Heart defects that allow desaturated blood to enter the systemic system without passing through the lungs result in hypoxemia and cyanosis. Hypoxemia occurs when arterial oxygen tension is below normal and results in low oxygen arterial saturations and cellular function alteration. **Cyanosis**, a blue discoloration of the mucous membranes and nail beds, results from deoxygenated hemoglobin in a concentration of at least 5 g/dL of blood or from arterial saturations less than 85%.^{2,5} Anemia may mask the signs of hypoxemia, whereas children who are polycythemic with a normal arterial saturation may appear cyanotic. Older children who have an unrepaired septal defect with a left-to-right shunt may become cyanotic because of pulmonary vascular changes secondary to increased pulmonary blood flow. Because of these progressive pulmonary vascular changes, PVR increases to exceed or equal SVR, resulting in a reversal of shunting known as **Eisenmenger syndrome**. Three types of defects cause hypoxemia and cyanosis:

1. Lesions that cause right ventricular outflow tract obstruction and shunting from the right side of the heart to the left side, as in tetralogy of Fallot (see [Classification of Congenital Heart Defects and Associated Conditions section](#)).
2. Defects involving the mixing of saturated and unsaturated blood within the heart chambers, as in a univentricular heart (also referred to as a *single ventricle*)
3. Defects in children with transposition of the great arteries (see [Classification of Congenital Heart Defects and Associated Conditions section](#)), in which two parallel circulations exist and survival depends on the existence of a patent ductus

arteriosus or septal defect

◀Clinical Manifestations.

Infants with mild hypoxemia may show signs of cyanosis only occasionally when stressed; otherwise, they may exhibit near-normal age-projected growth and development. Infants with severe hypoxemia may display signs of feeding intolerance, poor weight gain, tachypnea, and dyspnea. Children with chronic hypoxemia are small for their age, may display cognitive and motor skill delays, experience shortness of breath with exertion, fatigue easily, and have exercise intolerance. Acute, severe hypoxemia will lead to tissue hypoxia, metabolic acidosis, hyperventilation, poor perfusion, and eventually shock.

In response to chronic hypoxemia, polycythemia occurs as the body generates additional red blood cells to increase the oxygen-carrying capacity of the blood. In some infants, however, microcytic anemia may result because of limited stores of iron. Polycythemia or hyperviscosity and the associated platelet dysfunction also place children at risk for thromboembolic events, especially infants with severe cyanosis and iron deficiency anemia. Children with right-to-left shunting are at risk for systemic embolic events, cerebrovascular accident (stroke), and brain abscess.⁵ Clubbing of the nail beds occurs because of chronic tissue hypoxemia and polycythemia.

Defects Increasing Pulmonary Blood Flow

Cardiac lesions that increase pulmonary blood flow include defects that involve septal abnormalities or communications between the great arteries. These allow the shunting of blood from the high-pressure left side to the lower-pressure right side. Infants with left-to-right shunts are acyanotic and, depending on the degree of shunting, may develop signs and symptoms of HF. Children with significant left-to-right shunts left untreated are at risk for development of irreversible pulmonary hypertension.

Patent Ductus Arteriosus

The **patent ductus arteriosus (PDA)** is a vessel located between the junction of the main and left pulmonary arteries and the lesser curvature of the descending aorta, usually just distal to the left subclavian artery (Fig. 34.5, A and B). During fetal circulation the PDA allows blood to shunt from the PA to the aorta. At birth, once the placenta is removed and the lungs are expanded, the PDA will start to constrict within the first hours of life. Closure of the PDA in full-term infants is usually noted in the first few weeks of life.⁷ As an isolated defect, PDA occurs in 5% to 10% of all CHD, but the incidence of PDA is much higher in preterm infants because of high circulating levels of prostaglandins and immature pulmonary vascular smooth muscle.^{2,8}

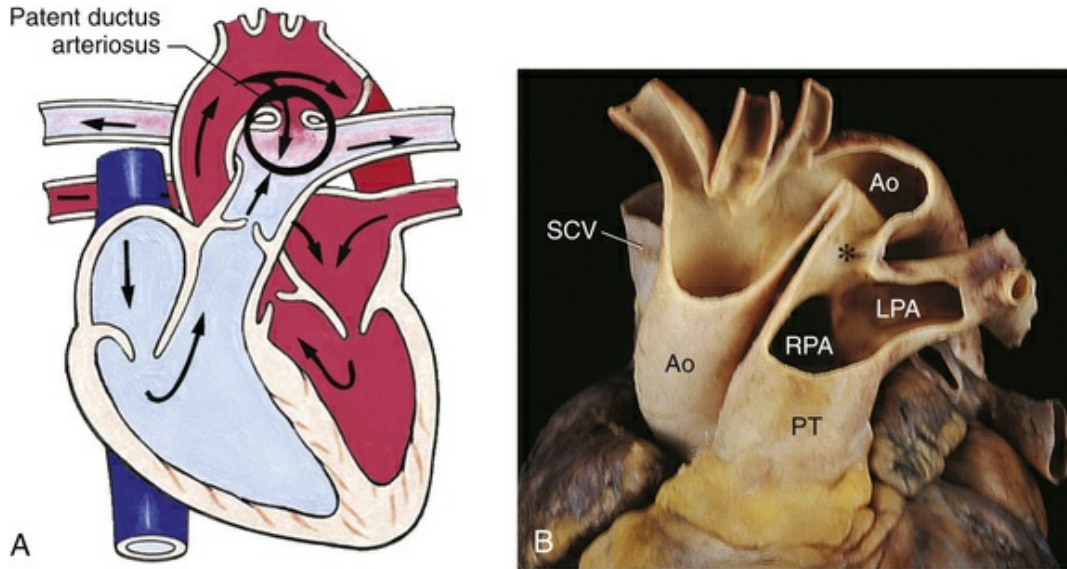

FIGURE 34.5 Patent Ductus Arteriosus (PDA). A, PDA with left-to-right shunt. B, PDA (asterisk) in an adult with pulmonary hypertension. C, Changes in oxygen saturation, left ventricular volume, and the myocardium caused by left-to-right shunt through a PDA. Ao, Aorta; LA, left atrium; LPA, left pulmonary artery; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SCV, subclavian vein. (A from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby; B from Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

◆Pathophysiology.

Failure of the PDA to close results in persistent patency of the ductus arteriosus. The hemodynamic effects of PDA depend on the size of the lumen and the resistance in the pulmonary and systemic circulations. At birth the PVR and SVR are almost equal and are reflected in the PA and aorta, respectively; therefore shunting is minimal. However, as PVR falls, a reversal of fetal shunting occurs. Blood now begins to shunt left to right, from the aorta to the PA. The hemodynamic effect is increased pulmonary blood flow, resulting in increased pulmonary venous return to the LA and LV with increased workload on the left side of the heart (see Fig. 34.5, C). The increased workload is caused by increased pulmonary venous return to the LA and, potentially, an increase in right ventricular pressure if pulmonary vascular changes occur in response to the increased blood flow, leading to an increase in pulmonary vascular pressure.

◆Clinical Manifestations.

If PVR has fallen, infants with PDA will characteristically have a continuous-machinery type murmur heard best at the left upper sternal border throughout systole and diastole. If the PDA is significant, the infant also will have bounding pulses, an active precordium, a thrill upon palpation, and signs and symptoms of pulmonary overcirculation. Infants with a small PDA will usually remain asymptomatic.

◆Evaluation and Treatment.

Chest radiograph will reveal cardiomegaly and increased pulmonary vascular markings. An ECG may demonstrate ventricular enlargement, particularly on the left, but in most cases it is within the normal range. Echocardiography and auscultation confirm the diagnosis based on the characteristic continuous-machinery type of murmur.

PDA closure in asymptomatic children with a murmur is

recommended because of the risk of infective endocarditis or pulmonary overcirculation that may lead to pulmonary hypertension and eventually develop a right-to-left shunt.⁹ Treatment of a small PDA in a child with the absence of a murmur or other cardiac conditions remains controversial.⁹ Premature infants who develop respiratory distress are initially given indomethacin or ibuprofen (both prostaglandin inhibitors) to close the duct. If this is unsuccessful or contraindicated because of renal impairment, surgical ligation and division may be warranted.

Historically the most widely used method for PDA closure is surgical repair involving ligation and division of the ductus with extremely low surgical mortality. However, there continues to be some morbidity associated with the approach through a left thoracotomy incision.

Several other options for PDA closure are available depending on the size of the child and the PDA. Many specialists perform transcatheter closure of the PDA during cardiac catheterization. The catheter is advanced into the ductal opening whereby coils or other devices are placed into the lumen that prohibit flow through the ductus. The greatest advantages to this procedure are the avoidance of a thoracotomy incision, reduced pain, and a shorter hospital stay.

Another surgical option is closure through video-assisted thoracoscopic surgery. This procedure involves making three small incisions in the left lateral chest wall, through which a tube is inserted. Through the tube, a clip is then placed across the ductus to occlude it. An advantage of this procedure over open surgical procedures is that there is less associated morbidity because of the avoidance of a thoracotomy incision.¹⁰

Atrial Septal Defect

An **atrial septal defect (ASD)** is an abnormal communication between the atria (Fig. 34.6, A and B). Isolated ASD occurs in 5% to 10% of all congenital cardiac defects. The three major types are (1) an ostium primum defect, an opening found low in the septum that may be associated with AV valve abnormalities, especially mitral

insufficiency; (2) an ostium secundum defect, an opening in the center of the septum (this is the most common type of atrial defect); and (3) a sinus venosus defect, an opening that occurs high up in the atrial septum near the superior vena cava and RA junction. This defect is often associated with partial anomalous pulmonary venous connection.

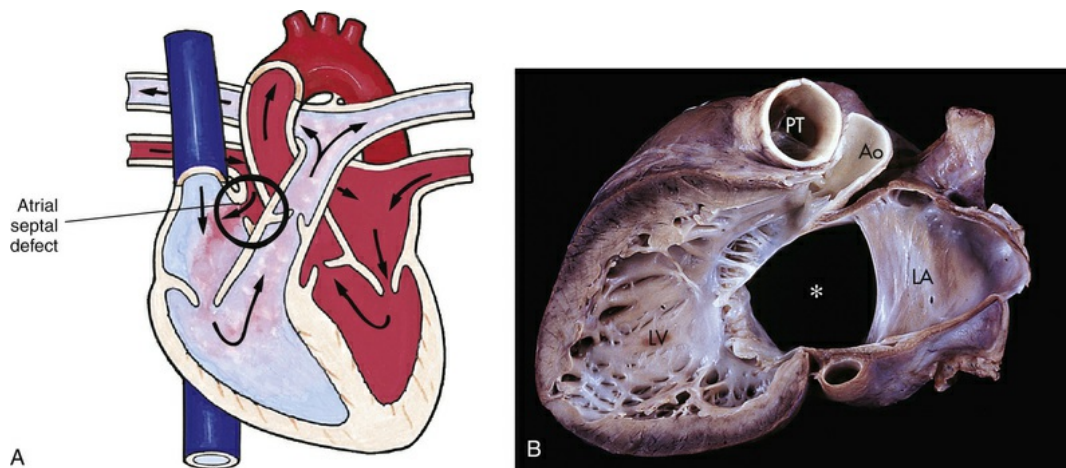

FIGURE 34.6 Atrial Septal Defect (ASD). A, Abnormal opening between the atria causing blood from the higher-pressure left atrium to flow into the lower-pressure right atrium. B, Complete ASD (*asterisk*) form in children. Ao, Aorta; LA, left atrium; LV, left ventricle; PT, pulmonary artery trunk. (A from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby; B from Damjanov I, Linder J, editors: *Anderson's Pathology*, ed 10, St Louis, 1996, Mosby.)

◆Pathophysiology.

Although the pressure difference between the two atria is minimal, the ASD allows blood to be shunted from left to right because of the slightly higher pressure of the left atrial chamber and lower PVR as compared with SVR. Right atrial and ventricular enlargement develops as a result of left-to-right shunting. Children with ASD are generally asymptomatic and rarely display signs of pulmonary overcirculation. Moderate to large ASDs allow an increase in pulmonary blood flow and, over time, pulmonary vascular changes can occur that may, although rarely, result in pulmonary hypertension.

◀Clinical Manifestations.

Because most children with ASD are asymptomatic, diagnosis usually is made during a routine physical examination by the auscultation of a crescendo-decrescendo systolic ejection murmur that reflects increased blood flow through the pulmonary valve. The location of the murmur is between the second and third intercostal spaces along the left sternal border. A wide fixed splitting of the second heart sound is also characteristic of ASD, reflecting volume overload to the RV, causing prolonged ejection time and delay of pulmonic valve closure.

◀Evaluation and Treatment.

In most cases an echocardiogram is sufficient to confirm the diagnosis of an ASD. A chest radiograph may reveal cardiomegaly and increased pulmonary vascular markings in an asymptomatic child. An ECG may demonstrate right-axis deviation and diastolic overload of the RV manifested as right ventricular hypertrophy.²

ASDs are generally closed before school age. If left unrepaired, continued left-to-right shunting through the ASD may result in pulmonary hypertension and right ventricular hypertrophy, placing the child at risk for the development of HF, atrial dysrhythmias, or embolic events. Surgical closure involves a pericardial patch or suture closure of the defect, depending on the size of the opening. Repair can be done through a sternotomy or right anterior thoracotomy approach with the use of cardiopulmonary bypass. Some centers perform minimally invasive techniques for ASD repair in adults and children. Sinus venosus defects require a slightly different approach that consists of a synthetic or pericardial patch to close the opening and baffle the anomalous right pulmonary venous drainage to the LA. Surgical mortality and morbidity are extremely low.⁷ Depending on the size and location of the ASD, a routinely used alternative to surgery is transcatheter closure performed in the catheterization laboratory using various septal occluder devices.⁹ In the United States, the Amplatzer (AGA Medical Corporation) and Helex (Gore Medical) septal occluders are the only FDA-approved devices for transcatheter

ASD closure. Advantages of transcatheter ASD closure include reduced pain, no surgical incision, and same day or overnight hospital stay. Potential complications include rare device embolization, which may require surgical retrieval, and rare device erosion.⁹

Ventricular Septal Defect

A **ventricular septal defect (VSD)** is an abnormal communication between the ventricles (Fig. 34.7, A). VSDs are the most common type of congenital heart lesion and account for 15% to 20% of all CHDs. The four types of VSDs are based on location in the septum. The perimembranous type, which occurs in the outflow tract of the LV immediately below the aortic valve, is the most common type, accounting for up to 80% of all VSDs that require treatment. Muscular VSDs, which occur low or anterior in the ventricular septum between the trabeculae (see Fig. 34.7, B) are most likely to close spontaneously and are difficult to close surgically because of their location low in the ventricular apex. Most muscular VSDs are hemodynamically insignificant and require no medical or surgical treatment. Supracristal VSDs (also called *outlet VSDs*) occur in the right ventricular outflow tract or infundibulum, below the pulmonary valve. AV canal or inlet VSDs occur posterior and inferior to the membranous septum, beneath the septal cusp of the tricuspid valve, and inferior to the papillary muscles of the conus.

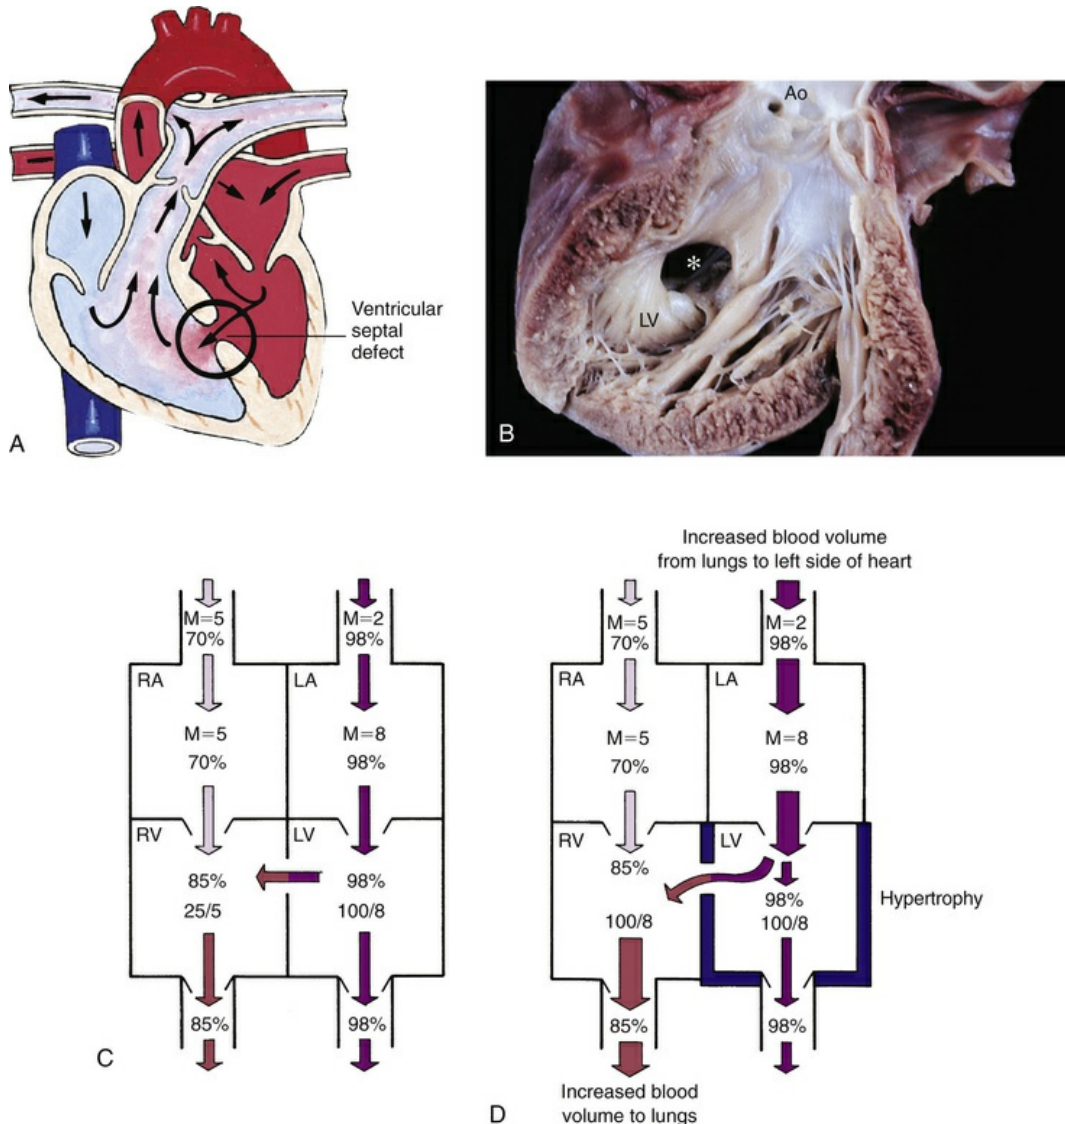

FIGURE 34.7 Ventricular Septal Defects (VSDs). A, VSD with left-to-right shunt. B, Muscular (*asterisk*) defect (opened left ventricle). C, Hemodynamics of a small VSD with left-to-right shunt. Mean (*M*) indicates mean of pressure; systolic/diastolic pressures are in mmHg; and percentages indicate oxygen saturation. D, Hemodynamics of a large VSD with left-to-right shunt. Like the shunting that occurs in preductal coarctation of the aorta, the shunting pictured here causes left ventricular overload and hypertrophy. *Ao*, Aorta; *LA*, left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle. (A from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby; B from Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

◆ Pathophysiology.

The direction of shunting in a child with a VSD is from the high-

pressure left side to the lower-pressure right side. The amount of shunting depends on the size of the defect and the degree of PVR. Small VSDs present increased resistance to shunting and limit blood flow through the defect; thus the degree of pulmonary vascular congestion and ventricular chamber enlargement is minimal (see Fig. 34.7, C).

After 1 to 2 weeks of life, when PVR has decreased, moderate-sized to large VSDs allow a large amount of shunting from left to right. The shunted blood flows directly out the RV outflow tract and into the PA rather than remain in the RV cavity (see Fig. 34.7, D). Therefore the main PA, LA, and LV all enlarge. LV hypertrophy occurs to effectively pump the additional volume. Pulmonary overcirculation accounts for the symptoms associated with a large VSD in most cases.

Over time the pulmonary bed also undergoes changes because of increased pulmonary blood flow caused by the left-to-right shunting. The smooth muscle layer in the arteriolar walls thickens, and proliferation of the intimal layer occurs. The effect of these changes is a decrease in the diameter of the pulmonary vessels, which increases the resistance to blood flow. If the PVR is severely increased, these changes eventually become irreversible, and PVR continues to rise. In some cases it exceeds SVR, causing the shunt through the VSD to reverse direction. Deoxygenated blood now flows into the systemic circulation, and cyanosis occurs, a phenomenon known as *Eisenmenger syndrome*.

◆Clinical Manifestations.

Clinical manifestations in children with VSDs depend on the age of the child, size of the defect, and level of PVR. Newborns with small VSDs are relatively asymptomatic. Initially no murmur is present because the newborn's high PVR causes equalization of the pressures between both ventricles. Once PVR has dropped, left-to-right shunting occurs, creating a murmur. Infants with large VSDs display symptoms of HF and poor weight gain. Adults who develop pulmonary hypertension as a result of unrepaired VSD will be cyanotic and have clubbing.

On physical examination a loud, harsh, holosystolic murmur and systolic thrill can be detected at the left lower sternal border. The intensity of the murmur reflects the pressure gradient across the VSD. An apical diastolic rumble may be present with a moderate to large defect, reflecting increased flow across the mitral valve.

◆Evaluation and Treatment.

ECG and chest radiographs reflect the amount of shunting through the defect. The ECG of an individual with a small VSD may be normal, whereas the ECG of an individual with a large VSD may reveal biventricular hypertrophy and LA enlargement. Chest roentgenographic findings are significant for cardiomegaly and increased pulmonary vascular markings; again, the severity is directly related to the magnitude of shunting. An echocardiogram identifies the position, size, direction of shunting, and dimensions of the LA, LV, and RV chambers. It also can provide an estimate of PA and RV pressures. Cardiac catheterization may be performed to determine hemodynamics and, in some instances, the location of other defects and additional VSDs.

Many VSDs spontaneously close during the first year of life.² Infants with symptoms of HF and poor weight gain despite medical management should have their VSD corrected as soon as possible. Left-to-right shunting with a pulmonary flow/systemic flow (Q_p/Q_s) ratio of greater than 2:1 or evidence of elevated PVR are indications for closure. Closure of the VSD at this time is to prevent the development of pulmonary hypertension.

Placement of a PA band to decrease the amount of pulmonary blood flow was initially used as a palliative procedure but is now rarely used unless the presence of an additional lesion makes complete repair difficult. Patch closure, using a synthetic material or pericardium, is accomplished through a sternotomy and with the use of cardiopulmonary bypass. A transatrial approach is preferable to a right ventriculotomy because of the increased incidence of conduction disturbances and impaired RV function associated with ventriculotomy. Contraindications for VSD closure include evidence

of pulmonary hypertension or Eisenmenger syndrome.^{2,7} Septal occluder devices for perimembranous VSD closure (performed in the cardiac catheterization laboratory) are not currently available in the United States but are under clinical evaluation in Europe.⁹ However, transcatheter muscular VSD devices are currently available for use depending on size and location of the defect.⁹

Atrioventricular Canal Defect

An **atrioventricular canal (AVC) defect** results from nonfusion of the endocardial cushions during fetal life, yielding abnormalities in both the atrial and ventricular septa and the AV valves (Fig. 34.8). This defect accounts for as many as 2% of all CHD, and approximately 70% of complete AVC defects occur in children with trisomy 21 (also referred to as *Down syndrome*).⁷ The three types of AVC defects are based on the cardiac components involved. **Complete AVC (CAVC) defects** consist of an inlet VSD, a primum type of ASD, and defects in both the mitral and tricuspid valves. **Partial AVC (PAVC) defects** consist of a primum type of ASD and a cleft in the septal or anterior leaflet of the mitral valve. **Transitional AVC (TAVC) defects** involve partial fusion of the endocardial cushions, resulting in variable AV valve abnormalities.⁷

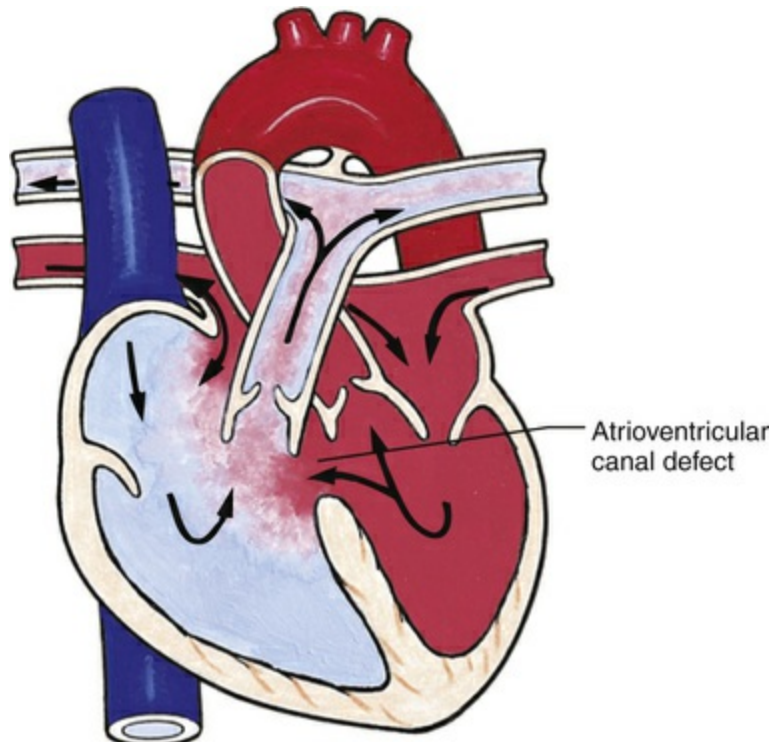

FIGURE 34.8 Atrioventricular Canal Defect. (From Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby.)

◆Pathophysiology.

Hemodynamic abnormalities seen in AVC defects depend on the components of the lesion and the level of PVR. Shunting is minimal during the neonatal period when PVR is high. However, once PVR drops, left-to-right shunting occurs through the septal defects, resulting in increased pulmonary blood flow and HF.

PAVC defects mimic the hemodynamics of secundum ASD in which the left-to-right shunting through the primum ASD causes RA and RV dilation and increased pulmonary blood flow. The mitral regurgitation that occurs, caused by the cleft mitral valve, is usually hemodynamically insignificant.

CAVC defects reflect the hemodynamics of an ASD and a VSD, resulting in biatrial and biventricular enlargement. RA and RV volume overload occurs because of shunting through the primum ASD and tricuspid regurgitation. Likewise, LA and LV volume overload occurs because of shunting through the VSD, increased

pulmonary venous return, and mitral regurgitation.

◆Clinical Manifestations.

Children with PAVC defects are generally asymptomatic. Findings on physical examination are similar to those of secundum ASD with the addition of a holosystolic, regurgitant murmur of mitral regurgitation at the apex. At 4 to 12 weeks of age, when PVR drops, children with CAVC defects usually begin to show symptoms of HF. Physical findings are similar to those found in individuals with VSDs with the addition of a holosystolic murmur radiating to the back and apex, reflecting mitral regurgitation. A mid-diastolic rumble at the left lower sternal border or apex reflects relative stenosis of the mitral or tricuspid valve from increased flow. Infants with CAVC may have signs of HF and frequent respiratory tract infections.

◆Evaluation and Treatment.

The ECG generally demonstrates a superior left-axis deviation (-90 to -180 degrees), first-degree AV block, and RV hypertrophy or right bundle branch block. The ECG of CAVC defects also may show LV hypertrophy. Chest radiograph shows cardiomegaly, increased pulmonary vascular markings, and a prominent main PA. Echocardiography allows visualization of the components of the defect, including continuity between the AV valves, their sizes, and chordal attachments. Cardiac catheterization is rarely indicated but may be performed to evaluate the reversibility of pulmonary vascular disease. Timing of surgical repair depends on the severity of symptoms, degree of shunting, and level of PVR. The trend is to perform complete repair between 3 and 6 months after birth to avoid the development of pulmonary vascular changes. Surgical repair is performed through a sternotomy, implementing a one- or two-patch repair to close the septal defects and repair the involved AV valves. Mortality is low unless the child is a newborn, has severe AV valve incompetence, or has univentricular anatomy (unbalanced AV canal).¹¹ Postoperative complications include heart block, dysrhythmias, or mitral regurgitation requiring further surgical

intervention or valve replacement.^{7,11}

Defects Decreasing Pulmonary Blood Flow

Defects decreasing pulmonary blood flow involve obstruction to pulmonary blood flow and septal communications. Because of RV outflow tract obstruction, right-sided pressures exceed left-sided pressures, resulting in right-to-left shunting. Children with these defects have hypoxemia and cyanosis.

Tetralogy of Fallot

Tetralogy of Fallot (TOF) consists of four defects: a large VSD that is high in the septum, an overriding aorta that straddles the VSD, pulmonary stenosis (PS), and RV hypertrophy ([Fig. 34.9, A](#)). It is the most common cyanotic congenital heart defect and accounts for 5% to 10% of all defects.²

FIGURE 34.9 Tetralogy of Fallot. A, Anatomic defects in tetralogy of Fallot. B, Hemodynamics of tetralogy of Fallot with right-to-left shunt. Ao, Aorta; LA, left atrium; LV, left ventricle; PT, pulmonary artery trunk; RA, right atrium; RV, right ventricle. (A from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby.)

◆Pathophysiology.

The pathophysiology associated with TOF varies widely, depending primarily on the degree of pulmonary stenosis, the size of the VSD, and the pulmonary and systemic resistance to flow. Because the VSD is usually large, pressures are equal in the RV and LV. Therefore the major determinant of shunt direction through the VSD is the difference between PVR and SVR (see [Fig. 34.9, B](#)). Infants who have little or no right-to-left shunting are acyanotic and are known as *pink tets*. They may have a net left-to-right shunt similar to a large VSD. If PVR is higher than SVR, the shunt is from right to left. Because many factors can alter the balance between PVR and SVR, shunt direction is not necessarily constant.

Pulmonary stenosis decreases blood flow to the lungs and, consequently, the amount of oxygenated blood that returns to the left heart. If blood also shunts from right to left through the VSD, deoxygenated blood mixes with the oxygenated blood returning from the lungs. The result is low oxygen saturation (hypoxemia) in the systemic circulation. The body attempts to compensate for chronic hypoxemia by producing more red blood cells (thereby causing polycythemia) and by increasing blood flow to the lungs through collateral bronchial vessels in long-standing cases.

◆Clinical Manifestations.

In cases with decreased pulmonary flow through the right ventricular outflow tract as long as the ductus arteriosus remains open, the newborn's pulmonary blood flow may be adequate. As the ductus closes, however, cyanosis becomes apparent. Chronic hypoxemia causes clubbing of the fingers and toes (see [Chapter 36](#)).

A rare manifestation of TOF is the sudden onset of dyspnea, cyanosis, and restlessness, sometimes called a *hypercyanotic spell* or a *tet spell*, that generally occurs with crying and exertion. The cause of these episodes is unknown, but it is theorized that the RV outflow tract goes into spasm or the systemic resistance drops suddenly. In either case the relative or actual increase in PVR increases the right-to-left shunt and the cyanosis. Hypercyanotic spells are often the event

that initiates surgical intervention. If the spells are frequent or do not terminate spontaneously, they are considered a medical-surgical emergency.⁷

Infants with TOF may have difficulty with feeding because the exertion required increases hypoxia, and therefore they experience slow growth and FTT. However, most infants with TOF grow normally.

Squatting is a spontaneous compensatory mechanism used by older children with unrepaired TOF to alleviate hypercyanotic spells. Squatting and its variants increase SVR while decreasing venous return to the heart from the inferior vena cava. The decrease of systemic venous return makes relatively more oxygenated blood available to the body. The increase of systemic resistance also reverses the shunt through the VSD to a left-to-right shunt, which has the effect of increasing pulmonary blood flow. Through both of these mechanisms, squatting temporarily decreases the degree of hypoxemia. Squatting is rarely witnessed because most cases are surgically palliated in early infancy.

The typical heart murmur of TOF is a pulmonary systolic ejection murmur caused by the obstruction in the outflow tract, which creates turbulence during systole. More obstruction to flow (e.g., smaller orifice for the flow of blood) produces a louder murmur. This explains why the murmur often disappears during a hypoxic spell, when obstruction increases and pulmonary blood flow decreases to a minimal amount. The second heart sound seems to be single, but in fact it is not. The pulmonary component is very soft and delayed and usually is not heard, although it is present. The enlarged RV may cause the left side of the chest to be more prominent, and a “heave” also may be palpated.

◆Evaluation and Treatment.

The ECG indicates RV hypertrophy. Chest radiographic examination shows that the heart is shaped like a boot (upturned apex because of a small main PA) and that pulmonary vascular markings are decreased. Echocardiograms and angiograms enable the clinician to see the size

and position of the VSD, the stenotic pulmonary infundibulum or valve, the smaller-than-normal PA, and the overriding aorta. Diagnostic cardiac catheterization is rarely indicated, except to define unusual coronary artery anatomy crossing the RV outflow tract that may complicate surgical palliation.

The current practice is to repair acyanotic TOF before 1 year of age, and cyanotic TOF in early infancy. Staged procedures include the placement of a shunt from the subclavian or innominate artery to pulmonary artery known as the *modified Blalock-Taussig shunt* (using a prosthetic graft) or *classic Blalock-Taussig shunt* (using the native subclavian artery) to increase pulmonary blood flow. These shunts may cause PA distortion but may be necessary in a very small symptomatic child. Corrective repair involves patch closure of the VSD, resection of infundibular or valvular stenosis, and patch augmentation of the RV outflow tract that can extend across the pulmonary valve annulus (transannular patch). The procedure is done through a sternotomy incision while the child is on cardiopulmonary bypass. Operative mortality is low, and potential complications include dysrhythmias, low cardiac output because of RV dysfunction, and occasionally heart block. Many children require further surgery or transcatheter intervention to relieve recurrent pulmonary artery stenosis or treat severe pulmonary insufficiency.¹² More recently, a less invasive treatment for severe pulmonary insufficiency, depending on the size of the pulmonary outflow tract, is transcatheter pulmonary valve replacement performed in the catheterization laboratory.⁹

Tricuspid Atresia

Tricuspid atresia consists of an imperforate tricuspid valve, resulting in no communication between the RA and RV (Fig. 34.10). This defect accounts for 1% to 3% of congenital heart defects and is the third most common cyanotic heart defect. Tricuspid atresia is a combination of defects, including the imperforate tricuspid valve as well as a septal defect, hypoplastic or absent RV, enlarged mitral valve and LV, and varying degrees of pulmonic stenosis. Tricuspid atresia also may be associated with transposition of the great vessels. The most common

type of tricuspid atresia involves a hypoplastic RA with decreased pulmonary blood flow, ASD, VSD, and normally related great vessels.²

FIGURE 34.10 Tricuspid Atresia. A, No communication from the right atrium to the right ventricle. B, Tricuspid atresia with absent right atrioventricular connection with a hypoplastic right ventricle (four-chamber view). LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (A from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby; B from Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

◆Pathophysiology.

Systemic blood returns through the superior and inferior venae cavae to the RA. Venous return flows through the ASD into the LA, mixing with blood returning from the pulmonary circulation. The blood then enters the LV. Most of this blood passes into the systemic circulation through the aorta, but varying amounts flow through the VSD into the hypoplastic RV and to the lungs. Pulmonary circulation depends on the presence of a VSD and the presence of a functioning RV of reasonable capacity. If the RV is absent, the pulmonary valve is usually imperforate as well. If this is the case, a PDA is necessary to ensure that some blood flows into the pulmonary circulation.⁷

Pulmonary circulation also depends on the relationship between PVR and SVR. As long as PVR is lower than SVR, blood flows through

the VSD from left to right, feeding the pulmonary circulation. If PVR rises above SVR, pulmonary blood flow will be significantly diminished.

◆Clinical Manifestations.

Some degree of central cyanosis is common in tricuspid atresia, depending on the amount of pulmonary blood flow. Growth failure also is common. Children experience exertional dyspnea, tachypnea, and hypoxemia. Long-term effects of hypoxia are polycythemia and clubbing. These children also may display hypercyanotic spells. Hepatomegaly may be present if the ASD is restrictive or CHF occurs as a result of increased pulmonary blood flow.

The murmur heard with tricuspid atresia may have several components. The VSD causes a systolic regurgitant murmur; the murmur is likely to be softer and shorter as the VSD enlarges. A narrowly split second heart sound caused by decreased pulmonary blood flow may be present, or the second heart sound may be single if there is pulmonary atresia.

◆Evaluation and Treatment.

Chest radiographic examination shows a heart size that is normal or slightly increased. ECG usually shows RA, LA, and LV hypertrophy with left-axis deviation. Echocardiography depicts left-to-right shunting at the ventricular level, inability of blood flow to enter the RV from the absent tricuspid opening, and the presence of associated defects.

Newborns with ductal dependent pulmonary blood flow are immediately given prostaglandins to maintain adequate pulmonary blood flow. Treatment is accomplished in stages. Initial surgical intervention involves the placement of a Blalock-Taussig shunt (or its modification). If the ASD is restrictive, a Rashkind procedure (balloon atrial septostomy) may be performed during catheterization or under echocardiographic guidance at the bedside. Children who experience increased pulmonary blood flow may require the placement of a PA band.

Further surgery is undertaken between 4 and 8 months of age, depending on the child's growth and degree of cyanosis. The second-stage procedure is the bidirectional Glenn shunt, in which the SVC is anastomosed to the PA. At that time, the PA may be ligated and the Blalock-Taussig shunt is removed. The final separation of the pulmonary circulation to the systemic circulation is the modified Fontan procedure. In this stage, the inferior vena cava blood flow is routed to the PA using an intra- or extracardiac tube graft or baffle. The procedure is typically performed between 2 and 4 years of age. Surgical outcomes are best in the child with normal ventricular function, minimal systemic valve regurgitation, and low PVR. For children with borderline PVR, a fenestration (or opening) can be created in the baffle or graft to relieve high systemic pulmonary venous pressures if needed. Postoperative complications that increase hospital stay include pleural effusions, elevated pulmonary vascular resistance, and ventricular dysfunction.^{12,13} Exercise tolerance is limited in many children following the Fontan procedure, but their general health is usually good.

Obstructive Defects

Obstructive defects are conditions in which anatomic stenosis (narrowing) in either the right or the left outflow tract obstructs blood flow and results in a pressure load on the affected ventricle. The gradient reflects the severity of the narrowing; the higher the gradient, the more obstruction to flow and the more afterload on the ventricle. Valvular stenosis refers to stenosis of the valve itself; subvalvular indicates that the obstruction is below the valve or in the ventricular outflow tract; and supra-valvular is the area above the valve in the great artery. The obstructive defects include coarctation of the aorta, aortic stenosis, and pulmonary stenosis. Symptoms associated with the defect depend on the site and severity of stenosis.

