agents (heat/cold) on the healing process.
9. Identify precautions, contraindications, and basic principles underlying PAMs commonly used in occupational therapy.
10. Demonstrate clinical reasoning in the therapeutic use of PAMs in occupational therapy treatment.

CHAPTER OUTLINE

Introduction
Competency and Regulatory Issues
Theoretical Framework for Clinical Application
Incorporating Physical Agents into Typical Occupational Therapy Treatment
Superficial Thermal Agents
Ultrasound
Electrotherapy
Laser Therapy (Low-Level Laser Therapy)
Surface Electromyographic Biofeedback
Case Study

TERMINOLOGY

- Biofeedback:** involves procedures or techniques used to provide individuals with auditory or visual cues, or feedback, to learn and gain volitional control over a physiological response.
- Cryotherapy:** the application of a superficial cold agent to decrease the tissue temperature of the body.
- Deep thermal agents:** therapeutic modalities used for the application of energy to soft-tissue structures that penetrate to a depth of 5 cm or more.
- Low-level laser (light) therapy (LLLT):** modalities that apply low-level (low-power) lasers or light-emitting diodes (LEDs) to the body to facilitate biostimulation.
- Neuromuscular electrical stimulation (NMES):** an electrotherapeutic modality that applies low levels of alternating current to selected muscle nerves to facilitate a sensory or motor response.
- Phonophoresis:** the use of therapeutic ultrasound to move a topical medication into the underlying tissue by increasing cell membrane permeability.

Physical agents: therapeutic interventions or technologies, which use force or energy to manipulate the healing process and biophysiology of the body.

Superficial thermal agents: modalities that apply energy to modify tissue temperature to a depth of 1 to 2 cm.

Thermotherapy: the therapeutic use or application of heat that is greater than body temperature, to conduct the heat from the device/modality to the body, thus elevating tissue temperature.

Thermal agents: physical agents that provide a change in tissue temperature, either through the application of heat or cold.

Transcutaneous electrical nerve stimulation (TENS): an electrotherapeutic modality that delivers low-level modulated alternating current to the body to stimulate sensory nerves or a physiological response to modulate the perception of pain.

Ultrasound: a therapeutic modality that applies sound energy to soft tissue, causing thermal and nonthermal effects to modify or produce a biophysiological response.

Introduction

Physical agent modalities (PAMs) are those procedures and interventions that are systematically applied and use various forms of force or energy to modify specific client factors when neurological, musculoskeletal, or skin conditions are present that may limit occupational performance. Physical agents are used in preparation for or concurrently with purposeful and occupation-based activities.^{1,2} Understanding the biophysiological effects of physical agents on the anatomical systems (client factors) involved in injury or disability is requisite for safe and effective use.

Classifying types of physical agents provides a framework for determining the effect and energy applied to tissues. There are four primary classifications of physical agents:

1. **Thermal agents** provide a change in tissue temperature, heating or cooling tissue, and include hot packs, cold packs, and **ultrasound (US)**, which have a thermal and mechanical effect.
2. Electromagnetic agents use magnetic and electrical fields or spectrums and move through the air without need for a specific conductor or medium through which to focus the energy.
3. Electrotherapeutic modalities use electrical current.
4. Mechanical agents apply force (energy) or controlled stress to anatomical structures to manipulate tissue healing.

Physical agents are described by depth of penetration and mechanism of action. Superficial thermal agents, such as hot or cold packs, penetrate 1 to 2 cm, whereas deep thermal agents penetrate to 5 cm. US has either a deep or superficial effect depending on parameters set and has either a thermal (heating effect) or nonthermal, mechanical (healing) effect, leading to different biophysiological impact.

Superficial thermal agents include hydrotherapy/whirlpool, cryotherapy, Fluidotherapy, hot packs, paraffin, and infrared heating. **Deep thermal agents** include therapeutic US, phonophoresis (the use of US to deliver medication), and short wave and microwave diathermy. Electrotherapeutic agents include neuromuscular electrical stimulation (NMES), functional electrical stimulation (FES), **transcutaneous electrical nerve stimulation (TENS)**, high-voltage galvanic stimulation (HVGS), electrical stimulation for tissue repair (ESTR), and iontophoresis that is the use of electrical current to administer medication. Electromagnetic agents include low-level laser (light) therapy (LLLT) or cold lasers that have a therapeutic effect for tissue healing and pain modulation for both acute and chronic pain. Electromagnetic agents also include diathermy, which uses short wave or high-frequency microwaves to influence tissue healing, or higher frequencies that cause tissue heating.

Competency and Regulatory Issues

Changes in health care require clinicians with the ability to implement and articulate the science supporting our scope of practice.^{3,4} Physical agents are tools therapists can leverage as a component of the therapeutic process to facilitate patient outcomes and engagement in occupation.⁵ When applied judiciously within correct parameters, physical agents are safe and effective. Without a complete understanding of the biophysiological effects on the body, errors can lead to tissue damage, burns, and potentially life-threatening events with iontophoretic medications.

A therapist should always include occupation and performance as key components in the clinical reasoning process to effectively use physical agents. The American Occupational Therapy Association (AOTA) specifies that physical agents may only be applied by therapists with documented evidence of possessing the theoretical background and technical skills for safe and competent integration of the modality into occupational therapy intervention plans.⁶ This statement should be of critical concern to clinicians practicing in states without specific regulatory language or licensing requirements regulating physical agents.

The intent of licensure and regulatory language is to protect the public health, safety, and welfare and to ensure that service providers have the minimal necessary competency. Clinical use of physical agents is associated with risk in terms of client safety and professional liability. There are three primary issues when deciding whether to use physical agents in clinical practice: (1) AOTA's position on the use of PAMs; (2) personal competency in the specific agent used; and (3) federal, state, and institutional rules and guidelines regarding physical agent use in occupational therapy practice.

It is beyond the scope of this chapter to present all information needed to use physical agents safely and effectively. The reader is encouraged to obtain additional training and education in safe and efficacious physical agent use and to meet all state regulatory requirements. Incorrect use can disrupt healing and cause injury. Therapists have an ethical and legal responsibility to ensure they possess the fundamental training and education to safely use physical agents. All therapists who anticipate using physical agents should contact their respective state regulatory board to obtain the most current information and should be able to document and defend their education and training in meeting regulatory requirements.

Theoretical Framework for Clinical Application

A frequent argument against physical agent use in clinical practice is the apparent “lack” of evidence-based research. Research is often contradictory, lacking in rigor, consistency in design, and with variability of therapeutic parameters or measures. This does not mean the research is insignificant or not applicable; the parameters or amount of energy applied may be inconsistent because of variability of the clinical diagnosis and research design inefficacy.⁷

Physical agents are often applied without appreciation of their biophysiological impact. Understanding the impact of force and energy on injured body systems is critical. The Occupational Therapy Practice Framework states that client factors are needed, either “in whole or in part,” for an individual to successfully engage in an occupation.⁸ Use of physical agents provides a means of applying force or energy to client factors to facilitate healing, decrease pain, and improve occupational performance.

The body's response to injury is a dynamic series of events at a micro and macro level.^{9,10} Pain is a warning sign, indicating potential or actual tissue damage. Pain is associated with acute injury, becoming chronic when continuing beyond the stage where tissue healing has occurred. Pain is afferent and efferent with two primary theories: the gate control theory and the opioid theory.^{11,12} Clinical conditions may involve damage to soft-tissue structures. Healing is the body's attempt to repair and replace injured or damaged tissue and return structures to homeostasis and function. The connection between the impact of disease or injury to body systems and structures requires understanding the biophysiological responses to therapeutic interventions, including physical agents that modify and facilitate healing.

Tissue healing is a complex series of events with physical and psychological components. A wound is a pathological state with disruption of the normal anatomical tissue structure and loss of function. Healing involves a variety of repair mechanisms as the body attempts to compartmentalize the injury and restore damaged tissue function. Comorbidities, advanced

age, foreign object presence, infection, poor nutrition, and medications may slow the healing process.¹³ The three phases of healing include inflammation, proliferation, and maturation. These processes are overlapping and occur in all injuries, including soft-tissue structures such as tendons, muscles, ligaments, nerves, articular capsules, and vascular structures.

Physical agents use force or energy, including heat, cold, light, water, sound, electricity, and the electromagnetic spectrum, to manipulate healing through impact on the unique client factors involved in the injury or condition. Physical agents modulate pain, facilitate or stabilize movement, decrease edema, increase circulation and tissue extensibility, improve strength and functional movement, and manipulate scar and skin conditions with the end goal of successful performance in occupational tasks. Physical agents are integrated within a comprehensive occupational therapy approach and are applied to the body for specific goals and objectives.

Phase I: Inflammatory Phase

The initial response to tissue injury is inflammation, consisting of vascular and cellular components lasting up to 72 hours. The initial response is vasodilation causing the wound to bleed, cleaning the area, and removing foreign bodies to prevent infection. Vasoconstriction then occurs, with aggregation of platelets, blood coagulation, and an encapsulation of the impacted area to compartmentalize and limit further damage. Fluid from the vascular system is released along with histochemicals such as histamine, prostaglandins, bradykinins, and growth factors, causing an increase in hydrostatic pressure and swelling. Inflammation is characterized with the classic signs of redness, heat, swelling, and associated pain, and changes in skin color (petechia) with red, blue, or purple tissue discoloration. Injury to soft tissues below the skin is dependent on the nature of the causative factor, location (superficial or deep), and the material properties of the tissue.

Inflammation prepares the wound for the proliferative phase of healing. Chronic inflammation indicates an abnormality in the healing response. Prolonged inflammation can lead to scar tissue development, decreased range of motion (ROM), and function loss. Too little inflammation can delay or slow healing. The primary goal during the inflammatory phase is to decrease or limit factors that prolong or prevent inflammation.

Treatment activities and interventions are focused on assisting the role of the macrophage activity through use of antibiotics; debridement; wound cleaning and dressings; position, rest, ice/cryotherapy, and compression; low-intensity pulsed ultrasound (LIPUS); and limiting active, forceful movements or activities that may disrupt the healing tissue. The main goal is to minimize all factors that can prevent or prolong inflammation.

Phase II: Proliferative Phase

Macrophage activity cleans the debris and wound in preparation for injured tissue to be repaired. The proliferative phase overlaps with inflammation, epithelialization, fibroplasia, and angiogenesis to resurface the area and strengthen the wound. Proliferation lasts approximately 3 weeks. Fibroblasts synthesize collagen molecules. Granulation tissue occurs when the body forms a matrix of connective tissue, including collagen, filling in the wound bed and closing the wound. Wound contraction pulls the outer edges of the wound together and from the bottom up. Collagen becomes cross-linked increasing tensile strength of the scar. Fibroblasts grow in the wound as inflammation decreases, with collagen synthesis affected by age, tension, pressure, and stress, and continuing for approximately 2 to 4 weeks.

Angiogenesis, cell budding with capillary development, occurs. Epithelialization provides a protective layer between the wound and the external environment. Proliferation can be facilitated through physical agent use such as LIPUS and electrical stimulation. As tissue heals and strengthens, controlled motion can be initiated. Care must be taken to avoid applying too much force or energy to the tissue. Infections, edema, or incorrect handling can cause the area to become enflamed, complicating and delaying healing.

Phase III: Maturation Phase

The maturation phase lasts from 21 days up to 2 years. During maturation, the new tissue is modified and gains strength and flexibility. Collagen fibers mature to assume the characteristics of the tissue they are replacing. When fully remodeled, new tissue has

approximately 80% of the tissue's preinjured strength. During the maturation phase, new tissue is fragile, but slowly gains strength and flexibility. Healing can be delayed or interrupted owing to local or systemic factors, including moisture, infection, maceration, nutrition, and comorbidities such as diabetes and age.

Because the tissue has increased tensile strength, greater forces and energy can be systematically applied to the healing tissue to foster differentiation, tissue extensibility, and function. Physical agents that impact the maturation phase include heat, electrotherapy, thermal US, diathermy, superficial thermal agents, iontophoresis, dynamic splinting, and use of silicone and compressional wraps and dressings.

Pain

Pain is the body's response to potential or actual tissue damage and is a protective function. Pain negatively affects occupational performance because of decreased ROM, guarding of an extremity, muscle weakness, and a myriad of psychosocial and behavioral aspects including sleep disorder, irritability, anxiety, depression, and emotional distress. Pain is classified as acute or chronic and triggered by injury causing release of endogenous pain-producing substances, including bradykinin, histamine, and leukotrienes. Pain may be referred from the body structure to a different site or area. Acute pain has an identifiable cause and resolves during the course of normal healing. Chronic pain persists beyond the normal stage of healing, or past 3 months.

Pain perception is both afferent and efferent. There are two primary pathways involved in pain perception: the gate control theory and the opioid theory. The gate control theory involves both a peripheral and central mechanism consisting of small-diameter A-delta fibers that carry fast pain signals and C-fibers that carry chronic or continuous pain—both of which impact T cells in the spinal cord dorsal horn and which inhibit or transmit signals to higher brain centers. Stimulation of A-beta fibers overrides or shuts down pain transmitting nerve pathways and accounts for the effectiveness of heat, massage, and other thermal modalities.

The endogenous opiate theory involves the body's natural histochemicals, enkephalins, endorphins, serotonin, and dopamine in an efferent process that blocks pain neurotransmitters, effectively closing the gate. These neurotransmitters can be stimulated by muscle fatigue or intense exercise, intense pain, acupuncture, laughter or meditation, and TENS or electrotherapy.

Incorporating Physical Agents into Typical Occupational Therapy Treatment

Physical agents are a precursor or an adjunct to functional activity, movement, and engagement in occupational tasks and are a consideration after thorough examination and evaluation. Physical agents are used to address pain and to impact biophysiological client factors interfering with occupational engagement. Physical agents should be considered to facilitate tissue healing and improve occupational performance in patients presenting with pain, inflammation, edema, muscle spasm or guarding, decreased ROM, and muscle weakness.

Superficial Thermal Agents

Thermal therapy is the application of heat or cold to change the cutaneous, intra-articular, or core temperature of soft tissue. The application of heat is referred to as **thermotherapy**. The application of cold is referred to as **cryotherapy**. Thermal agents modify or change the cutaneous, intra-articular temperature of soft tissue to impact the symptoms of specific clinical conditions. Thermotherapy can be applied locally to produce a biophysiological change in tissue and is used with musculoskeletal or soft-tissue injuries. Most thermal applications are passive and place the extremity in a dependent position, contributing to edema.

Thermal conductivity refers to the ability of different tissues, such as the skin, muscle, bone, and blood, to conduct or absorb energy, resulting in temperature changes. Adipose tissue acts as a barrier or insulating layer, inhibiting energy transfer (heat/cold) to deeper tissues and minimizing tissue temperature change. Thermal agents are categorized as superficial, penetrating to a depth of 1 to 2 cm, or deep, penetrating to a depth of 5 cm. Deep thermal

agents include diathermy and US. Hot packs, cold packs, paraffin, and Fluidotherapy are examples of superficial methods. Because of ease and convenience, thermal agents are often used as part of home programs. Patients and families are provided education in precautions, contraindications, and application instructions.

Thermotherapy or Heat Agents

Thermotherapy, or heat agents, increase biophysiological effects. Primary considerations for use involve determining whether the condition is acute or chronic, location and tissue depth involved, and whether to increase or decrease the biophysiological effects. Heat can be beneficial to tissue healing in chronic conditions, inflammation, and scar tissue; heat tends to worsen acute inflammation and edema. Physiological effects of heat include increased tissue temperature; metabolic activity; capillary permeability; lymphatic and venous drainage; axon reflex activity; elasticity of muscles, ligaments, and articular capsule fibers; formation of edema; decreased muscle tone; spasticity; and viscosity.

General dosage guidelines provide a starting point for agent selection and for application parameters. *Dosage* refers to the amount of heat or cold applied to tissue that then elevates tissue temperature. A positive physiological effect occurs when soft-tissue temperature is increased to the range of 104°F to 113°F (38°C–45°C). If soft tissue is heated to temperatures less than 104°F (38°C), cell metabolism may not be stimulated adequately enough to elicit a therapeutic response. If tissue is heated to a temperature greater than 113°F (45°C), tissue damage may occur.

Superficial thermal agents will heat or cool the surface tissue to a depth of 1-2 cm. The normal temperature range of the body varies between 36.3-37.3°C (97.3-99.1°F). The therapeutic range for the physiological effects of heat occur between 104-113 °F (40-45°C). Mild applications of heat $\leq 40^{\circ}\text{C}$ (104°F) provide relaxation and pain relief. Many home remedies (dry heating pad, whirlpool) provide this dosage. An increase of 2-3°C in temperature (ranging from 42-43°C; 107-109 F) provides a moderate dose, increases blood flow and decrease pain and spasm. Vigorous doses, an increase 4-5°C, (43-45°C; 107-113 F) elevate tissue temperature with vascular, metabolic, and connective-tissue responses. With higher temperature increases beyond 45°C (113°F), burning of the tissue and discomfort will occur. Therapists should closely monitor the patients skin color and response during application.