Coarctation of the Aorta

Coarctation of the aorta (COA) is a narrowing of the lumen of the

aorta that impedes blood flow. This defect accounts for 8% to 10% of all congenital heart defects. COA is almost always in a juxtaductal position, although it can occur anywhere between the origin of the aortic arch and the bifurcation of the aorta in the lower abdomen. About 50% to 80% of individuals with COA have a bicuspid aortic valve and also may have an associated VSD (Fig. 34.11).²

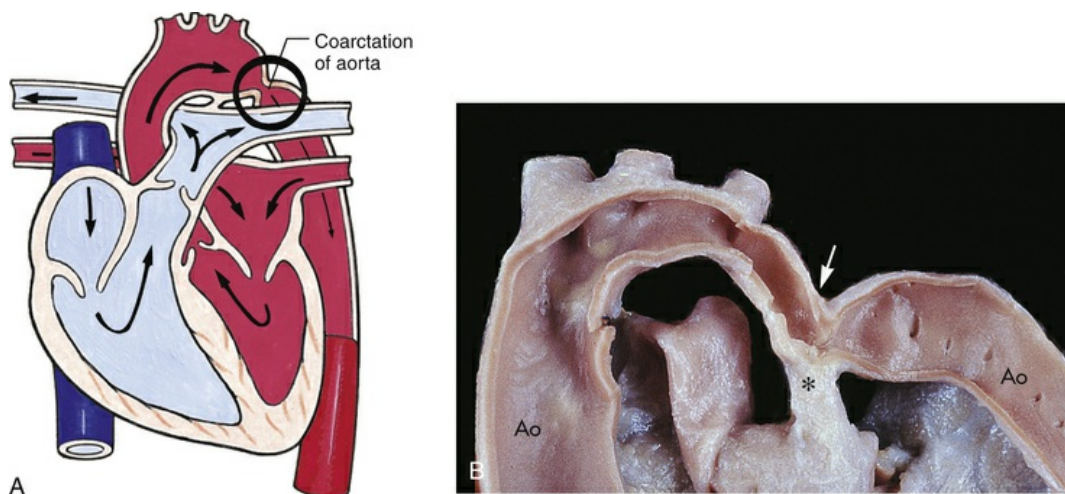

FIGURE 34.11 Postductal Coarctation of the Aorta. A, Postductal coarctation occurs distal to (“after”) the insertion of the closed ductus arteriosus into the aortic arch. The coarctation consists of a flap of tissue that protrudes from the tunica media of the aortic wall. B, Coarctation of the aorta with typical indentation of the aortic wall (*arrow*) opposite the ductal arterial ligament (*asterisk*). Ao, Aorta. (A from Hockenberry MJ, Wilson D: *Wong’s essentials of pediatric nursing*, ed 10, St Louis, 2015, Mosby; B from Damjanov I, Linder J, editors: *Anderson’s pathology*, ed 10, St Louis, 1996, Mosby.)

◆Pathophysiology.

COA may develop because of abnormal contractile ductal tissue that constricts at the time of ductal closure. COA causes a condition in which there are higher pressures proximal to the site of stenosis and lower pressures distal to the site. In the neonate with a preductal COA, the RV acts as a systemic pump, sending unoxygenated blood through the ductus (right to left) into the descending aorta below the coarctation. As the PVR drops, blood will start to shunt left to right through the ductus, and symptoms of HF will appear (Fig. 34.12). In

postductal COA the RV cannot pump enough blood through the ductus to the descending aorta because of pressure caused by the narrowed aorta. Systolic pressure increases in the ascending aorta and LV and decreases in the descending aorta beyond the COA (Fig. 34.13). In neonates with severe COA, adequate systemic blood flow may depend on the presence of a PDA to supply blood flow distal to the obstruction. In long-standing COA, collateral circulation, which involves small arteries arising from the subclavian arteries, joins intercostal arteries that flow into the descending aorta. These collateral vessels bypass the COA and supply blood to the lower extremities. The direction of shunting through the ductus, if present, depends on the pressure difference between the PA and aorta and the location of the ductus. When blood pressure is greater in the aorta than in the PA, blood flow through the ductus will be left to right toward the lungs, resulting in increased pulmonary venous return to the left side of the heart. This may place an additional strain on the LA and LV, leading to increased volume and workload. With time, prolonged LV hypertrophy will cause HF symptoms because of increased afterload and obstruction to flow caused by the coarctation.

FIGURE 34.12 Hemodynamics of Preductal Coarctation of the Aorta with a Patent Ductus Arteriosus. The left-to-right shunt through the ductus arteriosus increases the volume of blood in the pulmonary circulation. Afterload (*small black arrows*) is increased in the left heart by increased return from the lungs and decreased ventricular outflow caused by the coarctation. The outcome is heart failure. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

FIGURE 34.13 Hemodynamics of Postductal Coarctation of the Aorta. Blood pressure increases in the ascending aorta and subclavian artery and decreases in the descending aorta. These pressure changes eventually occur in the parts of the systemic circulation served by arteries that branch from the aorta before and after the coarctation.

◆Clinical Manifestations.

Clinical manifestations vary depending on the severity of the coarctation and age of presentation. In newborns the onset of symptoms depends on the timing of ductal closure after a fall in PVR, the location of the COA, and the presence of associated defects. The newborn usually presents with HF symptoms. Once the ductus closes, these infants will deteriorate rapidly from the development of hypotension, acidosis, and shock. Older children may not be diagnosed until hypertension is noted. Hypertension is noted in the upper extremities with decreased or absent pulses in the lower extremities. Children may have cool, mottled skin and occasionally leg cramps during exercise. A systolic ejection murmur, heard best at the left interscapular area, is caused by rapid blood flow through the

narrowed area.

◆ Evaluation and Treatment.

A chest radiograph shows an enlarged heart with congested lung fields in newborns. Rib notching between the fourth and eighth ribs may be seen in children older than 5 years, reflecting erosion of the ribs as a result of enlarged collateral vessels from the ascending aorta to the descending aorta, bypassing the coarctation. An ECG may be normal or reveal LV hypertrophy. An echocardiogram will confirm the diagnosis and rule out other intracardiac defects. Cardiac catheterization and/or magnetic resonance imaging (MRI) is performed only if the echocardiogram is inconclusive.

The first step in treatment of the symptomatic infant is stabilization, which may require prostaglandin administration, mechanical ventilation, and inotropic support to maintain adequate cardiac output. Once this is achieved, surgical intervention is indicated. Surgical repair consists of a resection with end-to-end anastomosis of the arch segments, arch augmentation, or subclavian flap aortoplasty technique to enlarge the constricted area. Depending on the arch morphology (hypoplastic transverse arch), a modification of this procedure enlarges the aorta beyond the area of constriction.¹² Cardiopulmonary bypass may not be required in isolated COA, and approach can be through a left thoracotomy incision. However, COA repair may be a part of a more complex operation, and sternotomy incision with cardiopulmonary bypass may be required.

Operative mortality is relatively low. Postoperative complications include recoarctation and paradoxical postoperative hypertension. Residual permanent hypertension requiring continued medical therapy is related to age at repair; therefore surgical intervention is recommended at the time of diagnosis. Percutaneous balloon dilation angioplasty with or without stent implantation may be a less invasive option for treating native COA (greater than 6 months of age) or for reducing significant residual COA in most children. However, aortic aneurysm formation and blood vessel injury from arterial access have been noted.^{9,12,14}

Aortic Stenosis

Aortic stenosis (AS) is a narrowing of the aortic outflow tract (Fig. 34.14). The lesion accounts for up to 10% of all congenital heart defects.² Valvular stenosis is caused by malformation or fusion of the cusps. It is the most common type of AS, tends to be progressive, and, in rare cases, can lead to sudden death as a result of low cardiac output or myocardial ischemia. For children with mild AS, no exercise restrictions may be needed. For those with moderate AS, some exercise limitations may be advised. Severe AS is an indication for limiting exercise until the repair is accomplished. Less common forms of AS are subvalvular stenosis caused by a constricting fibrous ring below the valve and supra-ventricular stenosis that occurs above the valve.⁷

FIGURE 34.14 Aortic Stenosis. Narrowing of the aortic valve causing resistance to blood flow in the left ventricle, decreased cardiac output, left ventricular hypertrophy, and pulmonary congestion. (From Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby.)

◆Pathophysiology.

Obstruction to blood flowing out of the aorta causes an increased workload on the LV, resulting in left ventricle hypertrophy (LVH). LV failure may develop, leading to an increase in LA pressure and a backup in the system, eventually resulting in pulmonary vascular congestion and pulmonary arterial hypertension. LVH can decrease coronary artery perfusion, resulting in myocardial ischemia, and it can alter the LV papillary muscle, causing mitral insufficiency.

◆Clinical Manifestations.

Most children with mild to moderate AS are asymptomatic. Signs of exercise intolerance may not appear until preadolescence. Syncopal episodes, epigastric pain, and exertional chest pain may occur in more severe forms of AS. A systolic ejection murmur at the right upper sternal border that transmits to the neck and left lower sternal border is produced by blood flow through the stenotic area. An ejection click may be heard with valvular AS. Severe forms of AS, especially critical AS in the newborn, result in shock and require immediate intervention.

◆Evaluation and Treatment.

Diagnosis may be made based on previous medical history and physical findings. Chest radiographic examination may reveal a dilated ascending aorta or LV enlargement. Increased pulmonary vascular markings may be seen in severe forms. In mild cases the ECG is normal. LVH with strain pattern (features of LVH with inverted T waves in the lateral precordial leads) may be seen in severe forms. An echocardiogram may reveal a thickened and poorly functioning LV with abnormal structure, opening and closure of the aortic valve. Diagnostic cardiac catheterization is rarely indicated, but may be performed for intervention, such as balloon aortic valvuloplasty.

The presence of ST-segment changes on ECG, manifestation of severe HF, and evidence of discrete severe stenosis at the aortic outflow tract are indications for intervention. Balloon aortic valvuloplasty is a palliative procedure performed for valvular AS;

however, it is associated with complications, including aortic insufficiency and dysrhythmia.⁹ Children undergoing this procedure almost always require surgical intervention at some time to relieve recurrent narrowing or worsening regurgitation. Surgical treatment for valvular AS depends on the severity of the stenosis, previous interventions, and age of the child. Aortic valve commissurotomy or valvotomy may be performed as an initial procedure for severe valvular AS. Aortic valve replacement (Ross procedure or mechanical valve replacement) may be required if the valve is severely dysplastic.

Subvalvular AS and supra-ventricular AS require surgical repair involving excision of the area causing the constriction. For subvalvular AS involving a small LV outflow tract and aortic annulus, a Konno procedure may be required to enlarge the LV outflow tract and aortic annulus with a patch.^{12,15} Severe supra-ventricular AS may require balloon angioplasty and stent placement or surgical enlargement with coronary reimplantation.

Pulmonary Stenosis

Pulmonary stenosis (PS) is the narrowing of the pulmonary outflow tract. This may be in the form of abnormal thickening of the valve leaflets or narrowing of the arterial (supra-ventricular) or ventricular (subvalvular) side of the valve ([Fig. 34.15, A](#)). **Pulmonary atresia** is the severe form of PS and involves complete fusion of the commissures and narrowing of the main PA, allowing no blood flow out of the RV to the PA. Pulmonary blood flow to the lungs is now dependent on a PDA or from extra blood vessels (multiple aortopulmonary collaterals) that arise from the aorta and connect to the pulmonary arteries with decompression of the RV through an ASD/PFO or, in rare cases, a VSD for survival. PS accounts for 8% to 12% of all congenital heart defects.²

FIGURE 34.15 Pulmonary Stenosis. **A**, Obstruction of right ventricular outflow caused by pulmonic stenosis. Pressure on the ventricular side of the pulmonic semilunar valve (pulmonary valve) is much greater than that on the pulmonary arterial side. This difference disrupts the normal pressure gradient across the valve. Pulmonary stenosis increases ventricular afterload by decreasing blood flow through the valve, which causes ventricular hypertrophy. **B**, The backup of ventricular afterload into the right atrium reopens the foramen ovale. Venous blood then flows from the area of higher pressure (the right atrium) to the area of lower pressure (the left atrium), causing a right-to-left shunt. Cyanosis occurs if enough venous blood shunts from right to left to reduce oxygen saturation in the systemic circulation by 3% to 5%. LA, Left atrium; RA, right atrium. (A from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby.)

◆Pathophysiology.

PS creates resistance to blood flow from the RV to the PA. The narrowed orifice (valve) produces increased resistance (afterload) to ejection. In order for the RV to maintain adequate cardiac output, the myocardium hypertrophies. If the RV outflow tract obstruction is severe, blood may back up into the RA, causing dilation. This may result in reopening of the foramen ovale with resultant unoxygenated blood shunting to the LA, causing cyanosis (see [Fig. 34.15, B](#)).

◆Clinical Manifestations.

Clinical manifestations depend on the severity of PS. A systolic ejection murmur at the left upper sternal border reflects obstruction to flow through the narrowed pulmonary valve. In some children a

variable systolic ejection click is present with valvular stenosis at the upper left sternal border. A thrill also may be palpated at the upper left sternal border. Children with moderate PS may have exertional dyspnea and fatigability because of the inability of the body to increase pulmonary blood flow to meet demands for increased cardiac output. Severe PS will produce cyanosis and HF.

◆Evaluation and Treatment.

A chest radiograph shows a normal-size heart with a prominent main PA caused by poststenotic dilation. An ECG is usually normal but may reveal right-axis deviation and RV hypertrophy with moderate PS. Echocardiography confirms the diagnosis and detects associated defects. Cardiac catheterization, if performed for interventional purposes, further demonstrates PA anatomy.

Mild to moderate PS will not likely require intervention but should be observed closely. Most mild PS is not progressive. Treatment is indicated when a significant pressure gradient is detected across the RV outflow tract.

Critical (severe) PS must be addressed immediately. The treatment of choice is balloon angioplasty. This procedure is considered highly effective in decreasing the pressure gradient across the pulmonic valve and is noted to have few associated complications.⁹ Surgical correction involves a pulmonary valvotomy incising the fused commissures.² Both valvotomy and balloon angioplasty may result in some pulmonary valve incompetence, and long-term follow-up may reveal the need for pulmonary valve replacement. Treatment for PA depends on the size of the native/branch pulmonary arteries and associated cardiac defects. Initial treatment may consist of an aortopulmonary shunt to supply stable blood flow to the lungs and later a second procedure to connect the RV to the PA.

Mixing Defects

Many complex defects are classified as mixing defects because of their dependence on the mixing of pulmonary and systemic circulations for survival during the postnatal period. This mixing results in

desaturated systemic blood flow and cyanosis. Pulmonary congestion occurs because of preferential pulmonary blood flow because PVR is normally lower than SVR. Clinically each defect has varying degrees of cyanosis and HF depending on the various components of the lesion.

Transposition of the Great Arteries

Transposition of the great arteries (TGA) refers to a condition in which the aorta arises from the RV and the PA from the LV (Fig. 34.16, A). The result is two separate, parallel circuits in which unoxygenated blood circulates continuously through the systemic circulation and oxygenated blood circulates repeatedly through the pulmonary circulation. This condition is incompatible with extrauterine life unless a communication exists between the two circuits to provide the necessary oxygen to the body. Communication is accomplished by mixing of pulmonary and systemic circulations through a PDA, ASD, or VSD (see Fig. 34.16, B). Dextro-transposition of the great arteries (D-TGA) accounts for 5% to 7% of all congenital heart defects; *dextro* refers to the aorta remaining to the right of the PA.^{2,7}

FIGURE 34.16 Hemodynamics in Transposition of the Great Arteries (TGA). A, Complete transposition of the great vessels with an intact interventricular septum. The aorta arises from the right ventricle and the pulmonary artery from the left. B, Oxygen saturation in the two parallel circuits. Ao, Aorta; ASD, atrial septal defect; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PDA, patent ductus arteriosus; RA, right atrium; RV, right ventricle; VSD, ventricular septal defect. (A from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing*, ed 10,

Two factors allow newborns with complete transposition to survive long enough to be treated. First, blood from the two closed systems can mix through the ductus arteriosus for a short time after birth if PVR remains high. Some mixing also may occur through the foramen ovale. If the child has a VSD, mixing occurs through that opening as well.

◆Pathophysiology.

It is not known precisely which embryologic events lead to transposition, but researchers have proposed that the fault lies in the development of conal tissue in the fibrous skeleton of the heart.¹ The **conus** is a segment of muscle that separates the AV (tricuspid and mitral) valves from the semilunar (aortic and pulmonic) valves. (The fibrous skeleton and heart valves are described and illustrated in [Chapter 32](#); see [Fig. 32.4](#).) The interventricular septum is intact in about 60% to 70% of cases of transposition; a VSD is present in the remaining 30% to 40%.^{2,7} The following discussion is limited to the pathophysiology of transposition with an intact interventricular septum.

◆Clinical Manifestations.

The degree of mixing permitted by fetal structures determines the type and severity of clinical manifestations. Cyanosis may be mild shortly after birth and worsen during the first day because of functional closure of the ductus arteriosus. Low oxygen levels in the blood (hypoxemia) cause metabolic acidosis, tachycardia, and tachypnea. The presence of a PDA or large ASD allows for more mixing and results in only mild cyanosis, but the infant may develop HF.

The first heart sound is normal, and the second sound may be heard as a single sound even though both the aortic and pulmonic valves are functioning. The loud single S_2 may occur because transposition places the aortic valve closer to the chest wall than the pulmonic valve. No murmur is noted with transposition of the great arteries

with an intact ventricular septum.

◆Evaluation and Treatment.

On chest radiograph the heart has a characteristic shape—like an egg on its side—and pulmonary vascular markings are increased. The heart may be enlarged if the infant is a few weeks old and has a VSD. ECG findings reveal a right-axis deviation and some RV hypertrophy. Echocardiography confirms the diagnosis of transposition of the great arteries. Cardiac catheterization or bedside echocardiogram-guided balloon atrial septostomy may be needed for additional mixing in children with intact ventricular septum and severe hypoxemia.⁹

The most preferred type of surgical repair for D-TGA, performed in the first weeks of life, is the arterial switch procedure. The arterial switch involves transecting the great arteries and anastomosing the main pulmonary artery to the native proximal aorta and anastomosing the ascending AO to the native proximal PA. The coronary arteries are reimplanted with a *button* of tissue onto the new aortic outflow. Reimplantation of the coronary arteries is critical to survival, and they must be reattached without kinking or torsion. Potential complications include narrowing of the great artery anastomosis, neo-aortic valve regurgitation, and coronary artery insufficiency. Long-term results for the arterial switch operation are usually good.⁷

The Rastelli procedure is used in children with transposition, VSD, and severe PS. This procedure involves closing the VSD with a baffle by rerouting LV blood through the VSD to the aorta. The pulmonary valve is closed, and an RV-to-PA prosthetic or homograft valve conduit is placed. This procedure requires prosthetic conduit replacement as the child grows and is associated with ventricular failure and dysrhythmias in the postoperative period.⁷

Total Anomalous Pulmonary Venous Connection

Total anomalous pulmonary venous connection (TAPVC), or total anomalous pulmonary venous return, occurs when the pulmonary veins abnormally connect to the right side of the heart either directly

or through one or more systemic veins that drain into the RA (Fig. 34.17). An ASD also is generally present. This defect is extremely rare, accounting for only 1% of all congenital heart defects. The four types of TAPVC are based on the site of drainage. Supracardiac TAPVCs are the most common form (50%) and drain to the superior vena cava through the vertical or innominate vein. Cardiac TAPVCs (20%) drain directly into the RA or through the coronary sinus. Infracardiac TAPVCs (20%) traverse the diaphragm and drain into the portal or hepatic vein or the inferior vena cava. Mixed TAPVCs (10%) are a combination of the various types. Partial anomalous venous connection is a condition in which only one or two of the pulmonary veins, usually the right-sided veins, drain into the RA or one of its tributaries.²

FIGURE 34.17 Hemodynamics of Total Anomalous Pulmonary Venous Connection (TAPVC). In the supracardiac form of TAPVC represented here, the pulmonary veins enter the left anomalous vertical vein instead of the left atrium. From the left anomalous vertical vein, the mixed blood from the lungs flows into the superior vena cava through an innominate vein (literally, a “vein without a name”). Oxygen saturation within the four heart chambers, the pulmonary artery, and the aorta is the same. Blood pressure

in the right heart exceeds that in the left heart because the right heart is receiving blood from both the pulmonary and systemic circulatory systems. Abnormal vessels are shaded. (From Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing*, ed 10, St Louis, 2015, Mosby.)

◀Pathophysiology.

Physiologically TAPVC can be differentiated into two groups: nonobstructive and obstructive, depending on the absence or presence of obstruction to pulmonary venous drainage. The hemodynamics of the nonobstructive group involve the RA receiving the oxygenated blood that would normally flow into the LA. The amount of blood shunted into the LA vs. the volume entering the RV depends on the size of the ASD and compliance of the RV. Therefore if the ASD is restrictive and RV compliance approaches normal, more blood will enter the RV than the LA, resulting in RA and RV enlargement, as well as increased pulmonary blood flow. This causes increased pulmonary venous blood return and larger amounts of saturated blood in the RA. If the ASD is unrestrictive and the RV does not become thinner to increase compliance, the majority of mixed saturated blood is shunted from the higher-pressure RA to the LA.

The hemodynamics of obstructed TAPVC cause pulmonary venous hypertension because of resistance caused by the obstruction resulting in an elevation in pulmonary vascular and RV pressures. Pulmonary edema occurs from hydrostatic capillary pressure exceeding the osmotic pressure of the blood and eventually contributing to the development of HF. This group has a strong association with the infracardiac type of TAPVC and is a surgical emergency.

◀Clinical Manifestations.

The predominant clinical manifestation in infants with TAPVC is cyanosis caused by mixture of oxygenated and deoxygenated blood entering the systemic circulation. The degree of cyanosis is inversely related to the amount of pulmonary blood flow. Children with unobstructed TAPVC may be asymptomatic until PVR drops, at which time pulmonary blood flow will increase, resulting in signs of pulmonary overcirculation, particularly slow growth and frequent

pulmonary infections, in addition to mild cyanosis. Obstructed TAPVC results in cyanosis and rapid deterioration necessitating immediate surgical correction, or death will occur.

Physical examination may reveal a systolic murmur at the left upper sternal border and a mid-diastolic murmur at the left lower sternal border. A murmur may be absent in obstructed TAPVC. A characteristic quadruple rhythm, consisting of S_1 , widely split S_2 , and S_3 or S_4 , or a gallop rhythm also is present.

◆Evaluation and Treatment.

The ECG shows a right-axis deviation, RV hypertrophy, and occasionally RA hypertrophy. The chest radiograph of unobstructed TAPVC reveals cardiomegaly, increased pulmonary vascular markings, and a snowman or figure-eight appearance in the supracardiac type. A chest roentgenogram of obstructed TAPVC shows a normal-size heart and a ground-glass appearance of the lung fields, reflecting pulmonary venous congestion or edema. The echocardiogram reveals the abnormal pulmonary venous connections.

Surgical repair varies with the type of TAPVC and whether the defect is obstructed or unobstructed. Obstructed lesions are repaired at the time of diagnosis, whereas the unobstructed type generally is repaired during infancy. The procedure is performed while the patient is on cardiopulmonary bypass and involves anastomosis of the common pulmonary vein to the LA and closing the ASD, as in the supracardiac and infracardiac types. Repair of the supracardiac type involves baffling the pulmonary venous drainage to the LA. This repair has the highest success rate because of the low technical difficulty, whereas infracardiac repair is associated with a high mortality and morbidity. Potential complications include reobstruction at the anastomosis site; atrial dysrhythmias, including sick sinus syndrome; PA hypertension; and LV dysfunction.¹²

Truncus Arteriosus

Truncus arteriosus is the failure of the large embryonic artery, the

truncus arteriosus, to divide into the PA and the aorta. This results in a single vessel arising from both ventricles, providing blood flow to the pulmonary and systemic circulations (Fig. 34.18, A). This common trunk straddles the VSD (always present) and has a single valve with three or four leaflets, which may result in stenosis, regurgitation, or both. The incidence is 1% of all CHD and a right aortic arch is present 30% of the time. There are four types of truncus arteriosus. Type I is the most common and involves the main PA arising from the truncus and then dividing into the right and left PAs. Type II is less common and involves the PAs arising from the posterior aspect of the truncus. Type III is the least common and involves the PAs arising from the lateral aspect of the truncus. Type IV, also known as *pseudotruncus*, is now considered a severe form of TOF with the bronchial arteries arising from the descending aorta to supply the lungs.² Types 1 and II constitute 85% of cases, with types III and IV constituting the remaining 15%.

FIGURE 34.18 Truncus Arteriosus. A, Persistent truncus arteriosus. The truncus arteriosus fails to divide into the pulmonary artery and aorta, and the interventricular septum fails to close at the top. Blood from both ventricles mixes in the truncus arteriosus and then enters the pulmonary and systemic circuits. B, Alterations of hemodynamics and oxygen saturation by persistent truncus arteriosus. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (A from Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing*, ed 10, St Louis, 2015,

◆Pathophysiology.

Blood flow from the RV and LV is pumped into the main truncus, resulting in mixing of the pulmonary and systemic circulations (see Fig. 34.18, B). The differential flow out to either the pulmonary bed or the systemic circulation depends on the PVR and SVR. Generally, the PVR is less than the SVR, resulting in the majority of blood flow traveling to the lungs. This may be altered, however, because of PS, small pulmonary arteries, or increased PVR. Pulmonary vascular disease develops early with this defect because of increased pulmonary blood flow.

◆Clinical Manifestations.

Physical findings depend on the amount of pulmonary blood flow and the presence of other cardiac anomalies. If PS is present, a newborn will present with cyanosis, caused by already elevated PVR, but no HF. Conversely, if PS is not present, the newborn initially will have mild to moderate cyanosis that worsens with activity. Once PVR drops, the pulmonary bed will receive preferential flow and the infant will have signs of HF. A harsh systolic regurgitant murmur is usually present along the left sternal border as a result of the VSD, and a systolic click at the apex and left upper sternal border may be present, reflecting opening of the truncal valve. An apical rumble with or without a gallop rhythm also may be present because of increased pulmonary blood flow. If truncal valve insufficiency exists, an early diastolic, high-pitched decrescendo murmur may be present.

◆Evaluation and Treatment.

An ECG generally reveals biventricular hypertrophy and occasionally LA enlargement. A chest radiograph reveals cardiomegaly with biventricular and LA enlargement, as well as increased pulmonary vascular markings. When PS is present, the heart size is normal and the pulmonary vascular markings are decreased. Echocardiography determines the type of truncal defect, competency of the truncal valve,

and differential blood flow.

Surgical repair in early infancy is recommended to prevent the sequelae of severe HF and pulmonary vascular disease. The definitive repair consists of a modified Rastelli procedure involving VSD patch closure to divert the blood flow from the LV outflow tract into the truncus. The pulmonary arteries are excised from the aorta and connected to the RV through a tissue homograft (cadaver conduit). Postoperative complications include HF, residual VSD, truncal valve (now the aorta) stenosis or insufficiency, dysrhythmias, and pulmonary hypertension. These children require additional procedures to replace the conduit as its size becomes inadequate in relation to growth or narrows because of calcification over time.¹²

Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome (HLHS) refers to the abnormal development of the left-sided cardiac structures, resulting in obstruction to blood flow from the LV outflow tract. HLHS involves underdevelopment of the LV, aorta, and aortic arch, as well as mitral atresia or stenosis (Fig. 34.19). Therefore infants with HLHS must have a well-functioning RV and the presence of a PDA and atrial septal communication for survival. HLHS accounts for 5% of all congenital heart defects and is considered the most complex congenital defect.⁷

FIGURE 34.19 Hypoplastic Left Heart Syndrome. (From Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing*, ed 10, St Louis, 2015, Mosby.)

◆Pathophysiology.

Because of the high pressures caused by LV outflow tract obstruction, saturated blood enters the LA and mixes with desaturated blood in the RA through an atrial septal communication. Blood flow follows the normal pathways through the right side of the heart. Exiting the PA, the mixed-saturation blood flows through the ductus and to the descending aorta. The amount of blood flow that travels to the pulmonary and systemic circulations depends on vascular resistance in the respective systems. Retrograde blood flow through the hypoplastic ascending aorta provides coronary and cerebral blood flow if there is complete aortic atresia.

◆Clinical Manifestations.

Newborns with HLHS generally are born full-term and initially appear healthy. As the ductus closes, systemic perfusion is decreased resulting in hypoxemia, acidosis, and shock. Usually no heart murmur

is detected and the second heart sound is loud and single because of aortic atresia.

◆Evaluation and Treatment.

A chest radiograph shows cardiomegaly and increased pulmonary venous congestion. ECG shows RV hypertrophy and diminished left-sided forces. Echocardiography reveals the components of the defect with a diminutive LV cavity, hypoplastic aortic valve and arch, hypoplastic or absent mitral valve, and an enlarged RV cavity. Interventional cardiac catheterization or echocardiographically guided with balloon atrial septostomy may be necessary if the atrial communication is restrictive. Infants with restrictive atrial septum causing obstructive pulmonary venous return are at high risk for interventions.⁷

Prostaglandin infusion to maintain patency of the ductus arteriosus is essential for newborn infant survival. Immediate correction of acidosis, inotropic support for adequate cardiac output, and ventilatory manipulation to balance systemic and pulmonary blood flow prevent further deterioration and achieve stabilization.

Surgical intervention includes a three-stage approach that classically begins with the Norwood procedure. The Norwood procedure consists of an atrial septectomy, placement of a pulmonary-to-systemic artery shunt to maintain adequate pulmonary blood flow, creation of a permanent communication between the RV and aorta, and patch augmentation of the hypoplastic aorta. The Sano modification of the Norwood procedure uses a tube graft between the RV and PA to provide stable pulmonary blood flow rather than a pulmonary-to-systemic arterial shunt.¹⁶ Postoperative complications include imbalance of systemic and pulmonary blood flow leading to inadequate cardiac output and persistent HF. Although the procedure is considered to be high risk, survival in most centers is now averaging greater than 80%.

Another option for high-risk infants with HLHS (those with significant comorbidities or prematurity) is the Hybrid Stage I palliation. This procedure involves placement of bilateral pulmonary

artery bands to regulate PBF, stenting the ductus arteriosus to provide stable systemic blood flow, and a balloon atrial septostomy to allow unobstructed pulmonary venous return. This procedure can be done without the use of cardiopulmonary bypass and systemic heparinization. However, the second-stage bidirectional Glenn procedure will require the addition of an aortic arch augmentation as described in the original Norwood procedure.

The second stage is the bidirectional Glenn procedure, and the third stage is the modified Fontan procedure, which were described previously in the section [Tricuspid Atresia](#). Long-term health problems following the Fontan procedure are related to reduced ventricular function and high central venous pressures.¹³

Few centers perform cardiac transplant as a primary treatment for HLHS because of the scarcity of neonatal donors. Disadvantages of neonatal transplantation include risk of rejection, long-term problems with chronic immunosuppression, and infection. Infants who are not candidates for staged procedures or transplantations are offered palliative care. Infants with HLHS have improved survival rates because of advances in surgical and medical technology. However, many infants and children with complex CHD have long-term neurodevelopmental disabilities.^{7,17}

Acquired Cardiovascular Disorders

Acquired heart diseases are those disease processes or abnormalities that occur after birth. They result from various causes, such as infection, genetic disorders, autoimmune processes in response to infection, environmental factors, or autoimmune diseases. Examples of acquired heart diseases include Kawasaki disease, myocarditis, rheumatic heart disease, cardiomyopathy, and systemic hypertension. This chapter discusses Kawasaki disease and systemic hypertension. Myocarditis, rheumatic heart disease, and cardiomyopathy are discussed in [Chapter 33](#).

Kawasaki Disease

Kawasaki disease, formerly known as *mucocutaneous lymph node syndrome*, is an acute, self-limiting systemic vasculitis that may result in cardiac sequelae. Although Kawasaki disease occurs throughout the world, the greatest number of cases are reported in Japan.

Kawasaki disease is primarily a condition of young children: 80% of cases are seen in children younger than 5 years of age, with the incidence peaking in the toddler age group. Males are affected slightly more than females. Its peak incidence is in winter and spring.¹⁸

The etiology of Kawasaki disease remains unknown. Theories center on an immunologic response to an infectious, toxic, or antigenic substance (including superantigens).^{2,7,18}

◆Pathophysiology.

Kawasaki disease progresses pathologically and clinically in the following stages:

Stage I (days 1 to 12): Small capillaries, arterioles, and venules become inflamed, as does the heart itself.

Stage II (days 13 to 25): Inflammation spreads to larger vessels, and aneurysms of the coronary arteries develop.

Stage III (days 26 to 40): Medium-size arteries begin the granulation process, causing coronary artery thickening; inflammation resolves in the microcirculation; and there is risk of thrombus formation.

Stage IV (day 41 and beyond): Vessels develop scarring, intimal thickening, calcification, and stenosis of coronary arteries.

◆Clinical Manifestations.

The clinical course of the disease progresses in three stages: acute, subacute, and convalescent. In the acute phase the child has fever, conjunctivitis, oral changes (“strawberry” tongue), rash, and lymphadenopathy and is often irritable. During this phase myocarditis in addition to the vasculitis may develop. The subacute phase begins when the fever ends and continues until the clinical signs have resolved. It is at this time that the child is most at risk for

coronary artery aneurysm development. Desquamation of the palms and soles occurs at this time, as well as marked thrombocytosis. The convalescent phase is marked by the continued elevation of the erythrocyte sedimentation rate and platelet count. Arthritis still may be present. This phase continues until all laboratory values return to normal—usually about 6 to 8 weeks after onset.

◆ Evaluation and Treatment.

The diagnosis is based on the diagnostic criteria for Kawasaki disease, which state that the child must exhibit five of six criteria, including fever (Box 34.3). These children usually have leukocytosis, increased erythrocyte sedimentation rates, marked thrombocytosis, and elevated levels of liver enzymes. An echocardiogram is obtained at the time of diagnosis as a baseline to assess for coronary aneurysms or inflammation. Serial echocardiograms are obtained after treatment to assess for future development of coronary aneurysms.

Box 34.3

Diagnostic Criteria for Kawasaki Disease

The child must exhibit five of the following six criteria, including fever:

1. Fever for 5 or more days (often diagnosed with shorter duration of fever if other symptoms are present)
2. Bilateral conjunctival infection without exudation
3. Changes in the oral mucous membranes, such as erythema, dryness, and fissuring of the lips; oropharyngeal reddening; or “strawberry tongue”
4. Changes in the extremities, such as peripheral edema, peripheral erythema, and desquamation of palms and soles, particularly periungual peeling
5. Polymorphous rash, often accentuated in the perineal area
6. Cervical lymphadenopathy (one lymph node >1.5 cm)

Modified from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 10, St Louis, 2015, Mosby.

The use of aspirin and intravenous immunoglobulin during the acute phase has decreased the mortality of Kawasaki disease and has reduced the incidence of coronary abnormalities from approximately 25% to 5% at 6 to 8 weeks after initiation of therapy. Most children recover completely from Kawasaki disease, including the regression of aneurysms. The most common, although rare, cardiovascular sequela is coronary artery aneurysms and resulting thrombosis or myocardial infarction. On average, studies have shown 30-year survival rates up to 90%; however, some children with giant aneurysms may require coronary artery bypass grafting (CABG).¹⁸

Systemic Hypertension

Hypertension (HTN) in children differs from adult HTN in etiology and presentation. Children diagnosed with HTN are often found to have some underlying disease, such as renal disease or COA (Box 34.4). In recent years an increased prevalence of primary HTN in older children has been noted. Research has shown that primary HTN in older children, as well as other risk factors such as obesity, diabetes, and dyslipidemia, is related to the development of early atherosclerotic disease.¹⁹

Box 34.4

Conditions Associated With Secondary Hypertension in Children

Renal Disorders

Congenital defects

Polycystic kidney, ectopic kidney, horseshoe kidney,

- etc.
- Obstructive anomalies
 - Hydronephrosis
- Renal tumor
 - Wilms tumor
 - Retrovascular tumor
- Abnormalities of renal arteries
- Renal vein thrombosis
- Acquired disorders
 - Glomerulonephritis—acute or chronic
 - Pyelonephritis
 - Nephritis associated with collagen disease

Cardiovascular Disease

- Coarctation of the aorta
- Arteriovenous fistulae
- Patent ductus arteriosus
- Aortic or mitral insufficiency

Metabolic and Endocrine Diseases

- Adrenal tumors
 - Adenoma
 - Pheochromocytoma
 - Neuroblastoma
 - Cushing syndrome
 - Adrenogenital syndrome
- Hyperthyroidism
- Aldosteronism
- Hypercalcemia
- Diabetes mellitus

Neurologic Disorders

Space-occupying lesions of cranium (increased intracranial pressure)

Tumors, cysts, hematoma

Cerebral edema

Encephalitis (including Guillain-Barré and Reye syndromes)

Miscellaneous Causes

Drugs (corticosteroids, oral contraceptives, pressor agents, amphetamines)

Burns

Genitourinary surgery

Trauma (e.g., stretching of femoral nerve with leg traction)

Insect bites (e.g., scorpion)

Intravascular overload (blood, fluid)

Hypernatremia

Toxemia of pregnancy

Heavy metal poisoning

From Hockenberry MJ, Wilson D: *Wong's essentials of pediatric nursing*, ed 10, St Louis, 2015, Mosby.

Systemic hypertension in children is defined as systolic and diastolic blood pressure levels greater than the 95th percentile for age and sex on at least three occasions. The Fourth Task Force on Blood Pressure Control in Children uses height as an additional criterion to the blood pressure guide.^{20,20a}

◆Pathophysiology.

Hypertension is classified as (1) primary (or essential) hypertension, in which a specific cause cannot be identified; or (2) secondary hypertension, in which a cause is secondary to another alteration such as renal disease or COA (see [Box 34.4](#)). In infants and children, the

most common type of HTN is secondary HTN; this requires a thorough history and physical examination to identify the cause.¹⁹ Primary HTN is more common in males than females, and among Hispanic and black children.⁵

The pathophysiology of primary HTN in children is not clearly understood but may result from complex interactions between modifiable risk factors, such as obesity and sedentary lifestyle, and nonmodifiable risk factors, such as genetics, race, and socioeconomic factors. These risk factors may result in inflammatory processes, activation of the sympathetic nervous system which leads to upregulation of the renin-angiotensin-aldosterone (RAAS) system, increased sodium reabsorption, and increased vascular reactivity with the end result leading to hypertension²¹ (Fig. 34.20). New studies have shown an increased level of leptin, a hormone produced by adipose tissue, to be associated with HTN in obese children.²²

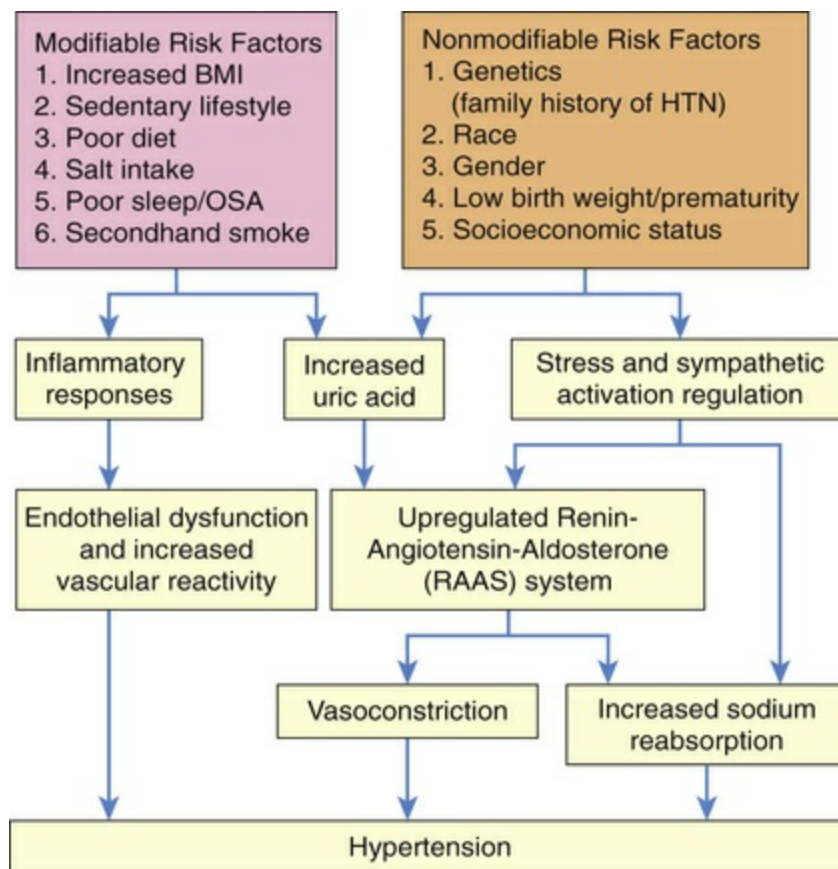

FIGURE 34.20 Mechanisms Believed to Influence Blood Pressure in Children. According to this model, a critical factor in the development of hypertension is obesity during childhood. Increased body mass, coupled with excessive sodium intake, can cause primary hypertension in children or set the stage for its development later in life. *BMI*, Body mass index; *HTN*, hypertension; *OSA*, obstructive sleep apnea.