Cryotherapy or Cold Agents

Cryotherapy or cold agents slow down or decrease biophysiological effects, including local tissue temperature, local metabolism, nerve conduction velocity, leukocyte and phagocyte delivery, lymphatic and venous drainage, muscle excitability, muscle spindle depolarization, and edema (Fig. 24-1). Cryotherapy also causes vasoconstriction of arterioles and capillaries, increases viscosity, and has an anesthetic effect. Physiological effects of cold occur at 80.6°F (27°C). Care must be taken when applying cryotherapy because frostbite can occur if left on too long. Contraindications include patients with cold sensitivities such as cold urticaria, cryoglobulinemia or Raynaud disease, or past history of frostbite.

Figure 24-1 Application of ice pack for cooling of tissue. Note the use of wrapping to maintain the ice pack in place and to provide greater energy conduction.

Mechanisms Underlying Function/Action

The principle underlying thermal therapy is the application of heat or cold to change the cutaneous, intra-articular or core temperature of soft tissue. The mechanism for energy transfer (heat/cold loss or gain) is accomplished through the process of conduction, convection, or conversion.

- **Conduction** occurs when there is direct contact between the modality and tissue, each possessing different temperatures. Because body temperature is less than that of a hot pack, heat is transferred and absorbed by the body.
- **Convection** refers to thermal energy transfer to a body part as the energy (heat/cold) circulates around the extremity in the air, liquid, or other medium. An example of convection is Fluidotherapy or whirlpool.
- **Conversion** refers to tissue temperature change when energy is transformed from one form into another. An example is thermal US, in which sound waves—a form of mechanical energy—are transferred to kinetic energy as they are absorbed by the tissue that vibrates, turning kinetic energy into heat.

Four primary biophysiological effects of thermotherapy are analgesic, vascular, metabolic, and connective-tissue responses.

- **Analgesic effects** reduce pain symptoms. Heat acts selectively on free nerve endings, tissues, and peripheral nerve fibers, which directly or indirectly reduces pain, elevates pain tolerance, and promotes relaxation.
- **Vascular effects** aid in pain relief and in decreasing muscle spasm and spasticity. As tissue temperature elevates, substances such as histamines are released into the bloodstream,

resulting in vasodilation. This increased blood flow reduces ischemia, muscle spindle activity, tonic muscle contractions, spasticity, and pain.

- **Metabolic effects** influence tissue repair and modulate pain. In addition to the vascular effect of increased circulation, thermal agents affect inflammation and healing because of chemical reactions. Increases in blood flow and oxygen within the tissues bring a greater number of antibodies, leukocytes, nutrients, and enzymes to injured tissues. Pain is reduced through removal of by-products of the inflammatory process. Nutrition is enhanced at the cellular level and repair occurs.
- **Connective-tissue response** to heat refers to the fact that biological tissues are more easily stretched after heating. Collagen is the primary component protein of the skin, tendon, bone cartilage, and connective tissue. Tissues containing collagen can become shortened because of immobilization or limited ROM as a result of weakness, injury, or pain. Improvement in the properties of collagen and extensibility of tissues occurs when heat is combined with passive or active mobilization and/or engagement in occupation. This ultimately results in reduced joint stiffness and increased ROM.

Clinical Conditions for Which Modality Can Be Used

Thermotherapy and cryotherapy are used when a change or variation in tissue temperature to impact tissue biophysiology is the intended effect. Cryotherapy is used with acute, inflammatory conditions; thermotherapy (heat), with subacute and chronic conditions. Common conditions, which may benefit from heat, include musculoskeletal disorders where there is movement limitation, muscle guarding or spasm, scar tissue, osteoarthritis, joint pain, and stiffness. Deeper tissues require longer applications to reach a therapeutic temperature and the associated biophysiological effects. Superficial structures, such as the hand or dorsal aspect of the forearm, require shorter time periods for superficial agents to reach a therapeutic effect. Adipose tissue acts as an insulator; heating tissues located below body fat may require longer time periods.

Injuries in the early inflammatory phase should be treated with cryotherapy, not heat, to avoid increased edema and to facilitate movement into the proliferative healing phase. Tissues in the remodeling recovery stage should be treated with heat to facilitate the remodeling processes of collagen alignment and differentiation. Following heat application, there is a 10-minute window of opportunity where the viscoelastic properties of collagen, tendon, and muscle are at optimal points. Patients with limited ROM secondary to scar tissue development, or adhesions such as adhesive capsulitis (frozen shoulder), benefit from heat agent use. Patients with joint stiffness, muscle guarding, or pain can use either heat or cold agents depending on their preference.

Precautions

Care must be used to avoid burning patient skin. In addition to determining tissue depth and the amount of adipose tissue, three primary factors to consider when applying thermal agents (hot/cold) are the rate at which the temperature is applied to targeted tissue, application duration, and tissue area or volume.

Elderly, obese, thin, and fragile patients should be monitored closely—including blood pressure and respiration—and observed for systemic reactions. Patients can be burned when tissue temperatures have been elevated beyond 113°F (45°C); however, individual sensitivity to heat varies from patient to patient. Heat should be avoided in patients with sensory loss, confusion or comatose, acute hemorrhage, cancer, peripheral vascular disease, acute inflammation, or inability to communicate with therapists. Patients' skin condition should be monitored during and 5 minutes after application. Therapeutic heating should always be discontinued if patients report pain or burning during application.

Thermotherapy: Hot Packs

Hot packs provide a moderate or vigorous dose of moist heat and are available in a variety of sizes and shapes that contour to extremities. Hot packs are stored in thermostatically controlled tanks in which the water is maintained at temperatures between 158°F and 168°F (70°C–76°C), high enough to kill bacteria.

Clinical Conditions for Which Modality Can Be Used

Hot packs are used for a variety of subacute and chronic musculoskeletal conditions, arthropathies, joint contractures, pain, and muscle spasm.

Effect

Biophysiological effects including analgesic, vascular, metabolic, and connective-tissue responses.

General Instructions for Hot Packs

The temperature of the hot pack can be maintained for approximately 30 to 45 minutes when removed from the tank. Dry padding should be used between hot packs and skin to avoid burns and maintain temperature between 104°F and 115°F (40°C–46°C).

- Skin should be protected with a minimum of six Turkish towels to avoid burns with the patient placed in a comfortable position.
- Commercial hot pack covers are comparable to two Turkish towels; the hot pack is placed inside the hot pack cover. When using commercial covers, a minimum of four additional towel layers are placed over the treated area.
- Owing to high temperatures, hot packs should never be placed directly on skin. Larger hot packs, which are heavier, may be uncomfortable, necessitating use of the correct size for the treated area. Extra padding and care should be used when hot packs are placed over or around bony prominences.
- If toweling and hot pack covers become damp from repeated use, more heat is transferred from the hot pack to the body. Therefore, padding should be rotated and allowed to dry, or more layers of padding will be needed to avoid tissue burns.
- To facilitate conduction, hot packs draped over an extremity can be positioned and secured with an elastic bandage. This will pull the hot pack tighter to the skin, increasing conduction. Care should be used because it may cause a more vigorous exchange of heat and burn the patient.
- The patient's skin should be checked after 5 minutes of application for redness, blistering, or potential burns, and the patient asked about his or her comfort level. Patients should be closely monitored for a systemic reaction, and hot packs should be removed if patients express discomfort or pain.
- Hot packs should be left on for 15 to 20 minutes to achieve a therapeutic effect. Patients often think that hot packs should be "hot" when ideally they should be warm, but not uncomfortable.
- Following application, hot packs should be removed and placed in the hydrocollator. Therapists should assess patient skin for redness, blistering, or burns. If there is evidence of overheating, cold packs can be applied to the area to stop the overheating response. Following application, it will take approximately 30 minutes for hot packs to return to a therapeutic temperature range.

Thermotherapy: Whirlpool

Whirlpool is the use of water that can be circulated or agitated to remove gross contaminants and toxic debris, including surface bacteria, increase local circulation, decrease wound pain, decrease suppuration, decrease fever, help soak and gently remove dressings, and, ultimately, accelerate healing.^{14,15} Whirlpools or hydrotherapy can be used for mild, moderate, or vigorous heat dosages. Whirlpools consist of a stainless steel or fiberglass tank that vary in size and are mobile or stationary consisting of a turbine, drain, and thermostatically controlled water. The turbine mixes air and water that provides water aeration and can be adjusted to increase water agitation. Smaller "hand" whirlpools typically hold 25 gallons of water.

Effect

- Debridement or cleaning open wounds can be achieved by soaking or irrigating the area. Agitation can be used for wound care or removing macerated or dry skin following cast removal. When used with warm water, vasodilation occurs with the biophysiological effects, including increased blood flow, oxygen, nutrition, and metabolic activity.

- Increased blood flow facilitates movement of leukocytes and aids in phagocytosis.
- Water buoyancy allows for active movement of the extremity in a gravity-minimized environment.
- Patients may report decreased pain and increased ROM if actively moving the extremity in the whirlpool.

Clinical Conditions for Which Modality Can Be Used

- Whirlpool can be used for healing tissue and open wounds and for debridement of macerated or dry tissue following cast removal (Colles, wrist, or digital fractures).
- Limited ROM: Whirlpool baths are more effective than hot packs when used to increase ROM with patients after radial fracture.^{15,16}
- Careful determination of patients with open wounds is necessary. Whirlpool facilitates the healing process when used judiciously and affects the inflammatory healing phase. Whirlpool loosens necrotic tissue and slough, cleansing the wound and stimulating granulation tissue. Water agitation must be controlled.

General Instructions for Whirlpool

- Review patient evaluation and diagnosis for consideration of the healing stage and integrity of the healing structures to determine whether whirlpool is an effective medium to use. If used too early in the healing process, viable granulation tissue may be disrupted, and the healing process impacted.
- Fill the whirlpool with the appropriate level of water to cover the agitator.
- Monitor water temperature to avoid burns; add hot/cold water as needed.
- If used for debridement, low agitation should be used with tepid or body temperature water (92°F; 33°C). Remove bandages or dressings. Adjust clothing to avoid getting wet.
- Position patient at a comfortable height and support the extremity for comfort.
- Turn on the turbine and adjust the agitation to the desired level.
- Treatment time is between 10 and 20 minutes. Monitor patient response.
- Thorough tank and turbine cleaning are necessary. Chemical agents can be added to avoid infection.

Precautions

- Patients with skin grafts, intravenous, active infection, or conditions, which would be exacerbated by the dependent position, are contraindicated for whirlpools.
- Clean and sanitize the tank to prevent contamination or infection. Appropriate additives such as chloramine-T (Chlorazine), a bactericidal, should be added to the water.
- Do not use with patients who lack sensation in the extremity.
- Determination of water temperature, turbine agitation, and time length in the water is based on the goals for whirlpool use and on the healing stage.
- Do not leave patient unattended.

Thermotherapy: Fluidotherapy

Fluidotherapy uses fine particles of organic cellulose circulated in a hot air stream inside a containment unit to heat an extremity through convection (Fig. 24-2). The force of the air and circulating particles can be graded via the blower speed.

Figure 24-2 Fluidotherapy uses fine particles of organic cellulose circulated in a hot air stream inside a containment unit to heat an extremity through convection.

Effect

- Fluidotherapy simultaneously performs the functions of applied heat, massage, sensory stimulation, levitation, and pressure oscillations.
- Biophysiological effects of heat applications:
 - Relieves localized pain and increases localized blood circulation and ROM.
 - Decreases minor pain and stiffness associated with osteoarthritis.

Clinical Conditions for Which Modality Can Be Used

- Decreased ROM
- Hypersensitization
- Pain and stiffness
- Desensitization of digital amputations/painful neuromas
- Acute or subacute traumatic or nontraumatic musculoskeletal disorders of the extremities

Precautions

- Patients who may have difficulty regulating systemic temperature

Contraindications

- Cancerous lesions in treated area
- Open wounds, sutures, staples, or infections
- Systemic infectious diseases with fever or inability to suppress or modulate body temperature
- Severe circulatory obstruction disorders (arterial, venous, or lymphatic)

General Instructions for Fluidotherapy

- Review patient evaluation and diagnosis for consideration of the healing stage and integrity of the healing structures to determine whether Fluidotherapy is an effective medium to use.
- Patient should thoroughly wash the extremity and remove jewelry.
- Preheat the Fluidotherapy unit and set the temperature. Temperature is controlled by a thermostat and set between 105°F and 118°F (40.5°C–47.7°C).
- Place the extremity in the machine; ensure that the sleeve is fully closed around the extremity to avoid loss of the medium.
- Instruct patient if active movement is desired or if positional heat/stretch will be applied.
- Treatment time is approximately 20 minutes.
- Adjust the air flow for desired effect and sensory input.

An advantage of Fluidotherapy is the ease of implementation: the patient can actively exercise the extremity as the tissue heats up, the therapist has easy access to the extremity to provide active-assistive and passive mobilization, and the dry cellulose particles can provide desensitization therapy. Because of the medium, open lesions or wounds must be covered completely before use to avoid contamination or the cellulose medium from entering the wound.

Thermotherapy: Paraffin Baths

Paraffin baths involve application of a warmed melted mineral wax mixture that provides moist superficial heat that can be applied by dipping the extremity into the medium or brushed onto the skin surface (Fig. 24-3). Commercial units can be purchased for home use. Paraffin temperature should be checked regularly and monitored prior to use because there is no thermostat or way to modulate temperature.

Figure 24-3 Paraffin baths involve application of a warmed melted mineral wax mixture that provides moist superficial heat that can be applied by dipping the extremity into the medium or brushed onto the skin surface.

Effect

Biophysiological effects of superficial heat:

- Increased blood flow
- Increased metabolic effects
- Pain modulation
- Decreased muscle spasm
- Increased tissue extensibility
- Softened skin; provides moisture

Clinical Conditions for Which Modality Can Be Used

- Arthritis/osteoarthritis
- Joint stiffness

- Pain
- Acute or subacute traumatic or nontraumatic musculoskeletal disorders of the extremities
- Limited ROM
- Hand injuries, digital fractures

Contraindications

- Cancerous lesions in treated area
- Open wounds, suture, staples, cuts, lacerations, or abrasions
- Infections or systemic infectious diseases with fever or inability to suppress or modulate body temperature
- General physiological heat contraindications and precautions
- A disadvantage to paraffin treatment is that the hand needs to remain still during the heating process, limiting active and active-assistive mobilization.

General Instructions for Paraffin Bath

Therapeutic paraffin baths consist of a thermostatically controlled heating unit filled with a commercial mixture of paraffin wax and mineral oil. Mineral oil lowers paraffin melting point.

- Review patient evaluation and diagnosis for consideration of the healing stage and integrity of the healing structures to determine whether paraffin is an effective medium to use.
- Remove jewelry; avoid placing clothing in contact with the wax.
- Check paraffin temperature to ensure a therapeutic range between 125°F and 130°F (48.8°C–54.4°C).
- Immerse the hand in the bath for 1 to 2 seconds and withdraw it to allow the paraffin to harden and conform to hand contours. Patients should be instructed not to move their fingers or wrists.
- Repeat the gloving process 8 to 10 times. The first dip is always deepest to avoid hotter wax from being caught under the existing layers with the potential to burn the patient.
- For positional heat and stretch, the digits of the hand can be placed into flexion, for example, held in place with Coban tape, and the dip method then applied.
- The paraffin, bag, and towel are left on for 15 to 20 minutes.
- The paraffin is removed and discarded after treatment end.

Cryotherapy

Cryotherapy or cold therapy is the therapeutic application of physical agents to lower tissue temperature.

General Instructions for Cryotherapy

Cryotherapy applications, because of their colder temperatures than the body, conduct heat out of the body into the cooling agent. This can be achieved through conduction, such as the application of a cold pack on an extremity, or convection, placing the extremity in a cold-water bath. A less commonly used method involves topical cold sprays, which are liquid when applied, but absorb heat as the medium evaporates, effectively cooling the area. In addition to these application methods, heat can also be transmitted out of the body through evaporation.

Selection of the cooling agent used is based on the volume or area to be treated, the cooling agent rate or intensity, and the duration or time for which the modality is applied. Consideration of the anatomical structure depth (deep or superficial) and adipose tissue amount are also critical factors. Therapists should monitor patients' skin and response to the modality. Commonly used cooling agents include commercial and homemade ice packs, and ice massage. Cold packs can be made by combining three-parts water to one-part isopropyl alcohol in a plastic zip-seal bag and freezing. The alcohol will keep the mixture from fully freezing, resulting in a slushy soft cold pack similar in consistency to some commercial gel packs. Cold packs should always be covered with a material such as toweling or a pillow case. A dry covering will make the initial contact with the patient more comfortable and slow the cooling process.