◀Clinical Manifestations.

Most children with systemic HTN are asymptomatic. It is necessary that a thorough history (including family history of HTN and heart disease) and physical examination be obtained. The examination should include an accurate blood pressure measurement obtained on the right arm with the arm supported at the level of the heart; three separate measurements should be taken using a cuff of appropriate size (Tables 34.6 and 34.7).

TABLE 34.6

SUGGESTED NORMAL BP VALUES (mmHg) BY AUSCULTATORY METHOD (SYSTOLIC/DIASTOLIC K5)

AGE (YEARS)	MEAN BP LEVELS	90th PERCENTILE	95th PERCENTILE
6–7	104/55	114/73	117/78
8–9	106/58	117/76	120/82
10–11*	108/60	120/77	124/82
12–13*	112/62	124/78	128/83

BP, Blood pressure.

From Park MK: *Pediatric cardiology for practitioners*, ed 6, Philadelphia, 2014, Mosby; modified from Park MK, Menard SM: *Am J Dis Child* 143:860, 1989.

Many factors influence blood pressure in children, including smoking, obesity, and sedentary lifestyles. However, obesity is one of the most important factors in the increasing prevalence of HTN in children.

◆ **Evaluation and Treatment.**

In children the history and physical examination should be directed at determining the etiology of HTN (Table 34.8). Blood pressure difference between upper and lower extremities and echocardiogram are performed to identify COA. If COA is found, surgical correction or balloon angioplasty with or without stent implantation is performed, depending on the child's age and severity of the coarctation. A complete blood count, serum chemistry levels, urinalysis, urine culture, lipid profile, and renal ultrasound are part of the routine evaluation for renal disease (Table 34.9).

TABLE 34.8

MOST COMMON CAUSES OF CHRONIC SUSTAINED HYPERTENSION

AGE GROUP	CAUSES
Newborn	Renal artery thrombosis, renal artery stenosis, congenital renal malformation, COA,

	bronchopulmonary dysplasia
<6 years	Renal parenchymal disease, COA, renal artery stenosis
6–10 years	Renal artery stenosis, renal parenchymal disease, primary hypertension
>10 years	Primary hypertension, renal parenchymal disease

COA, Coarctation of the aorta.

TABLE 34.9

ROUTINE AND SPECIAL LABORATORY TESTS FOR HYPERTENSION

LABORATORY TEST	SIGNIFICANCE OF ABNORMAL RESULTS
Urinalysis, urine culture, blood urea nitrogen, creatinine, uric acid	Renal parenchymal disease
Serum electrolyte levels (hypokalemia)	Hyperaldosteronism (primary or secondary)
	Adrenogenital syndrome
	Renin-producing tumors
ECG, chest x-ray studies, and possibly echocardiography	Cardiac cause of hypertension, also baseline function
Intravenous pyelogram (or ultrasonography, radionuclide studies, computed tomography, or magnetic resonance imaging of the kidneys)	Renal parenchymal disease Renovascular hypertension Tumors (neuroblastoma, Wilms tumor)
Plasma renin activity (peripheral)	High-renin hypertension (renovascular hypertension, renin-producing tumors, some Cushing syndrome, some essential hypertension)
	Low-renin hypertension (adrenogenital syndrome, primary hyperaldosteronism)
24-hour urine collection for 17-ketosteroids and 17-hydroxycorticosteroids	Cushing syndrome
	Adrenogenital syndrome
24-hour urine collection for catecholamine levels and vanillylmandelic acid	Pheochromocytoma
	Neuroblastoma
Aldosterone	Hyperaldosteronism (primary or secondary)

	Renovascular hypertension
	Renin-producing tumors
Renal vein plasma renin activity	Unilateral renal parenchymal disease
	Renovascular hypertension
Abdominal aortogram	Renovascular hypertension
	Abdominal coarctation of the aorta
	Unilateral renal parenchymal diseases
	Pheochromocytoma
Intraarterial digital subtraction angiography	Renovascular hypertension

ECG, Electrocardiogram.

Although the criteria for the diagnosis of hypertension are based on the use of a standard blood pressure cuff, some children have what is termed “white coat hypertension.” Elevated blood pressure readings in these children occur only when measured in the clinic and may be caused by fear and anxiety. The use of ambulatory blood pressure monitoring (ABPM) records the blood pressure over a 24-hour period. In addition to identifying children with white coat hypertension, ABPM has been found to be useful in children with hypertension that is resistant to treatment (see [Box 34.4](#) and [What’s New? Ambulatory Blood Pressure Monitoring in Children](#)).^{23,24}

What's New?

Ambulatory Blood Pressure Monitoring in Children

Ambulatory blood pressure monitoring (ABPM) records blood pressure over a 24-hour period. Its use in children was endorsed by the Fourth Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Children primarily to help identify those children with “white coat hypertension.” Paradoxically, some children have normal blood

pressure readings in the clinic but are hypertensive during other parts of the day. This is called *masked hypertension* and also can be identified by ABPM. ABPM is useful in documenting what is called the *BP load*, which is the total amount of time the blood pressure (BP) is elevated above normal limits during a 24-hour period. By measuring BP load, ABPM may be able to identify those children who are at greatest risk for target organ damage. It can also help with management of children who suffer hypotensive episodes in response to pharmacologic therapy for their hypertension. Finally, ABPM facilitates medication changes in those with hypertension resistant to medication.

Data from Flynn JT et al: *Hypertension* 63(5):1116-1135, 2014.

If HTN is found to be essential, or primary, in nature, nonpharmacologic, lifestyle-based therapy is used initially. Moderate weight loss can decrease systolic and diastolic pressures in many children. Appropriate diet, regular physical activity, and avoidance of smoking have been shown to be effective in reducing blood pressure.¹⁹

Pharmacologic therapy is controversial in children with primary hypertension; however, when nonpharmacologic therapy fails, a staged approach with the use of ACE inhibitors, angiotensin receptor blockers (ARB), and calcium channel blockers is indicated. Effective treatment of HTN in children may reduce the incidence of long-term sequelae, such as left ventricular hypertrophy, renal failure, and cerebrovascular accident (CVA or stroke). The emphasis on preventive cardiology, especially for children, is significant because many investigators believe signs of atherosclerosis and other cardiovascular risk factors are present from childhood.¹⁹

Childhood Obesity

Childhood obesity is considered an epidemic not only in the United States but also in other countries.^{25,26} The prevalence of obesity in children and young adults has remained fairly steady in the past two

decades, with approximately 31.8% of children aged 2 to 19 years being overweight or obese, and 16.9% being obese.²⁵ Attention from U.S. federal and state initiatives has kept childhood obesity in the spotlight and, although obesity rates have not increased, obesity continues to be an important contributor to lifelong health problems. Percentile of body mass index (BMI) expressed as weight/height² (BMI-kg/m²) is used to identify overweight and obesity in children and adolescents. The Centers for Disease Control and Prevention (CDC), the supplier of national growth charts and prevalence data, classifies *overweight* as BMI from the 85th percentile to less than the 95th percentile for age, and *obese* as BMI at 95th percentile or greater for age.²⁷

Causes of obesity in young children and adolescents are multivariable and multidimensional. Risk factors associated with developing childhood obesity include race, socioeconomic status, and lack of health insurance. Children of black and Hispanic race are at higher risk, as well as children with no insurance.^{25,28} The presence of parental obesity also is associated with childhood obesity.²⁶ In addition, early childhood nutrition, level of physical activity, sleep disturbances, and engagement in sedentary activities, such as watching television and computer use, are associated with the development of overweight and obese children.^{25,26,29,30}

Similar to obese adults, overweight and obese children are at risk for acquiring numerous other serious and potentially life-threatening illnesses, such as asthma, sleep apnea, HTN, type 2 diabetes, dyslipidemia, and cardiovascular disease.^{7,28,31} Researchers also have reported a multitude of social and economic consequences in adolescents as a result of being overweight. Obese children have been reported to have increased anxiety and depression, as well as decreased self-esteem and quality of life and poorer school performance, and they are more likely to be the target of bullying compared to nonobese children.^{28,31}

As in other acquired diseases, efforts should be focused on prevention (see [What's New? Guidelines on Reducing Cardiovascular Disease in Children](#)). The initial approach is a combined program of

physical activity with nutritional improvements. Healthcare professionals play a vital role in recognizing the need for intervention, immediate referral, and support. Successful outcomes for most overweight and obese children require support, change in lifestyle at home, and involvement of family members. Researchers are involving school-based programs in preventing obesity in the young.^{26,32,33}

What's New?

Guidelines on Reducing Cardiovascular Disease in Children

In 2011, the National Heart Lung and Blood Institute (NHLBI) released cardiovascular disease (CVD) guidelines for children and adolescents that are endorsed by the American Academy of Pediatrics (AAP) and American Heart Association (AHA) and are integrated into the *Bright Futures* guidelines on pediatric health maintenance. These universal lipid screening guidelines include (1) all children should undergo cholesterol screening once between ages 9 to 11 years and once between ages 17 to 21 years; (2) nonfasting total cholesterol and high-density lipoprotein (HDL) can be used for the initial lipid screening test; (3) clinicians may recommend low-fat or no-fat dairy at age 1 year for high-risk children; (4) for children who fail lifestyle changes and require lipid-lowering medications, pharmacologic treatment should be considered at age 10 years; and (5) once low-density lipoprotein (LDL) is optimized, high non-HDL cholesterol may be targeted for residual CVD risk reduction. However, the U.S. Preventive Services Task Force (USPSTF) evaluated the evidence to support such screening and issued a statement in 2016 that the current evidence is “insufficient” to assess the risk versus benefit of screening for lipid disorders in children and adolescents <20 years of age. The USPSTF statement has created controversy among leading experts in pediatric dyslipidemia. Although change in practice should be based on the highest level of evidence, randomized controlled trials

(RCTs) are often lacking in the pediatric population. With the mounting evidence of early atherosclerosis development in children at high risk (obesity, hypertension, and type 2 diabetes) or with a genetic predisposition to dyslipidemia (e.g., familial hypercholesterolemia; more than 500,000 infants born each year), clinical decision making on whether to provide universal lipid screening to children and adolescents may need to be based on more than available evidence. All agree that future RCTs are needed to support universal lipid screening.

Summary Review

Development of the Cardiovascular System

1. The heart arises from the mesenchyme and begins as an enlarged blood vessel with a large lumen and a muscular wall. By approximately the seventh week of gestation, all structures of the fetal heart and vascular system are present.
2. The endocardial cushions are instrumental in closing the atrial septum, dividing the AV canals into the right and left AV orifices, and closing the septum.
3. In the fetus the pulmonary and systemic circulatory systems are connected by the foramen ovale, an opening between the atria; by the ductus arteriosus, a fetal vessel that joins the PA to the aorta; and by the ductus venosus, a fetal vessel that connects the inferior vena cava to the umbilical vein.
4. Fetal circulation is different from postnatal circulation because of the presence of fetal shunts and altered metabolic needs of the various organs.
5. Fetal blood flow depends on resistance for its distribution through the body. Resistance in the pulmonary circulation is

higher than resistance in the systemic circulation, so myocardial thickness is about the same in the right heart and the left heart.

6. After birth, SVR increases and PVR decreases.
7. PVR drops suddenly at birth because the lungs expand and the pulmonary vessels dilate. It continues to decrease gradually during the first 8 weeks after birth. Decreased PVR causes the right myocardium to become thinner.
8. SVR increases markedly at birth because severance of the umbilical cord removes the low-resistance placenta from the systemic circulation. Increased SVR causes the left myocardium to become dominant and thicken over time.
9. Changes in resistance cause disappearance of the fetal connections between the pulmonary and systemic circulatory systems. The foramen ovale closes functionally at birth and anatomically several months later; the ductus arteriosus closes functionally 15 hours after birth and anatomically within the first several weeks; and the ductus venosus closes within 1 week after birth.
10. At birth a series of circulatory changes occur that affect blood flow, vascular resistance, and oxygen tension. The most important change is the shift of gas exchange from the placenta to the lungs.
11. After birth, significant postnatal changes occur, including thinning of the right ventricular myocardium as the PVR drops. As the SVR increases, the left ventricular myocardium becomes thicker and more dominant as it is in the adult heart.

Congenital Heart Defects

1. Most congenital cardiovascular defects have begun to develop by the fourth week of gestation, and most have many causes, both environmental and genetic.
2. Environmental risk factors associated with the incidence of CHD typically are maternal conditions. Among these are viral

infections, diabetes, drug intake, alcohol intake, metabolic disorders, and advanced maternal age.

3. Genetic factors associated with CHD include, but are not limited to, trisomy 21 or Down syndrome, trisomy 13, trisomy 18, cri du chat syndrome, and Turner syndrome. It now appears, however, that most genetic mechanisms of causation are multifactorial.
4. Classification of CHDs is based on whether they (a) cause blood flow to the lungs to increase or decrease, (b) obstruct ventricular blood flow patterns, or (c) cause mixing of unoxygenated and oxygenated blood.
5. Symptoms of HF are usually the result of CHDs that increase blood volume and pressure in the pulmonary circulation, or myocardial failure. Clinical manifestations are almost the same as the manifestations of HF in adults, with the addition of FTT in children.
6. Cyanosis, a bluish discoloration of the skin, indicates that the tissues are not receiving fully adequate oxygenated blood. Cyanosis can be caused by defects that (a) reduce pulmonary blood flow; (b) overload the pulmonary circulation, causing pulmonary hypertension, pulmonary edema, and respiratory difficulty; and (c) cause large amounts of unoxygenated blood to shunt from the pulmonary to the systemic circulation.
7. Congenital heart defects that maintain or create direct communication between the pulmonary and systemic circulatory systems cause blood to shunt from one system to another, mixing oxygenated and unoxygenated blood and increasing blood volume and pressure on the receiving side of the shunt.
8. The direction of shunting through an abnormal communication depends on differences in pressure and resistance between the two systems. Flow is always from an area of high pressure to an area of low pressure. The resistance to flow determines the volume of the shunting.
9. Acyanotic CHDs that increase pulmonary blood flow consist of

abnormal openings (PDA, ASD, VSD, AVC defect, or truncus arteriosus) that permit blood to shunt from left (systemic circulation) to right (pulmonary circulation). Cyanosis does not occur because the left-to-right shunt does not interfere with the flow of oxygenated blood through the systemic circulation.

10. If the abnormal communication between the left and right circuits is large, volume and pressure overload in the pulmonary circulation leads to HF.
11. In truncus arteriosus the main trunk fails to divide longitudinally into the aorta and PA. All blood from both ventricles enters the truncus, so that mixed blood is delivered by both circulatory systems, causing varying degrees of cyanosis and HF.
12. In CHDs that decrease pulmonary blood flow (TOF, tricuspid atresia), myocardial hypertrophy cannot compensate for restricted right ventricular outflow. Flow to the lungs decreases, and cyanosis is caused by mixing of systemic and pulmonary venous return.
13. Obstruction of ventricular outflow commonly is caused by PS, AS, COA, or interrupted aortic arch.
14. Despite obstruction, ventricular output remains normal for a long time because of compensatory ventricular hypertrophy stimulated by increased afterload and, in postductal COA, development of collateral circulation around the coarctation.
15. Complex CHDs that depend on mixing of the pulmonary and systemic circulations for survival during the postnatal period include TGA, HLHS, and TAPVC. This mixing results in desaturated systemic blood flow and cyanosis.
16. In TGA the circulatory systems are not connected serially or through a shunt, so that oxygenated blood remains permanently in the pulmonary circulation and unoxygenated blood remains in the systemic circulation. Survival depends on patency of the ductus arteriosus; in the absence of patency, surgical intervention is mandatory.

17. TAPVC is caused by abnormal pulmonary vein development and the lack of direct pulmonary venous return to the LA. All blood from the pulmonary and systemic circulations enters the RA. Mixed blood enters the LA through an ASD; it then flows into the systemic circulation and causes cyanosis.
18. Tricuspid atresia [left] and HLHS [right] are types of single-ventricle defects that commonly require three staged palliative surgical procedures.
19. Treatment for all hemodynamically severe CHDs is surgical or interventional palliation of the anomaly and management of cyanosis and HF.

Acquired Cardiovascular Disorders

1. The most common acquired cardiovascular disorders of childhood are Kawasaki disease, rheumatic heart disease (see [Chapter 33](#)), obesity, and HTN.
2. Kawasaki disease is an acute systemic vasculitis that may result in the development of coronary artery aneurysms and thrombosis.
3. Essential or primary HTN in children is the same as that in adults, except that it is more likely to be diagnosed at a younger age and most are at an asymptomatic stage. Most cases of secondary HTN in young children are because of an underlying cause, such as renal disease or COA.
4. Obesity in childhood is epidemic in the United States and other countries, but more recent data shows that obesity prevalence is not increasing.
5. Obese children are at risk for acquiring numerous other serious and potentially life-threatening illnesses, such as asthma, sleep apnea, HTN, type 2 diabetes mellitus, dyslipidemia, and cardiovascular disease.

AGING and the Pulmonary System, 1159

The primary function of the pulmonary system is the exchange of gases between the environmental air and the blood. There are three steps in this process: (1) ventilation, the movement of air into and out of the lungs; (2) diffusion, the movement of gases between air spaces in the lungs and the bloodstream; and (3) perfusion, the movement of

blood into and out of the capillary beds of the lungs to body organs and tissues. The first two functions are carried out by the pulmonary system and the third by the cardiovascular system (see [Chapter 32](#)). Normally the pulmonary system functions efficiently under a variety of conditions and with little energy expenditure.

Structures of the Pulmonary System

The pulmonary system includes two lungs and the upper and lower airways, and the blood vessels that serve them ([Fig. 35.1](#)); the chest wall, or thoracic cage; and the diaphragm. The lungs are divided into lobes: three in the right lung (upper, middle, lower) and two in the left lung (upper, lower). Each lobe is further divided into segments and lobules. The **mediastinum** is the space between the lungs and contains the heart, great vessels, and esophagus. A set of conducting airways, or bronchi, delivers air to each section of the lung. The lung tissue that surrounds the airways supports them, preventing their distortion or collapse as gas moves in and out during ventilation. The diaphragm is a dome-shaped muscle that separates the thoracic and abdominal cavities and is involved in ventilation.

FIGURE 35.1 Structural Plan of the Respiratory System. The inset shows alveolar sacs where the interchange of oxygen and carbon dioxide takes place through the walls of the grapelike alveoli. Capillaries surround the alveoli. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

The lungs are protected from a variety of exogenous contaminants by a series of mechanical and cellular defenses (Table 35.1). These defense mechanisms are so effective that in the healthy individual, contamination of the lung tissue itself, particularly by infectious agents, is rare.

TABLE 35.1

PULMONARY DEFENSE MECHANISMS

STRUCTURE	MECHANISM OF DEFENSE
OR	
SUBSTANCE	

Upper respiratory tract mucosa	Maintains constant temperature and humidification of gas entering the lungs; traps and removes foreign particles, some bacteria, and noxious gases from inspired air
Nasal hairs and turbinates	Trap and remove foreign particles, some bacteria, and noxious gases from inspired air
Branching airways	Disrupt laminar flow and enhance deposition of particles and pathogens on ciliated mucosa
Mucous blanket	Protects trachea and bronchi from injury; traps most foreign particles and bacteria that reach the lower airways
Innate immune proteins	Lysozyme, lactoferrin, defensins, collectins (surfactant protein A [SP-A] and surfactant protein D [SP-D]), and immunoglobulin A (IgA); recognize and promote killing of pathogens
Cilia	Propel mucous blanket and entrapped particles toward the oropharynx, where they can be swallowed or expectorated
Alveolar macrophages	Ingest and remove bacteria and other foreign material from alveoli by phagocytosis (see Chapter 7)
Surfactant	Enhances phagocytosis of pathogens and allergens in alveoli; down-regulates inflammatory responses
Irritant receptors in nares (nostrils)	Stimulation by chemical or mechanical irritants triggers sneeze reflex, which results in rapid removal of irritants from nasal passages
Irritant receptors in trachea and large airways	Stimulation by chemical or mechanical irritants triggers cough reflex, which results in removal of irritants from the trachea and large airways

Conducting Airways

The conducting airways provide a passage for the movement of air into and out of the gas-exchange structures of the lung. The **nasopharynx**, **oropharynx**, and related structures are called the *upper airway* ([Fig. 35.2](#)). These structures are lined with ciliated mucosa with a rich vascular supply that warms and humidifies inspired air and removes foreign particles from it as it passes into the lungs. The mouth and oropharynx provide for ventilation when the nose is obstructed or when increased flow is required, for example, during exercise. Filtering and humidifying are not as efficient with mouth breathing.

FIGURE 35.2 Structures of the Upper Airway. (Redrawn from Thompson JM et al: *Mosby's clinical nursing*, ed 5, St Louis, 2002, Mosby.)

The **larynx** connects the upper and lower airways and consists of the endolarynx and its surrounding triangular-shaped bony and cartilaginous structures. The endolarynx is formed by two pairs of folds: the false vocal cords (supraglottis) and the true vocal cords. The slit-shaped space between the true cords forms the glottis (see [Fig. 35.2](#)). The vestibule is the space above the false vocal cords. The laryngeal box is formed by three large cartilages—the epiglottis, thyroid, and cricoid—and three smaller cartilages—the arytenoid, corniculate, and cuneiform—connected by ligaments. The supporting cartilages prevent collapse of the larynx during inspiration and swallowing. The internal laryngeal muscles control vocal cord length and tension, and the external laryngeal muscles move the larynx as a whole. Both sets of muscles are important to swallowing, respiration, and vocalization. The internal muscles contract during swallowing to

prevent aspiration into the trachea and contribute to voice pitch.¹

The **trachea**, which is supported by U-shaped cartilage, connects the larynx to the **bronchi**, the conducting airways of the lungs. The trachea divides into the two main airways, or bronchi, at the **carina** (see [Fig. 35.1](#)). This area is very sensitive and when stimulated can cause coughing and airway narrowing. The left mainstem bronchus branches from the trachea at about a 45-degree angle. The right mainstem bronchus is slightly larger and more vertical than the left (branches at about a 20- to 30-degree angle from the trachea). Aspirated fluids or foreign particles thus tend to enter the right lung rather than the left. The right and left main bronchi enter the lungs at the **hila**, or “roots” of the lungs, along with the pulmonary blood and lymphatic vessels. From the hila the main bronchi branch into lobar bronchi and then to segmental and subsegmental bronchi, and finally end at the sixteenth division in the smallest of the conducting airways, the terminal **bronchioles** ([Fig. 35.3](#)). With these multiple divisions, the cross-sectional area of the airways increases to 20 times that of the trachea. This results in decreased velocity of airflow into the gas-exchange portion of the lung and allows for optimal gas diffusion.

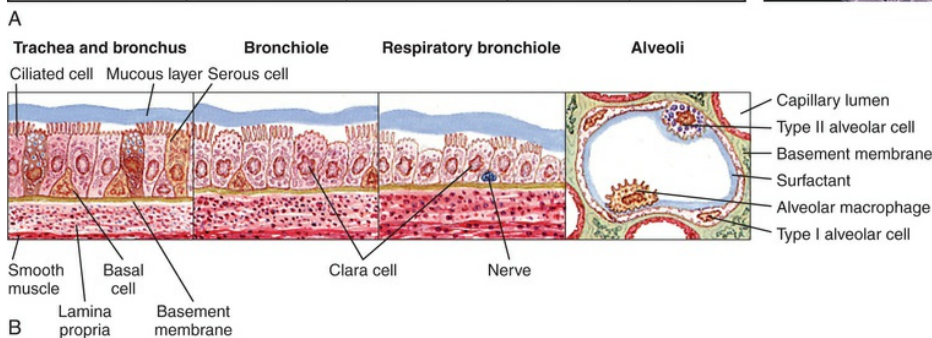

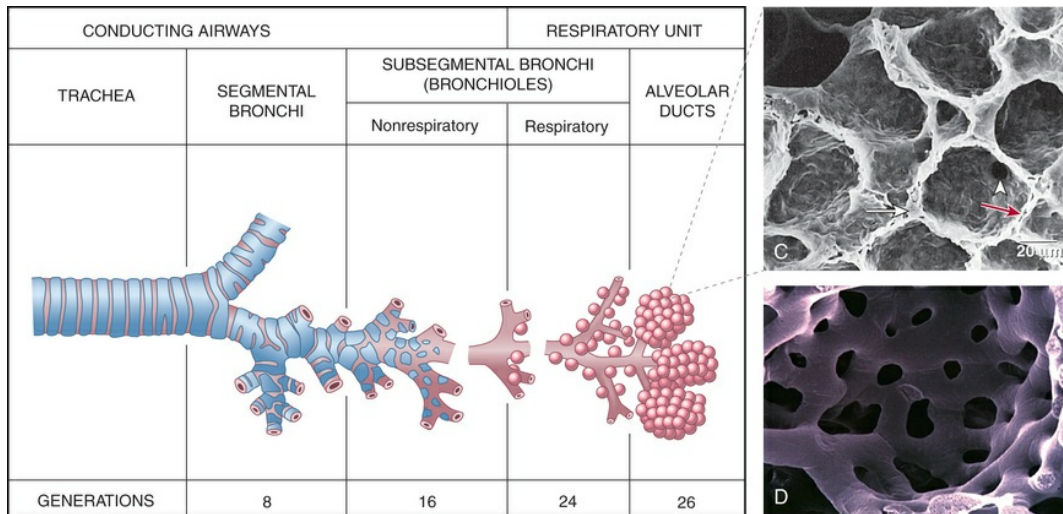

FIGURE 35.3 Conducting Airways and Respiratory Unit. **A**, Structures of respiratory airways. **B**, Changes in bronchial wall with progressive branching. **C**, Electron micrograph of alveoli: long white arrow identifies type II alveolar cells (pneumocytes - secretes surfactant); short white arrowhead identifies pores of Kohn; red arrow identifies alveolar capillary. **D**, Plastic cast of pulmonary capillaries at high magnification. (A redrawn from Thompson JM et al: *Mosby's clinical nursing*, ed 5, St Louis, 2002, Mosby; B from Wilson SF, Thompson JM: *Respiratory disorders*, St Louis, 1990, Mosby; C from Mason RJ et al: *Murray and Nadel's textbook of respiratory medicine*, ed 5, Philadelphia, 2010, Saunders; D courtesy A. Churg, MD, and J. Wright, MD, Vancouver, Canada. From Leslie KO, Wick MR: *Practical pulmonary pathology: a diagnostic approach*, ed 2, Philadelphia, 2011, Saunders.)

The bronchial walls have three layers: an epithelial lining, a smooth muscle layer, and a connective tissue layer. In the large bronchi (up to approximately the tenth division), the connective tissue layer contains cartilage. The epithelial lining of the bronchi contains single-celled exocrine glands—the mucus-secreting **goblet cells**—and ciliated cells. High columnar pseudostratified epithelium lines the larger airways and becomes progressively thinner, changing to columnar cuboidal epithelium in the bronchioles and squamous epithelium in the alveoli (types of epithelia are reviewed in [Chapter 1](#)). The submucosal glands

of the bronchial lining produce a mucous blanket that protects the bronchial epithelium. The ciliated epithelial cells rhythmically beat this mucous blanket toward the trachea and pharynx, where it can be swallowed or expectorated by coughing. Toward the terminal bronchioles, ciliated cells and goblet cells become more sparse, and smooth muscle and connective tissue layers thin (see [Fig. 35.3](#)).

Gas-Exchange Airways

The conducting airways terminate in the respiratory (terminal) bronchioles, alveolar ducts, and alveoli (*sing.*, alveolus). These thin-walled structures participate in gas exchange, and the clusters of alveoli are sometimes called the **acinus** (see [Fig. 35.3](#)).

The bronchioles from the sixteenth through the twenty-third divisions contain increasing numbers of alveoli and are called *respiratory bronchioles*. The walls of the respiratory bronchioles are very thin, consisting of an epithelial layer devoid of cilia and goblet cells, very little smooth muscle fiber, and a very thin and elastic connective tissue layer. These bronchioles end in **alveolar ducts**, which lead to alveolar sacs made up of numerous alveoli.

The **alveoli** are the primary gas-exchange units of the lung, where oxygen enters the blood and CO₂ is removed ([Fig. 35.4](#)). Tiny passages called *pores of Kohn* permit some air to pass through the septa from alveolus to alveolus, promoting collateral ventilation and even distribution of air among the alveoli. The lungs contain approximately 50 million alveoli at birth and about 480 million by adulthood.²

FIGURE 35.4 Alveoli. Bronchioles subdivide to form tiny tubes called *alveolar ducts* that end in clusters of alveoli called *alveolar sacs*. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

Lung epithelial cells provide a protective interface with the environment and are essential for adequate gas exchange, preventing entry of foreign agents, regulating ion and water transport, and maintaining mechanical stability of the alveoli. The alveolar septa consist of an epithelial layer and a thin, elastic basement membrane but no muscle layer (see Fig. 35.3). Two major types of epithelial cells (pneumocytes) appear in the alveolus. Type I alveolar cells provide structure, and type II alveolar cells secrete **surfactant**, a lipoprotein that coats the inner surface of the alveolus and facilitates its expansion during inspiration, which lowers alveolar surface tension at end-expiration, thereby preventing lung collapse (atelectasis). Surfactant proteins contribute to control of lung inflammation by decreasing release of proinflammatory mediators, preventing oxidative injury, and regulating the role of fibroblasts in airway remodeling. Surfactant proteins also are bacteriostatic and function as opsonins in presenting pathogens to alveolar macrophages.³

Macrophages are the most numerous immune cells present in the lung environment and provide innate immune defense of the airway from the bronchi to the alveoli. In the alveoli, *alveolar macrophages* provide protection by clearing surfactant from the lung and ingesting foreign material and pathogens that reach the alveolus, preparing these substances for removal through the lymphatics.⁴ (Phagocytosis and the mononuclear phagocyte system are described in [Chapters 7 and 8](#).) Surfactant and alveolar macrophages work together with the normal pulmonary microbiota to prevent lower lung infection. Changes in the pulmonary microbiome are associated with many pulmonary diseases (see [What's New? The Pulmonary Microbiome](#)).

What's New?

The Pulmonary Microbiome

Until recently, it was believed that the lower lungs were sterile. The first report of a healthy lung microbiome was published in 2010, and many more confirmatory articles have been published since then. The pulmonary microbiome is dynamic and is constantly influenced by the movement of air, mucus, and microbes in and out of the lung. The lung's natural defense mechanisms, such as the presence of bacteriostatic surfactant and active bronchial and alveolar macrophages, limit bacterial density along the mucosal surfaces, but those microorganisms that do survive provide important immunologic roles in preventing disease.¹ There is an interaction between the oral and gut mucosa and the pulmonary microbiome (gut-lung axis), and these relationships are just beginning to be understood in terms of causing and treating lung disease.²

A healthy pulmonary microbiome confers protection against many infectious and inflammatory conditions. Changes in lung microbiota have been associated with tobacco smoking, use of corticosteroids and antibiotics, and frequency of exacerbations in bronchiectasis, cystic fibrosis, asthma, and chronic obstructive

pulmonary disease (COPD). Alterations in the pulmonary microbiome result in increased mortality in idiopathic pulmonary fibrosis and decreased responsiveness to corticosteroids in patients with asthma. Pulmonary changes include the presence of pathogenic species and alterations in the distribution and diversity of microbes normally found in healthy states.³⁻⁵

Pulmonary and Bronchial Circulation

The **pulmonary circulation** provides an extensive surface area for gas exchange, delivers nutrients to lung tissues, acts as a blood reservoir for the left ventricle, and serves as a filtering system that removes clots, air, and other debris from the circulation ([Fig. 35.5](#)). The pulmonary vasculature is composed of three compartments connected in series: arteries, capillaries, and veins.

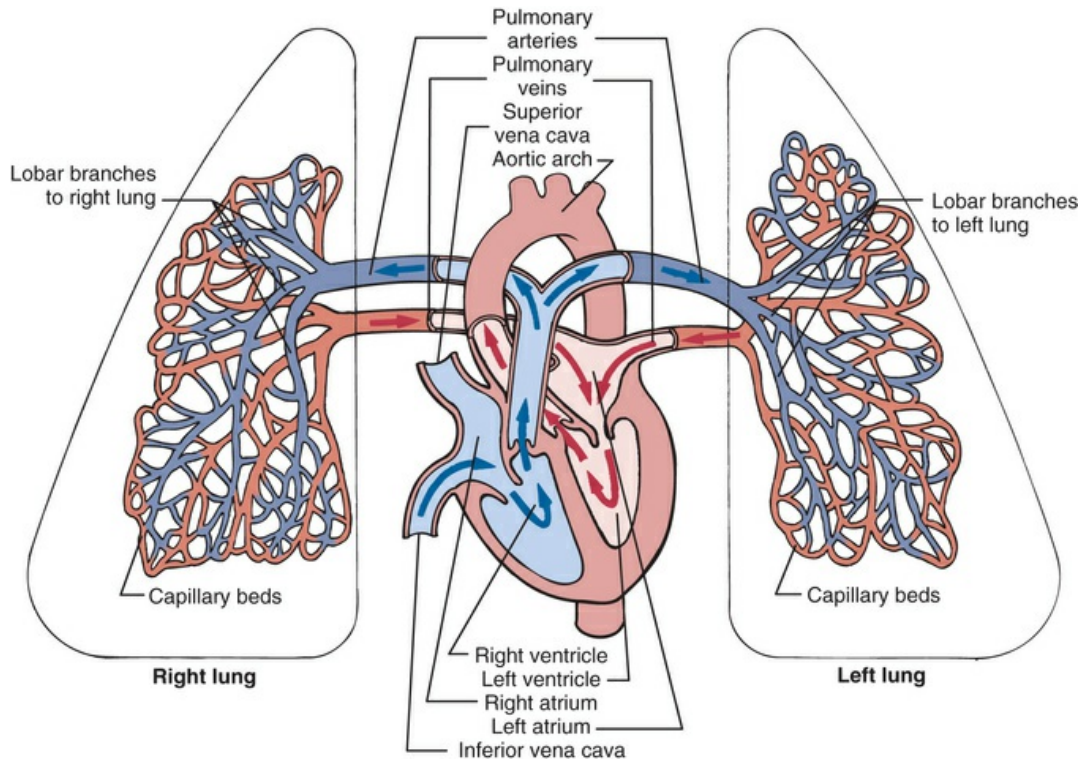

FIGURE 35.5 The Pulmonary Circulation. The right and left pulmonary veins and arteries and the branching capillaries are illustrated. Note the pulmonary artery carries venous blood, and the pulmonary vein carries arterial blood.

Although the entire cardiac output from the right ventricle goes into the lungs, the pulmonary circulation has a lower pressure and resistance than the systemic circulation. Pulmonary arteries are exposed to about one-fifth the pressure of the systemic circulation and have a much thinner muscle layer. (Systemic vessels are described in [Chapter 32](#).) Mean pulmonary artery pressure is 18 mmHg; mean aortic pressure is 90 mmHg. About one-third of the pulmonary vessels are filled with blood (perfused) at any given time. More vessels become perfused when right ventricular cardiac output increases. Therefore, increased delivery of blood to the lungs does not normally increase mean pulmonary artery pressure. During exercise, pulmonary arterial pressure will normally increase, but not to more than 30 mmHg and is age and sex dependent.⁵

The **pulmonary artery** divides and enters the lung at the hilus, branching with each main bronchus, and with the bronchi at every division. Thus every bronchus and bronchiole has an accompanying

artery or arteriole. The arterioles divide at the terminal bronchiole to form a network of **pulmonary capillaries** around the acinus. Capillary walls consist of an endothelial layer and a thin basement membrane, which often fuses with the basement membrane of the alveolar septum (see Fig. 35.3).

The shared alveolar and capillary walls compose the **alveolocapillary membrane**, a very thin membrane made up of the alveolar epithelium, the alveolar basement membrane, an interstitial space, the capillary basement membrane, and the capillary endothelium (Fig. 35.6). There is only about a 0.2- μm separation between blood in the capillary and gas in the alveolus.⁶ Gas exchange occurs across the alveolocapillary membrane. These extremely thin alveolar walls are easily damaged and can leak plasma and blood into the alveolar space. With normal perfusion, approximately 100 mL of blood in the pulmonary capillary bed is spread very thinly over about 70 to 100 m^2 of alveolar surface area. Any disorder that thickens the membrane impairs gas exchange (e.g., fibrotic lung disease).

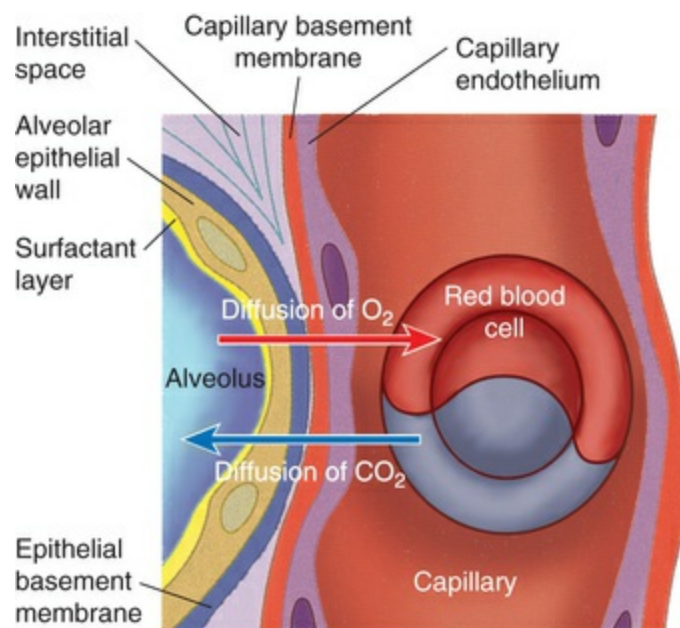

FIGURE 35.6 Cross Section Through an Alveolus Showing Histology of the Alveolar-Capillary Membrane (Respiratory Membrane). The dense network of capillaries forms an almost continuous sheet of blood in the alveolar walls, providing a very efficient arrangement for gas exchange. (Adapted from Montague SE, Watson R, Herbert R: *Physiology from*

Each **pulmonary vein** drains several pulmonary capillaries. Unlike the pulmonary arteries, which follow the branching bronchi, pulmonary veins are dispersed randomly throughout the lungs and then leave the lung at the hila and enter the left atrium. They are similar to veins in the systemic circulation, but they have no valves.

The **bronchial circulation** is part of the systemic circulation and receives 1% of the cardiac output. The bronchial arteries supply blood to the trachea, bronchi and its branches, esophagus, visceral pleura, the vasa vasorum of the thoracic aorta, and the pulmonary arteries and to the nerves, pulmonary veins, and lymph nodes in the thorax.⁷ Not all of the capillaries drain into their own venous system. Some empty into the pulmonary vein and contribute to the normal venous admixture of oxygenated and deoxygenated blood or right-to-left shunt (right-to-left shunts are described in [Chapter 36](#)). The bronchial circulation does not participate in gas exchange.