Effect

- Primary biophysiological effects of cryotherapy are analgesic, vascular, metabolic, and neuromuscular. Cold therapy agents decrease tissue temperature to a depth of 2 cm.¹⁷
- The analgesic effect of cold decreases pain through counterirritation and by decreasing nerve conduction velocity in superficial sensory nerves.^{18,19}
- Vascular effects include both vasoconstriction (when cold is applied for <15 minutes) and vasodilation (when cold is applied for longer than 15 minutes).¹⁷ Decreased circulation.
- Short-term application of cold therapy can help reduce edema.
- Metabolic processes are slowed decreasing inflammation, edema, and tissue repair.
- Neuromuscular effects influence muscle tone. Cold therapy can temporarily reduce spasticity in patients with upper motor neuron lesions.²⁰
- Decrease muscle spasm, nerve conduction velocity, and may break the cycle of pain-spasm-pain
- Decrease pain

Clinical Conditions for Which Modality Can Be Used

- Inflammatory phase, post surgical procedures, and combined with compression following acute injuries²¹
- Cold is used in the management of acute inflammation, trauma, and pain due in part to vasoconstriction and decreased metabolic rate, and can be more effective when combined with compression.²²
- Edema
- Exercise-induced delayed muscle soreness
- Arthritic exacerbation, acute bursitis, or tendonitis
- Spasticity
- Acute or chronic pain secondary to muscle spasm

Contraindications

- Hypertension (due to secondary vasoconstriction)
- Raynaud disease
- Rheumatoid arthritis
- Local limb ischemia
- History of vascular impairment, such as frostbite or arteriosclerosis
- Cold allergy (cold urticaria)
- Paroxysmal cold hemoglobinuria

Precautions

- Changes in skin temperature occur quickly and tissue may be damaged before the desired biophysical effects are achieved.
- Monitor the skin for tissue damage.
- Caution is advised for patients with decreased sensation or mentation.
- Cold therapy normally turns skin pink or light red. It should be immediately discontinued if skin turns bright red, white, pale, or grayish yellow, or develops welts.

Cryotherapy: Ice Massage

General Instructions for Ice Massage

Ice massage is a localized application of cold directly onto the skin surface and is often used to treat relatively small areas or to break the pain cycle of a trigger point, muscle spasm, or spasticity (Fig. 24-4).

Figure 24-4 Ice massage. Note the towel used to drape the treatment area and the redness of the tissue secondary to cooling.

- Review patient evaluation and diagnosis for consideration of the healing stage and integrity of the healing structures to determine whether ice massage is an effective medium to use.
- A towel should be placed under the area to be treated to collect the water as the ice melts.
- Inform patients of the treatment process and the sensations they may experience.
- Ice cubes or water placed in a paper or Styrofoam cup and frozen can be used as the medium. Cups are easier for therapists to use, because of the insulating effect of the cup on their fingers.
- The ice cube or cup is rubbed in small, slow circles staying in direct contact with the skin.
- Patients will subjectively describe cooling stages as a “burning” feeling, “aching,” and “numbness.”
- Treatment times are relatively short, approximately 5 to 10 minutes because of the limited treatment area.
- Discontinue ice massage shortly after the patient reports “numbness,” indicating analgesia.
- Monitor the patient for signs of cold intolerance or tissue damage.

Ice massage is an inexpensive, relatively convenient way to apply a localized application of cold, leading to analgesia. Some patients will not tolerate the intensity of the application and the sensory response of burning and aching that occur. Alternative methods for cooling should be considered for those individuals.

Cryotherapy: Cold Packs

General Instructions for Cold Packs

Cold packs are convenient, effective, and can easily be made at home using a simple bag of ice or frozen peas. Commercial units are stored in thermostatically controlled freezers, which maintain sealed gel packs at an effective temperature. Gel packs can be used over and

recooled. Gel packs warm more quickly than ice packs made with ice cubes and have an effective application of approximately 10 minutes.

- Review patient evaluation and diagnosis for consideration of the healing stage and integrity of the healing structures to determine whether cryotherapy is an effective medium to use.
- Describe the treatment technique and process to patients. Inform patients of the sensations they may experience during cooling stages. Instruct patients to inform the therapist if they encounter discomfort, pain, or distress.
- Depending on the patient and treatment area, a dry thin towel or pillow case is placed over the treatment area; a moist thin towel or paper towel can be used if a more rapid energy transfer rate is needed.
- Ice packs are made by placing cubed or crushed ice into a plastic bag and sealing it. A thin towel can be placed over the treated tissue and the ice pack conformed to the treatment area.
- Ace wraps or elastic straps can be used to hold ice packs in place and conform more directly to treatment areas.
- Ice packs or cold packs are applied for approximately 10 to 15 minutes.

Ultrasound

US is a form of mechanical energy in which a piezoelectric crystal expands and contracts, creating sound waves that are propagated longitudinally in a frequency between 1.0 and 3.0 MHz. Therapeutic US has both a healing and heating effect (Fig. 24-5).

Figure 24-5 Application of therapeutic ultrasound. Effective treatment area is equal to twice the size of the soundhead.

Four variables must be selected to safely apply therapeutic US:

1. **Frequency** (1 or 3 MHz), which determines sound wave penetration depth

2. **Duty cycle** (or pulsed or continuous) (20%, 50%, 100%), which is the on/off time of the US wave and determines the amount of energy transmitted to the underlying tissue
3. **Intensity** (0–2.5 W/cm²), which determines sound wave strength
4. **Duration** (0–16 minutes), which determines treatment length and amount of energy applied

Effect

US uses acoustic energy or sound waves and is a deep or superficial modality. US has two primary effects: a thermal (heat) or nonthermal (mechanical) effect to facilitate tissue healing. *Thermal effects* refer to biophysiological changes produced by cellular heating, whereas *nonthermal*, mechanical effects refer to biophysiological changes produced by the cellular effects of cavitation, microstreaming, or acoustic streaming. Both thermal and nonthermal US can be used to facilitate healing and improve occupational function.

A lubricant gel is necessary to transmit the sound energy to a small area of tissue over the treatment area. Sound energy is transmitted longitudinally, causing the cells to compress and decompress. When sound energy encounters bone, it is deflected, causing a transverse or shear wave that is negligible in terms of tissue temperature elevation.¹⁷ Sound energy has peaks and valleys that affect penetration depth and is referred to as beam nonuniformity ratio (BNR). These factors create hot spots and potential tissue overheating. To avoid tissue overheating, the transducer is moved in slow circles over the treatment area.

Body fluids such as blood and water have the lowest impedance and acoustic absorption coefficient. Bone, along with other protein-dense structures—such as scars, joint capsules, ligaments, and tendons—possess high impedance and absorption coefficients, absorbing the sound energy allowing for targeted application.^{23,24}

Energy Distribution

Frequency

Frequency refers to the number of cycles or waves that are produced each second. Clinically, frequencies of 1 MHz travel further and penetrate to a depth between 3 and 5 cm. A frequency of 3 MHz penetrates superficially to 1.5 cm. Frequency selection is determined by the depth of the anatomical structure to be treated.

Intensity

Intensity describes the strength of the acoustic energy at the application site and is a significant factor in determining tissue response. Intensity is documented as Watts per square centimeter (W/cm²). As US is absorbed into tissue, the molecules oscillate, converting sound energy into kinetic energy resulting in a heating effect.

Duty Cycle

Duty cycle determines the amount of acoustic energy transmitted, contributes to determining the tissue response, and reflects the ratio of on/off time. *Continuous ultrasound* (100%) refers to the constant flow of sound energy. *Pulsed ultrasound* refers to an interruption in the acoustic energy as the US machine cycles on-and-off. Commonly used duty cycles are 20% (healing), 50% (warming), and 100% (heat) or continuous acoustic energy. The determination of which duty cycle to use is based on pathology, healing stage, and treatment area.¹⁷

- Thermal effects can occur with frequencies of 1 or 3 MHz and use of continuous US (100% duty cycle).
- Less vigorous forms of heat may be applied (50%) for patients in the subacute, proliferative healing phase along with lower intensities (0.3–0.7 W/cm²) resulting from the decreased strength, integrity, and viability of the healing structures.
- Acute injuries in the inflammatory healing phase can be treated with nonthermal US parameters of 0.2 W/cm².^{23,25,26}

Types of Clinical Conditions: Heal (Nonthermal) or Heat (Thermal) Ultrasound

A thorough evaluation of a patient is necessary to confirm the clinical diagnosis, symptoms and functional deficits, healing stage, and tissue depth to be treated. Clinicians may use US to achieve thermal or nonthermal effects based on desired therapeutic effect.

- Clinical diagnoses that benefit from US to facilitate healing include tendinitis, bursitis, epicondylitis, trigger points, contusions, pain, acute or chronic inflammation, bone fractures, and tendon repairs (nonthermal).
- Thermal US is often used when patients present with scar tissue, joint contracture, adhesive capsulitis, movement limitation, or decreased ROM secondary to soft-tissue injury and pain.
- Therapeutic parameters and outcomes of thermal US vary in the research but demonstrate effectiveness (Table 24-1).²⁷⁻²⁹

Table 24-1. Clinical Parameters for Ultrasound Based on Healing Stage

TISSUE STATE	INTENSITY REQUIRED AT THE LESION (W/cm ²)
Acute (inflammatory phase)	0.2
Subacute (proliferative phase)	0.3–0.7
Chronic (maturation phase)	0.8–2.0

Thermal doses of US are dependent on the treatment goal and presenting problem. It is important to respect the stretching window following high-intensity applications because tissue temperature will cool approximately 2°C (3.6°F) within 5 to 10 minutes.^{30,31}

When treating subacute inflammation, thermal effects should be mild—that is, an increase in tissue temperature of approximately 1°C (1.8°F). Moderate thermal effects are used for pain modulation/altered nerve conduction velocity, muscle relaxation/stiffness, muscle spasm, and chronic inflammation.

Nonthermal US exerts mechanical effects at the cellular level to facilitate the healing process but does not elevate tissue temperature. US is applied using a 20% duty cycle. Nonthermal effects of pulsed US occur at the cell membrane because of stable cavitation, acoustic streaming, and micro massage.^{32,33} Second-order effects of nonthermal US are caused by the destabilization of the cellular membrane. This contributes to the enhancement of the inflammatory response to accelerate tissue healing.^{34,35}

Phonophoresis

Phonophoresis is the use of US to facilitate the delivery of topically applied drugs or medication to selected tissue. Anti-inflammatory medication, such as betamethasone, is administered using US to decrease the inflammatory process. Research related to its effectiveness is inconsistent because of variability in treatment parameters. Phonophoresis does not allow therapists to effectively dose or measure the amount of drug patients receive. Other methods such as iontophoresis may be a more appropriate choice.³⁶

Contraindications

Most contraindications and precautions for US use are because of thermal effects.

- Hemorrhagic regions, reproductive organs
- Impaired sensation
- Over electronic implants (pacemakers, neurostim systems)
- Directly over the spinal cord after laminectomy
- Over areas suspected to be cancerous or precancerous
- In front of the upper neck (carotid sinus)
- Over joints or tissues that have been injected with medication within the last 3 months
- Over plastic or cement implants
- Directly over the skull or bony prominences (bony part of elbow)

Precautions

- Acute inflammation
- Epiphyseal plates
- Fracture healing (high dose)
- Breast implants
- Application of cryotherapy
- Primary repair of tendon or ligament

General Instructions or Directions for Ultrasound Use

- Review patient evaluation to determine whether US is indicated for the clinical condition; review precautions and contraindications.
- Determine treatment tissue depth (superficial or deep) to establish frequency. Identify tissue healing phase to determine therapeutic parameters (heat or heal). Check skin condition.
- Clean the area and sound head; apply US gel to the targeted tissue.
- Explain the procedure to patients; they may feel a gentle warmth, but not intense heat or pain during application.
- Remove jewelry, position the patient, and drape area being treated.
- Set the therapeutic parameters of frequency (deep 1 MHz or superficial 3 MHz), duty cycle (20% heal, 50% warm, 100% heat), intensity (0.2 W/cm² heal; higher intensities to heat), and treatment time (10–15 minutes for large area and vigorous dose and 1 MHz; 2–7 minutes for small areas and 3 MHz).
- Move soundhead slowly, approximately 4 cm per second, keeping the soundhead in contact with the skin. Positional heat and stretch technique can be used to increase ROM.
- If patient reports pain or heat, add additional gel, decrease intensity and duty cycle, and move the sound head.
- When treatment is complete, wipe the gel off and clean the soundhead.
- Document the treatment, therapeutic parameters, and patient response.

The larger the treatment area, the greater the time required. The area that can be effectively treated is twice the size of the soundhead. The transducer should be kept flat during application with a gentle pressure and adequate amount of US gel. Preset intensities should be avoided because they will likely not be effective in generating desired treatment outcomes and benefits of therapeutic US.^{29,37} Research has identified that higher doses of US energy and longer applications were found to have more positive outcomes (Table 24-2).

Table 24-2. Thermal and Nonthermal Effects of Therapeutic Ultrasound

THERMAL EFFECTS	NONTHERMAL EFFECTS
Increases extensibility of collagen fibers	Increases phagocytic activity of macrophages/attracts immune cells to tissue
Decreases muscle stiffness	Increases protein synthesis
Reduces muscle spasm	Increases capillary density
Alters nerve conduction velocity/diminishes pain perception	Regenerates tissue
Increases metabolism and blood flow	Heals wounds and fractures
Provides all of the effects of nonthermal ultrasound	

Precautions for Ultrasound Use

Patients should be monitored during US, and any pain or discomfort may indicate that the intensity is too high or that there is an inadequate amount of gel. When using US as a thermal agent, one must follow general contraindications and precautions for any thermal modality.

Electrotherapy

Advances in technology, a focus on pain control, clinical outcomes, and availability, have facilitated the increased interest and use of electrotherapy in clinical practice. Electricity is a form of energy consisting of charged particles (electrons) and which has magnetic, chemical, mechanical, and thermal properties. There are a variety of electrotherapeutic devices available, which use specific currents and modifications to impact tissue healing, muscle strength and endurance, pain modulation, inflammation, and muscle spasm. Surface electromyography

biofeedback monitors the electrical activity level in muscles (helps determine how well someone is able to recruit muscle activity on their own) and is often paired with NMES.

Forms of Electrotherapy

- **Neuromuscular electrical stimulation (NMES)** uses pulsating, alternating current to activate muscles through stimulation of intact peripheral nerves to cause a motor response. Stimulation of the motor nerve is used to decrease muscle spasm, strengthen muscle, and for muscle pumping that can reduce edema. NMES to innervated muscle is used for muscle reeducation, atrophy prevention, and muscle spasm and edema reduction.
- **Functional electrical stimulation (FES)** is electrical stimulation used to activate targeted muscle groups for orthotic substitution or to facilitate performance of functional activities or movements. FES is often used with individuals who have shoulder subluxation, weak grasp/release, or foot drop after a stroke.
- **Transcutaneous electrical nerve stimulation (TENS)** uses pulsed alternating current for pain control. TENS uses surface electrodes placed strategically over the area of pain to stimulate afferent sensory nerve fibers to modulate pain perception. TENS is used for targeting smaller areas, trigger points, muscle spasm, and acupuncture points.
- **Electrical muscle stimulation (EMS)** is electrical stimulation of denervated muscle to facilitate viability and to prevent atrophy, degeneration, and fiber fibrosis. EMS facilitates nerve regeneration and muscle reinnervation.
- **Interferential current therapy (IFC)** utilizes two channels (four electrodes placed in a vector pattern) simultaneously with different frequencies. This allows deeper tissue penetration to facilitate pain reduction and physiological effects. IFC is used for treatment of large areas and deeper tissues.
- **Iontophoresis** is the use of low-voltage direct current to ionize topically applied medication into tissue. Iontophoresis is often used in the treatment of inflammatory conditions or for scar formation and management.
- **Electrical stimulation for tissue repair (ESTR)**, also known as high-voltage galvanic stimulation (HVGS), has been used for tissue healing. Because of its complexity, use requires highly advanced training, and therefore, it is not reviewed in this chapter.

Principles of Electricity

The clinical use of electrotherapy and integrating the concepts and parameters necessary for safe use require advanced training and knowledge. The reader is encouraged to pursue additional education and training to ensure service competency and safe, effective use of electrotherapy. It is beyond the scope of this textbook to discuss all aspects of electrotherapy, but the primary concepts will be highlighted.

There are two primary forms of electrical current, alternating current (AC) and direct current (DC), both of which can be modified or pulsed. DC is unidirectional, with the electrons moving continuously in one direction, and the electrodes maintaining their polarity. AC is characterized by periodic changes in the polarity of the current flow (positive-to-negative, sinus wave form). The current is uninterrupted and bidirectional, without any true positive or negative pole. Household electricity uses AC. Pulsed current is the term used when electron flow is periodically interrupted for very short periods of milliseconds or microseconds. *Modulation* refers to changes or modifications made in one or more aspects of the current.

Electric current is represented graphically by a waveform and provides a visual representation of the current flow. The amplitude (intensity/output) is the level or distance the impulse rises above or below a baseline (zero electric charge), whereas the pulse duration is the length of time that is required to complete the shape of the electrical flow. A pulsed waveform is classified as either monophasic (consisting of a single phase), biphasic (two phases with current flow in both directions), or polyphasic (multiple phases). Electrical stimulation at low current intensity evokes a sensory response. If the current intensity is high enough to exceed the motor threshold, a muscle contraction will occur.

The principles underlying all forms of electrotherapy include selection of the appropriate form of electrotherapy based on the therapeutic goals for the patient, and the concepts of amplitude,

pulse duration, and pulse frequency. The peak amplitude is the most frequent level of intensity used in clinical settings and is measured in amperes, micro amperes, or for most electrotherapy equipment used clinically milliamperes (mA), which is one thousandth of an ampere, a measure for small electric currents. Pulse duration (pulse width) consists of the length of time the electric flow is “on” and is measured in microseconds or milliseconds (ms). As pulse width increases, more muscle fibers are stimulated. A narrow pulse width is typically better for pain control.³⁸ The pulse rate or pulse frequency is the number of pulses or wave forms per second and is measured in pulses per second (pps) or Hz. If pulse duration is too short, an action potential won’t be reached. The higher the intensity and frequency of pulses, the stronger the muscle contraction.