Lung vasculature also includes deep and superficial **pulmonary lymphatic capillaries**. The deep lymphatic capillaries begin at the level of the terminal bronchioles. Fluid and alveolar macrophages migrate from the alveoli to the terminal bronchioles, where they enter the lymphatic system. The superficial lymphatic capillaries drain the membrane that surrounds the lungs. Both deep and superficial lymphatic vessels leave the lung at the hilum through a series of mediastinal lymph nodes. The lymphatic system plays an important role in keeping the lung free of fluid and providing immune defense.⁸ (The lymphatic system is described in [Chapter 32](#).)

Control of the Pulmonary Circulation

The caliber of pulmonary artery lumina decreases as smooth muscle in the arterial walls contracts. Contraction increases pulmonary artery pressure. Caliber increases as these muscles relax, decreasing blood pressure. Contraction (vasoconstriction) and relaxation (vasodilation) primarily occur in response to local humoral conditions, even though the pulmonary circulation is innervated by the autonomic nervous

system (ANS), as is the systemic circulation.

The most important cause of pulmonary artery constriction is a low alveolar partial pressure of oxygen (PAO₂). Vasoconstriction caused by alveolar and pulmonary venous hypoxia, often termed **hypoxic pulmonary vasoconstriction**, results from an increase in intracellular calcium levels in vascular smooth muscle cells in response to low oxygen concentration and the presence of charged oxygen molecules called *oxygen free radicals*. It can affect only one segment of the lung (i.e., one lobe that is obstructed, decreasing its PAO₂) or the entire lung. If only one segment of the lung is involved, the arterioles to that segment constrict, shunting blood to other, well-ventilated portions of the lung. This reflex improves the lung's efficiency by better matching ventilation and perfusion. If all segments of the lung are affected, vasoconstriction occurs throughout the pulmonary vasculature, and pulmonary hypertension (elevated pulmonary artery pressure) can result. The pulmonary vasoconstriction caused by low PAO₂ values is reversible if the PAO₂ level is corrected. Chronic alveolar hypoxia can result in inflammation and structural remodeling in pulmonary arterioles, causing permanent pulmonary artery hypertension that eventually leads to right heart failure⁹ (see [What's New? Update on Hypoxic Pulmonary Vasoconstriction](#)).

What's New?

Update on Hypoxic Pulmonary Vasoconstriction

Hypoxic pulmonary vasoconstriction is a physiologic response to changes in the environment and pulmonary pathologic conditions that affect alveolar oxygen content (PAO₂). Decreases in PAO₂ to less than 12% of normal induce a locally controlled constriction of preacinar arteriolar smooth muscle and endothelial cells and therefore decrease blood flow through those vessels. When a pulmonary disorder is characterized by localized areas of acutely decreased alveolar oxygen content, vasoconstriction of the arterioles perfusing those areas is a positive compensatory mechanism that

reduces shunt (wasted perfusion). However, in diffuse and chronic lung disorders (e.g., chronic obstructive pulmonary disease [COPD] or cystic fibrosis), widespread and persistent hypoxic pulmonary vasoconstriction creates resistance to pulmonary blood flow and raises the pressure in the pulmonary artery, causing a condition known as *secondary pulmonary artery hypertension*. Pulmonary hypertension can cause permanent arteriolar remodeling, and when it is severe enough to impede right ventricular ejection, it can lead to right heart failure, known as *cor pulmonale*. To prevent these complications, the processes involved in hypoxic pulmonary vasoconstriction are being studied intensely. The release of reactive oxygen species during hypoxia causes changes in smooth muscle cell membrane ion channels, particularly those for calcium and potassium. Calcium influx into the cell occurs through transient receptor potential (TRP) channels such as TRPV4 and TRPC6, causing vasoconstriction. Inhibitors of these channels are being studied for the treatment of secondary pulmonary artery hypertension. Other mechanisms that are being studied include microRNA dysregulation of potassium channels and alterations in tissue renin-angiotensin-aldosterone pathways. Of particular interest is the potential role of the cystic fibrosis transmembrane conductance regulator (CFTR) protein. This protein regulates sphingolipids in smooth muscle cell membranes and promotes hypoxic pulmonary vasoconstriction. Blockers of this protein are also being studied.

Data from Dunham-Snary KJ et al: *Chest* 151(1):181-192, 2017; Evans AM et al: *Adv Exp Med Biol* 860:89-99, 2015; Jernigan NL: *Exp Physiol* 100(2):111-120, 2015; Lai N, Lu W, Wang J: *Int J Clin Exp Pathol* 8(2):1081-1092, 2015; Sommer N et al: *Eur Respir J* 47:288-303, 2016; Tabeling C et al: *Proc Natl Acad Sci U S A* 112(13):E1614-1623, 2015.

Acidemia also causes pulmonary artery constriction. If the acidemia is corrected, the vasoconstriction is reversed. (Respiratory acidosis and metabolic acidosis are described in [Chapter 3](#).) An elevated PaCO₂ value without a drop in pH does not cause pulmonary artery constriction. Other biochemical factors that affect the caliber of vessels

in pulmonary circulation are histamine, prostaglandins, endothelin, serotonin, nitric oxide, and bradykinin.

Chest Wall and Pleura

The chest wall (skin, ribs, intercostal muscles) protects the lungs from injury. The intercostal muscles of the chest wall, in conjunction with the **diaphragm**, perform the muscular work of breathing. The **thoracic cavity** is contained by the chest wall and encases the lungs (Fig. 35.7). A serous membrane called the **pleura** adheres firmly to the lungs. It then folds over itself and attaches firmly to the chest wall. The membrane covering the lungs is the *visceral pleura*; that lining the thoracic cavity is the *parietal pleura*. The area between the two pleurae is called the **pleural space**, or **pleural cavity**. Normally only a thin layer of fluid secreted by the pleura (pleural fluid) fills the pleural space. About 18 mL of fluid is in the pleural space with a pH of about 7.6, a few cells, about 1 g/dL protein, and glucose and electrolyte concentrations that approximate those of the plasma. This lubricates the pleural surfaces, allowing the two layers to slide over each other without separating. Pressure in the pleural space is usually negative or subatmospheric (−4 to −10 mmHg).

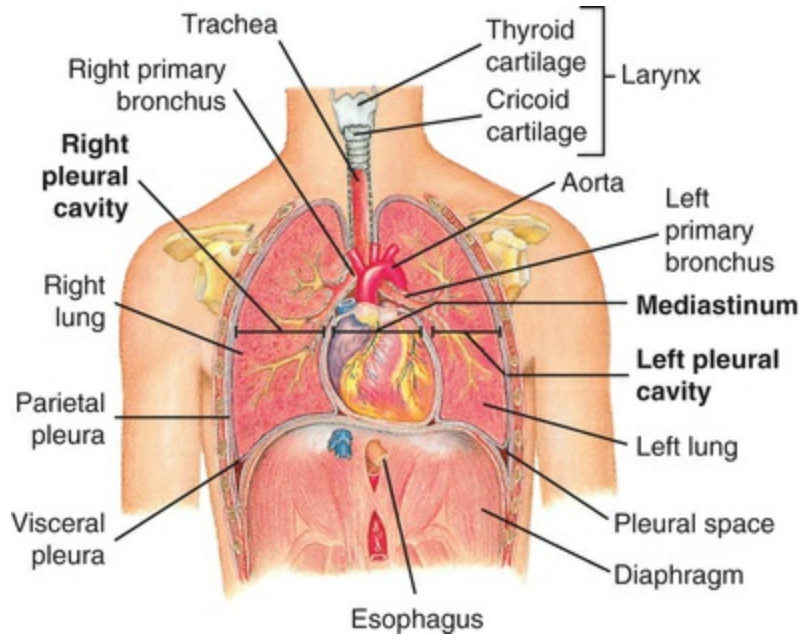

FIGURE 35.7 Thoracic (Chest) Cavity and Related Structures. The thoracic cavity is divided into three subdivisions (left and right pleural divisions and mediastinum) by a partition formed by a serous membrane called the *pleura*. (From Thibodeau GA, Patton KT: *Anatomy & physiology*, ed 3, St Louis, 1996, Mosby.)

Functions of the Pulmonary System

The pulmonary system (1) ventilates the alveoli, (2) diffuses gases into and out of the blood, and (3) perfuses the lungs so that the organs and tissues of the body receive blood that is rich in oxygen and low in CO₂. Each component of the pulmonary system contributes to one or more of these functions (Fig. 35.8).

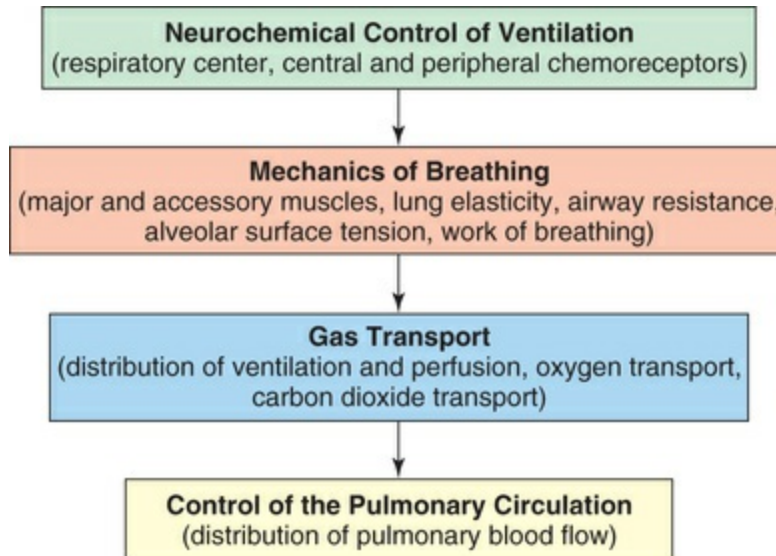

FIGURE 35.8 Functional Components of the Respiratory System. The central nervous system responds to neurochemical stimulation of ventilation and sends signals to the chest wall musculature. The response of the respiratory system to these impulses is influenced by several factors that affect the mechanisms of breathing and therefore affect the adequacy of ventilation. Gas transport between the alveoli and pulmonary capillary blood depends on a variety of physical and chemical activities. The control of the pulmonary circulation plays a role in the appropriate distribution of blood flow.

Ventilation

Ventilation is the mechanical movement of gas or air into and out of the lungs. Ventilation often is misnamed **respiration**, which is actually the exchange of O_2 and CO_2 during cellular metabolism. The ventilatory rate (or respiratory rate) is the number of times gas is inspired and expired per minute. The amount of effective ventilation is calculated by multiplying the ventilatory rate (breaths per minute) by the volume of air per breath (liters per breath, tidal volume). This is termed the **minute volume** (or **minute ventilation**) and is expressed in liters per minute.

CO_2 , the gaseous form of carbonic acid (H_2CO_3), is a product of cellular metabolism. The lung eliminates about 10,000 milliequivalents (mEq) of carbonic acid per day in the form of CO_2 , which is produced at the rate of approximately 200 mL/minute. CO_2 elimination is necessary to maintain a normal partial pressure of arterial CO_2 ($PaCO_2$)

of 40 mmHg and normal acid-base balance (see [Chapter 3](#) for a discussion of acid-base regulation). The adequacy of **alveolar ventilation** *cannot* be accurately determined by observation of ventilatory rate, pattern, or effort. If a healthcare professional needs to determine the adequacy of ventilation, an arterial blood gas analysis must be performed to measure PaCO₂.

Neurochemical Control of Ventilation

Breathing is usually involuntary, because homeostatic changes in the ventilatory rate and volume are adjusted automatically by the nervous system to maintain normal gas exchange. Voluntary breathing is necessary for talking, singing, laughing, and holding one's breath.

The **respiratory center** in the brainstem controls respiration by transmitting impulses to the respiratory muscles, causing them to contract and relax ([Fig. 35.9](#)). The medullary rhythmicity area is composed of interconnected groups of neurons located bilaterally in the brainstem: the dorsal respiratory group (DRG) and the ventral respiratory group (VRG).¹⁰ The basic automatic rhythm of respiration is set by the VRG, a cluster of inspiratory nerve cells located in the medulla that sends efferent impulses to the diaphragm and inspiratory intercostal muscles. The DRG receives afferent impulses from peripheral chemoreceptors in the carotid and aortic bodies; from mechanical, neural, and chemical stimuli; and from receptors in the lungs, and it alters breathing patterns to restore normal blood gases. The pontine respiratory center and apneustic center, situated in the pons, do not generate primary rhythm, but rather act as modifiers of the rhythm established by the medullary rhythmicity area. Breathing can be modified by input from the cortex, the limbic system, and the hypothalamus, and the pattern of breathing can be influenced by emotion and by disease.

FIGURE 35.9 Neurochemical Respiratory Control System.

Chemoreceptors.

Chemoreceptors monitor pH, $PaCO_2$, and PaO_2 . **Central chemoreceptors** monitor arterial blood indirectly by sensing changes in the pH of cerebrospinal fluid (CSF). They are located near the respiratory center and are sensitive to hydrogen ion concentration in brain interstitial fluid and the CSF (Chapter 3 describes the relationship between ions and the pH, or acid-base status, of body fluids). The pH, or concentration of hydrogen ions in the CSF, reflects arterial pH because CO_2 in arterial blood diffuses across the blood-

brain barrier (the capillary wall separating blood from cells of the central nervous system) into the CSF until the partial pressure of CO_2 (PCO_2) is equal on both sides. CO_2 that has entered the CSF combines with H_2O to form carbonic acid, which subsequently dissociates into hydrogen ions that are capable of stimulating the central chemoreceptors. In this way PaCO_2 regulates ventilation through its effect on the pH (hydrogen ion content) of the CSF.¹¹

If alveolar ventilation is inadequate, PaCO_2 increases. CO_2 diffuses across the blood-brain barrier until PCO_2 values in the blood and the CSF reach equilibrium. Because the central chemoreceptors sense the resulting decrease in pH (increase in hydrogen ion concentration), they stimulate the respiratory center to increase the depth and rate of ventilation. Increased ventilation causes the PaCO_2 of arterial blood to decrease below that of the CSF, and CO_2 diffuses out of the CSF, returning its pH to normal.

The central chemoreceptors are sensitive to very small changes in the pH of CSF (equivalent to a 1 to 2 mmHg change in PCO_2) and are able to maintain a normal PaCO_2 level under many different conditions, including strenuous exercise.¹¹ If inadequate ventilation, or hypoventilation, is a long-term condition (e.g., in chronic obstructive pulmonary disease), these receptors become insensitive to small changes in PaCO_2 and regulate ventilation poorly. In addition, prolonged increases in PaCO_2 result in renal compensation through bicarbonate retention. This bicarbonate gradually diffuses into the CSF, where it normalizes the pH and negates the effect on ventilatory drive.

The **peripheral chemoreceptors** are located in aortic bodies, the aortic arch, and carotid bodies at the bifurcation of the carotids, near the baroreceptors (see [Chapter 32](#)). They are somewhat sensitive to changes in PaCO_2 and pH but are primarily sensitive to oxygen levels in arterial blood (PaO_2). As PaO_2 and pH decrease, peripheral chemoreceptors, particularly in the carotid bodies, send signals to the respiratory center to increase ventilation. However, the PaO_2 must drop well below normal (to approximately 60 mmHg) before the

peripheral chemoreceptors have much influence on ventilation. If PaCO₂ is elevated as well, ventilation increases much more than it would in response to either abnormality alone. The peripheral chemoreceptors become the major stimulus to ventilation when the central chemoreceptors are “reset” by chronic hypoventilation.¹²

Lung Innervation.

Three types of lung sensory receptors send impulses from the lungs to the dorsal respiratory group:

1. **Irritant receptors** (rapidly adapting receptors) are found in the epithelium of the conducting airways.¹³ They are sensitive to noxious aerosols (vapors), gases, and particulate matter (e.g., inhaled dusts), which cause them to initiate the cough reflex. When stimulated, irritant receptors also cause bronchoconstriction and increased ventilatory rate. These receptors are located primarily in the proximal larger airways and are nearly absent in the distal airways; thus it is possible for secretions to accumulate in the distal respiratory tree without initiating cough.
2. **Stretch receptors** (slowly adapting receptors) are located in the smooth muscles of airways and are sensitive to increases in the size or volume of the lungs. They decrease ventilatory rate and volume when stimulated, an occurrence sometimes referred to as the *Hering-Breuer expiratory reflex*. This reflex is active in newborns and assists with ventilation.¹⁴ In adults, this reflex is active only at high tidal volumes (such as with exercise and mechanical ventilation) and may play a role in protecting against excess lung inflation.
3. **Pulmonary C-fiber receptors** (previously known as *J-receptors juxtapulmonary capillary receptors*) are located near the capillaries in the alveolar septa and in other airway locations as nociceptors. They are sensitive to increased pulmonary capillary pressure, which stimulates them to initiate rapid, shallow breathing; laryngeal constriction on expiration and

mucus secretion; hypotension; and bradycardia. They may be associated with the sensation of dyspnea.¹⁵

The lung is innervated by the autonomic nervous system (ANS). Fibers of the sympathetic division of the ANS in the lung branch from the upper thoracic and cervical ganglia of the spinal cord. Fibers of the parasympathetic division of the ANS travel in the vagus nerve to the lung. (Structures and function of the ANS are discussed in detail in [Chapter 15](#).) The parasympathetic and sympathetic divisions of the ANS control airway caliber (interior diameter of the airway lumen) by stimulating bronchial smooth muscle to contract or relax. The parasympathetic receptors cause smooth muscle to contract, whereas sympathetic receptors cause it to relax. Bronchial smooth muscle tone depends on equilibrium, that is, equal stimulation of contraction and relaxation. The parasympathetic division of the ANS is the main controller of airway caliber under normal conditions.¹⁶ Constriction occurs if the irritant receptors in the airway epithelium are stimulated by irritants in inspired air, by inflammatory mediators (e.g., histamine, serotonin, prostaglandins), by many drugs, and by humoral substances.

Mechanics of Breathing

The mechanical aspects of inspiration and expiration are known collectively as the *mechanics of breathing* and involve (1) major and accessory muscles of inspiration and expiration, (2) elastic properties of the lungs and chest wall, and (3) resistance to airflow through the conducting airways. Alterations in any of these properties increase the work of breathing, and thus the metabolic energy that must be exerted to achieve adequate ventilation and oxygenation of the blood.

Major and Accessory Muscles.

The major muscles of inspiration are the diaphragm and the external intercostal muscles (muscles between the ribs) ([Fig. 35.10](#)). The diaphragm is the primary muscle of ventilation, is dome-shaped, and separates the abdominal and thoracic cavities. It has multiple

intrathoracic attachments and is innervated by the paired phrenic nerves. When the diaphragm contracts, it flattens downward, increasing the volume of the thoracic cavity, and creates a negative pressure that draws gas into the lungs through the upper airways and trachea. Contraction of external intercostal muscles elevates the anterior portion of the ribs. This increases the volume of the thoracic cavity by increasing its front-to-back (anteroposterior [AP]) diameter. Although the external intercostal muscles may contract during quiet breathing, inspiration at rest usually is assisted by the diaphragm only.

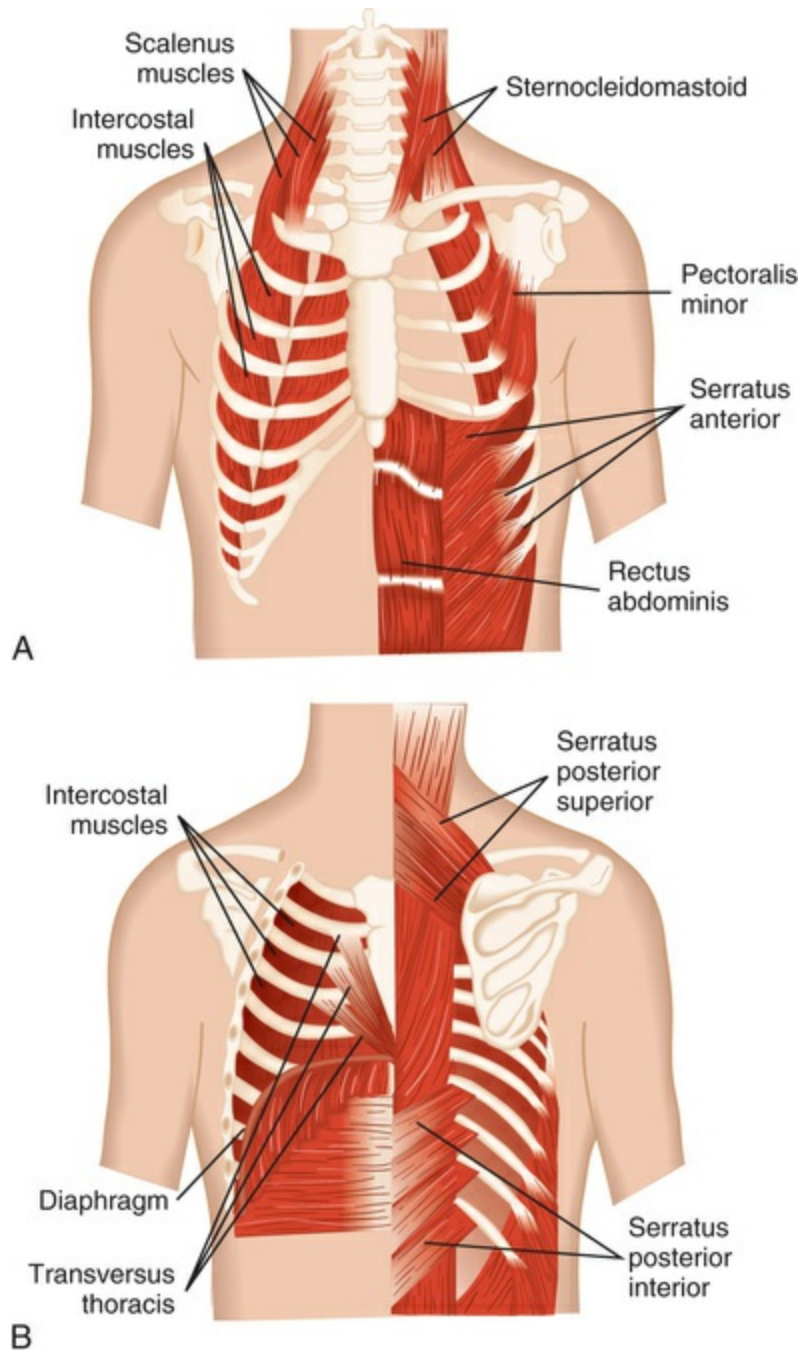

FIGURE 35.10 Muscles of Ventilation. A, Anterior view. B, Posterior view. (Modified from Thompson JM et al: *Mosby's clinical nursing*, ed 5, St Louis, 2002, Mosby.)

The accessory muscles of inspiration are the sternocleidomastoid and scalene muscles. Like the external intercostal muscles, these muscles enlarge the thorax by increasing its AP diameter. The accessory muscles of inspiration assist inspiration when the minute

volume (volume of air inspired and expired per minute) is very high, such as during strenuous exercise or when the work of breathing is increased because of disease. The accessory muscles do not increase the volume of the thorax as efficiently as the diaphragm does.¹⁷

There are no major muscles of expiration because normal, relaxed expiration is passive and requires no muscular effort. The accessory muscles of expiration, the abdominal and internal intercostal muscles, assist expiration when minute volume is high, when the person coughs, or when airway obstruction is present. When the abdominal muscles contract, intraabdominal pressure increases, pushing up the diaphragm and decreasing the volume of the thorax. The internal intercostal muscles pull down the anterior ribs, decreasing the AP diameter of the thorax.

Alveolar Surface Tension.

Surface tension occurs at any gas-liquid interface and refers to the tendency for liquid molecules that are exposed to air to adhere to one another. This phenomenon can be seen in the way liquids “bead” when splashed onto a waterproof surface, decreasing the surface area exposed to the air.

Within a sphere, such as an alveolus, surface tension tends to make expansion difficult. According to the law of Laplace, the pressure (P) required to inflate a sphere is equal to two times the surface tension ($2T$) divided by the radius (r) of the sphere, or $P = 2T/r$. As the radius of the sphere (or alveolus) becomes smaller, more and more pressure is required to inflate it. If the alveoli were lined with a water-like fluid, taking breaths would be extremely difficult.

Alveolar ventilation, or distention, is made possible by surfactant, which lowers the surface tension by coating the air-liquid interface in the alveoli (see [Fig. 35.3](#)). Surfactant, a lipoprotein (90% lipids and 10% protein) produced by type II alveolar cells, includes two groups of surfactant proteins (SPs). One group (SP-B and SP-C) consists of small hydrophobic molecules that have a detergent-like effect that separates the liquid molecules, thereby decreasing alveolar surface tension. The second group (SP-A and SP-D) consists of large

hydrophilic molecules called **collectins** (pattern recognition molecules) that are capable of inhibiting foreign pathogens³ (see [Chapter 7](#)).

Surfactant lines the alveolar side of the alveolocapillary membrane and, in effect, reverses the law of Laplace. As the radius of a surfactant-lined sphere (alveolus) becomes smaller, the surface tension *decreases*, and as the radius grows larger, the surface tension *increases*. This occurs because the surfactant molecules have much weaker intermolecular attraction than do liquid molecules. The surfactant molecules occupy most of the air-fluid interface and disrupt the intermolecular forces that tend to collapse the alveoli. Therefore, the alveoli are much easier to inflate at low lung volumes (i.e., after expiration) than at high volumes (i.e., after inspiration). The decrease in surface tension caused by surfactant also is responsible for keeping the alveoli free of fluid. If surfactant production is disrupted or surfactant is not produced in adequate quantities (e.g., as in premature infants), alveolar surface tension increases, causing alveolar collapse, decreased lung expansion, increased work of breathing, and severe gas-exchange abnormalities.

Elastic Properties of the Lung and Chest Wall.

The lung and chest wall have elastic properties that permit expansion during inspiration and return to resting volume during expiration. The elasticity of the lungs is caused both by elastin fibers in the alveolar walls and in the surrounding small airways and pulmonary capillaries and by surface tension at the alveolar air-liquid interface. The elasticity of the chest wall is supported by the configuration of its bones and musculature.

Elastic recoil is the tendency of the lungs to return to the resting state after inspiration. Normal elastic recoil permits passive expiration, eliminating the need for major muscles of expiration. Passive elastic recoil may be insufficient during labored breathing (high minute volume), in which case the accessory muscles of expiration may be needed. The accessory muscles also are used if disease compromises elastic recoil (e.g., in emphysema) or blocks the

conducting airways.

Normal elastic recoil depends on the equilibrium between opposing forces of recoil in the lungs and chest wall. Under normal conditions the chest wall tends to recoil by expanding outward. When the sternum is split to open the thoracic cavity, the chest wall moves outward laterally. The tendency of the chest wall to recoil by expanding is balanced by the tendency of the lungs to recoil or collapse inward around the hila. This reaction is caused by elastic recoil and surface tension in the alveoli. The opposing forces of the chest wall and lungs create, in part, the small negative intrapleural pressure.

Balance between the outward recoil of the chest wall and the inward recoil of the lungs occurs at the resting level, at the end of expiration. During inspiration the diaphragm and intercostal muscles contract, air flows into the lungs, and the chest wall expands. Muscular effort is needed to overcome the resistance of the lungs to expansion. During expiration the muscles relax and the elastic recoil of the lungs causes the thorax to decrease in volume until, once again, balance between the chest wall and lung recoil forces is reached¹⁸ (Fig. 35.11).

FIGURE 35.11 Interaction of Forces During Inspiration and Expiration. **A**, Outward recoil of the chest wall equals inward recoil of the lungs at the end of expiration. **B**, During inspiration, contraction of respiratory muscles, assisted by chest wall recoil, overcomes tendency of lungs to recoil. **C**, At the end of inspiration, respiratory muscle contraction maintains lung expansion. **D**, During expiration, respiratory muscles relax, allowing elastic recoil of the lungs to deflate the lungs.

Compliance is the measure of lung and chest wall distensibility. It represents the relative ease with which these structures can be stretched. Compliance is therefore the reciprocal of elasticity. Compliance is determined by the alveolar surface tension and the elastic recoil of the lung and chest wall. It can be measured with the following formula:

$$C = \frac{\Delta V}{\Delta P}$$

where C = compliance in liters per centimeter of water, ΔV = volume change (usually tidal volume), and ΔP = pressure change (airway or pleural pressure) in centimeters of water.

Increased compliance indicates that the lungs or chest wall is abnormally easy to inflate and has lost some elastic recoil. A decrease in compliance indicates that the lungs or chest wall is abnormally stiff or difficult to inflate. Compliance increases with normal aging and with disorders such as emphysema; it decreases in individuals with acute respiratory distress syndrome, pneumonia, pulmonary edema, and fibrosis. (These disorders are described in [Chapter 36](#).)

Airway Resistance.

Airway resistance, which is similar to resistance to blood flow (described in [Chapter 32](#)), is determined by the length, radius, and cross-sectional area of the airways and by the density, viscosity, and velocity of the gas (Poiseuille's law). Resistance is computed by dividing change in pressure (P) by rate of flow (F), or $R = P/F$ (Ohm's law), and can easily be measured in the pulmonary function laboratory.¹⁹ Airway resistance is normally very low. One-half to two-thirds of total airway resistance occur in the nose. The next highest resistance is in the oropharynx and larynx. Airway resistance also is affected by the diameter of the airways, and there is very little resistance in the conducting airways of the lungs because of their large cross-sectional area. **Bronchodilation**, which decreases resistance to airflow, is caused by β_2 -adrenergic receptor stimulation. **Bronchoconstriction**, which increases airway resistance, can be caused by stimulation of parasympathetic receptors in the bronchial smooth muscle and by numerous irritants and inflammatory mediators. Airway resistance also can be increased by edema of the bronchial mucosa and by airway obstructions such as mucus, tumors, or foreign bodies. Pulmonary function tests (PFTs) measure lung volumes and flow rates and can be used to diagnose lung disease.

Work of Breathing.

The **work of breathing** is determined by the muscular effort (and

therefore oxygen and energy) required for ventilation. The work of breathing is normally very low, but may increase considerably in disease states that disrupt the equilibrium between forces exerted by the lung and chest wall. More muscular effort is required when lung compliance is decreased (e.g., in pulmonary edema), chest wall compliance is decreased (e.g., in spinal deformity or obesity), or airways are obstructed by bronchospasm or mucous plugging (e.g., in asthma or bronchitis). An increase in the work of breathing can result in a marked increase in oxygen consumption and an inability to maintain adequate ventilation.

Gas Transport

Gas transport, the delivery of oxygen to the cells of the body, requires four steps:

1. Ventilation of the lungs
2. Diffusion of oxygen from the alveoli into the capillary blood
3. Perfusion of systemic capillaries with oxygenated blood
4. Diffusion of oxygen from systemic capillaries into the cells

The removal of CO_2 also has four steps and occurs in reverse order of oxygen delivery:

1. Diffusion of CO_2 from the cells into the systemic capillaries
2. Perfusion of the pulmonary capillary bed by venous blood
3. Diffusion of CO_2 into the alveoli
4. Removal of CO_2 from the lung by ventilation

If any step in gas transport is impaired by a respiratory or cardiovascular disorder, gas exchange at the cellular level is compromised.

Measurement of Gas Pressure

The properties of air, once it enters the body, are determined by interactions among gas molecules at a given temperature. The millions of gas molecules are moving randomly, colliding with each other and the wall of the space in which they are contained. These collisions exert pressure. If the same number of gas molecules is contained in a small and a large container, the pressure is greater in the small container because more collisions occur in the smaller space (Fig. 35.12). Heat increases the speed of the molecules, which increases the number of collisions and, therefore, the pressure.

FIGURE 35.12 Relationship Between Number of Gas Molecules and Pressure Exerted by the Gas in an Enclosed Space. A, Theoretically, 10 molecules of the same gas exert a total pressure of 10 mmHg within the space. B, If the number of molecules is increased to 20, the total pressure is 20 mmHg. C, If there are different gases in the space, each gas exerts a partial pressure: here the partial pressure of nitrogen (yellow) is 18, the partial pressure of oxygen (blue) is 6, and the total pressure is 24 mmHg.

Barometric pressure (P_B) (atmospheric pressure) is the pressure exerted by gas molecules in air at specific altitudes. At sea level, barometric pressure is 760 mmHg. This number is the sum of the pressure exerted by each gas in the air at sea level. The portion of the total pressure exerted by any individual gas is its **partial pressure** (see Fig. 35.12). At sea level the air is made up of oxygen (20.9%), nitrogen (78.1%), and a few other trace gases. The partial pressure of oxygen is equal to the percentage of oxygen in the air (20.9%) times the total P_B (760 mmHg), or 159 mmHg ($760 \times 0.209 = 158.84$ mmHg). (Symbols used in the measurement of gas pressures and pulmonary ventilation

are defined in [Table 35.2](#).)

TABLE 35.2

COMMON PULMONARY ABBREVIATIONS

SYMBOL*	DEFINITION
V	Volume or amount of gas
Q	Perfusion or blood flow
P	Pressure (usually partial pressure) of a gas
PiO ₂	Partial pressure of inspired oxygen (varies with altitude)
PaO ₂	Partial pressure of oxygen in arterial blood
PAO ₂	Partial pressure of oxygen in alveolar blood
PaCO ₂	Partial pressure of carbon dioxide in arterial blood
PH ₂ O	Partial pressure of water vapor
PN ₂	Partial pressure of nitrogen
PvO ₂	Partial pressure of oxygen in mixed venous or pulmonary artery blood
P(A-a)O ₂	Difference between alveolar and arterial partial pressure of oxygen (A-a gradient)
P _B	Barometric or atmospheric pressure
SaO ₂	Saturation of hemoglobin (in arterial blood) with oxygen
$\bar{S}vO_2$	Saturation of hemoglobin (in mixed venous blood)
V _A	Alveolar ventilation—effective total lung capacity
V _D	Dead-space ventilation
V _E	Minute capacity
V _T	Tidal volume or average breath
V/Q	Ratio of ventilation to perfusion
FiO ₂	Fraction (percent) of inspired oxygen (0.21)
FRC	Functional residual capacity
FVC	Forced vital capacity
FEV ₁	Forced expiratory volume in 1 second
ERV	Expiratory reserve volume
IRV	Inspiratory reserve volume
IC	Inspiratory capacity

*Subscripts identify the particular gas, volume, or pressure being discussed. An overhead dot, such as in \dot{V}/\dot{Q} , means measurement over time, usually 1 minute.

From Kacmarek RM, Stoller JK, Heuer AJ: *Egan's fundamentals of respiratory care*, ed 11, St Louis, 2017, Mosby.

The amount of water vapor contained in a gas mixture is determined by the temperature of the gas and is unrelated to P_B . Gas that enters the lungs becomes saturated with water vapor (humidified) as it passes through the upper airway. At body temperature (37°C [98.6°F]), water vapor exerts a pressure of 47 mmHg regardless of total P_B . The partial pressure of water vapor must be subtracted from the P_B before the partial pressure of other gases in the mixture can be determined. In air saturated with water at sea level, the partial pressure of oxygen is therefore $(760 - 47) \times 0.209 = 149$ mmHg. All pressure and volume measurements made in pulmonary function laboratories specify the temperature and humidity of a gas at the time of measurement.

Distribution of Ventilation and Perfusion

Effective gas exchange depends on an approximately even distribution of gas (ventilation) and blood (perfusion) in all portions of the lungs. The lungs are suspended from the hila in the thoracic cavity. When the individual is in an upright position (sitting or standing), gravity pulls the lungs down toward the diaphragm and creates a greater negative pleural pressure in the upper portions, or apices of the lungs, than at the base. The alveoli in the apices also contain a greater residual volume of gas and are larger and less numerous than those in the lower portions. Surface tension increases as the alveoli become larger. The combination of greater negative pleural pressure and higher surface tension in the larger alveoli in the apex of the lung makes them more difficult to inflate (less compliant, or less distensible) than the smaller alveoli in the lower portions of the lung. Therefore, during ventilation most of the tidal volume is distributed to the bases of the lungs, where compliance is greater.

The heart pumps against gravity to perfuse the pulmonary

circulation. As blood is pumped into the lung apices of a sitting or standing individual, some blood pressure is dissipated in overcoming gravity. As a result, blood pressure at the apices is lower than that at the bases. Because greater pressure causes greater perfusion, the bases of the lungs are better perfused than the apices (Fig. 35.13). Thus ventilation and perfusion are greatest in the same lung portions: the lower lobes. Ventilation and perfusion depend on body position. If a standing individual assumes a supine or side-lying position, the areas of the lungs that are then most dependent become the best ventilated and perfused.

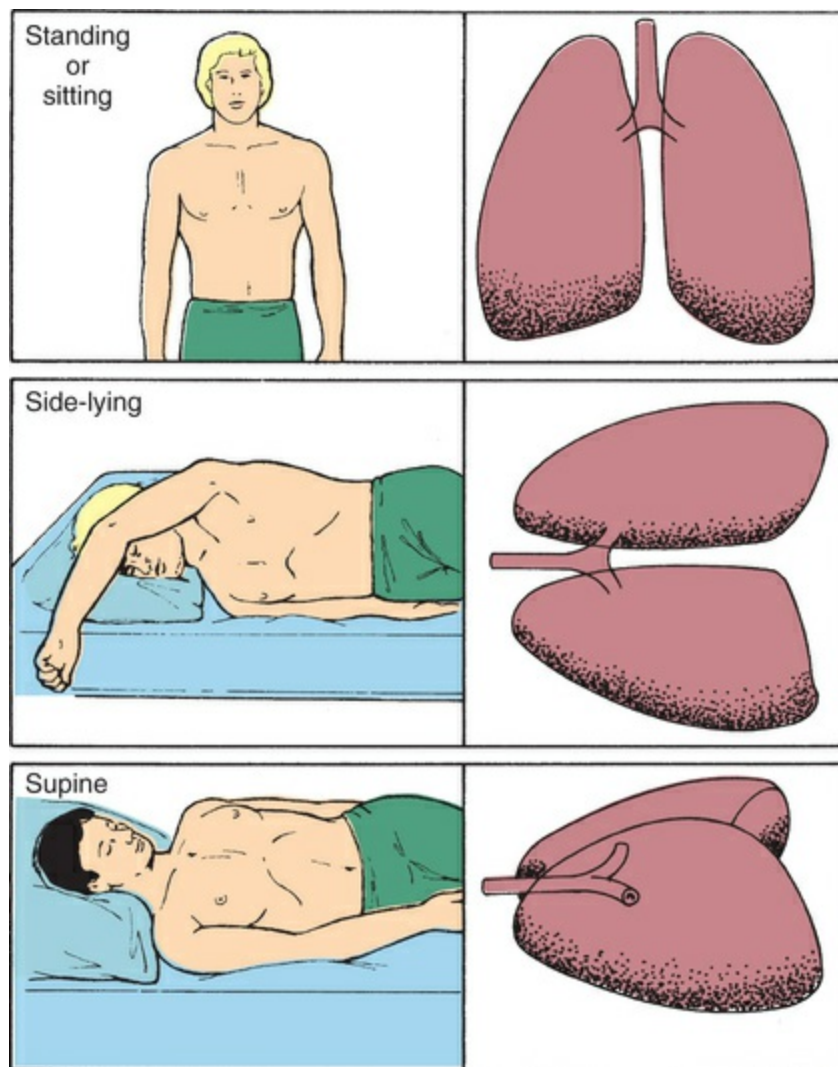

FIGURE 35.13 Pulmonary Blood Flow and Gravity. The greatest volume of pulmonary blood flow will normally occur in the gravity-dependent areas of

the lungs. Body position has a significant effect on the distribution of pulmonary blood flow. Shaded areas represent gravity-dependent pulmonary blood flow.

Distribution of perfusion in the pulmonary circulation also is affected by alveolar pressure (gas pressure in the alveoli). The pulmonary capillary bed differs from the systemic capillary bed in that it is surrounded by gas-containing alveoli. If the gas pressure in the alveoli exceeds the blood pressure in the capillary, the capillary collapses and flow ceases. This occurs in portions of the lung where blood pressure is lowest and alveolar gas pressure is greatest, that is, the apex of the lung. The lungs are divided into three zones on the basis of the combination of factors affecting pulmonary blood flow. Alveolar pressure and the forces of gravity, arterial blood pressure, and venous blood pressure determine the distribution of perfusion (Fig. 35.14).

FIGURE 35.14 Gravity and Alveolar Pressures. Effects of gravity and alveolar pressure on pulmonary blood flow in the three lung zones. In zone I, alveolar pressure (P_A) is greater than both arterial and venous pressures, and no blood flow occurs. In zone II, arterial pressure (P_a) exceeds alveolar pressure, but alveolar pressure exceeds venous pressure (P_v). Blood flow occurs in this zone, but alveolar pressure compresses the venules (venous ends of the capillaries). In zone III, both arterial and venous pressures are greater than alveolar pressure and blood flow fluctuates, depending on the

difference between arterial and venous pressures.

In zone I, alveolar pressure exceeds pulmonary arterial and venous pressures. The capillary bed collapses, and normal blood flow ceases. Zone I is a very small part of the lung at the apex. In zone II, alveolar pressure is greater than venous pressure, but not greater than arterial pressure. Blood flows through zone II, but it is impeded to a certain extent by alveolar pressure. Zone II is above the level of the left atrium. In zone III arterial and venous pressures are greater than alveolar pressure and blood flow is not affected by alveolar pressure. Zone III is in the base of the lung. Blood flow through the pulmonary capillary bed increases in regular increments from the apex to the base.

Although blood flow and ventilation are greater at the base of the lungs than at the apexes, they are not perfectly matched in any zone. Perfusion exceeds ventilation in the bases, and ventilation exceeds perfusion in the apexes of the lung. The relationship between ventilation and perfusion is expressed as a ratio called the **ventilation-perfusion ratio**, or V/Q . The normal V/Q ratio is 0.8. This is the amount by which perfusion exceeds ventilation under normal conditions.

Oxygen Transport

Approximately 1000 mL (1 L) of oxygen is transported to the cells of the body each minute. Oxygen is transported in the blood in two forms: a small amount dissolves in plasma, and the remainder binds to hemoglobin molecules. Without hemoglobin, oxygen would not reach the cells in amounts sufficient to maintain normal metabolic function. (Hemoglobin is discussed in detail in [Chapter 28](#); cellular metabolism is discussed in [Chapter 1](#).)

Diffusion Across the Alveolocapillary Membrane.

The alveolocapillary membrane is the ideal medium for oxygen diffusion, because it has a large total surface area (70 to 100 m²) and is very thin (0.5 μm). In addition, the partial pressure of oxygen

molecules (PO_2) is much greater in alveolar gas than in capillary blood, a condition that promotes rapid diffusion down the concentration gradient from the alveolus into the capillary.²⁰

The amount of oxygen in the alveoli (PAO_2) depends on the amount of oxygen in the inspired air and on the amount of oxygen that remains in the alveoli and tracheobronchial tree (**physiologic dead space**) between breaths (i.e., the amount of oxygen that has not been consumed).²¹ The PAO_2 can be estimated by using the alveolar gas equation:

$$\text{PAO}_2 = \text{PiO}_2 - \text{PaCO}_2 / 0.8 \text{ (the respiratory quotient)}$$

where PiO_2 is the inspired partial pressure of oxygen and is calculated as:

$$\text{PiO}_2 = (\text{Barometric pressure} - 47 \text{ mmHg [vapor pressure of water]}) \times \text{FiO}_2 (0.21)$$

The PAO_2 value is approximately 104 mmHg at sea level with relaxed breathing; therefore a pressure gradient of approximately 60 mmHg facilitates the diffusion of oxygen from the alveolus into the capillary (Fig. 35.15). Different values for PAO_2 can be calculated if there are changes in the inspired oxygen content or the PaCO_2 , which are common occurrences in clinical settings.

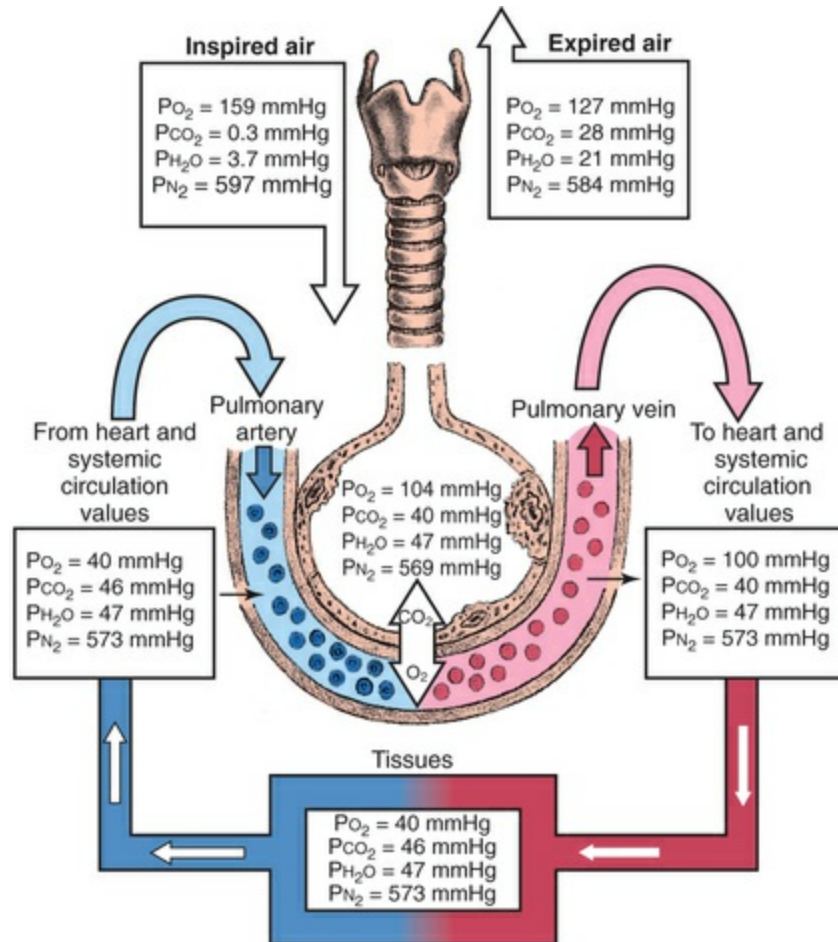

FIGURE 35.15 Partial Pressure of Respiratory Gases in Normal Respiration. These are average values. The values of PO_2 , PCO_2 , and PN_2 fluctuate from breath to breath. CO_2 , Carbon dioxide; O_2 , oxygen; PCO_2 , partial pressure of carbon dioxide; PH_2O , partial pressure of water; PN_2 , partial pressure of nitrogen; PO_2 , partial pressure of oxygen.

Blood remains in the pulmonary capillary for about 0.75 second, but only 0.25 second is required for oxygen concentration to equilibrate (equalize) across the alveolocapillary membrane. Therefore, oxygen has ample time to diffuse into the blood, even during increased cardiac output, which speeds blood flow, shortening the time the blood remains in the capillary.

Determinants of Arterial Oxygenation.

As oxygen diffuses across the alveolocapillary membrane, it dissolves in the plasma, where it exerts pressure (the partial pressure of oxygen in arterial blood, or PaO_2). As the PaO_2 increases, oxygen moves from

the plasma into the red blood cells (erythrocytes) and binds with hemoglobin molecules. Oxygen continues to bind with hemoglobin until the hemoglobin binding sites are filled or saturated. Oxygen then continues to diffuse across the alveolocapillary membrane until the P_{aO_2} and P_{AO_2} equilibrate, eliminating the pressure gradient across the alveolocapillary membrane. At this point diffusion ceases (see [Fig. 35.15](#)).

The majority (97%) of the oxygen that enters the blood is bound to hemoglobin. The remaining 3% stays in the plasma. The P_{aO_2} can be measured in the blood by obtaining an arterial blood gas measurement. The oxygen saturation (S_{aO_2}) is the percentage of the available hemoglobin that is bound to oxygen and can be measured using a device called an *oximeter*. The total amount of oxygen carried in the blood is the **oxygen content** and is measured in milliliters per deciliter (1 dL = 100 mL) of blood. It is the combined value of the oxygen in oxygen-saturated hemoglobin and the oxygen dissolved in the blood.

To calculate the total arterial oxygen content, one must know (1) the hemoglobin concentration, or the amount of hemoglobin that is available to bind with oxygen (hemoglobin [Hb] in grams per deciliter); (2) the oxygen saturation, or the percentage of available hemoglobin that is bound to oxygen (S_{aO_2}); and (3) the partial pressure of oxygen (P_{aO_2}). The maximum amount of oxygen that can be transported by hemoglobin is 1.34 mL/g. The amount of oxygen that can be physically dissolved in blood is 0.003 mL/dL per mmHg. With the specific values known, the oxygen content of arterial blood can be calculated. To calculate the oxygen content of venous blood, the partial pressure of mixed venous blood (P_{vO_2}) and venous oxygen saturation (S_{vO_2}) are substituted for the arterial values in the basic formula. Normal venous oxygen content is 15 to 16 mL/dL.

Because hemoglobin transports all but a small fraction of the oxygen carried in arterial blood, increases in hemoglobin concentration affect the oxygen content of the blood. Decreases in hemoglobin concentration below the normal value of about 15 mL/dL of blood reduce oxygen content. Increases in hemoglobin

concentration may increase oxygen content, minimizing the effect of impaired gas exchange. In fact, increased hemoglobin concentration is a major compensatory mechanism in pulmonary diseases that impair gas exchange. For this reason, measurement of hemoglobin concentration is important in assessing individuals with pulmonary disease. If cardiovascular function is normal, the body's initial response to low oxygen content is to accelerate cardiac output. In individuals who also have cardiovascular disease, this compensatory mechanism is ineffective. An elevated Hb level can compensate for an inability to accelerate cardiac output, making increased hemoglobin concentration an even more important compensatory mechanism.

Oxyhemoglobin Association and Dissociation.

Oxyhemoglobin (HbO₂) forms when hemoglobin molecules bind with oxygen. Binding occurs in the lungs and is called *oxyhemoglobin association* or *hemoglobin saturation with oxygen* (SaO₂). The reverse process, where oxygen is released from hemoglobin, occurs in the body tissues at the cellular level and is called *hemoglobin desaturation*. When hemoglobin saturation and desaturation are plotted on a graph, the result is a distinctive S-shaped curve known as the **oxyhemoglobin dissociation curve** (Fig. 35.16). For PaO₂ values less than 60 mmHg, oxygen is readily unloaded to peripheral tissues and hemoglobin's affinity for oxygen diminishes, reflecting the steep part of the curve. For PaO₂ values greater than 60 mmHg, the curve becomes relatively flat, reflecting the maximum saturation of hemoglobin with oxygen in the lungs.

FIGURE 35.16 Oxyhemoglobin Dissociation Curve. The horizontal or flat segment of the curve at the top of the graph is the arterial or association portion, or that part of the curve where oxygen is bound to hemoglobin and occurs in the lungs. This portion of the curve is flat because partial pressure changes of oxygen between 60 and 100 mmHg do not significantly alter the percentage saturation of hemoglobin with oxygen and allow adequate hemoglobin saturation at a variety of altitudes. If the relationship between SaO_2 and PaO_2 was linear (in a downward sloping straight line) instead of flat between 60 and 100 mmHg, there would be inadequate saturation of hemoglobin with oxygen. The steep part of the oxyhemoglobin dissociation curve represents the rapid dissociation of oxygen from hemoglobin that occurs in the tissues. During this phase, there is rapid diffusion of oxygen from the blood into tissue cells. The P_{50} is the PaO_2 at which hemoglobin is 50% saturated, normally 26.6 mmHg. A lower than normal P_{50} represents increased affinity of hemoglobin for O_2 ; a high P_{50} is seen with decreased affinity. Note that variation from the normal is associated with decreased (low P_{50}) or increased (high P_{50}) availability of O_2 to tissues (*dashed lines*). The shaded area shows the entire oxyhemoglobin dissociation curve under the same circumstances. 2,3-DPG, 2,3-Diphosphoglycerate. (From Lane EE, Walker JF: *Clinical arterial blood gas analysis*, St Louis, 1987, Mosby.)

Several factors can change the relationship between PaO_2 and SaO_2 and influence hemoglobin's affinity for oxygen (see Fig. 35.16). At a PaO_2 of 26.6 mmHg, hemoglobin is 50% saturated, known as P_{50} . An increase in the P_{50} value shifts the curve to the right, indicating hemoglobin's decreased affinity for oxygen or an increase in the ease

with which oxyhemoglobin dissociates and oxygen moves into the cells. A larger partial pressure is necessary to maintain 50% oxygen saturation. A shift to the left depicts hemoglobin's increased affinity for oxygen, which promotes association in the lungs and inhibits dissociation in the tissues. A lower partial pressure is necessary to maintain 50% oxygen saturation.

The oxyhemoglobin dissociation curve is shifted to the right by acidosis (low pH) and hypercapnia (increased PaCO_2). In the tissues, increased levels of CO_2 and hydrogen ions produced by metabolic activity decrease the affinity of hemoglobin for oxygen. Hyperthermia and increased levels of 2,3-diphosphoglycerate (2,3-DPG, a substance normally present in erythrocytes) also shift the curve to the right. The curve is shifted to the left by alkalosis (high pH), hypocapnia (decreased PaCO_2), hypothermia, and decreased 2,3-DPG levels.

In the lungs, as CO_2 diffuses from the blood into the alveoli, the blood CO_2 level is reduced and the affinity of hemoglobin for oxygen is increased. The shift in the oxyhemoglobin dissociation curve caused by changes in CO_2 and hydrogen ion concentration in the blood is called the **Bohr effect**.

Carbon Dioxide Transport

Approximately 200 mL of CO_2 is produced by the tissues per minute at rest as a byproduct of cellular metabolism. This CO_2 equilibrates with carbonic acid (H_2CO_3) and must be eliminated continuously to prevent acidosis. The elimination of CO_2 by the lungs plays an important role in the regulation of acid-base balance (see [Chapter 3](#)).

CO_2 is carried in the blood in three ways: (1) dissolved in plasma, (2) transported as bicarbonate, and (3) combined with blood proteins to form carbamino compounds. As CO_2 diffuses out of the cells into the blood, it dissolves in the plasma. Approximately 10% of the total CO_2 in venous blood and 5% of the CO_2 in arterial blood are carried dissolved in the plasma. As CO_2 moves into the blood, it diffuses into the red blood cells. Within the red blood cells, CO_2 , with the help of

the enzyme carbonic anhydrase, combines with water to form carbonic acid and then quickly dissociates into H^+ and HCO_3^- . As carbonic acid dissociates, the H^+ binds to hemoglobin, where it is buffered, and the HCO_3^- moves out of the red blood cell into the plasma. Approximately 60% of the CO_2 in venous blood and 90% of the CO_2 in arterial blood are carried in the form of bicarbonate. The remainder combines with blood proteins, hemoglobin in particular, to form carbamino compounds (see Fig. 3.13). Approximately 30% of the CO_2 in venous blood and 5% of the CO_2 in arterial blood are carried as carbamino compounds.

CO_2 is 20 times more soluble than O_2 and diffuses quickly from the tissue cells into the blood. The amount of CO_2 that is able to enter the blood is enhanced by diffusion of oxygen out of the blood and into the cells. Reduced hemoglobin (hemoglobin that is dissociated from oxygen) is able to carry more CO_2 than hemoglobin that is saturated with O_2 . Therefore, the drop in SaO_2 at the tissue level increases the ability of hemoglobin to carry CO_2 back to the lung.

The diffusion gradient for CO_2 in the lung is only approximately 6 mmHg (venous $PvCO_2 = 46$ mmHg; alveolar $PACO_2 = 40$ mmHg), yet CO_2 is so soluble in the alveolocapillary membrane that the CO_2 in the blood quickly diffuses into the alveoli, where it is removed from the lung with each expiration. Diffusion of CO_2 in the lung is so efficient that diffusion defects that cause hypoxemia (low oxygen content of the blood) do not cause hypercapnia (excessive CO_2 in the blood).

The diffusion of CO_2 out of the blood also is enhanced by oxygen binding with hemoglobin in the lung. As hemoglobin binds with O_2 , the amount of CO_2 carried by the blood is decreased. Thus in the tissue capillaries, O_2 dissociation from hemoglobin facilitates the pickup of CO_2 , and the binding of O_2 to hemoglobin in the lungs facilitates the release of CO_2 from the blood. This effect of oxygen on CO_2 transport is called the **Haldane effect**.

Tests of Pulmonary Function

Several laboratory tests aid in the diagnosis and evaluation of pulmonary system abnormalities. Most of them are easy to perform at hospitals and clinics. They provide valuable information about the possible cause of a respiratory abnormality and evaluate the progression or resolution of disease.²² Spirometry measures the volume and flow of air inhaled and exhaled and is plotted against time (flow rate) during different breathing maneuvers. Several different types of spirometer are available. The procedure produces a spirogram, which is a record of the individual's ventilation in relation to time (Fig. 35.17). Clinically the most important spirometric tests are the forced vital capacity (FVC) and the forced expiratory volume in 1 second (FEV_1). (These tests and other important measurements are described in Table 35.3.) Spirometry enables clinicians to detect restrictive or obstructive deficits early in the course of disease. *Restrictive lung diseases* restrict the lungs' volume; the lungs are unable to expand normally, diminishing the amount of gas that can be inspired and reducing the FVC. *Obstructive lung diseases* affect gas flow; airflow into and out of the lungs is obstructed, reducing the FEV_1 .

A

B

FIGURE 35.17 Pulmonary Ventilation and Lung Capacities. A, Spirogram. During normal, quiet respirations the atmosphere and lungs exchange about 500 mL of air (V_T). With a forcible inspiration, about 3300 mL more air can be inhaled (*IRV*). After a normal inspiration and normal expiration, approximately 1000 mL more air can be forcibly expired (*ERV*). Vital capacity is the amount of air that can be forcibly expired after a maximal inspiration and indicates, therefore, the largest amount of air that can enter and leave the lungs during respiration. Residual volume (*RV*) is the air that remains trapped in the alveoli. B, Lung capacities. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

TABLE 35.3

VALUES MEASURED BY SPIROMETRY

VALUES MEASURED BY SPIROMETRY

SYMBOL VENTILATORY PROPERTY MEASURED	
FVC	Forced vital capacity; maximum amount of gas that can be displaced from the lung during a forced expiration
FEV ₁	Forced expiratory volume in 1 second; maximum amount of air that can be expired from the lung in 1 second
FEV ₁ /FVC	Percentage of maximum inspiration that is expired in 1 second; usually 80% of FVC
FEV ₃	Forced expiratory volume in 3 seconds; maximum amount of gas that can be expired in 3 seconds
FEV ₃ /FVC	Percentage of FVC that is expired in 3 seconds; usually 95% of FVC
FEF _{25-75%}	Forced expiratory flow rate during the middle 50% of expiration; sometimes reported as maximum midexpiratory flow rate (MMFR)
MVV	Maximum voluntary ventilation
PEF	Peak expiratory flow

Lung capacities, such as vital capacity (sum of inspiratory reserve volume, tidal volume, and expiratory reserve volume) and total lung capacity (sum of the vital capacity and the residual capacity), are always the sum of two or more volumes. Norms for volumes and capacities are based on age, sex, and height and are referred to as *predicted values*. Differences from predicted or changes from baseline values are taken into account in diagnosing and assessing respiratory disorders.

Pulmonary diffusing capacity (transfer factor) is a measure of the rate of gas diffusion across the alveolocapillary membrane. Oxygen, or more commonly carbon monoxide, is used to measure diffusing capacity. Carbon monoxide has high affinity for hemoglobin and is not limited by pulmonary blood flow and therefore is an excellent measure of diffusion. The measurement is made by determining how much carbon monoxide is taken up by the blood and dividing this amount by the pressure gradient across the alveolocapillary membrane. Helium (an inert gas poorly soluble in alveolar blood and lung tissue) often is added to the gas mixture to obtain a simultaneous measurement of **residual volume (RV)**, **functional residual capacity (FRC)**, and **total lung capacity (TLC)**. Individuals are asked to perform ventilatory maneuvers similar to those used in spirometry testing. A decreased diffusing capacity can be the result of an

abnormal ventilation-perfusion ratio or an actual diffusion defect. For example, diffusing capacity is decreased in individuals with emphysema, where there is a decrease in the surface area of pulmonary capillaries available for gas exchange.

Oximetry is commonly performed for individuals with suggested or diagnosed pulmonary disease. It indirectly measures hemoglobin oxygen saturation and can suggest that the PaO_2 is low. However, it is prone to inaccurate measurements, particularly in individuals with poor peripheral circulation, and does not measure the PaCO_2 or pH of the blood. **Capnography** measures the amount of CO_2 in expired air and thus estimates PaCO_2 , but this test is also prone to inaccuracy. **Arterial blood gas analysis** is the direct measurement of the pH and gas concentrations in arterial blood and provides more accurate and complete information about an individual's gas exchange and acid-base status. Acidosis (low pH), alkalosis (high pH), ventilatory alterations, and decreased PaO_2 can be diagnosed accurately only by arterial blood gas analysis. A blood gas report may be divided into an acid-base/ventilation portion and an oxygenation portion. (Normal values for arterial blood gases are given in [Table 35.4](#); acid-base alterations are described in [Chapter 3](#).) Oximetry can be used to monitor oxygen saturation once the arterial blood gas analysis has accurately measured the PaO_2 , but it does not measure PaCO_2 or pH.

TABLE 35.4

NORMAL RANGES FOR ARTERIAL AND MIXED VENOUS BLOOD GASES

MEASUREMENT	ARTERIAL BLOOD	MIXED VENOUS BLOOD*	CLINICAL NOTES
Acid-base status (pH)	7.35–7.45	7.33–7.43	Most important acid-base value; detects acidosis or alkalosis
Partial pressure of carbon dioxide (PCO_2)	35–45 mmHg	41–57 mmHg	Measures adequacy of ventilation and respiratory contribution of acid-base abnormality (respiratory acidosis)
Bicarbonate concentration	22–26 mEq/L	24–28 mEq/L	Measures metabolic contribution to acid-base abnormality (metabolic acidosis); calculated

(HCO ₃ ⁻)			from pH and PCO ₂
Base excess (BE)	-2 to +2	0 to +4	Reflects deviation of bicarbonate concentration from normal
Partial pressure of oxygen (PO ₂) (sea level)	80–100 mmHg	35–40 mmHg	Indicates driving pressure that causes oxyhemoglobin binding; varies with age and barometric pressure
Saturation of hemoglobin with oxygen (SO ₂)	96%–98%	70%–75%	Indicates abnormalities of oxyhemoglobin association and dissociation; may be measured directly or calculated from PCO ₂ , pH, and body temperature
Concentration of hemoglobin in the blood	15 g/dL	15 g/dL	Detects alterations of gas transport caused by anemia

* Mixed venous (pulmonary artery) blood is analyzed for critically ill individuals and those undergoing cardiac catheterization (it is not practical to withdraw samples except from a pulmonary artery catheter). Mixed venous blood gas analysis, in conjunction with arterial analysis, provides important information about the adequacy of cardiac output and tissue oxygenation.

Signs and symptoms of most respiratory abnormalities first appear when the system is stressed during exercise. Therefore, if pulmonary disease is suspected, the individual is evaluated at rest and during exercise. Evaluation during exercise usually entails spirometry and oximetry to monitor hemoglobin saturation. The exercise usually consists of riding a stationary bicycle or walking on a treadmill. Exercise testing enables clinicians to detect early changes in respiratory function and thus begin treatment. Exercise tests also are used in planning and evaluating exercise and rehabilitation programs.

Thoracic imaging techniques are among the most common examinations for diagnosis and detection of pulmonary disease and tumors and for evaluation of disease progression. Numerous techniques are available and include chest radiography, computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography, and ultrasonography. Pulmonary angiography is used for detection of pulmonary embolism and pulmonary arteriovenous malformations. Techniques may be combined for the best evaluation of pulmonary structure and function.

Aging and the Pulmonary System

Most knowledge about pulmonary structure and function is based on norms for the middle-age years. Less is known about structure and function in the very young (see [Chapter 37](#)) and in older adults, but a few normal physiologic (developmental and degenerative) changes are known to occur from birth to old age. An understanding of these changes is needed to provide appropriate care and to differentiate between age-associated alterations and disease. Normal alterations in the pulmonary system include (1) loss of elastic recoil, (2) stiffening of the chest wall, (3) changes in gas exchange, and (4) increases in flow resistance. These changes, which affect lung volumes, are gradual and usually without adverse consequences in healthy individuals ([Fig. 35.18](#)). They are influenced by genetics, sociocultural factors, nutritional status, exercise, decreased immune function, respiratory disease, body size, sex, and race. Exposure to environmental toxins, such as some respiratory tract infections, tobacco smoke, air pollution, and occupational dusts, also contributes to decreased lung function with aging. These changes contribute to increased lung disease morbidity and mortality in older adults, including chronic obstructive lung disease, lung cancer, pulmonary fibrosis, and infection.²³

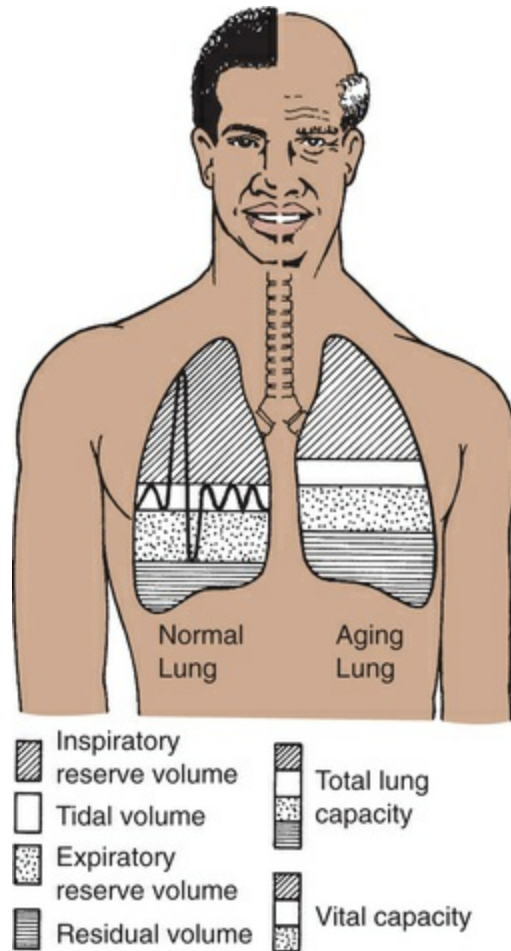

FIGURE 35.18 Changes in Lung Volumes with Aging. In aging, vital capacity decreases and residual volume increases.

During adulthood and as age advances, the alveoli tend to lose alveoli wall tissue and capillaries. This process increases alveolar size, diminishes the alveolar surface area available for gas diffusion, and decreases airway support provided by normal lung tissues. These changes are similar to those seen in emphysema and change the elastic properties of the lungs. Chest wall compliance decreases with age, because the ribs become ossified (less flexible) and the joints become stiffer. As a result the chest wall loses some of its ability to expand. In addition, respiratory muscle strength and endurance decrease by up to 20% by age 70. These mechanical changes in the lung and chest wall, along with structural changes in the alveoli, reduce the ventilatory capacity in older adults. Vital capacity decreases and residual volume increases; however, total lung capacity remains

unchanged. These changes decrease ventilatory reserves and lead to decreased ventilation-perfusion ratios. With advancing age there is also increased immune dysregulation, asymptomatic low-grade inflammation (“inflamm-aging”), and increased risk of infection.²⁴

Alterations in gas exchange are reflected by blood gas analysis. With advancing age, pH and PaCO₂ levels do not change much, even though it has been documented that the chemoreceptors become less sensitive to gas partial pressures with age.²⁵ Older adults have a decreased compensatory response to hypercapnia and hypoxemia; however, the perception of dyspnea remains intact and is even enhanced. PaO₂ declines with age as a result of structural and mechanical changes, such as loss of alveolar surface area, thickening of plural septa, loss of lung elasticity, and increase in ventilation-perfusion mismatch. The maximum PaO₂ value in an older adult at sea level can be estimated by multiplying the person's age by 0.3 and subtracting the product from 100. For example, an 80-year-old individual would have an estimated maximum PaO₂ of 76 mmHg ($0.3 \times 80 = 24$; $100 - 24 = 76$).²⁶

The decrease in PaO₂ and the diminished ventilatory reserve in an older adult lead to a decrease in exercise tolerance. Respiratory muscle strength and endurance decrease with age.²⁷ Furthermore, older adults are at greater risk for respiratory depression caused by medications. Changes in respiratory structure and function can vary considerably from person to person, however. Changes also are affected by activity and fitness earlier in life.²⁸

Summary Review

Structures of the Pulmonary System

1. The pulmonary system consists of the two lungs, upper and lower airways, chest wall, diaphragm, and pulmonary and bronchial circulations.
2. Air is inspired and expired through the conducting airways,

- which include the nasopharynx, oropharynx, trachea, bronchi, and bronchioles to the sixteenth division.
3. Gas exchange occurs in structures beyond the sixteenth division: the respiratory bronchioles, alveolar ducts, and alveoli. Together these structures comprise the acinus.
 4. The chief gas-exchange units of the lungs are the alveoli. The membrane that surrounds each alveolus and contains the pulmonary capillaries is called the *alveolocapillary membrane*.
 5. The gas-exchange airways are served by the pulmonary circulation, a separate division of the circulatory system. The bronchi and other lung structures are served by a branch of the systemic circulation called the *bronchial circulation*.
 6. The pulmonary circulation is innervated by the ANS, but vasodilation and vasoconstriction are controlled mainly by local and humoral factors, particularly arterial oxygenation and acid-base status.
 7. Vasoconstriction of the pulmonary arterial system is caused by alveolar hypoxia, acidemia, and inflammatory mediators (histamine, serotonin, prostaglandins, and bradykinin).
 8. The chest wall, which contains and protects the contents of the thoracic cavity, consists of the skin, ribs, and intercostal muscles, which lie between the ribs.
 9. The chest wall is lined by a serous membrane called the *parietal pleura*; the lungs are encased in a separate membrane called the *visceral pleura*. The area where these two pleurae come into contact and slide over each another is called the *pleural space*.

Functions of the Pulmonary System

1. The pulmonary system enables oxygen to diffuse into the blood and CO₂ to diffuse out of the blood.
2. Ventilation is the process by which air flows into and out of the gas-exchange airways.
3. Ventilation is involuntary most of the time. It is controlled by the respiratory center in the brainstem and by the sympathetic

and parasympathetic divisions of the ANS, which adjust airway caliber (by causing bronchial smooth muscle to contract or relax) and control the rate and depth of ventilation.

4. Neuroreceptors in the lungs (lung receptors) monitor the mechanical aspects of ventilation. Irritant receptors sense the need to expel unwanted substances and stretch receptors sense lung volume (lung expansion), and *J*-receptors sense alveolar size.
5. Chemoreceptors in the circulatory system and brainstem sense the effectiveness of ventilation by monitoring the pH status of cerebrospinal fluid and the oxygen and carbon dioxide content of arterial blood (PaO_2 and PaCO_2).
6. Successful ventilation involves the mechanics of breathing: the interaction of forces and counterforces involving the muscles of inspiration and expiration, alveolar surface tension, elastic properties of the lungs and chest wall, and resistance to airflow.
7. The major muscle of inspiration is the diaphragm. When the diaphragm contracts, it moves downward in the thoracic cavity, creating a vacuum that causes air to flow into the lungs. There are no major muscles in expiration. Normal elastic recoil permits passive expiration.
8. The alveoli produce surfactant, created by type II alveolar cells. Surfactant is a lipoprotein that lines the alveoli. Surfactant reduces alveolar surface tension and permits the alveoli to expand more easily with air intake.
9. Elastic recoil is the tendency of the lungs and chest wall to return to their resting states after inspiration. The elastic recoil forces of the lungs and chest wall are in opposition and pull on each other, creating the normally negative pressure of the pleural space.
10. Compliance is a measure of lung and chest wall distensibility during inspiration. Lung compliance is determined by the adequate production of surfactant and the elastic recoil of the lungs and chest wall.

11. Airway resistance is determined by the length, radius, and cross-sectional area of the airways and by the density, viscosity, and velocity of the gas. Airway resistance is normally very low because of the large cross-sectional area of the lungs.
12. The work of breathing is determined by the muscular effort (i.e., the energy required to achieve adequate oxygenation) necessary for ventilation.
13. Gas transport depends on ventilation of the alveoli, diffusion across the alveolocapillary membrane, perfusion of the pulmonary and systemic capillaries, and diffusion between systemic capillaries and tissue cells.
14. Efficient gas exchange depends on an even distribution of ventilation and perfusion within the lungs. Ventilation and perfusion are greatest in the bases of the lungs because the alveoli in the bases are more compliant, and perfusion is greater as a result of gravity.
15. Almost all of the oxygen that diffuses into pulmonary capillary blood is transported by hemoglobin, a protein contained within red blood cells. The remainder of the oxygen is transported dissolved in plasma.
16. Oxygen enters the body by diffusing down the concentration gradient, from high concentrations in the alveoli to lower concentrations in the capillaries. Diffusion ceases when alveolar and capillary oxygen pressures equilibrate.
17. Oxygen is loaded onto hemoglobin by the driving pressure exerted by PaO_2 in the plasma. As pressure decreases at tissue level, oxygen dissociates from hemoglobin and enters tissue cells by diffusion, again down the concentration gradient.
18. CO_2 is more soluble in plasma than oxygen is and diffuses readily from tissue cells into plasma. CO_2 returns to the lungs dissolved in plasma, transported as bicarbonate, or combined with blood proteins to form carbamino compounds (e.g., bound to hemoglobin).

Tests of Pulmonary Function

1. Spirometry measures the volume and flow rate of air during forced expiration.
2. The alveolar-arterial oxygen gradient is used to evaluate the cause of hypoxia.
3. Diffusing capacity is a measure of the gas diffusion rate at the alveolocapillary membrane.
4. Arterial blood gas analysis can be used to determine pH and oxygen and CO₂ concentrations.
5. Thoracic imaging techniques are used to detect pulmonary disease and tumors and to evaluate disease progression.

Aging and the Pulmonary System

1. Aging affects the mechanical aspects of ventilation by decreasing chest wall compliance and elastic recoil of the lungs. Changes in these elastic properties reduce ventilatory reserve.
2. Aging causes loss of alveolar wall tissue and alveolar enlargement, thus diminishing the surface area available for gas diffusion.
3. Aging can cause the PaO₂ level to decrease but does not affect the PaCO₂ level.
4. Vital capacity decreases and residual volume increases with age; however, total lung capacity remains unchanged.

Respiratory Tract Infections, 1185

Pulmonary Vascular Disease, 1190

Malignancies of the Respiratory Tract, 1193

Pulmonary disease is often classified as acute or chronic, obstructive or restrictive, and infectious or noninfectious. The symptoms and

signs of lung disease, such as dyspnea and tachypnea, are common and associated not only with primary lung disorders but also with diseases of other organ systems, particularly the heart.

Clinical Manifestations of Pulmonary Alterations

Signs and Symptoms of Pulmonary Disease

Pulmonary disease is associated with many signs and symptoms and their specific characteristics often help in identifying the underlying disorder. The most common are dyspnea and cough. Others include abnormal sputum, hemoptysis, altered breathing patterns, hypoventilation and hyperventilation, cyanosis, clubbing of the digits, and chest pain.

Dyspnea

Dyspnea is a subjective experience of breathing discomfort and is the most common symptom of cardiac and respiratory diseases. It also can occur with pain, trauma, anxiety, and psychogenic disorders. The experience derives from interactions among multiple physiologic, psychologic, social, and environmental factors, and it may induce secondary physiologic and behavioral responses. The American Thoracic Society proposes that dyspnea evolves across three different constructs: sensory (intensity), affective (distress), and impact on daily activities.¹ It is comprised of qualitatively distinct sensations that vary in intensity. Individuals with dyspnea may complain of breathlessness, air hunger, shortness of breath, increased work of breathing, chest tightness, and preoccupation with breathing.

The severity of the experience of dyspnea may not directly correlate with the severity of the underlying disease. Either diffuse or focal disturbances of ventilation, gas exchange, or ventilation-perfusion relationships can cause dyspnea, as can increased work of breathing or diseases that damage lung tissue (lung parenchyma).

Neurophysiologic mechanisms for dyspnea involve an impaired sense of effort where the perceived work of breathing is greater than the actual motor response generated. Stimulation of a variety of receptors can contribute to the sensation experience of dyspnea, including lower airway mechanoreceptors (the stretch receptors, irritant receptors, and C-fiber receptors [J-receptors]), upper airway receptors, and central and peripheral chemoreceptors that interact with the respiratory center and the sensory and motor cortex.² The more severe signs of dyspnea include flaring of the nostrils and use of accessory muscles of respiration. Retraction (pulling back) of the supracostal or intercostal spaces predominates in children. In dyspnea caused by parenchymal disease (e.g., pneumonia), retractions of tissue between the ribs (subcostal and intercostal retractions) are observed more often than supercostal retractions (retractions of tissues above the ribs), which predominate in upper airway obstruction. Retractions of any type are more commonly seen in children or in adults who are thin and have poorly developed thoracic musculature. Dyspnea can be quantified by the use of ordinal rating scales or visual analog scales.³

Dyspnea can occur transiently or can become chronic. Dyspnea first presents during exercise and is called **dyspnea on exertion**. **Orthopnea** is dyspnea that occurs during heart failure when an individual is recumbent, which causes the abdominal contents to exert pressure on the diaphragm and decreases the efficiency of the respiratory muscles. **Paroxysmal nocturnal dyspnea (PND)** occurs when individuals with pulmonary or cardiac disease awake at night gasping for air and must sit up or stand to relieve the dyspnea.

Cough

Cough is a protective reflex that helps clear the airways by an explosive expiration. Inhaled particles, accumulated mucus, inflammation, or the presence of a foreign body initiates the cough reflex by stimulating irritant receptors in the airway. There are few such receptors in the most distal bronchi and the alveoli; thus it is possible for significant amounts of secretions to accumulate in the distal respiratory tree without cough being initiated. Stimulation of

cough receptors is transmitted centrally through the vagus nerve. The cough reflex consists of inspiration of air, closure of the glottis and vocal cords, contraction of the expiratory muscles, and reopening of the glottis, causing a sudden, forceful expiration that removes the offending matter. The effectiveness of the cough depends on the depth of the inspiration and the degree to which the airways narrow, increasing the velocity of expiratory gas flow. Somatosensory nerves innervating the chest wall, diaphragm, and abdominal musculature regulate cough patterning and sensitivity. Cough occurs frequently in healthy individuals, and those with an inability to cough effectively are at greater risk for pneumonia. Cough, the urge-to-cough sensation, and the cough motor response can be manipulated by distraction and cognitive states, such as anxiety, reflecting a voluntary component of cough.⁴ Central modulation of the cough reflex can be influenced by opiates and serotonergic agents.⁵

Acute cough is cough that resolves within 2 to 3 weeks of the onset of illness or resolves with treatment of the underlying condition. It is most commonly the result of upper respiratory tract infections, allergic rhinitis, acute bronchitis, pneumonia, congestive heart failure, pulmonary embolus, or aspiration. **Chronic cough** is defined as cough that has persisted for more than 3 weeks, although some researchers have suggested that 7 or 8 weeks is a more appropriate timeframe because acute cough and bronchial hyperreactivity can be prolonged in some cases of viral infection. In persons who do not smoke, chronic cough is commonly caused by postnasal drainage syndrome, nonasthmatic eosinophilic bronchitis, asthma, gastroesophageal reflux disease, or heightened cough reflex sensitivity.⁶ In those individuals who smoke, chronic bronchitis is the most common cause of chronic cough, although lung cancer must always be considered. Individuals taking angiotensin-converting enzyme inhibitors for hypertension may develop chronic cough that resolves with discontinuation of the drug.

Abnormal Sputum

Changes in the amount, consistency, color, and odor of **sputum**

provide information about the progression of disease and the effectiveness of therapy. The gross and microscopic appearances of sputum enable the clinician to identify cellular debris or microorganisms that aid in diagnosis and choice of therapy.

Hemoptysis is the expectoration of blood or bloody secretions from the lower respiratory tract. This is sometimes confused with hematemesis, which is the vomiting of blood. Blood that is expectorated is usually bright red, has an alkaline pH, and is mixed with frothy sputum. Blood that is vomited is dark, has an acidic pH, and is mixed with food particles.

Hemoptysis usually indicates infection or inflammation that damages the bronchi (bronchitis, bronchiectasis) or the lung parenchyma (pneumonia, tuberculosis, lung abscess). Other causes include cancer and pulmonary infarction. The amount and duration of bleeding provide important clues about its source. Bronchoscopy, combined with chest imaging, is used to confirm the site of bleeding.⁷

Abnormal Breathing Patterns

Normal breathing (eupnea) is rhythmic and effortless. The ventilatory rate is 8 to 16 breaths per minute, and the tidal volume ranges from 400 to 800 mL. A short expiratory pause occurs with each breath, and the individual takes an occasional deeper breath or sigh. Sigh breaths, which help maintain normal lung function, are usually 1.5 to 2 times the normal tidal volume and occur approximately 10 to 12 times per hour.

The rate, depth, regularity, and effort of breathing undergo characteristic alterations in response to physiologic and pathophysiologic conditions. Patterns of breathing automatically adjust to minimize the work of respiratory muscles. Strenuous exercise or metabolic acidosis induces **Kussmaul respirations (hyperpnea)**. Kussmaul respirations are characterized by a slightly increased ventilatory rate, very large tidal volume, and no expiratory pause.

Labored breathing occurs whenever there is an increased work of breathing, especially if the airways are obstructed, as in chronic

obstructive pulmonary disease (COPD). If the large airways are obstructed, a slowed ventilatory rate, increased effort, prolonged inspiration or expiration, and stridor (high-pitched sounds made during inspiration) or audible wheezing (whistling sounds on expiration) are typical. In small airway obstruction, like that seen in asthma and chronic obstructive pulmonary disease, a rapid ventilatory rate, small tidal volume, increased effort, prolonged expiration, and wheezing are often present. *Restricted breathing* is commonly caused by disorders such as pulmonary fibrosis that stiffen the lungs or chest wall and decrease compliance, resulting in small tidal volumes and rapid ventilatory rate (tachypnea).

Shock and severe cerebral hypoxia (insufficient oxygen in the brain) contribute to gasping respirations that consist of irregular, quick inspirations with an expiratory pause. Anxiety can cause sighing respirations that consist of irregular breathing characterized by frequent, deep sighing inspirations. **Cheyne-Stokes respirations** are characterized by alternating periods of deep and shallow breathing. Apnea lasting 15 to 60 seconds is followed by ventilations that increase in volume until a peak is reached, after which ventilation (tidal volume) decreases again to apnea. Cheyne-Stokes respirations result from any condition that slows the blood flow to the brainstem, which in turn slows impulses sending information to the respiratory centers of the brainstem. Neurologic impairment above the brainstem is also a contributing factor (see [Table 17.4](#) and [Fig. 17.1](#)).

Hypoventilation and Hyperventilation

Hypoventilation is inadequate alveolar ventilation in relation to metabolic demands. Hypoventilation occurs when the minute volume (tidal volume \times respiratory rate) is reduced. It is caused by alterations in pulmonary mechanics or in the neurologic control of breathing. When alveolar ventilation is normal, carbon dioxide (CO₂) is removed from the lungs at the same rate at which it is produced by cellular metabolism, and arterial CO₂ pressure (PaCO₂) remains at normal levels (40 mmHg). With hypoventilation, CO₂ removal lags behind

CO₂ production and PaCO₂ increases, causing hypercapnia (PaCO₂ greater than 44 mmHg). (Table 35.1 contains the definition of gas partial pressure and other pulmonary abbreviations.) This results in an increase in hydrogen ion concentration in the blood, termed respiratory acidosis, which can affect the function of many tissues throughout the body.

Hypoventilation is often overlooked until it is severe because breathing pattern and ventilatory rate may appear normal, and changes in tidal volume can be difficult to detect clinically. Blood gas analysis (i.e., measurement of the PaCO₂ level of arterial blood) or capnography (i.e., measurement of the CO₂ concentration in expired air) reveals the hypoventilation (hypercapnia). Pronounced hypoventilation can cause somnolence or disorientation and secondary hypoxemia because the accumulation of alveolar CO₂ displaces oxygen (see [Hypercapnia under Conditions Caused by Pulmonary Disease or Injury](#)).

Hyperventilation is alveolar ventilation that exceeds metabolic demands. The lungs remove CO₂ at a higher rate than it is produced by cellular metabolism, resulting in decreased PaCO₂ or **hypocapnia** (PaCO₂ less than 36 mmHg). Hypocapnia results in respiratory alkalosis that also can interfere with tissue function. Like hypoventilation, hyperventilation can be verified by arterial blood gas analysis or capnography. Hyperventilation commonly occurs with severe anxiety, acute head injury, and conditions that cause hypoxemia.

Cyanosis

Cyanosis is a bluish discoloration of the skin and mucous membranes caused by increasing amounts of desaturated or reduced hemoglobin (which is bluish) in the blood. It generally develops when 5 g of hemoglobin is desaturated, regardless of hemoglobin concentration.

Peripheral cyanosis (slow blood circulation in fingers and toes) is most often caused by poor circulation resulting from intense peripheral vasoconstriction, like that seen in Raynaud's disease, cold

environments, or severe stress. Peripheral cyanosis is best seen in the nail beds. *Central cyanosis* is caused by decreased arterial oxygenation (low PaO₂) from pulmonary diseases or pulmonary or cardiac right-to-left shunts. Central cyanosis is best seen in buccal mucous membranes and lips.

Lack of cyanosis does not necessarily indicate that oxygenation is normal. In adults, cyanosis is not evident until severe hypoxemia is present and, therefore, is an insensitive indication of respiratory failure. Severe anemia (inadequate hemoglobin concentration) and carbon monoxide poisoning (in which hemoglobin binds with carbon monoxide instead of binding with oxygen) can result in inadequate oxygenation of tissues without causing cyanosis. Individuals with polycythemia (an abnormal increase in numbers of red blood cells), however, may have cyanosis when tissue oxygenation is adequate. Therefore the significance of cyanosis as a clinical finding must be interpreted in relation to the underlying pathophysiology. If cyanosis is observed, the PaO₂ level should be measured.

Clubbing

Clubbing is the selective bulbous enlargement of the end (distal segment) of a digit (finger or toe) ([Fig. 36.1](#)); its severity can be graded from 1 to 5 based on the extent of nail bed hypertrophy and the number of changes in the nails themselves. It is usually painless and develops gradually over weeks. Clubbing is commonly associated with diseases that disrupt the normal pulmonary circulation and cause chronic hypoxemia, such as bronchiectasis, cystic fibrosis, pulmonary fibrosis, lung abscess, and congenital heart disease. It is rarely reversible with treatment of the underlying pulmonary condition.

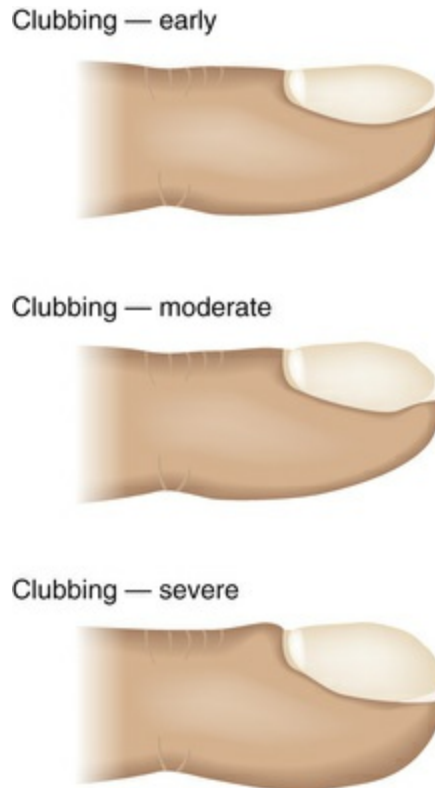

FIGURE 36.1 Clubbing of Fingers Caused by Chronic Hypoxemia. (From Seidel HM et al: *Mosby's guide to physical examination*, ed 7, St Louis, 2011, Mosby.)

Although the pathogenesis of clubbing is unknown, the megakaryocyte hypothesis proposes that megakaryocytes and platelet clumps escape filtration in the pulmonary bed and enter the systemic circulation. Platelets may then release platelet-derived growth factor at the nail bed, causing periosteal changes. *Secondary hypertrophic osteoarthropathy* can sometimes be seen in individuals with lung cancer even without hypoxemia because of the effects of inflammatory cytokines and growth factors.⁸

Pain

Pain caused by pulmonary disorders originates in the pleurae, airways, or chest wall.⁹ Pleural pain is the most common pain caused by pulmonary disease and is usually sharp or stabbing in character. Infection and inflammation of the parietal pleura (pleuritis or pleurisy) cause pain when the pleurae stretch during inspiration. The

pain is usually localized to a portion of the chest wall, where a unique breath sound called a *pleural friction rub* may be heard over the painful area. Laughing or coughing makes pleural pain worse.

Infection and inflammation either of the trachea or of the bronchi (tracheitis or tracheobronchitis, respectively) can cause central chest pain that is pronounced after coughing. Central chest pain can be difficult to differentiate from cardiac pain (see [Chapter 33](#)). High blood pressure in the pulmonary circulation (pulmonary hypertension) can cause pain during exercise that is often mistaken for cardiac pain (angina pectoris). Pleural pain is also common with pulmonary infarction (tissue death) caused by pulmonary embolism and emanates from the area around the infarction.

Pain in the chest wall is muscle pain or rib pain. The common causes of chest wall pain are rib fractures and excessive coughing, which make the muscles sore. Inflammation of the costochondral junction (costochondritis) also can cause chest wall pain. Chest wall pain can often be reproduced by pressing on the sternum or ribs.

Conditions Caused by Pulmonary Disease or Injury

Hypercapnia

Hypercapnia, or increased CO_2 concentration in the arterial blood (increased PaCO_2), is caused by hypoventilation of the alveoli. CO_2 is easily diffused from the blood into the alveolar space; thus minute volume (respiratory rate \times tidal volume) determines not only alveolar ventilation but also PaCO_2 . Hypoventilation is often overlooked because the breathing pattern and ventilatory rate may appear normal; it is important to obtain blood gas analysis to determine the severity of hypercapnia and resultant respiratory acidosis (acid-base balance is described in [Chapter 3](#)).

There are many causes of hypercapnia. Most are a result of a decreased drive to breathe or an inadequate ability to respond to ventilatory stimulation. Causes include (1) depression of the respiratory center by drugs; (2) diseases of the medulla, including

infections of the central nervous system or trauma; (3) abnormalities of the spinal conducting pathways, as in spinal cord disruption or poliomyelitis; (4) diseases of the neuromuscular junction or of the respiratory muscles themselves, as in myasthenia gravis or muscular dystrophy; (5) abnormalities of the thoracic cage, as in chest injury or congenital deformity; (6) obstruction of the large airways, as in tumors or sleep apnea; and (7) increased work of breathing or increased physiologic dead space, as in emphysema.

Hypercapnia and the associated respiratory acidosis can result in several important clinical manifestations. Of greatest concern are electrolyte abnormalities that occur in response to the low pH that may cause dysrhythmias. Individuals also may have somnolence and even be in a coma because of changes in intracranial pressure associated with high levels of arterial carbon dioxide, which causes cerebral vasodilation. Alveolar hypoventilation with increased alveolar carbon dioxide concentration limits the amount of alveolar oxygen available for diffusion into the blood, leading to secondary hypoxemia.

Hypoxemia

Hypoxemia, or reduced oxygenation of arterial blood (reduced PaO_2), is caused by respiratory alterations, whereas **hypoxia (ischemia)**, or reduced oxygenation of cells in tissues, may be caused by alterations of other systems as well. Cyanosis, hypoxemia, and hypoxia can exist independently of each other but they are interrelated.¹⁰ For example, although hypoxemia can lead to tissue hypoxia, tissue hypoxia can result from other abnormalities, such as low cardiac output or cyanide poisoning.

Hypoxemia results from problems with one or more of the major mechanisms of oxygenation¹¹:

1. Oxygen delivery to the alveoli
 - a. Oxygen content of the inspired air (FiO_2)
 - b. Ventilation of the alveoli

2. Diffusion of oxygen from the alveoli into the blood
 - a. Balance between alveolar ventilation and perfusion (V/Q mismatch)
 - b. Diffusion of oxygen across the alveolocapillary membrane
3. Perfusion of pulmonary capillaries

Table 36.1 lists some of the common clinical causes of these problems.

TABLE 36.1

CAUSES OF HYPOXEMIA

MECHANISM	COMMON CLINICAL CAUSES
Decrease in inspired oxygen (decreased F_{iO_2})	High altitude Low oxygen content of gas mixture Enclosed breathing spaces (suffocation)
Hypoventilation of the alveoli	Lack of neurologic stimulation of the respiratory center (oversedation, drug overdose, neurologic damage)
	Defects in chest wall mechanics (neuromuscular disease, trauma, chest deformity, air trapping)
	Large airway obstruction (laryngospasm, foreign body aspiration, neoplasm)
	Increased work of breathing (emphysema, severe asthma)
Ventilation-perfusion mismatch	Asthma Chronic bronchitis Pneumonia Acute respiratory distress syndrome Atelectasis Pulmonary embolism
Alveolocapillary diffusion abnormality	Edema Fibrosis Emphysema
Decreased pulmonary capillary perfusion	Intracardiac defects Intrapulmonary arteriovenous malformations

The partial pressure of oxygen in the alveoli is called PAO_2 and is dependent on two factors. The first factor is amount of oxygen in

inspired air and is expressed as the percentage or fraction of air that is composed of oxygen, called the FiO_2 . The FiO_2 of air at sea level is approximately 21% or 0.21. Anything that decreases the FiO_2 (such as high altitude) decreases the PAO_2 . A second factor is the amount of alveolar minute ventilation (tidal volume \times respiratory rate). Hypoventilation results in an increase in $PACO_2$ and a decrease in PAO_2 such that there is less oxygen available in the alveoli for diffusion into the blood. This type of hypoxemia can be completely corrected if alveolar ventilation is improved by increases in the rate and depth of breathing. Examples of conditions in which hypoventilation causes hypoxemia include unconsciousness; neurologic, muscular, or bone diseases that restrict chest expansion; and COPD.

Diffusion of oxygen from the alveoli into the blood is also dependent on two factors. The first is the balance between the amount of air getting into alveoli (V) and the amount of blood perfusing the capillaries around the alveoli (Q). An abnormal ventilation-perfusion ratio (V/Q) is the most common cause of hypoxemia (Fig. 36.2). In the healthy lung, alveolocapillary lung units receive almost equal amounts of ventilation and perfusion. The normal V/Q is 0.8 to 0.9 because perfusion is somewhat greater than ventilation in the lung bases and because some blood is normally shunted to the bronchial circulation. V/Q mismatch refers to an abnormal distribution of ventilation and perfusion. Hypoxemia can be caused by inadequate ventilation of well-perfused areas of the lung (low V/Q). Mismatching of this type, called **shunting**, occurs in atelectasis, in asthma as a result of bronchoconstriction, and in pulmonary edema and pneumonia when alveoli are filled with fluid. When blood passes through portions of the pulmonary capillary bed that receive no ventilation, right-to-left shunt occurs, resulting in decreased systemic PaO_2 and hypoxemia. Hypoxemia also can be caused by poor perfusion of well-ventilated portions of the lung (high V/Q), resulting in wasted ventilation. The most common cause of high V/Q is a pulmonary embolus that impairs blood flow to a segment of the lung. An area where alveoli are ventilated but not perfused is termed **alveolar dead**

space.

FIGURE 36.2 Ventilation-Perfusion Abnormalities. (Data from Glenny RW: *Adv Physiol Educ* 32[3]:192–195, 2008.)

A second factor affecting diffusion of oxygen from the alveoli into the blood is the alveolocapillary barrier. Diffusion of oxygen through the alveolocapillary membrane is impaired if the alveolocapillary membrane is thickened or the surface area available for diffusion is decreased. Abnormal thickness, as occurs with edema (tissue swelling) and fibrosis (formation of fibrous lesions), increases the time required for diffusion across the alveolocapillary membrane. If diffusion is slowed enough, the oxygen in the alveolar gas (PAO_2) and capillary blood does not have time to equilibrate during the fraction of a second that blood remains in the capillary. Destruction of alveoli, such as that which occurs in emphysema, decreases the alveolocapillary membrane surface area available for diffusion. Hypercapnia is rarely produced by impaired diffusion, because

carbon dioxide diffuses easily from capillary to alveolus even when oxygen diffusion is significantly impaired.

Hypoxemia also can result from blood flow bypassing the lungs. This can occur because of intracardiac defects that cause right-to-left shunting or because of intrapulmonary arteriovenous malformations. Administration of oxygen in these cases does not improve hypoxemia.

Hypoxemia is most often associated with a compensatory hyperventilation and resultant respiratory alkalosis (i.e., decreased PaCO₂ measurement and increased pH level). However, in individuals with associated ventilatory difficulties, hypoxemia may be complicated by hypercapnia and respiratory acidosis. Hypoxemia results in widespread tissue dysfunction and, when severe, can lead to organ infarction. In addition, hypoxic pulmonary vasoconstriction can contribute to increased pressures in the pulmonary artery (pulmonary artery hypertension) and lead to right-sided heart failure or *cor pulmonale* (see [Cor Pulmonale under Pulmonary Vascular Disease](#)). Clinical manifestations of acute hypoxemia may include cyanosis, confusion, tachycardia, edema, and decreased renal output.

Acute Respiratory Failure

Respiratory (lung) failure is defined as inadequate gas exchange, that is, hypoxemia in which PaO₂ is ≤ 50 mmHg or hypercapnia in which PaCO₂ is ≥ 50 mmHg with a pH ≤ 7.25 .¹² Respiratory failure can result from direct injury to the lungs, airways, or chest wall or can occur indirectly as a result of disease or injury involving another body system, such as the brain, spinal cord, liver, or heart. It can occur in individuals who have an otherwise normal respiratory system or in those with underlying chronic pulmonary disease. Most pulmonary diseases can cause episodes of acute respiratory failure. If the respiratory failure is primarily hypercapnic, it is the result of inadequate alveolar ventilation (see [Hypercapnia under Conditions Caused by Pulmonary Disease or Injury](#)) and the individual must receive ventilatory support, such as with a bag-valve mask, noninvasive positive pressure ventilation, or intubation and

placement on mechanical ventilation. If the respiratory failure is primarily hypoxemic, it is the result of inadequate exchange of oxygen between the alveoli and the capillaries (see [Hypoxemia under Conditions Caused by Pulmonary Disease or Injury](#)) and the individual must receive supplemental oxygen therapy. Many individuals have a combined hypercapnic and hypoxemic respiratory failure and require both kinds of support.

Respiratory failure is an important potential complication of any major surgical procedure, especially those that involve the central nervous system, thorax, or upper abdomen. Persons who smoke are at risk, particularly if they have preexisting lung disease. Limited cardiac reserve, chronic renal failure, chronic hepatic disease, underlying lung disease, and infection also increase the tendency to develop postoperative respiratory failure. The most common postoperative pulmonary problems are atelectasis, pneumonia, pulmonary edema, and pulmonary emboli (these conditions are discussed later in this chapter).

Prevention of postoperative respiratory failure includes frequent turning and position changes, deep breathing exercises, incentive spirometry, avoidance of oversedation, and early ambulation to prevent atelectasis and accumulation of secretions. Incentive spirometry gives individuals immediate feedback about tidal volumes, which encourages them to breathe deeply. Supplemental oxygen is given for hypoxemia, and antibiotics are given as appropriate to treat infection. If respiratory failure develops, the individual may require conventional mechanical ventilation, high-frequency ventilation, or extracorporeal membrane oxygenation.¹³

Disorders of the Chest Wall and Pleura

Disorders of the Chest Wall

Chest Wall Restriction

If the chest wall is deformed, traumatized, immobilized, or made heavy by fat, the work of breathing is increased and ventilation may

be compromised because of a decrease in tidal volume. The degree of ventilatory impairment depends on the severity of the chest wall abnormality. Grossly obese individuals are often dyspneic on exertion or when recumbent. Individuals with severe kyphoscoliosis (bending and rotation of the spinal column with distortion of the thoracic cage) often present with dyspnea on exertion that can progress to respiratory failure. Obesity and kyphoscoliosis are risk factors for respiratory failure or infection in individuals admitted to a hospital for other problems, particularly those who require surgery. Other musculoskeletal abnormalities that can impair ventilation are ankylosing spondylitis and pectus excavatum (a deformity characterized by depression of the sternum) (see [Chapters 45](#) and [46](#), respectively).

Impairment of respiratory muscle function caused by neuromuscular disease, such as poliomyelitis, muscular dystrophy, myasthenia gravis, and Guillain-Barré syndrome, also can restrict the chest wall or impair pulmonary function. Muscle weakness can result in hypoventilation and hypercapnia, inability to remove secretions, and hypoxemia.

Pain from chest wall injury, surgery, or disease can cause significant hypoventilation not only because of pain but also because of structural and mechanical changes that impair the ability of the chest to expand normally. **Flail chest** results from the fracture of several consecutive ribs in more than one place, or the fracture of the sternum and several consecutive ribs. These multiple fractures result in instability of a portion of the chest wall, causing paradoxical movement of the chest with breathing. During the negative intrathoracic pressure of inspiration, the unstable portion of the chest wall moves inward and during expiration it moves outward, impairing movement of gas in and out of the lungs ([Fig. 36.3](#)). Flail chest is usually associated with significant underlying lung contusion. The clinical manifestations of flail chest are pain, dyspnea, unequal chest expansion, and hypoventilation. Treatment is internal fixation by controlled mechanical ventilation until the chest wall is stabilized.

FIGURE 36.3 Flail Chest. Normal respiration: A, inspiration; B, expiration. Paradoxical motion: C, inspiration, area of lung underlying unstable chest wall sucks in on inspiration; D, expiration, unstable area balloons out. Note movement of mediastinum toward opposite lung during inspiration.

Chest wall restriction results in decreased tidal volume. An increase in respiratory rate can temporarily compensate and restore minute ventilation, but many individuals will eventually progress to hypercapnic respiratory failure. Diagnosis of chest restriction is made by pulmonary function testing (reduction in forced vital capacity [FVC]), arterial blood gas measurement (hypercapnia), and radiographs. Treatment is aimed at any reversible underlying cause, but is otherwise supportive. In severe cases, mechanical ventilation may be indicated.

Pleural Abnormalities

Pneumothorax

Pneumothorax is the presence of air or gas in the pleural space caused by a rupture in the visceral pleura (which surrounds the lungs) or the parietal pleura and chest wall (see [Chapter 35](#)). As air is drawn into the pleural space during inspiration, it separates the visceral and

parietal pleurae and destroys the negative pressure of the pleural space. This disrupts the state of equilibrium that normally exists between elastic recoil forces of the lung and chest wall. No longer held in check by the recoil forces of the chest wall, the lung fulfills its tendency to recoil by collapsing toward the hilum.

Primary (spontaneous) pneumothorax occurs unexpectedly in healthy individuals (usually men) between ages 20 and 40 years and is caused by the spontaneous rupture of blebs (blister-like formations) on the visceral pleura. Smoking is a risk factor.¹⁴ Bleb rupture can occur during sleep, rest, or exercise. The ruptured bleb or blebs are usually located in the apexes of the lungs. The cause of bleb formation is not known, although more than 80% of these individuals have been found to have emphysema-like changes in their lungs even if they have no history of smoking or no known genetic disorder. Approximately 10% of affected individuals have a significant family history of primary pneumothorax that has been linked to autosomal dominant mutations in the *folliculin* gene, which influences cell-to-cell adhesion and cell growth and causes cystic lung disease and kidney tumors (Birt-Hogg-Dubé syndrome).¹⁵ Ruptured blebs damage the visceral pleura and create a conduit for air to travel from the lower airways into the pleural space (bronchopleural fistulae).

Secondary (traumatic) pneumothorax can be caused by chest trauma, such as a rib fracture, stab or bullet wounds, or a surgical procedure that tears the pleura; rupture of a bleb or bulla (larger vesicle) as occurs in COPD; or mechanical ventilation, particularly if it includes positive end-expiratory pressure (PEEP).¹⁶ *Iatrogenic pneumothorax* is most commonly caused by transthoracic needle aspiration.¹⁷

Primary and secondary pneumothorax can present as either open or tension. In *open pneumothorax (communicating pneumothorax)*, air pressure in the pleural space equals barometric pressure because air that is drawn into the pleural space during inspiration (through the damaged chest wall and parietal pleura or through the lungs and damaged visceral pleura) is forced back out during expiration. In *tension pneumothorax*, however, the site of pleural rupture acts as a one-way valve, permitting air to enter on inspiration but preventing

its escape by closing during expiration. As more and more air enters the pleural space, air pressure in the pneumothorax begins to exceed barometric pressure. Air pressure in the pleural space pushes against the already recoiled lung, causing compression atelectasis, and against the mediastinum, compressing and displacing the heart, great vessels, and trachea (Fig. 36.4). The pathophysiologic effects of tension pneumothorax are life-threatening.

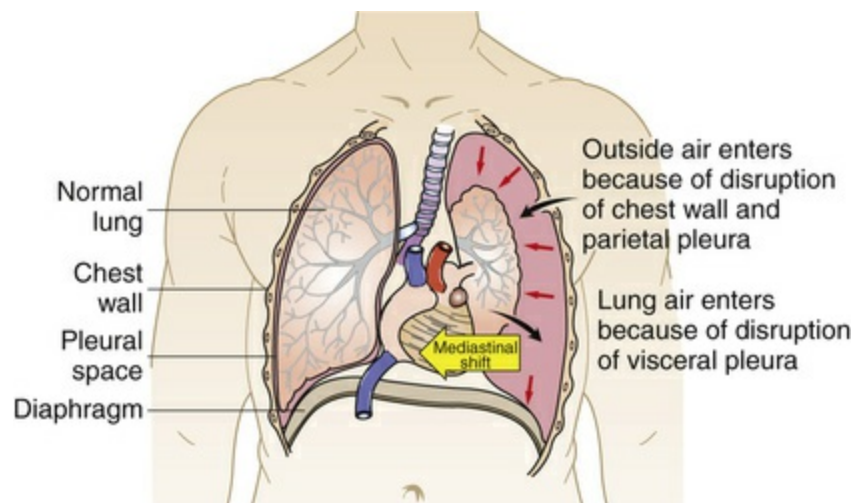

FIGURE 36.4 Tension Pneumothorax. Air in the pleural space causes the lung to collapse around the hilum and may shift the trachea and mediastinal contents (heart and great vessels) toward the other lung.

Clinical manifestations of primary or secondary pneumothorax begin with sudden pleural pain, tachypnea, and dyspnea. Depending on the size of the pneumothorax, physical examination may reveal absent or decreased breath sounds and hyperresonance to percussion on the affected side. Tension pneumothorax may be complicated by severe hypoxemia, tracheal deviation away from the affected lung, and hypotension (low blood pressure). Deterioration occurs rapidly and immediate treatment is required. Diagnosis of pneumothorax is made with chest radiographs, ultrasound, and computed tomography (CT). Pneumothorax is treated by aspiration, usually with insertion of a chest tube that is attached to a water-seal drainage system with suction. After the pneumothorax is evacuated and the pleural rupture is healed, the chest tube is removed. For individuals with persistent

air leaks, other interventions may be needed including thoracoscopic surgical techniques or pleurodesis (instillation of a caustic substance into the pleural space). Heimlich valves (one-way valves connected to the end of the chest drain) provide an option for home care in persistent spontaneous pneumothorax. Smoking cessation is strongly advised.¹⁸

Pleural Effusion

Pleural effusion is the presence of fluid in the pleural space. The source of the fluid is usually from blood vessels or lymphatic vessels lying beneath either pleura, but occasionally an abscess or other lesion may drain into the pleural space. Pleural effusions that enter the pleural space from intact blood vessels can be transudative (watery) or exudative (proteinaceous) with fluid accumulating at a rate faster than it can be removed by the lymphatics. Other types of pleural effusion are characterized by the presence of pus (empyema), blood (hemothorax), or chyle (lymphatic fluid [chylothorax]). Mechanisms of pleural effusion are summarized in [Table 36.2](#).

TABLE 36.2

MECHANISMS OF PLEURAL EFFUSION

TYPE OF FLUID/EFFUSION	SOURCE OF ACCUMULATION*	PRIMARY OR ASSOCIATED DISORDER
Transudate (hydrothorax)	Watery fluid that diffuses out of capillaries beneath the pleurae (i.e., capillaries in lung or chest wall)	Cardiovascular disease that causes high blood pressure; liver or kidney disease that disrupts plasma protein production, causing hypoproteinemia (decreased oncotic pressure in the blood vessels)
Exudate	Fluid rich in proteins (leukocytes, plasma proteins of all kinds; see Chapter 7) that migrates out of capillaries	Infection, inflammation, or malignancy of the pleurae that stimulates mast cells to release biochemical mediators that increase capillary permeability
Empyema (pus)	Detritus of infection (microorganisms, leukocytes, cellular debris) dumped into the pleural space by	Pulmonary infections, such as pneumonia; lung abscesses; infected wounds

	blocked lymphatic vessels	
Hemothorax (blood)	Hemorrhage into the pleural space	Traumatic injury, surgery, rupture, or malignancy that damages blood vessels
Chylothorax (chyle)	Chyle (milky fluid containing lymph and fat droplets) that is dumped by lymphatic vessels into the pleural space instead of passing from the gastrointestinal tract to the thoracic duct	Traumatic injury, infection, or disorder that disrupts lymphatic transport

*NOTE: The principles of diffusion are discussed in [Chapter 1](#); mechanisms that increase capillary permeability and cause exudation of cells and proteins are discussed in [Chapter 7](#).

Transudative pleural effusions are often clear or slightly discolored and contain few cells and little protein. Examples are congestive heart failure, in which venous and left atrial pressures are increased, and liver or kidney disorders that cause hypoproteinemia. Hypoproteinemia decreases capillary oncotic pressure, which promotes diffusion of water out of the capillaries. (This mechanism is discussed in [Chapter 3](#)). *Exudative effusion* occurs in response to inflammation, infection, or malignancy and involves inflammatory processes that increase capillary permeability (see [Chapter 7](#)). When stimulated by biochemical mediators of inflammation, junctions in the capillary endothelium separate slightly, which enables leukocytes and plasma proteins to migrate out into affected tissues. Thus high concentrations of white blood cells and plasma proteins are evident in exudative effusion. Exudative effusions that occur in association with pneumonia are called *parapneumonic effusions*. These often resolve with treatment of the underlying infection but can progress to empyema (see following section).

Small collections of fluid may not affect lung function and remain undetected. Most will be removed by the lymphatic system once the underlying condition is resolved. Dyspnea, compression atelectasis with impaired ventilation, and pleural pain are common in larger effusions. Mediastinal shift and cardiovascular manifestations occur in a large, rapidly developing effusion. Physical examination reveals decreased breath sounds and dullness to percussion on the affected

side. A pleural friction rub can be heard over areas of inflamed pleura.

Diagnosis is confirmed by chest imaging and thoracentesis (needle aspiration), which can determine the type of effusion and provide symptomatic relief. If the effusion is large, drainage usually requires the placement of a chest tube and surgical interventions may be needed to prevent recurrence of the effusion.¹⁹

Empyema

Empyema (infected pleural effusion) is the presence of pus in the pleural space and develops when the pulmonary lymphatics become blocked, leading to an outpouring of contaminated lymphatic fluid into the pleural space. Empyema progresses through three stages: (1) exudative stage, (2) fibrinopurulent stage, and (3) organizing stage with pleural peel formation. Empyema occurs most commonly in older adults and in children and usually develops as a complication of pneumonia, surgery, trauma, or bronchial obstruction from a tumor. Commonly documented infectious microorganisms include *Staphylococcus aureus*, *Escherichia coli*, anaerobic bacteria, and *Klebsiella pneumoniae*.

Individuals with empyema present clinically with cyanosis, fever, tachycardia (rapid heart rate), cough, and pleural pain. Breath sounds are decreased directly over the empyema. Diagnosis is made by chest radiographs, thoracentesis, and sputum culture. Treatment for empyema includes the administration of appropriate antimicrobials and drainage of the pleural space with a chest tube. In severe cases, ultrasound-guided pleural drainage, instillation of fibrinolytic agents, and/or injection of deoxyribonuclease (stimulates pleural fluid formation, reduces pleural fluid viscosity, and promotes resolution of systemic inflammation) into the pleural space may be needed to achieve adequate drainage. Surgical débridement may be required.²⁰

Pulmonary Disorders

Restrictive Lung Disorders

Restrictive lung disorders are characterized by decreased compliance of the lung tissue. This means that it takes more effort to expand the lungs during inspiration, which increases the work of breathing. Individuals with lung restriction have dyspnea, an increased respiratory rate, and decreased tidal volume. Pulmonary function testing reveals a decrease in FVC. Restrictive lung diseases can cause V/Q mismatch and affect the alveolocapillary membrane, which reduces the diffusion of oxygen from the alveoli into the blood and results in hypoxemia. Some of the most common restrictive lung diseases in adults are aspiration, atelectasis, bronchiectasis, bronchiolitis, pulmonary fibrosis, inhalational disorders, pneumoconiosis, allergic alveolitis, pulmonary edema, and acute respiratory distress syndrome. These disorders are characterized by activation of macrophages, polymorphonucleocytes, and lymphocytes with release of numerous inflammatory and immune cytokines.

Aspiration

Aspiration is the passage of fluid and solid particles into the lung. It tends to occur in individuals whose normal swallowing mechanism and cough reflex are impaired by a decreased level of consciousness or central nervous system abnormalities. Predisposing factors include altered level of consciousness caused by substance abuse, sedation, or anesthesia; seizure disorders; neuromuscular disorders that cause dysphagia; esophageal disorders, such as achalasia and esophageal strictures; and feeding through a nasogastric tube. Intubation of the trachea also is associated with aspiration. The right lung, particularly the right lower lobe, is more susceptible to aspiration than the left lung because the branching angle of the right mainstem bronchus is straighter than the branching angle of the left mainstem bronchus.

Aspiration of large food particles has serious consequences. Solid

food particles can obstruct a bronchus, resulting in bronchial inflammation and collapse of airways distal to the obstruction. If the aspirated solid is not identified and removed by bronchoscopy, a chronic, local inflammation develops that may lead to recurrent infection and bronchiectasis (permanent dilation of the bronchus).

Aspiration of oral or pharyngeal secretions can lead to aspiration pneumonia. Intubation of the trachea also can cause aspiration and bacterial pneumonia. Aspiration of acidic gastric fluid with a pH of less than 2.5 may cause severe pneumonitis. Bronchial damage includes inflammation, loss of ciliary function, and bronchospasm. In the alveoli, acidic fluid damages the alveolocapillary membrane. This allows plasma and blood cells to move from capillaries into the alveoli, resulting in hemorrhagic pneumonitis. The lung becomes stiff and noncompliant as surfactant production is disrupted, leading to further edema and collapse. Infection is a common complication. Hypoventilation may develop as this process progresses, and systematic complications, such as hypotension, may occur.

Clinical manifestations of aspiration include the sudden onset of choking and intractable cough with or without vomiting, fever, dyspnea, and wheezing. Some individuals have no symptoms acutely; instead they have recurrent lung infections, chronic cough, or persistent wheezing over months and even years.

Preventive measures for individuals at risk are more effective than treatment of known aspiration. The most important preventive measures include the avoidance of fully recumbent positioning and excessive sedation, surveillance of enteral feeding, and use of promotility agents. Individuals being administered general anesthetics should not receive food or fluid for several hours before or after surgery. Antacids are sometimes given to individuals at risk for aspiration to keep the gastric pH greater than 2.5. Nasogastric tubes, which often are used to remove stomach contents and reduce the risk for aspiration, also can cause aspiration if fluid and particulate matter are regurgitated as the tube is being placed.

Treatment of aspiration, pneumonia, or pneumonitis includes supplemental oxygen and may require mechanical ventilation. Fluid

intake may be restricted to decrease blood volume and minimize pulmonary edema. Corticosteroids may be administered during the first 72 hours after aspiration. Bacterial pneumonia that develops as a complication of aspiration pneumonitis must be treated with broad-spectrum antibiotics.²¹

Atelectasis

Atelectasis is the collapse of lung tissue. There are three types of atelectasis: compression, absorption, and surfactant impairment:

1. **Compression atelectasis** is caused by the external pressure exerted on lung tissue, such as occurs with tumors, or by fluid or air in the pleural space. Atelectasis at the base of the lungs can be caused by abdominal distention pressing on a portion of the lung, causing the alveoli to collapse.
2. **Absorption atelectasis** results from gradual absorption of air from obstructed or hypoventilated alveoli or from inhalation of concentrated oxygen or anesthetic agents.
3. **Surfactant impairment** results from decreased production or inactivation of surfactant, which is necessary to reduce surface tension in the alveoli and thus prevent lung collapse during expiration. Surfactant impairment can occur because of premature birth, acute respiratory distress syndrome, anesthesia, or mechanical ventilation.

Atelectasis tends to occur after surgery, especially in those who have been administered general anesthetics.²² Postoperative individuals are often in pain, breathe shallowly, are reluctant to change position, and produce viscous secretions that tend to pool in dependent portions of the lung, particularly those who have surgical procedures involving the thorax or upper abdomen. Atelectasis increases pulmonary shunt, decreases compliance, and may lead to perioperative hypoxemia.

Clinical manifestations of atelectasis are similar to those of pulmonary infection: dyspnea, cough, fever, and leukocytosis.

Prevention and treatment of postoperative atelectasis usually include deep breathing exercises (often with the aid of an incentive spirometer), frequent position changes, early ambulation, and pain management. Deep breathing is beneficial because it (1) promotes the ciliary clearance of secretions, (2) stabilizes the alveoli by redistributing surfactant, and (3) permits collateral ventilation of the alveoli through the pores of Kohn in the alveolar septa. The pores of Kohn, which open only during deep breathing, allow air to pass from well-ventilated alveoli to obstructed alveoli, minimizing their tendency to collapse and facilitating expectoration of the bronchial obstruction (Fig. 36.5).

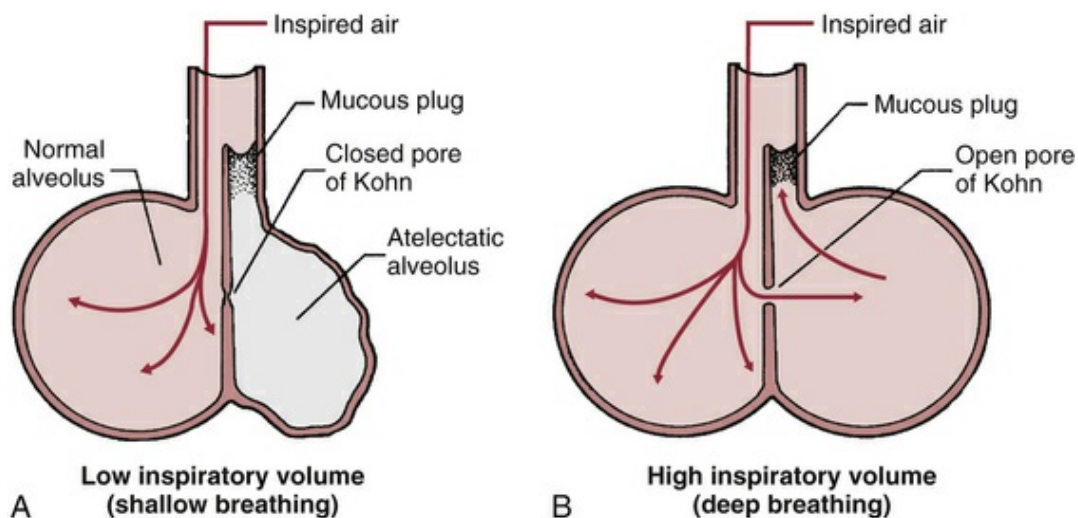

FIGURE 36.5 Pores of Kohn. A, Absorption atelectasis caused by lack of collateral ventilation through the pores of Kohn. B, Restoration of collateral ventilation during deep breathing.

Bronchiectasis

Bronchiectasis is persistent abnormal dilation of the bronchi. This disorder may result from a genetic predisposition or be caused by a defect in host defense. It usually occurs in conjunction with other respiratory conditions that are associated with chronic bronchial inflammation, such as obstruction of an airway with mucous plugs, atelectasis, aspiration of a foreign body, infection, cystic fibrosis,

tuberculosis, congenital weakness of the bronchial wall, or immunocompromised status. Bronchiectasis is also associated with a number of systemic disorders such as rheumatologic disease, inflammatory bowel disease, and immunodeficiency syndromes (e.g., acquired immunodeficiency syndrome [AIDS]).²³ There may be no known cause. Recurrent infection and chronic inflammation of the bronchi leads to destruction of elastic and muscular components of their walls, bronchial lumen obstruction, traction from adjacent fibrosis, and permanent dilation.²⁴

Bronchial dilation (Fig. 36.6) may be *cylindrical* (**cylindrical bronchiectasis**), with symmetrically dilated airways, as can be seen after pneumonia and is reversible; *saccular* (**saccular bronchiectasis**), in which the bronchi become large and balloon-like; or *varicose* (**varicose bronchiectasis**), in which constrictions and dilations deform the bronchi, creating a bulbous appearance. In both varicose and saccular bronchiectases, the smaller bronchial divisions are plugged with secretions or obliterated by fibrosis. Large anastomoses (connections) develop between the bronchial and pulmonary blood vessels, increasing blood flow through the bronchial circulation. These anastomoses are thought to cause the hemoptysis experienced by individuals with bronchiectasis. Airway damage leads to bronchospasm and colonization by bacteria that promote further lung damage, inhibit ciliary function, and produce copious amounts of purulent mucus. Ventilation-perfusion abnormalities develop and result in hypoxemia. In severe cases, minute ventilation is also compromised and the PaCO₂ level may become elevated.

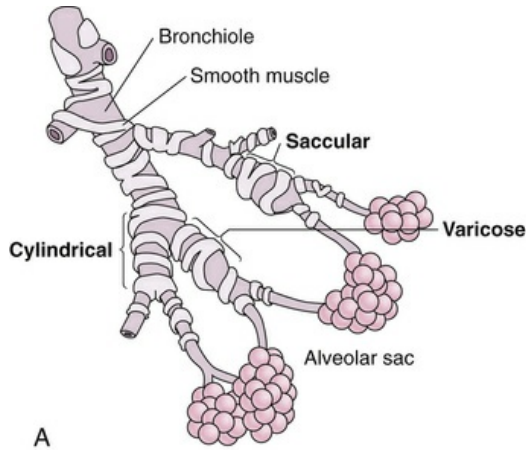

FIGURE 36.6 Bronchiectasis. A, Types of bronchiectasis. B, Left posterior oblique projection of a left bronchogram showing cylindrical bronchiectasis affecting the entire lower lobe except for the superior segment. Few side branches fill. The basal airways are crowded together, indicating volume loss of the lower lobe, a common feature in bronchiectasis. C, Cylindrical bronchiectasis. The dilated bronchi (A) and bronchioles (B) can be dissected almost to the pleural surface. (B from Hansell: *Imaging of diseases of the chest*, ed 5, St Louis, 2009, Mosby; C from Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

The primary symptom of bronchiectasis is chronic productive cough lasting for months or years. The disease is commonly associated with recurrent lower respiratory tract infections and expectoration of voluminous amounts of foul-smelling purulent sputum (measured in cups). If the individual is not receiving antibiotics, the sputum has a foul odor. Clubbing of the fingers from chronic hypoxemia is common. Hemoptysis can occur from mucosal inflammation and necrosis and, in some instances, can be massive.

Dyspnea, pleuritic chest pain, and fatigue are common. Pulmonary function studies show decreases in FVC and expiratory flow rates. Hypoxemia eventually leads to cor pulmonale (see [Cor Pulmonale under Pulmonary Vascular Disease](#)). Diagnosis is usually confirmed by the use of high-resolution CT. Bronchiectasis is treated with antibiotics, bronchodilators, antiinflammatory drugs, chest physiotherapy, and supplemental oxygen. In selected individuals with localized areas of involvement, surgery may be indicated to remove the affected portion of the lung. Lung transplant is an option in advanced disease.²⁵

Bronchiolitis

Bronchiolitis is diffuse inflammation of the small airways or bronchioles. It is most common in children (see [Chapter 37](#)). In adults it usually occurs with chronic bronchitis, but can occur in otherwise healthy individuals in association with an upper or lower airway viral infection (e.g., respiratory syncytial virus [RSV]) or with inhalation of toxic gases, or its etiology may be unknown.²⁶ Atelectasis or emphysematous destruction of the alveoli may develop distal to the inflammatory lesion. Bronchiolitis is usually diffuse. The resulting decrease in the ventilation-perfusion ratio results in hypoxemia. A decrease in minute ventilation with resulting carbon dioxide retention also may occur as lung restriction worsens.

Clinical manifestations include a rapid ventilatory rate; marked use of accessory muscles; low-grade fever; dry, nonproductive cough; and hyperinflated chest. If bronchiolitis is caused by an inhalation injury, pulmonary edema occurs rapidly. Respiratory distress with severe hypoxia frequently develops within 24 to 72 hours. Infiltrates can be seen on chest radiographs.²⁷ A decrease in the ventilation-perfusion ratio results in hypoxemia. Diagnosis is made by spirometry and bronchoscopy with biopsy. Bronchiolitis is treated with appropriate antibiotics, corticosteroids, immunosuppressive agents, and chest physical therapy (humidified air, coughing and deep breathing, postural drainage).

Bronchiolitis obliterans organizing pneumonia (BOOP) is a

complication of bronchiolitis obliterans in which the alveoli and bronchioles become filled with plugs of connective tissue. **Bronchiolitis obliterans syndrome (BOS)** is an inflammatory, fibrotic process that occurs as a complication of lung transplantation. It is associated with persistent loss of lung allograft function 3 or more months following transplantation and has a high morbidity. Diagnosis is made by spirometry and bronchoscopy with biopsy. Treatment includes corticosteroids and other immunomodulatory agents.²⁸

Pulmonary Fibrosis

Pulmonary fibrosis is an excessive amount of fibrous or connective tissue in the lung. Pulmonary fibrosis can be caused by formation of scar tissue after active pulmonary disease (e.g., acute respiratory distress syndrome, tuberculosis), in association with a variety of autoimmune disorders (e.g., rheumatoid arthritis, progressive systemic sclerosis, sarcoidosis), or by inhalation of harmful substances (e.g., coal dust, asbestos). Chronic inflammation leads to fibrosis with alveolar epithelialization and myofibroblast proliferation. Fibrosis causes a marked loss of lung compliance. The lung becomes stiff and difficult to ventilate, and the diffusing capacity of the alveolocapillary membrane may decrease, causing hypoxemia. Diffuse pulmonary fibrosis has a poor prognosis. When no specific cause for the development of fibrosis is known, it is called *idiopathic pulmonary fibrosis*.

Idiopathic Pulmonary Fibrosis.

Idiopathic pulmonary fibrosis (IPF) is the most common idiopathic interstitial lung disorder. It is more common in men than in women and most cases occur after age 60. The median survival is only 2 to 5 years after diagnosis. IPF is characterized by chronic inflammation, and recent studies suggest that it results from multiple injuries at different lung sites with aberrant alveolar wound healing, which probably occurs in response to the complex interaction of environmental insults and genetic, epigenetic, and metabolic factors.²⁹ Alveolar collapse and a fibroproliferative response result in

thickening of the alveolocapillary membrane, causing decreased oxygen diffusion and hypoxemia. Progression of the disease results in decreased lung compliance, causing increased work of breathing, decreased tidal volume, and resultant hypoventilation with hypercapnia. Acute exacerbations of IPF can occur with rapid decompensation and a death rate as high as 50%.³⁰

The primary symptom of IPF is increasing dyspnea on exertion. Examination shows diffuse inspiratory crackles, and diagnosis is confirmed by pulmonary function testing (decreased FVC), high-resolution CT, and lung biopsy. Treatment includes oxygen, corticosteroids, and cytotoxic drugs, although success rates are low and toxicities are high. Additional therapies may include antifibrotic drugs (*N*-acetylcysteine, pirfenidone, nintedanib), inhaled interferon, and anticoagulation therapy. Selected individuals may benefit from lung transplantation.^{31,32}

Environmental Lung Disorders

Exposure to Toxic Gases.

Inhalation of gaseous irritants can cause significant lung injury and respiratory dysfunction. Commonly encountered toxic gases include ammonia, hydrogen chloride, sulfur dioxide, chlorine, phosgene, and nitrogen dioxide. Inhalation injuries in burns can include toxic gases (e.g., carbon monoxide, cyanide, ammonia) from household or industrial combustants, heat, and smoke particles. Inhaled toxic particles can cause damage to the airway epithelium, cilia, and alveoli. There is increased secretion of mucus, promotion of inflammation, and development of mucosal and pulmonary edema with airway obstruction. Surfactant and other protective buffers and antioxidants are inactivated. The cellular effects of toxic gases and polluted air are described in [Chapter 2](#). Acute toxic inhalation is frequently complicated by the development of bronchoconstriction, airway obstruction with fibrous mucus, microcirculatory coagulopathy, and impaired gas exchange. Initial symptoms include burning of the eyes, nose, and throat; coughing; chest tightness; and dyspnea. Hypoxemia

is common. Secondary injury because of resuscitation, mechanical ventilation, and infection also can occur. Treatment includes supplemental oxygen, high frequency percussive ventilation, lung protective ventilation when possible, inhaled anticoagulants, bronchodilators, and support of the cardiovascular system. Inhaled beta agonists may help relieve bronchoconstriction. Most individuals respond quickly to therapy. Some, however, may improve initially and then deteriorate as a result of bronchiectasis or bronchiolitis.³³

Prolonged exposure to high concentrations of supplemental oxygen at normal atmospheric pressure can result in a relatively rare iatrogenic condition known as **oxygen toxicity**. The basic underlying mechanism of injury is a severe inflammatory response mediated primarily by oxygen free radicals. The result is cellular necrosis or apoptosis with diffuse damage to alveolocapillary membranes, disruption of surfactant production, development of interstitial and alveolar edema, and decrease in compliance.³⁴ Treatment involves ventilatory support and reduction of inspired oxygen concentration to less than 60%, as soon as tolerated.

Pneumoconiosis.

Pneumoconiosis represents any change in the lung caused by inhalation of inorganic dust particles, usually occurring in the workplace. As in all cases of environmentally acquired lung disease, the individual's history of exposure is important in determining the diagnosis. Pneumoconiosis often occurs after years of exposure to the offending dust with progressive fibrosis of lung tissue and an increased risk of lung cancer.

The dusts of silica, asbestos, and coal are the most common causes of pneumoconiosis. Others include talc, fiberglass, clays, mica, slate, cement, and metals (cadmium, beryllium, tungsten, cobalt, aluminum, iron, indium, and titanium dioxide nanoparticles). Deposition of these materials in the lungs causes the release of proinflammatory cytokines. This leads to chronic inflammation with scarring of the alveolocapillary membrane, resulting in pulmonary fibrosis and progressive pulmonary deterioration. Clinical manifestations with

advancement of disease may include cough, sputum production, dyspnea, decreased lung volumes, and hypoxemia. In most cases, diagnosis is made by performing chest x-ray or CT and by obtaining careful occupational history. Treatment is usually symptomatic and palliative and focuses on preventing further exposure and promoting dust-free working conditions, along with pulmonary rehabilitation and management of associated hypoxemia and bronchospasm.

Silicosis is a type of pneumoconiosis resulting from the inhalation of free silica (silicon dioxide) and silica-containing compounds, which occurs in mining and in industries involved with the extraction and processing of ores, the preparation and use of sand, and the manufacture of pipe, building, and roofing materials. Silica exposure activates innate and adaptive immune mechanisms, and triggers inflammation with subsequent fibrosis.³⁵ Acute inflammation contributes to bronchospasm and wheezing. Release of proteolytic enzymes and toxic oxygen free radicals increases the risk for lung cancer. Exposed individuals may remain asymptomatic long after the nodules are visible on chest radiography. When clinical manifestations do appear, they include cough and dyspnea. There is no curative treatment for the disease, although corticosteroids may produce some improvement in the early, more acute stages. Screening for lung cancer should be included in the management plan.³⁶

Coal worker pneumoconiosis (coal mine dust lung disease or anthracosis) is caused by coal dust deposits in the lung. Although coal dust itself is relatively well tolerated by the lung, it is frequently inhaled as a mixture of coal, silica, and quartz, which is strongly inflammatory and involves the small airways. Its mild form is asymptomatic, except for possible chronic bronchitis. Its advanced form manifests as severe pulmonary fibrosis. Individuals usually are seen with a productive cough and wheezing. Symptoms are more severe with advanced disease and mimic those of chronic bronchitis and emphysema. Diagnosis is made by obtaining a history of exposure and observing chest radiographs for characteristic signs. There is no specific treatment for coal worker pneumoconiosis. Individuals with the mild form of the disease usually have a favorable

prognosis. Those with more complicated forms often develop marked cardiopulmonary dysfunction.³⁷

Asbestos exposure affects not only factory workers but also individuals who live in areas of asbestos emission. Asbestos exposure can result in a type of pulmonary fibrosis called **asbestosis**, but can also cause lung cancer, mesothelioma (cancer of the pleura), or pleural plaques, especially in those also exposed to cigarette smoke.³⁸

Asbestosis is caused by inhalation of hydrous silicates of various metals in fibrous form. Asbestos fibers cause inflammation and alveolitis. Activated macrophages release toxic oxygen free radicals and cause cellular apoptosis, leading to both fibrosis and malignancy. The most prominent clinical manifestations of asbestosis with fibrosis are dyspnea on exertion, a nonproductive cough, diffuse inspiratory crackles on examination, hypoxemia, and decreased lung volume. Progressive disease may take years and leads to respiratory failure and cardiac complications. Diagnosis is made by pulmonary function testing and low-dose CT. Therapy is supportive.

Hypersensitivity Pneumonitis.

Hypersensitivity pneumonitis (extrinsic allergic alveolitis) is an allergic, inflammatory disease of the lungs caused by repeated inhalation of organic particles or fumes. Many allergens (antigens) can cause this disorder, including bacteria, fungi, and yeasts (moldy or contaminated hay, grain, compost, cork, or wood dust); mycobacteria (contaminated mists from standing water, showers, and hot tubs); animal proteins (bird droppings or feathers, animal pelts); and chemicals (fumes from paints, resins, and glues). A genetic predisposition may increase the risk for this disease. An autoimmune type III hypersensitivity response (see [Chapter 9](#)) is initiated by alveolar macrophages and results in immunoglobulin G (IgG) antibody production. Continued exposure results in a cellular immune type IV hypersensitivity response. The immune and inflammatory responses cause pneumonitis. Granuloma formation is common. Lung capacity and alveolocapillary diffusion are reduced.

Allergic alveolitis can be acute, subacute, or chronic. The acute form

causes flulike symptoms with fever, cough, dyspnea, and chills a few hours after exposure that resolve without treatment in 1 to 3 days. With continued exposure, the disease becomes chronic and pulmonary fibrosis develops. Chronic allergic alveolitis causes cough, fever, fatigue, and weight loss and gradually progressive respiratory failure. Diagnosis is made by obtaining a history of allergen exposure and by performing serum testing for precipitating IgG antibodies, inhalation challenge, chest x-ray, high-resolution CT, bronchoscopy with bronchioalveolar lavage, and in rare cases lung biopsy. Treatment consists of avoidance of the offending agent, stopping smoking, and corticosteroid administration.³⁹

Systemic Disorders and the Lungs

Several systemic diseases affect the airways, pleurae, or lung parenchyma, causing fibrosis, vasculitis, pulmonary hemorrhage, or granuloma formation. Clinical manifestations of lung involvement are usually nonspecific, and the diagnosis is based on involvement of other organs. There is usually no specific treatment, although corticosteroids often are used. Some of the systemic diseases affecting the lung are granulomatous disorders such as sarcoidosis, Wegener granulomatosis, lymphomatoid granulomatosis, and eosinophilic granuloma; connective tissue diseases such as rheumatoid arthritis, systemic lupus erythematosus, scleroderma, polymyositis or dermatomyositis, Sjögren syndrome, and polyarteritis nodosa; angioimmunoblastic or immunoblastic lymphadenopathy (a disease of the lymph nodes); cystic fibrosis (see [Chapter 37](#)); and Goodpasture syndrome (a pulmonary and renal disorder).

Pulmonary Edema

Pulmonary edema is excess water in the lung. The normal lung contains very little fluid and is kept dry by lymphatic drainage and a balance among capillary hydrostatic pressure, capillary oncotic pressure, and capillary permeability. In addition, surfactant lining the alveoli repels water, keeping fluid from entering the alveoli. Common

predisposing factors for pulmonary edema include left-sided heart disease, causing increased pulmonary venous pressure; injury to pulmonary capillary endothelium, like that seen with adult respiratory distress syndrome (ARDS) and inhalation of toxic gases; and lymphatic obstruction. The pathogenesis of pulmonary edema is illustrated in Fig. 36.7. Other causes include rapid pulmonary reexpansion after upper airway obstruction and exposure to high altitude.

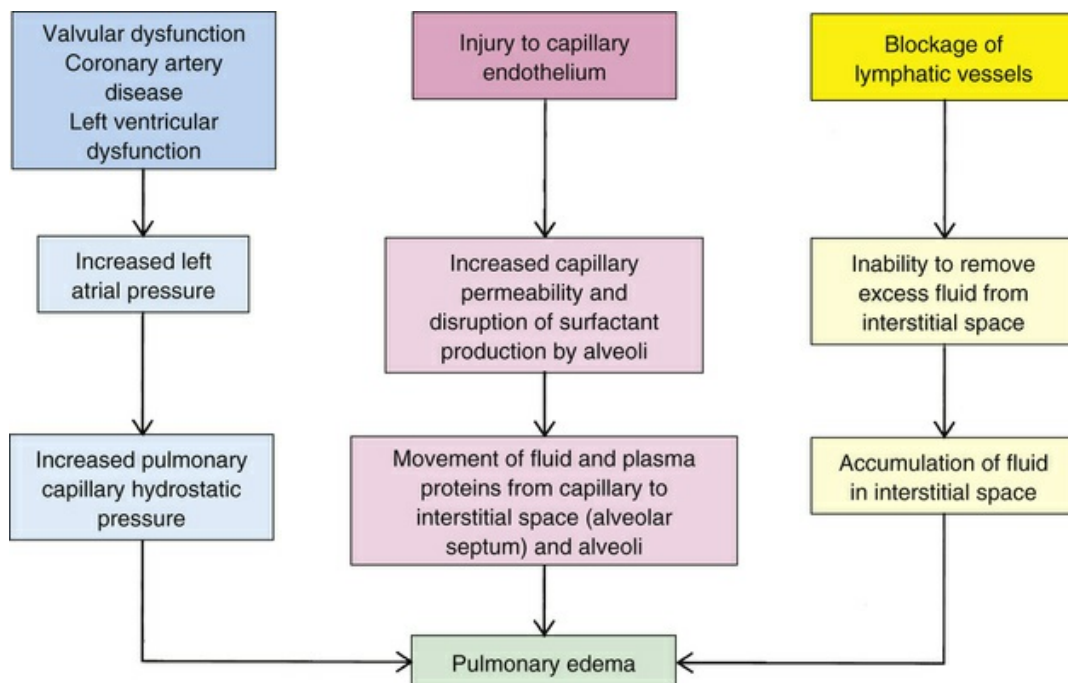

FIGURE 36.7 Pathogenesis of Pulmonary Edema.

The most common cause of pulmonary edema is left-sided heart disease (see Chapter 33). When the left ventricle fails, filling pressures on the left side of the heart increase and cause a concomitant increase in pulmonary capillary hydrostatic pressure. When hydrostatic pressure exceeds oncotic pressure, fluid moves into the interstitium, or interstitial space (the space within the alveolar septum between the alveolus and capillary). Fluid moves to the lymphatic vessels and is then removed from the lung. When the flow of fluid out of the capillaries exceeds the lymphatic system's ability to remove it,

alveolar flooding and pulmonary edema develop. Pulmonary edema usually begins to develop at a pulmonary capillary wedge pressure or left atrial pressure of 20 mmHg. If the capillary oncotic pressure is decreased for any reason (e.g., anemia, nephrotic syndrome, or liver disease), pulmonary edema develops at a lower hydrostatic pressure.

ARDS or inhalation of toxic gases causes injury to the alveolocapillary membrane. Capillary injury causes water and plasma proteins to leak out of the capillary and move into the interstitium. When plasma proteins move into the lung interstitium, they increase the interstitial oncotic pressure, which is usually very low. As the interstitial oncotic pressure begins to equal capillary oncotic pressure, water moves out of the capillary and into the lung. (Mechanisms of edema are discussed in [Chapter 3](#).) Lymphatic drainage can be blocked by compression of lymphatic vessels caused by edema, tumors, and fibrotic tissue or by increased systemic venous pressure that elevates the hydrostatic pressure of the large pulmonary veins into which the pulmonary lymphatic system drains.

Postobstructive pulmonary edema (POPE), negative pressure pulmonary edema, or reexpansion pulmonary edema is a rare life-threatening complication that can occur after relief of upper airway obstruction (e.g., postextubation laryngospasm after anesthesia, epiglottitis, laryngeal tumor, or obstructive tonsils). Attempted inspiration against an occluded airway creates excessive intrathoracic negative pressure, causing increased venous return and blood flow to the right side of the heart and decreased outflow from the left side of the heart from the increased afterload. This combination of events causes increased pulmonary blood volume and venous pressure and leads to pulmonary edema.⁴⁰

High-altitude pulmonary edema (HAPE) can occur after arrival at altitudes usually more than 8000 to 10,000 feet and are related to a hypobaric hypoxic environment. The pathophysiology is not clearly known but hypoxic pulmonary vasoconstriction and increased pulmonary capillary permeability from increased pulmonary artery pressure are proposed mechanisms. The mechanisms are noncardiogenic and noninflammatory. Treatment includes moving to

lower altitude and oxygen therapy. Drugs may be used for prevention.⁴¹

Clinical manifestations of pulmonary edema include dyspnea, hypoxemia, and increased work of breathing. Physical examination may reveal inspiratory crackles (rales), dullness to percussion over the lung bases, and evidence of ventricular dilation (S_3 gallop and cardiomegaly). In severe edema, pink and frothy sputum is expectorated, hypoxemia worsens, and hypoventilation with hypercapnia may develop.

The treatment of pulmonary edema depends on its cause. If the edema is caused by increased hydrostatic pressure resulting from heart failure, therapy is geared toward improving cardiac output and volume status with diuretics, vasodilators, and drugs that improve the contraction of the heart muscle. If edema is the result of increased capillary permeability resulting from injury, the treatment is focused on removing the offending agent and providing supportive therapy to maintain adequate oxygenation, ventilation, and circulation. POPE is treated with positive end-expiratory pressure ventilation. HAPE can be prevented with slow ascents, medications, and descent to lower altitudes when symptoms occur. Individuals with any type of pulmonary edema require supplemental oxygen. Mechanical ventilation may be needed if edema significantly impairs ventilation and oxygenation.

Acute Lung Injury/Acute Respiratory Distress Syndrome

Acute lung injury (ALI) and **acute respiratory distress syndrome (ARDS)** represent a spectrum of acute lung inflammation and diffuse alveolocapillary injury. ARDS is the most severe form and is defined as (1) the acute onset of bilateral infiltrates on chest radiograph not explained by cardiac failure or fluid overload and (2) a low ratio of the partial pressure of arterial oxygen to the fraction of inhaled oxygen.⁴² In the United States ARDS affects more than 190,000 people. Advances in therapy (particularly ventilator therapy) have decreased the overall

death rate to approximately 35% to 46%, depending on severity of illness and comorbidities.⁴³ Older people and those who have severe infections or are immunocompromised continue to have a much higher mortality. The most common predisposing factors for ARDS are genetic factors, sepsis, and multiple trauma (especially when multiple transfusions are received). However, there are many other causes, including pneumonia, burns, aspiration, cardiopulmonary bypass surgery, pancreatitis, drug overdose, smoke or noxious gas inhalation, oxygen toxicity, radiation therapy, and disseminated intravascular coagulation.⁴⁴ Alcohol abuse and smoking are preventable environmental risk factors.⁴⁵

◆Pathophysiology.

ARDS can occur directly (aspiration of highly acidic gastric contents, inhalation of toxic gases, development of pneumonia) or indirectly, as from circulating proinflammatory mediators released in response to systemic disorders, such as sepsis, trauma, and multiple transfusions. All disorders causing ARDS cause acute immune cell-mediated injury to the alveolocapillary membrane producing massive inflammation, increased capillary permeability, and alveolar flooding with protein-rich fluid that overwhelms ion channels and lymphatic removal of fluid. Increasingly severe pulmonary edema (referred to as *noncardiogenic pulmonary edema*) develops with associated shunting, V/Q mismatch, reduced lung compliance, and hypoxemia. ARDS progresses through three overlapping phases characterized by histologic changes in the lung: exudative (inflammatory), proliferative, and fibrotic (Figs. 36.8 and 36.9).⁴⁶

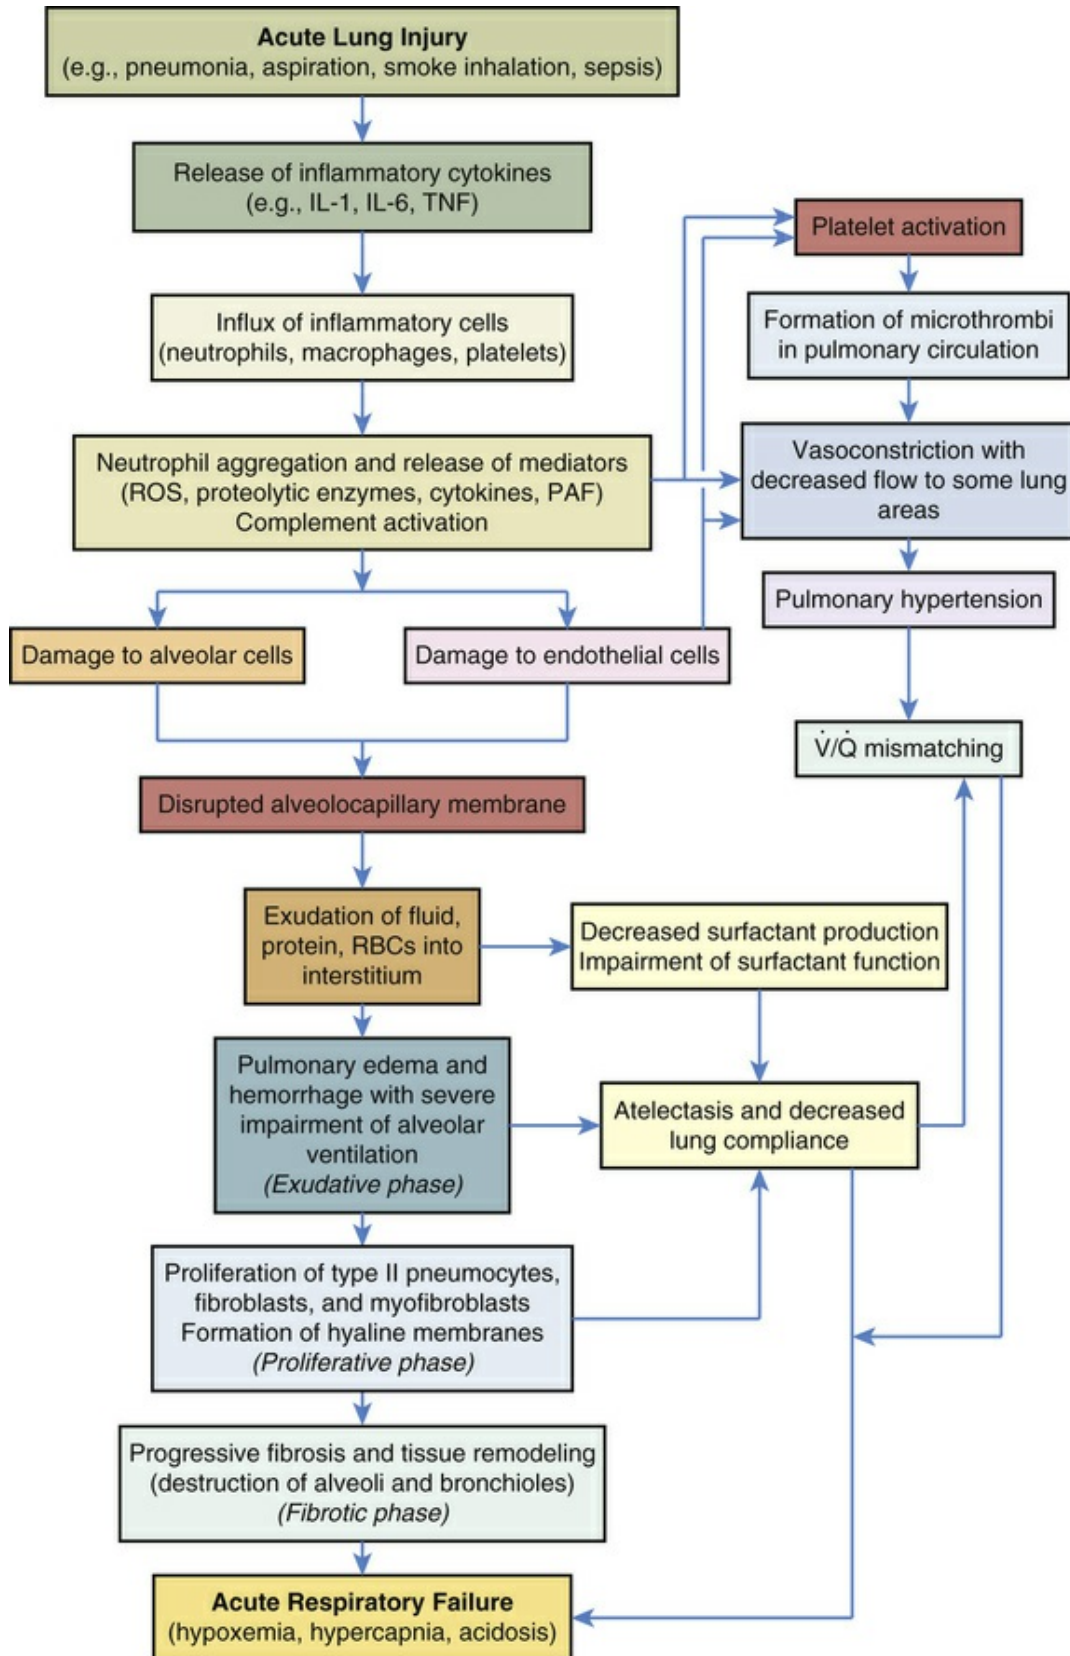

FIGURE 36.8 Pathogenesis of Acute Respiratory Distress Syndrome (ARDS). *IL-1*, Interleukin-1; *IL-6*, interleukin-6; *PAF*, platelet-activating

factor; RBCs, red blood cells; ROS, reactive oxygen species; TNF, tumor necrosis factor.

FIGURE 36.9 Acute Respiratory Distress Syndrome (ARDS). Cross-sectional views of alveoli in ARDS. A normal alveolus (A) plus the sequential exudative (B), proliferative (C), and fibrotic (D) phases in the pathogenesis of acute respiratory distress syndrome. (From Sweeney RM, McAuley DF: *Lancet* 388[10058]:2416–2430, 2016.)

Exudative (Inflammatory) Phase.

Within 72 hours lung injury results in the release of inflammatory

cytokines including interleukin-1 β (IL-1 β) and interleukin-6 (IL-6). This activates macrophages that release more proinflammatory cytokines, such as interleukin-8 (IL-8), tumor necrosis factor-alpha (TNF- α), surfactant protein-D (SPD), and mitochondrial DNA.^{47,48} Neutrophils also are activated and release proteolytic enzymes, such as neutrophil elastase and metalloproteinases. Neutrophils release reactive oxygen species (superoxide radicals, hydrogen peroxide, hydroxyl radicals, singlet oxygen), nitric oxide, arachidonic acid metabolites (prostaglandins, thromboxanes, leukotrienes), and platelet-activating factor that damage the alveolocapillary membrane and increase capillary permeability. Fluid, protein, and cells are exuded into the interstitium and then into the alveoli, resulting in V/Q mismatching.

Platelet and complement activation result in a hypercoagulable state with intravascular microthrombus formation and further damage to the lung capillary endothelium.⁴⁹ Furthermore, mediators released by platelets, neutrophils, and macrophages cause pulmonary vasoconstriction and microthrombus formation. Pulmonary hypertension occurs early in the course of the disease secondary to vasoconstriction.

Surfactant is inactivated, and its production by type II alveolar cells is impaired as alveoli and respiratory bronchioles fill with fluid or collapse. The intraalveolar hemorrhagic exudate becomes a cellular granulation tissue appearing as hyaline membranes and there is progressive hypoxemia. The lungs become less compliant, the work of breathing increases, ventilation of alveoli decreases, and hypercapnia develops.

Proliferative Phase.

Within 1 to 3 weeks after the initial lung injury, there is resolution of the pulmonary edema and proliferation of fibroblasts, myofibroblasts, and type II pneumocytes with surfactant recovery. Type I pneumocyte differentiation with epithelial cell regeneration also occurs. This phase overlaps with the fibrotic phase.

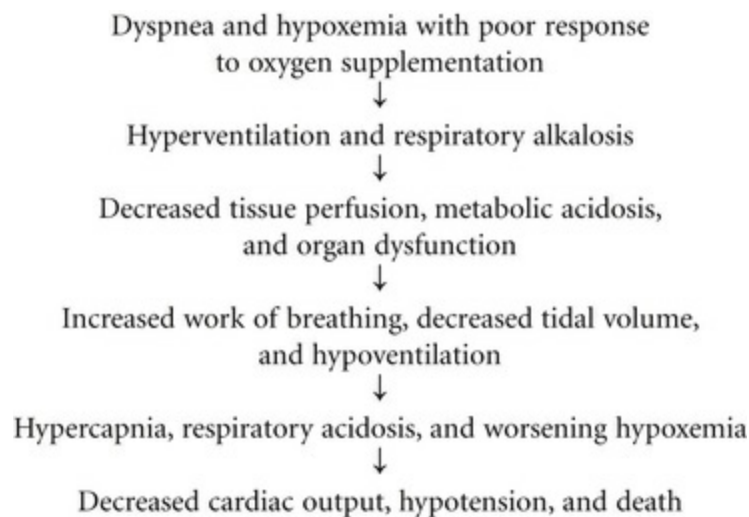

Fibrotic Phase.

About 2 to 3 weeks after the initial injury, remodeling (abnormal repair) and fibrosis occur. The fibrosis progressively obliterates the alveoli, respiratory bronchioles, and interstitium, leading to a decrease in functional residual capacity (FRC) and continuing V/Q mismatch with severe right-to-left shunt and respiratory failure. Fibrosis of pulmonary capillaries contributes to pulmonary hypertension.

The same chemical mediators responsible for the alveolocapillary damage of ARDS often cause inflammation, endothelial damage, and capillary permeability throughout the body, resulting in the systemic inflammatory response syndrome (SIRS). SIRS then leads to multiple organ dysfunction syndrome (MODS). In fact, death may not be caused by respiratory failure alone, but by MODS associated with ARDS. (MODS is discussed in [Chapter 49](#).)

◆Clinical Manifestations.

The clinical manifestations of ARDS progress as follows:

The new Berlin definition of ARDS provides categories of severity based on hypoxemia: mild ($200 \text{ mmHg} < \text{PaO}_2/\text{FiO}_2 \leq 300 \text{ mmHg}$), moderate ($100 \text{ mmHg} < \text{PaO}_2/\text{FiO}_2 \leq 200 \text{ mmHg}$), and severe ($\text{PaO}_2/\text{FiO}_2 \leq 100 \text{ mmHg}$) with bilateral infiltration on chest imaging which cannot be fully explained by cardiac failure or fluid overload.⁵⁰ Definitions for

children are reviewed in [Chapter 37](#).

Worsening hypoxemia and hypercapnia lead to respiratory failure. Decreased oxygen delivery to tissues results in metabolic acidosis and organ dysfunction (e.g., decreased urine output and a decline in cognitive functioning). Decreased cardiac output and hypotension may eventually lead to death.

◆ **Evaluation and Treatment.**

Diagnosis is made on the basis of a history of lung injury, physical examination, analysis of arterial blood gases, and chest radiographs. Initial physical examination may show fine inspiratory crackles. Over the first 24 to 48 hours after injury, interstitial and alveolar infiltrates appear on chest radiographs. Serum biomarkers, such as TNF- α , brain natriuretic peptide (BNP), IL-6 and IL-8, and surfactant proteins, are being studied for ARDS prediction and treatment outcomes.⁵¹

Treatment strategies include early detection and management of contributing etiologies, supportive therapy to prevent progression of lung injury, and prevention of complications such as pneumonia and stress ulcer. There are no FDA-approved treatments for ARDS. Modes of protective ventilation are being used to reduce lung injury, including low tidal volume ventilation, noninvasive (through the mouth or nose, or both, with an external interface) positive-pressure ventilation, permissive hypercapnia, prone positioning, neuromuscular blockade (paralytics), and extracorporeal lung assistance. Some of these methods have shown reductions in death rates.^{44,52}

Many studies are investigating new ways to prevent or treat ARDS. Prophylactic immunotherapy, antibodies against endotoxins, antioxidants, surfactant replacement therapy, nitric oxide inhalation, inhibition of various inflammatory mediators, gene therapy, and stem cells are among other possibilities being tested. Aspirin is currently being evaluated for treatment of sepsis-related ARDS.⁵³ The use of corticosteroids remains controversial but may be beneficial in persistent ARDS.⁵⁴ Some individuals who survive often have near-normal pulmonary function tests at 12 months postrecovery, while

others have persistent pulmonary dysfunction and poor quality of life associated with fibroproliferative changes in the lung, reduced exercise capacity, and long-term neurocognitive impairment.⁵⁵

Obstructive Pulmonary Disease

Obstructive pulmonary disease is characterized by airway obstruction that is worse with expiration. More force (i.e., use of accessory muscles of expiration) or more time is required to expire a given volume of air, and emptying of the lungs is slowed. These disorders are characterized by infiltration of the lung by inflammatory cells with the release of numerous cytokines that contribute to airway damage and mucus production. The unifying symptom of obstructive pulmonary disease is dyspnea and the unifying sign is wheezing. Individuals have an increased work of breathing, a mismatching of the ventilation-perfusion ratio, and a decreased forced expiratory volume in 1 second (FEV₁). The most common obstructive diseases are asthma and chronic obstructive pulmonary disease (COPD) (chronic bronchitis and emphysema).

Asthma

Asthma is a chronic inflammatory disorder of the bronchial mucosa that causes bronchial hyperresponsiveness, constriction of the airways, and variable airflow obstruction that is reversible. Asthma can develop at any age, with 6.3 million cases occurring among children (see [Chapter 37](#)) and 17.7 million cases occurring among adults in the United States. The prevalence is increasing.⁵⁶ Death rates are highest for adult females, black persons, and adults older than 65.⁵⁷

Asthma is a familial disorder and more than 100 genes have been identified that may play a role in the susceptibility, pathogenesis, and treatment response of asthma, including those that influence the production of IL-4, IL-5, IL-13, IL-17, and IL-33; IgE; eosinophils; mast cells; adrenergic receptors; leukotrienes; nitric oxide; and transmembrane proteins in the endoplasmic reticulum.⁵⁸ Asthma

phenotypes are observable characteristics not linked to a specific pathobiologic disease process. *Phenotypes* include eosinophilic asthma (allergic) versus neutrophilic asthma, recurrent respiratory tract viral infections, exercise-induced asthma, aspirin-sensitive asthma, age-at-onset asthma, or steroid nonresponsive asthma. Comorbidities associated with phenotypes include obesity, gastroesophageal reflux disease, allergic rhinitis, and vitamin D deficiency. *Endotypes* are subgroups that describe the specific underlying disease pathophysiology related to the observable phenotype (i.e., different clinical characteristics, histopathology, biomarkers including gene profiles, epidemiology, and treatment responses). An asthma endotype can encompass different phenotype clusters, and a specific phenotype may be present in several endotypes⁵⁹ (see [Chapter 37, What's New? Asthma Phenotypes and Endotypes in Children](#)).

Exposure to high levels of certain allergens during childhood increases the risk for asthma. Furthermore, decreased exposure to certain infectious organisms appears to create an immunologic imbalance that favors the development of allergy and asthma in some individuals. This complex relationship has been called the *hygiene hypothesis*⁶⁰ (see [Asthma under Disorders of the Lower Airways in Chapter 37](#) for more detail). Recently, the relationship between the microbiome and asthma risk is shedding light on these complex interactions (see [What's New? Asthma and the Lung Microbiome](#)).

What's New?

Asthma and the Lung Microbiome

The term *microbiome* refers to the community of microorganisms that live in the human body. In the lung, the microbiome has been found to be essential to the development and maintenance of well-adapted immune and inflammatory responses to inhaled and ingested allergens, particles, and viruses. Asthma has been linked to changes in the lung microbiome (dysbiosis), particularly early in life. Of particular interest is the recent finding that airway

colonization by large numbers of Proteobacteria, such as *Haemophilus influenzae* B and *Moraxella catarrhalis*, is more prevalent in individuals with asthma. Deleterious changes in the pulmonary microbiota have been associated with maternal and infant antibiotic use, maternal urinary tract infection, cesarean section mode of delivery, exposure to older siblings, vaccination, and changes in lifestyle and dietary habits. Newly developed sensitive methods for microbial detection have allowed researchers to more accurately explore in greater detail the relationship between the lung microbiome and pulmonary diseases. These studies will provide a foundation for developing new approaches for the prevention and treatment of asthma.

◆Pathophysiology.

Airway epithelial exposure to antigen initiates both an innate and an adaptive immune response in sensitized individuals (see [Chapter 9](#)).⁶¹ Many cells and cellular elements contribute to the persistent inflammation of the bronchial mucosa and hyperresponsiveness of the airways, including dendritic cells (antigen-presenting macrophages), T helper 2 (Th2) lymphocytes, B lymphocytes, mast cells, neutrophils, eosinophils, and basophils. There is both an immediate (early asthmatic response) and a late (delayed) response.

The *early asthmatic response* is a phase of acute bronchoconstriction that reaches a maximum in the first 30 minutes and resolves within 1 to 3 hours. During the early asthmatic response, antigen exposure to the bronchial mucosa activates dendritic cells to present the antigen to T helper cells (CD4+ T cells), which differentiate into Th2 cells releasing numerous inflammatory cytokines ([Box 36.1](#)). Together, these mediators activate inflammatory cells and cytokines, resulting in vasodilation, increased capillary permeability, mucosal edema,

bronchial smooth muscle contraction (bronchospasm), and tenacious mucus secretion from mucosal goblet cells with narrowing of the airways and obstruction to airflow (Figs. 36.10, 36.11, and 36.12).

Box 36.1

Asthma and Immune Cytokines

IL-4: Activates B lymphocytes (plasma cells) and eosinophils

IL-5: Stimulates the activation, migration, and proliferation of eosinophils, which cause direct tissue injury and release of toxic neuropeptides that contribute to increased bronchial hyperresponsiveness, fibroblast proliferation, epithelial injury, and airway scarring

IL-8: Activates neutrophils that contribute to a more exaggerated inflammatory response

IL-9: Promotes mast cell proliferation and differentiation and increases production of IgE by B cells

IL-13: Impairs mucociliary clearance, enhances fibroblast secretion, indirectly increases number of eosinophils, and contributes to bronchoconstriction and airway remodeling

IL-17: Increases neutrophilic inflammation

IL-22: Stimulates airway epithelial cells and airway smooth muscle, and plays an important role in stimulating further innate and adaptive immune responses and bronchoconstriction

IL-25: Promotes airway remodeling

IL-33: Contributes to airway remodeling and promotes steroid-resistant asthma (see text)

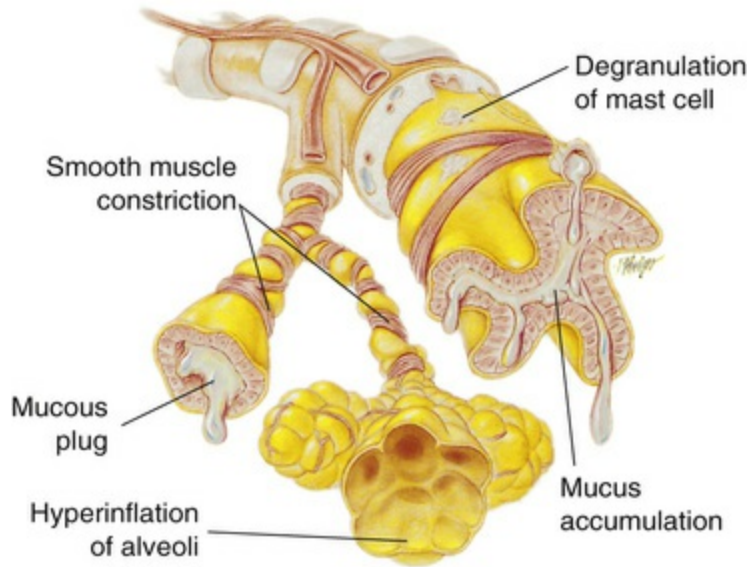

FIGURE 36.10 Bronchial Asthma. Thick mucus, mucosal edema, and smooth muscle spasm cause obstruction of small airways; breathing becomes labored and expiration is difficult. (Modified from Des Jardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease*, ed 3, St Louis, 1995, Mosby.)

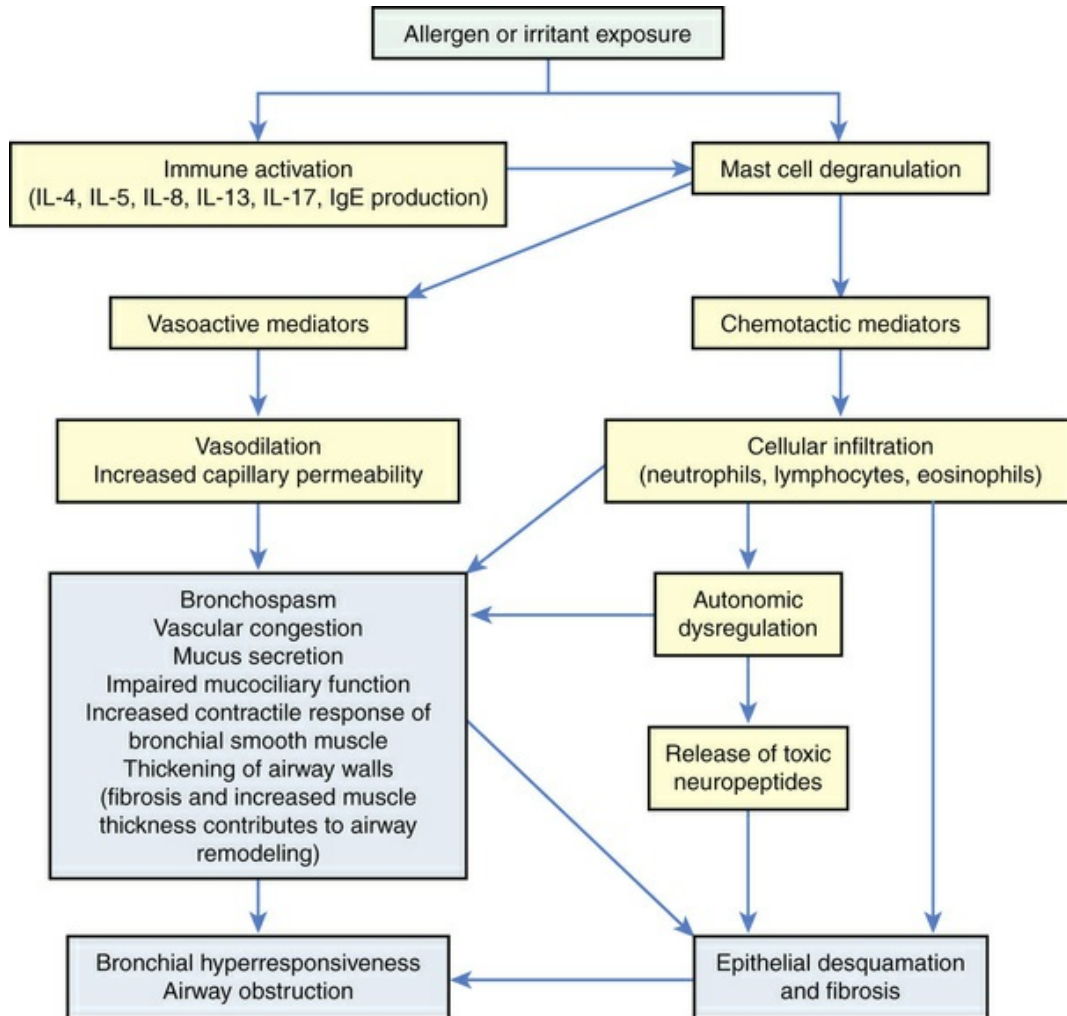

FIGURE 36.11 Pathophysiology of Asthma. Allergen or irritant exposure results in a cascade of inflammatory events leading to acute and chronic airway dysfunction. *IgE*, Immunoglobulin E; *IL*, interleukin.

FIGURE 36.12 Early and Late Asthmatic Responses. A, Early response: Inhaled antigen (1) binds to mast cells covered with preformed immunoglobulin E (IgE). Mast cells degranulate (2) and release inflammatory mediators such as histamine, bradykinins, leukotrienes, prostaglandins, platelet-activating factor, and interleukins. Secreted mediators (3) induce active bronchospasm (airway smooth muscle constriction), edema from increased capillary permeability, and airway mucus secretion from goblet cells. At the same time, antigen is detected by (4) dendritic cells that process and present it to T-helper 2 (Th2) cells (5), which produce interleukin-4 (*IL-4*) and many other interleukins (see text). *IL-4* promotes switching of B cells to favor IgE production. Th2 cells also produce *IL-5* (6), which activates eosinophils. Many inflammatory cells, including neutrophils (7), also contribute to the inflammatory process. **B, Late response:** Areas of epithelial damage and shedding caused, at least in part, by toxicity of eosinophil products (major basic protein, eosinophilic cationic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase). Many inflammatory cells are recruited by chemokines and upregulation of vascular cell adhesion molecules. Local T lymphocytes display a predominant Th2 cytokine profile. They produce *IL-4* and *IL-13*, which promote switching of B cells to favor IgE production; and *IL-3*, *IL-5*, and granulocyte-macrophage colony-stimulating factor, which encourage eosinophil differentiation and survival. Inflammatory mediators also activate sensory nerves, further stimulating bronchoconstriction.

The *late asthmatic response* begins 4 to 8 hours after the early response with an increase in airway hyperresponsiveness.⁶² Chemotactic recruitment of lymphocytes, eosinophils, neutrophils, basophils, and lymphocytes during the acute response causes a latent release of inflammatory mediators, and newly formed mediators (such as cysteinyl leukotrienes and prostaglandin D₂) cause bronchospasm, edema, and mucus secretion with obstruction to airflow. Eosinophil mediators cause direct tissue injury with fibroblast proliferation and airway scarring. Release of toxic neuropeptides (substance P, neurokinin A, and calcitonin gene-related peptide) contributes to increased bronchial hyperresponsiveness. Damage to ciliated epithelial cells contributes to impaired mucociliary function with accumulation of mucus and cellular debris forming plugs in the airways (increased synthesis of reactive nitrogen species [nitric oxide] contributes to oxidative injury and chronic inflammation).⁶³ A decrease in the number or function of T regulatory (Treg) cells also is associated with asthma.⁶⁴ Untreated inflammation can lead to long-term airway damage that is irreversible, known as *airway remodeling* (i.e., subepithelial fibrosis, smooth muscle and mucous gland hypertrophy).⁶⁵

Airway obstruction increases resistance to airflow and decreases flow rates, especially expiratory flow. Impaired expiration causes air trapping, hyperinflation distal to obstructions, and increased work of breathing. Changes in resistance to airflow are not uniform throughout the lungs and the distribution of inspired air is uneven, with more air flowing to the less resistant portions. Continued air trapping increases intrapleural and alveolar gas pressures and causes decreased perfusion of the alveoli. Increased alveolar gas pressure, decreased ventilation, and decreased perfusion lead to variable and uneven ventilation-perfusion relationships within different lung segments. Hyperventilation is triggered by lung receptors responding to increased lung volume and obstruction. The result is early hypoxemia without CO₂ retention. Hypoxemia further increases hyperventilation through stimulation of the respiratory center,

causing the levels of PaCO_2 to decrease and pH to increase (respiratory alkalosis). With progressive obstruction of expiratory airflow, air trapping becomes more severe and the lungs and thorax become hyperexpanded, putting the respiratory muscles at a mechanical disadvantage. This leads to a decrease in tidal volume with increasing CO_2 retention and respiratory acidosis. Respiratory acidosis signals respiratory failure.

◀Clinical Manifestations.

Individuals with asthma are asymptomatic between attacks and pulmonary function tests are normal. No clinical symptoms are present during partial remission, but pulmonary function tests are abnormal. At the beginning of an attack, the individual experiences chest constriction, expiratory wheezing, dyspnea, nonproductive coughing, prolonged expiration, tachycardia, and tachypnea. Severe attacks involve the use of accessory muscles of respiration, and wheezing is heard during both inspiration and expiration. A **pulsus paradoxus** (decrease in systolic blood pressure during inspiration of more than 10 mmHg) may be noted. Peak flow measurements should be obtained. Because the severity of blood gas alterations is difficult to evaluate by clinical signs alone, arterial blood gas tensions should be measured if oxygen saturation falls below 90%. Usual findings are hypoxemia with an associated respiratory alkalosis. In the late asthmatic response, symptoms can be even more severe than during the initial attack.

If bronchospasm is not reversed by usual measures, the individual is considered to have severe bronchospasm or **status asthmaticus**. If status asthmaticus continues, hypoxemia worsens, expiratory flow rates decrease further, and effective ventilation decreases. Acidosis develops as the arterial PaCO_2 value begins to rise. Asthma becomes life-threatening at this point if treatment does not reverse this process quickly. A silent chest (no audible air movement) and a PaCO_2 value greater than 70 mmHg are ominous signs of impending death.

◀Evaluation and Treatment.

The diagnosis of asthma is supported by a history of allergies and recurrent episodes of wheezing, dyspnea and cough, or exercise intolerance. Further evaluation includes spirometry, which may document reversible decreases in FEV₁ during an induced attack.

The evaluation of an acute asthma attack requires the rapid assessment of arterial blood gases and expiratory flow rates (using a peak flowmeter) and a search for underlying triggers, such as infection. Hypoxemia and respiratory alkalosis are expected early in the course of an acute attack. The development of hypercapnia with respiratory acidosis signals the need for mechanical ventilation. Management of the acute asthma attack requires immediate administration of oxygen and inhaled beta-agonist bronchodilators. In addition, inhaled corticosteroids should be administered early in the course of management.⁶⁶

Careful monitoring of gas exchange and airway obstruction in response to therapy provides information necessary to determine whether hospitalization is necessary. Antibiotics are not indicated for acute asthma unless there is a documented bacterial infection.

Management of asthma includes the avoidance of allergens and irritants, control of symptoms, and prevention of exacerbations. Individuals with asthma tend to underestimate the severity of their asthma and extensive education is important, including use of a peak flowmeter and adherence to an action plan should symptoms worsen. In the mildest form of asthma (intermittent), short-acting beta-agonist inhalers are prescribed. For all categories of persistent asthma, antiinflammatory medications are essential, and inhaled corticosteroids are the mainstay of therapy. In individuals whose symptoms are not adequately controlled using inhaled corticosteroids, leukotriene antagonists can be considered. In more severe asthma, long-acting beta agonists can be used to control persistent bronchospasm; however, these agonists can actually worsen asthma in some individuals with certain genetic polymorphisms. Immunotherapy has been shown to be an important tool in reducing asthma exacerbations and can now be given sublingually. Monoclonal antibodies to IgE (omalizumab) have been found to be helpful as

adjunctive therapy to inhaled corticosteroids.⁶⁷ The National Asthma Education and Prevention Program offers stepwise guidelines for the diagnosis and management of chronic asthma based on clinical severity, and they may be reviewed at <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>. More recent updates can be found at the Global Initiative for Asthma website (<http://ginasthma.org/>). Biomarkers and epigenetic markers are being evaluated to personalize treatment and reduce mortality.⁶⁸

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is defined as a common, preventable disease characterized by airflow limitation that is not fully reversible and is usually progressive. COPD includes two primary phenotypes that frequently overlap each other. **Chronic bronchitis** is defined as hypersecretion of mucus and chronic productive cough that continues for at least 3 months of the year (usually the winter months) for at least 2 consecutive years. **Emphysema** is abnormal permanent enlargement of gas-exchange airways (acini) accompanied by destruction of alveolar walls without obvious fibrosis. Both phenotypes are associated with an enhanced chronic inflammatory response in the airways to noxious particles or gases. Exacerbations and comorbidities contribute to the overall severity of disease. COPD is the third leading cause of death in the United States with 2014 death rates at 44.3 per 100,000 men and at 35.6 per 100,000 women.⁶⁹

Risk factors for COPD include tobacco smoke (cigarette, pipe, cigar, and environmental tobacco smoke), occupational dusts and chemicals (vapors, irritants, and fumes), indoor air pollution from biomass fuel used for cooking and heating (in poorly vented dwellings), and outdoor air pollution. Risks of lung disease with inhalation of marijuana are summarized in *What's New? Inhalation of Marijuana and Lung Disease*. The risk for COPD also is increased by factors that affect lung growth during gestation (smoking, antibiotic use, preterm birth, air pollution) and childhood (low birth weight, respiratory tract infections, obesity, childhood asthma).⁷⁰ Genetic and epigenetic

susceptibilities have been identified, including polymorphisms of genes that code for tumor necrosis factor, surfactant, proteases, antiproteases, and acquired failure of DNA repair.⁷¹ An inherited mutation in the α_1 -antitrypsin gene results in the development of COPD (emphysema) at an early age, even in individuals who do not smoke.⁷² The asthma-COPD overlap syndrome is a phenotype of chronic respiratory disease where there is an overlap of the clinical symptoms of asthma and COPD (see [What's New? The Asthma-Chronic Obstructive Pulmonary Disease Overlap Syndrome](#)).

What's New?

Inhalation of Marijuana and Lung Disease

Marijuana is the second most commonly smoked substance after tobacco. The recent legalization of marijuana (*Cannabis sativa*) in many states for recreational and medicinal use has raised questions about its health effects. To date, few investigations have explored the long-term lung effects of marijuana use and there is debate in the medical and scientific communities regarding its safety. Research has been limited because marijuana is an illegal drug according to federal law, although there has been some easing of restrictions on the study of cannabidiol for medical treatment (i.e., epilepsy, pain syndromes, and substance abuse disorders). *Cannabis* is a complex substance and contains 483 different compounds, including more than 80 cannabinoids.^{1,2} Two cannabinoid receptors, CB1 and CB2, have been identified in humans and both are found in lung and bronchial tissue. Both endogenous and exogenous cannabinoids activate these receptors.³ The general effect of cannabis on immune cells is to suppress immune function and inflammation, including immune cells in the lung. However, its overall impact on respiratory health remains unclear.

In some human studies, marijuana smoke has effects on the lungs similar to those caused by tobacco smoke, with large airway inflammation and symptoms of bronchitis, including increased

cough and sputum production. Heavy marijuana smoking is associated with lung hyperinflation, increased forced vital capacity (FVC), upper lobe emphysematous changes, bronchial epithelial ciliary loss, and impairment of the phagocytic and bactericidal actions of alveolar macrophages. Despite these findings, evidence remains inconclusive regarding possible associated risks for asthma, chronic obstructive pulmonary disease (COPD), or lower respiratory tract infection.⁴⁻⁷ Similarly, studies looking at the effects of marijuana on cancer risk also are inconclusive and contradictory. Epidemiologic studies regarding lung cancer development and smoking marijuana are inconsistent and not related to populations currently using marijuana legally. The carcinogenic effects of marijuana are unknown. Long-term heavy smoking of marijuana is associated with immunohistopathologic changes, and epidemiologic evidence suggests a potential risk for developing lung cancer. However, in animal studies, cannabidiol has been shown to inhibit the progression of different types of cancer, including lung cancer.^{8,9}

Marijuana is most commonly used by smoking, and the amount and depth of inhalation vary depending on the type of smoking device. Different varieties of marijuana, conditions of growth, stage of growth when harvested, and type of contaminants (such as pesticides, molds, and bacteria) affect the quality and number of active compounds contributing to the variability of their effects on the lungs and other tissues.¹⁰ Furthermore, smokers of marijuana also may smoke tobacco, vape nicotine products, smoke cocaine, or use alcohol or other drugs, making it difficult to discern the effects of marijuana on airway pathology. Together these factors make research on the lung effects of marijuana difficult. Thus the benefits and hazards of marijuana inhalation among the current population of users have yet to be determined. Collection of data relevant to the populations most likely to be exposed will require administration of pharmacologically approved preparations of marijuana in controlled trials. The Drug Enforcement Administration (DEA) has released new policies for supplying

marijuana to medical researchers, thus advancing opportunities for investigation.¹¹

What's New?

The Asthma-Chronic Obstructive Pulmonary Disease Overlap Syndrome

The asthma-COPD overlap syndrome (ACOS) is a condition in which a person has clinical features of both diseases. Asthma is an inflammatory disease of both the large and small airways with bouts of bronchial hyperresponsiveness, bronchoconstriction and airway obstruction with chest tightness, and coughing and wheezing. Asthma is mediated primarily by eosinophilic inflammation involving T-helper 2 (Th2) lymphocytes and is usually responsive to corticosteroid therapy. COPD is an inflammatory disease with primarily two phenotypes: (1) chronic bronchitis with inflammation and excessive mucus secretion in small airways and (2) emphysema characterized by inflammation with loss of alveolar structure. COPD is mediated primarily by neutrophils and CD8 lymphocytes (cytotoxic T lymphocytes) with low Th2 activation and may be treated with macrolides, chemokine antagonists, monoclonal antibodies, or phosphodiesterase E4 inhibitors. Some individuals with asthma, particularly those who smoke, develop irreversible airway obstruction attributable to airway remodeling and clinically resemble individuals with COPD. Likewise, some individuals with COPD have eosinophilic inflammation and reversible airway obstruction and clinically resemble individuals with asthma. The overlap of these symptoms is described as ACOS and occurs later in life than in those with pure asthma. ACOS is more common in those with a history of smoking. Criteria have been developed for the diagnosis and targeted treatment of this syndrome.

Data from Barnes PJ: *J Allergy Clin Immunol* 136(3):531–545, 2015; Global Initiative for Asthma: *Diagnosis of disease of chronic airflow limitation, asthma COPD and asthma-COPD overlap syndrome (ACOS)*, 2015. Available at: http://www.msssi.gob.es/organizacion/sns/planCalidadSNS/pdf/GOLD_ACOS_2015.pdf; Nielsen M, Barnes CB, Ulrik CS: *Int J Chron Obstruct Pulmon Dis* 10:1443–1454, 2015; Postma DS, Rabe KF: *N Engl J Med* 373(13):1241–1249, 2015; Slats A, Taube C: *Ther Adv Respir Dis*

◆Pathophysiology.

The pathologic changes of COPD occur in large central airways, small peripheral airways, and the lung parenchyma. In both chronic bronchitis and emphysema, chronic irritant exposure recruits neutrophils, macrophages, and lymphocytes to the lung, resulting in progressive damage from inflammation, oxidative stress, extracellular matrix proteolysis, and apoptotic and autophagic cell death.^{73,74}

In chronic bronchitis, inspired irritants promote bronchial inflammation, causing bronchial edema, increases in the size and number of mucous glands and goblet cells in the airway epithelium, smooth muscle hypertrophy with fibrosis, and narrowing of airways. Hypersecretion of thick, tenacious mucus occurs and cannot be cleared because of impaired ciliary function (Fig. 36.13). The lung's defense mechanisms are therefore compromised, increasing susceptibility to pulmonary infection, which contributes to airway injury and ineffective repair. Frequent infectious exacerbations from bacterial colonization of damaged airways are complicated by bronchospasm with dyspnea and productive cough.⁷⁵ The pathogenesis of chronic bronchitis and emphysema is shown in Fig. 36.14. Initially chronic bronchitis affects only the larger bronchi, but eventually all airways are involved. The thick mucus and hypertrophied bronchial smooth muscle narrow the airways and lead to obstruction, particularly during expiration when the airways are constricted. Obstruction also leads to ventilation-perfusion mismatch with hypoxemia.

FIGURE 36.13 Chronic Bronchitis. Inflammation and thickening of mucous membrane with accumulation of mucus and pus leading to obstruction characterized by productive cough. (Modified from Des Jardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease*, ed 3, St Louis, 1995, Mosby.)

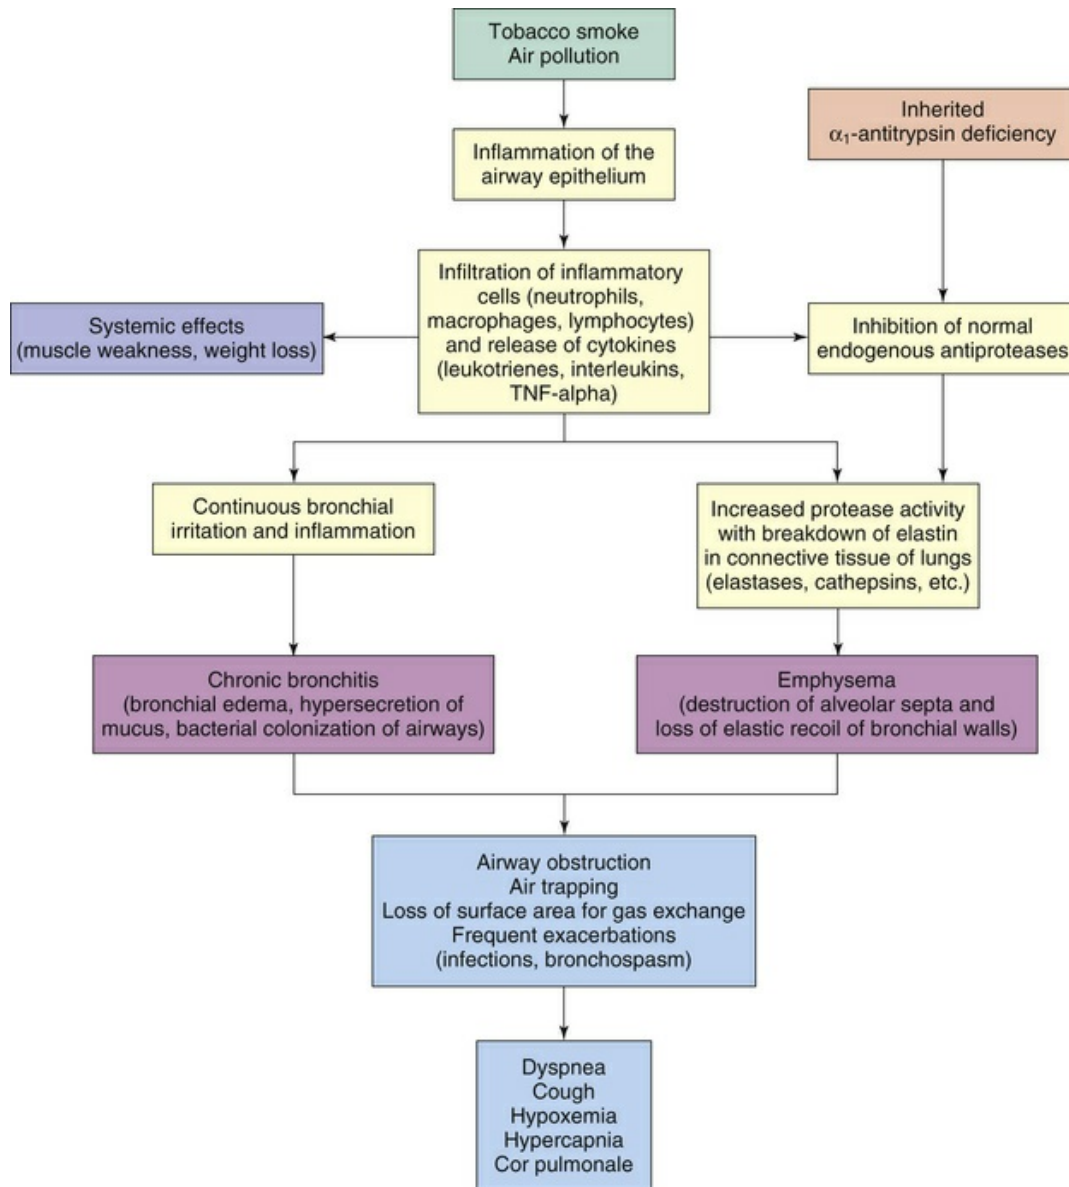

FIGURE 36.14 Pathogenesis of Chronic Bronchitis and Emphysema (Chronic Obstructive Pulmonary Disease [COPD]).

Emphysema is characterized by destruction of alveoli through the breakdown of elastin within the septa caused by an imbalance between proteases and antiproteases, oxidative stress, and apoptosis of lung structural cells^{76,77} (see Fig. 36.14). The number of neutrophils is increased in the airways of individuals with emphysema and they release elastase and proteases that cleave structural collagen and promote tissue breakdown, thus destroying bronchial and alveolar structures. Macrophages also are recruited to the lungs and enhance

the release of proinflammatory mediators (i.e., tumor necrosis factor- α [TNF- α], IL-8, and chemokines). The role of T cells is less well described, but they may promote apoptosis and autophagic alveolar destruction.⁷⁸ Cellular apoptosis and early cellular senescence contribute to loss of alveolar cells and reduced surface area for gas exchange, and there is significant ventilation-perfusion (V/Q) mismatching and hypoxemia.

Emphysema can be centriacinar (centrilobular), paraseptal, or panacinar (panlobular); these variations can also occur in combination (Fig. 36.15) depending on the site of involvement. In **centriacinar (centrilobular) emphysema**, septal destruction occurs in the respiratory bronchiolar walls and alveolar ducts in the center of the pulmonary lobule, usually in the upper lobes of the lung. The alveolar sac (alveoli distal to the respiratory bronchiole) remains intact. This type of emphysema tends to occur in smokers with chronic bronchitis. **Paraseptal emphysema** is similar to centriacinar emphysema but occurs adjacent to the pleura and septa of the pulmonary lobule and is associated with large bullae formation. **Panacinar emphysema** involves the alveolar and respiratory bronchiolar walls, resulting in global air space expansion with damage more randomly distributed and involving the lower lobes of the lung. It tends to occur in older adults and in those with α_1 -antitrypsin deficiency.⁷⁹ Alveolar destruction also produces large air spaces within the lung parenchyma (bullae) and air spaces adjacent to pleurae (blebs).

FIGURE 36.15 Types of Emphysema. Enlargement and destruction of alveolar walls with loss of elasticity and trapping of air. **A**, Normal lung. **B**, Centriacinar emphysema. **C**, Panacinar emphysema. **D**, Paraseptal emphysema. *AD*, Alveolar duct; *AS*, alveolar sac; *RB*, three orders of respiratory bronchioles; *TB*, terminal bronchiole. (From Corrin B, Nicholson AG: *Pathology of the lungs*, ed 3, Edinburgh, 2011, Churchill Livingstone.)

Primary emphysema, which accounts for 1% to 3% of all cases of emphysema, is commonly linked to an autosomal recessive inherited deficiency of the enzyme α_1 -antitrypsin.⁸⁰

Normally, α_1 -antitrypsin inhibits the action of many proteolytic enzymes; therefore individuals who have α_1 -antitrypsin deficiency increase their likelihood of developing emphysema because proteolysis in lung tissues is not inhibited. Homozygous individuals have a 70% to 80% likelihood of developing lung disease. α_1 -Antitrypsin deficiency is suggested in individuals who develop emphysema before 40 years of age and in those who do not smoke but still develop the disease.

Combined emphysema and idiopathic pulmonary fibrosis is increasingly recognized, particularly in heavy smokers with fibrosis predominant in the lower lobes and emphysema in the upper lobes. Symptoms are severe breathlessness and cough, and pulmonary hypertension is common. Specific pathogenic mechanisms are unknown. Diagnosis is confirmed with chest imaging and treatment is supportive.⁸¹

In COPD, expiration becomes difficult because of expiratory airway

obstruction caused by accumulation of mucus, epithelial edema, and/or loss of elastic recoil and airway collapse. This reduces the volume of air that can be expired passively and air is trapped in the lungs (Fig. 36.16). **Air trapping** causes hyperexpansion of the chest, which puts the muscles of respiration at a mechanical disadvantage, resulting in increased work of breathing; consequently, many individuals will develop hypoventilation and hypercapnia. Persistent inflammation in the airways can result in hyperreactivity of the bronchi with bronchoconstriction, which may be partially reversible with bronchodilators. Chronic inflammation also can have significant systemic effects including weight loss, muscle weakness, and increased susceptibility to comorbidities, such as infection.

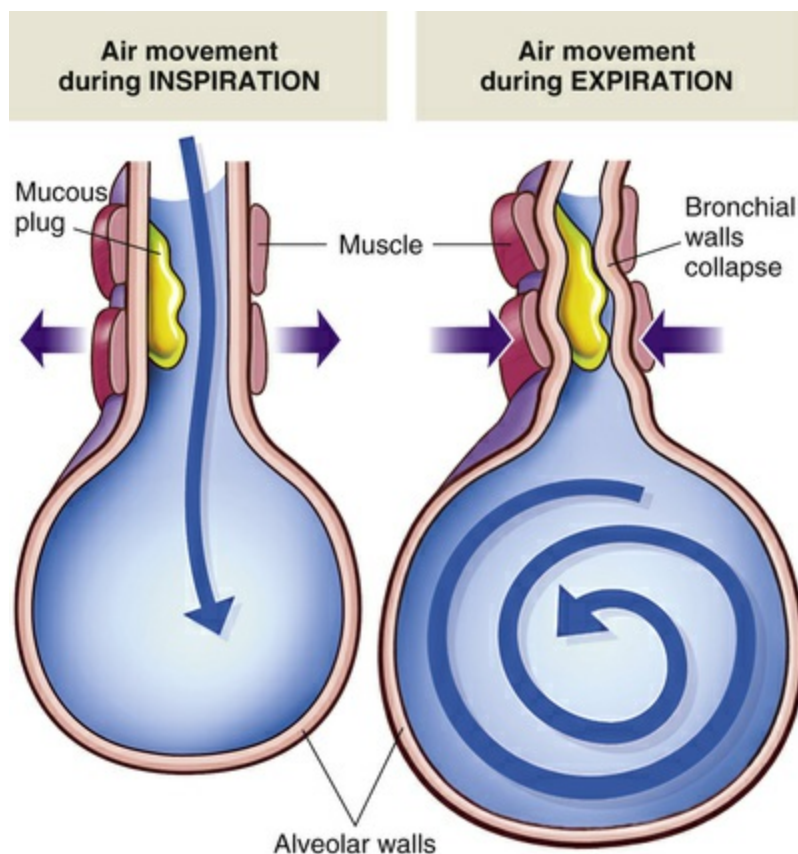

FIGURE 36.16 Mechanisms of Air Trapping in Chronic Obstructive Pulmonary Disease (COPD). Mucous plugs and narrowed airways cause air trapping and hyperinflation on expiration. During inspiration the airways are pulled open, allowing gas to flow past the obstruction. During expiration decreased elastic recoil of the bronchial walls results in collapse of the airways and prevents normal expiratory airflow.

◀Clinical Manifestations.

Dyspnea on exertion that progresses to marked dyspnea, even at rest, is the most common symptom of COPD (see [Table 36.3](#)). In chronic bronchitis, individuals have a productive cough whereas in emphysema, cough is usually productive only during acute exacerbations. As COPD progresses, copious amounts of sputum are produced, accompanied by frequent pulmonary infections.⁸² The individual with COPD is often thin, has tachypnea with prolonged expiration, and must use accessory muscles for ventilation. The anteroposterior diameter of the chest is increased (barrel chest), and the chest has a hyperresonant sound with percussion. To increase lung capacity, the individual often leans forward with arms extended and braced on knees when sitting. In addition, people with COPD often exhale through pursed lips, a position that helps prevent expiratory airway collapse.

TABLE 36.3

CLINICAL MANIFESTATIONS OF CHRONIC PULMONARY DISEASE

CLINICAL MANIFESTATIONS	CHRONIC BRONCHITIS	EMPHYSEMA
Productive cough	Classic sign	Late in course with infection
Dyspnea	Late in course	Common
Wheezing	Intermittent	Minimal
History of smoking	Common	Common
Barrel chest	Occasionally	Classic
Prolonged expiration	Always present	Always present
Cyanosis	Common	Uncommon
Chronic hypoventilation	Common	Late in course
Polycythemia	Common	Late in course
Cor pulmonale	Common	Late in course

Airway obstruction results in decreased alveolar ventilation and hypercapnia and V/Q mismatching with hypoxemia. Marked hypoxemia leads to polycythemia (overproduction of erythrocytes)

and cyanosis. If not reversed, respiratory failure leads to pulmonary hypertension and eventually results in cor pulmonale (see [Cor Pulmonale under Pulmonary Vascular Disease](#)), which leads to severe disability or death. ([Table 36.3](#) lists the common clinical manifestations of chronic bronchitis.)

◆Evaluation and Treatment.

Diagnosis is based on history of symptoms, physical examination, chest imaging, pulmonary function tests, and blood gas analyses.⁸³ Pulmonary function testing reveals airway obstruction (decreased FEV₁) that is progressive and unresponsive to bronchodilators. Hypoxemia may first occur with exercise