Duty cycle is the ratio the time the current is on to the time the current is off. For example, a treatment protocol in which electrical stimuli are delivered for 10 seconds followed by a 50-second off period is expressed as a 1:5 duty cycle. Most common duty cycles/protocols used for NMES are 1:1, 1:3, and 1:5 to allow for greater volitional extremity movement.

Effects

Human tissue is either excitable or nonexcitable. Excitable tissues respond to intensity, pulse duration, and pulse frequency. Excitable tissues, such as nerves and muscles, can initiate and propagate an action potential.

The diameter of the nerve, depth of the nerve, and duration of the pulse affect a nerve’s response to electrical stimulation (Fig. 24-6). Sensory nerves are stimulated first, followed by motor nerves, pain fibers, and finally muscle fibers. As the amplitude is increased, motor nerves reach threshold and with sufficient intensity, contraction of all muscle fibers attached to that nerve (motor unit) occurs.

Figure 24-6 The strength–duration curve of an electrical stimulus describes the relationship between the amplitude and duration of the stimulus needed to depolarize a specific nerve to achieve a response. MST, maximum sensory threshold.

In volitional movement, there is asynchronous recruitment of muscle. Electrodes act as the interface between the skin surface and the current flow from the stimulation device. Electrodes come in several sizes and should be selected based on muscle size and number of motor units stimulated. Electrodes are self-adhesive and should only be used with the same patient to avoid cross contamination.

Neuromuscular Electrical Stimulation

Neuromuscular electrical stimulation (NMES) refers to the use of electricity to elicit a muscle contraction of paralyzed or paretic muscles and is used for muscle reeducation, muscle strengthening, preventing disuse atrophy, and edema control, and requires an intact peripheral nerve (Fig. 24-7). FES is the use of NMES as an orthotic substitute (neuroprosthesis) to assist with a functional activity and movement.^{39,40}

Figure 24-7 A and B, Multichannel reaching. Common electrode placements for reaching patterns using two channels of stimulation.

Mechanisms Underlying Function/Effect

Stimulation of targeted peripheral or motor nerves with sufficient pulse width, frequency and amplitude to tetany, produces movement of an extremity to improve or restore motor function. Stimulation also provides proprioceptive, kinesthetic, and sensory input to the central nervous system.

Description of Clinical Conditions for Which Modality Can Be Used

Clinical conditions that may benefit from NMES, include individuals with paralysis or paresis such as stroke or spinal cord injury. NMES can also be used with patients with weakened muscle contraction or strength from disuse atrophy following prolonged immobilization (fractures), trauma, surgery, submaximal effort, or pain limiting movement and function. Due to the pumping action of muscle contraction, patients with edema may also be candidates for NMES or FES.⁴¹⁻⁴³

Precautions

Review precautions listed in the equipment's operating manual before applying electrical stimulation. The lowest effective current should be applied to patients with impaired mentation or sensation. Level of motor response and skin condition should be closely monitored. Areas of skin irritation, damage, or skin lesions can cause decreased tissue impedance and increased current that may result in pain and should be avoided.

Contraindications

Electrical stimulation should not be applied to the craniofacial or cervical region of patients who have stroke or seizure histories; areas of phrenic nerves or bladder stimulators; over the carotid sinus; near diathermy devices; over or near superficial metal pins, plates, or hardware; and patients with cancer, infection, tuberculosis, active hemorrhage, and cardiac pacemakers.

General Instructions or Directions for Use

- The patient should be reevaluated to determine whether the injury or problem is appropriate for NMES use and to identify therapeutic goals.
- Review precautions, contraindications, and identify movement patterns to determine which muscles or muscle groups are active, inactive, or weak. Identify which muscles will be targeted for stimulation and what movement patterns are required. Check and clean the area to be treated, do not place electrodes over cuts, abrasions, or lacerations.
- Review the specific characteristics of the equipment and select the parameters for the NMES unit that will be used.
- Explain the procedure to patients and describe the sensation they will experience (tingling/vibrating) followed by muscle twitching, fasciculations, and, finally, tetany with

muscle contraction and joint movement.

- Place the primary electrode over the bulk of the muscle fibers consistent with the desired contraction and/or movement with the other electrode parallel to the muscle fibers and at the distal or proximal end of the muscle (near origin or insertion). Connect the leads to the electrodes and stimulator (Fig. 24-8).

Figure 24-8 A and B, Multichannel reaching. Common electrode placements for reaching patterns using two channels of stimulation.

- Pulse rate for muscle contraction should be 30 to 35 pps for healthy patients (ortho); higher frequencies (such as 50 pps) will fatigue spastic muscles. Phase durations between 200 and 400 μ s will stimulate the motor nerve.
- Set the on/off time (duty cycle) for the intended amount of time with consideration of a 1:1, 1:3, or 1:5 ratio.
- Gradually increase the amplitude until sufficient to reach a tetanic contraction. Treatment time is between 10 and 30 minutes. For orthopedic patients or to increase muscle strength, the amplitude/intensity should be increased to the patient's maximum tolerance.
- Modify the electric current if the patient reports pain or discomfort. If the contraction is intolerable, a sensory response can be achieved by decreasing the amplitude or by modifying the pulse duration/width to 150 to 200 μ s. As the patient can tolerate the stimulation, parameters can be changed.
- When treatment is over, remove electrodes and check patient skin. When the patient displays volitional movement patterns, stimulation can be set at a sensory level to cue the patient as to the desired movement pattern, or the duty cycle can be modified to a 1:3 or 1:1 ratio for strength and endurance.

Transcutaneous Electrical Nerve Stimulation

TENS uses surface electrodes and low-voltage pulsed electrical current to stimulate superficial nerves to modulate the patient's pain perception.

Mechanism Underlying Function/Effect

Treatment applications using electrical stimulation for pain control employ pulsed or AC in a variety of stimulation patterns. Stimulation type is based on the physiological response to the stimulation with the goal being pain relief and comfort. Four levels of stimulation used include subsensory, sensory, motor, and noxious levels. Two primary theories on which the modulation of pain with TENS is based are the gate control theory and the opioid theory.^{11,44} Gate theory involves stimulation of afferent nerves to block pain by closing the gate in the spinal column to pain signals. Opioid theory asserts that natural beta endorphins are released with the application of intense beat frequency of TENS that inhibits pain signal transmission and occurs with muscle fatigue or physiological stress.^{45,46}

Clinical Conditions for Which Modality Can Be Used

Pain is one of the most common complaints that cause patients to seek medical care. Adequate pain management facilitates occupational function. TENS can be used to manage pain in musculoskeletal disorders, pre- and post-surgically, and for both acute and chronic pain.^{46,47}

General Instructions

- Treatment employs pulsed or AC in a variety of stimulation patterns.
- Review the clinical diagnosis, presenting signs and symptoms, and determine appropriateness for TENS use.
- Explain the treatment to the patient; describe current sensation (tingling, buzzing).
- Clean the area where the electrodes will be placed. Remove jewelry and clothing over the treatment area. Ensure skin integrity.
- Optimal electrode placements correlate with pain structures and sources, and include dermatomes, motor, trigger, and acupuncture points.
- Position electrodes securely to maintain conductivity. Electrodes can be parallel, crossed, front/back, bracketed, or crisscrossed over the area of pain. If the patient doesn't achieve pain modulation, electrodes should be moved and a different wave form tried. Increase amplitude after 10 minutes to avoid accommodation to the stimulation.
- Treatment time varies between 30 and 60 minutes. Patient can use the TENS unit as needed for pain or maintain a three to four times daily schedule.
- TENS units are often used at home. Therapists should explain the purpose of the equipment and instruct the patient in its operations and precautions (verbally and in writing).

Precautions

Review precautions listed in the equipment's operating manual before applying electrical stimulation. Amplitude is increased to patient comfort and tolerance. Parameters can be changed to avoid nerve accommodation. Patients should be instructed to avoid overactivity to prevent tissue damage or further injury by engaging in activities without pain sensation.

Contraindications

Same as NMES. Pain control should be avoided if there is no underlying diagnosis as pain is a protective response to potential or actual tissue damage.

Iontophoresis

Iontophoresis is an active drug delivery system that uses direct current to deliver medication through the skin. Iontophoresis is easily applied, the amount of drug is consistent, and it is essentially painless.

Mechanism of Action

The most commonly used medication for musculoskeletal conditions is dexamethasone, which has a negative ion. Because direct current is used, the like (same) charge is applied to the medicated electrode, repelling the medicated ion into the tissue. The black, negative lead is placed over the medicated electrode with the red lead connected to the dispersive electrode 4 to 5 inches away. Like charges repel the ion into the tissue where it exerts a biophysiological effect; for dexamethasone, it decreases inflammation.

Clinical Conditions for Which Modality Can Be Used

Iontophoresis can be used for treatment of acute inflammatory conditions such as epicondylitis, carpal tunnel syndrome, glenohumeral bursitis, ulnar nerve inflammation, wrist tendinitis, and tenosynovitis. Therapists should thoroughly understand patient pathophysiology, medications, and potential drug interactions. Documented orders should be obtained from physicians prior to using iontophoresis.⁴⁸

General Instructions

There are generators and patches that can be used to provide iontophoresis. Primary consideration is clinical diagnosis, area to be treated, and medication selection. Caution must be used because medications may cause an allergic or anaphylactic reaction, which is a life-

threatening condition and medical emergency. Patients should be asked for a list of current medications, any known allergies, sensitivities, or reactions to foods or medications.

Medication is placed in the electrode reservoir and positioned over the treatment tissue. The polarity of the ion determines which lead is placed on the medicated electrode. Electric current is turned on with treatment time between 10 and 20 minutes.⁴⁹ The most common side effect is skin irritation.

Laser Therapy (Low-Level Laser Therapy)

Low-level laser therapy (LLLT), or photobiomodulation therapy, is the application of a monochromatic, collimated red and near-infrared light to facilitate the healing process and modulate pain.

Mechanism of Action

The underlying mechanism of action of LLLT is not clear, but may be caused by improvement in microcirculation, the inflammatory response, and adenosine triphosphate production (ATP) that facilitate the healing process. There are physiological and therapeutic effects at a cellular level causing a disruption in the histochemicals and cell membrane that modify the inflammatory response, facilitating healing and modulating pain.^{50,51} LLLT lasers do not produce heat, sound, or vibration; have no thermal effect; and are called cold lasers.

Clinical Conditions for Which Modality Can Be Used

LLLT impacts the tissue at the cellular level. Research varies but supports its use for wound healing, inflammatory arthropathies, soft-tissue injuries, and pain modulation.⁵²

General Instructions

LLLT appears to affect the three phases of healing, particularly the inflammatory process and fibroplasia. LLLT increases connective-tissue repair and modifies the cell membrane, allowing histochemical changes that occur with healing and decreasing the inflammatory process. There are different wavelengths that vary from 600 to 900 nm and are most commonly used to treat a variety of musculoskeletal conditions. Patients and therapists should wear appropriate safety goggles, and the laser should never be aimed into the eyes. LLLT should not be used with patients with active cancer or secondary metastasis unless used for pain control for palliative care. LLLT should not be applied over the abdomen of pregnant women or those with seizure history.

Surface Electromyographic Biofeedback

Biofeedback refers to those procedures or techniques that provide individuals with an auditory or visual cue, “feedback,” to gain volitional control over a physiological response. Biofeedback provides an external mechanism for monitoring a specific physiological function and response, and through instant feedback, allows individuals to attempt to control or modify their behavior or response.

Clinical Conditions for Which Modality Can Be Used

Biofeedback is used to treat a variety of conditions, including migraine headaches, pain, anxiety, behavioral disorders, hyper/hypotension, paralysis, and movement disorders. In rehabilitation, surface electromyographic (sEMG) feedback is used for muscle reeducation and can be paired with electrical stimulation to provide movement and enhance motor control. It can also be used for women’s health and pelvic floor disorders and incontinence. Clinical use of sEMG paired with electrical stimulation has been demonstrated to be effective for improving performance and functional movements in the hemiplegic upper extremity (UE); dysphagia, muscle dysfunction, and myoclonus following spinal cord injuries; focal hand dystonia; and movement dysfunction in children with cerebral palsy.^{53–56}

Mechanism of Action

Biofeedback uses surface electrodes and instrumentation to measure and display the physiological response of the body, including respiratory, cardiovascular, and neuromuscular. Clinically, feedback measures activity in the neuromuscular system and is used for motor

reeducation, retraining of functional movement, and to improve performance in activities of daily living (ADLs). Biofeedback provides immediate feedback (auditory or visual), allowing patients to objectively measure, determine, and quantify muscle activity and track motor performance changes.

Following a stroke, there is often a disruption of motor control and an impairment in sensation, kinesthesia, and proprioception in the affected extremities, limiting functional ability and movement. sEMG provides a mechanism for providing feedback to enhance motor return and movement patterns.

General Instructions

Use of sEMG biofeedback for muscle reeducation uses auditory and visual feedback, which measures muscle activation level. These parameters or threshold for activation can be adjusted, which also allows grading of the activity or movement depending on the goal and sensory and kinesthetic feedback.

- Surface electrodes are placed over the targeted muscles to detect the electrical impulse that is generated with muscle contraction.
- Dependent on the threshold parameter, with the onset of a muscle contraction, the biofeedback unit will alert the patient through auditory or visual stimulus or both.
- As the contraction strengthens and movement progresses, the auditory tone may become louder as additional muscle fibers are recruited.
- Feedback sensitivity can be adjusted to provide the patient with immediate feedback about the desired movement or unwanted muscle activity.
- sEMG can be paired with electrical stimulation to allow for completion of developing movement patterns, such as reach, grasp, or release.
- As motor function improves, more complex movement patterns can be added to the therapy program.
- For chronic pain or muscle spasm, sEMG provides feedback related to hyperactive muscle contraction (spasm), alerting the patient to consciously relax those muscles.

As with all physical modalities used in occupational therapy, biofeedback is a component of the occupational therapy process and is used in preparation for or concurrently with purposeful and occupation-based activities.

CASE STUDY

Patient Information

Marie is a 36-year-old African American female who experienced a stroke affecting her left side secondary to a prothrombotic disorder with no prior history. The stroke occurred while vacationing with her husband and two sons (age 9 and 12). She was initially stabilized at a small community hospital, then airlifted to a university hospital where she was treated and began inpatient rehabilitation. She made consistent progress at the facility and was independent for most basic level ADLs. Her discharge plans included recommendation for outpatient treatment. She was discharged home with orders to continue outpatient therapy. Marie lives in a small town in a rural community. Prior to the cerebrovascular accident (CVA), she was employed as a lead surgical nurse at an area hospital. She was actively involved in her community and the children's school and was responsible for most household activities including cooking, preparing her son's school lunches, laundry, and cleaning. Marie attended extracurricular school activities such as soccer and baseball, assisted with classroom and school activities when her schedule permitted, and was actively involved in her church. She was right-hand dominant and independent in ADLs and instrumental ADLs (IADLs) prior to the CVA.

Assessment Process and Results

Marie was accompanied by her husband for the initial evaluation, was alert and oriented, but appeared apprehensive and subdued. Speech was clear, though slow, and responses appropriate. Marie ambulated independently, demonstrating good dynamic balance using a

standard cane and left ankle-foot orthosis (AFO). She displayed dynamic active movement in the left UE. Assessment results revealed fluctuating tone with volitional movement and difficulty combining left shoulder, elbow, and forearm/hand motions for performance of efficient forward, side, and overhead reaching; or when attempting to reach, combined with grasp/release patterns. She displayed fluctuating flexor tone in the biceps and finger flexors when attempting to grasp and move objects using the left UE, minimal left unilateral neglect, and diminished tactile sensation of the left arm and hand. She displayed increased flexor tone in the biceps, gross grasp, and beginning finger extension and release when attempting to grasp objects such as cups. She displayed active shoulder flexion and abduction (0° – 95°); elbow movement lacked 30° of active extension, but full passive extension was present. Active elbow flexion was 30° to 100° with flexor synergies noted when fatigued. Endurance was low. No confusion or cognitive impairment was noted.

Marie reports independence for feeding, drinking, and dressing, but requires additional time to complete tasks using compensatory techniques rather than consistent, active left UE use as an assist. She attempts to use the left UE for self-care and IADL tasks but mentions that she frequently becomes frustrated owing to lack of endurance and tonal changes. Marie is independent in gait and ambulation using a standard cane and AFO as an assist, and transfers independently with good static and dynamic balance. She requires minimal assistance for higher level IADL tasks, such as meal preparation, laundry, and bathing.

The significant limiting factor identified by Marie was the inability to use her left UE more functionally and fluidly with better reach, grasp, and release patterns to facilitate independence and completion rate. The Canadian Occupational Performance Measure (COPM) was administered to the client. Marie identified the following occupations as most important to her and in which she wants to engage: meal preparation, laundry, driving, and return to work.

Occupational Therapy Problem List

The following problems were identified during the assessment:
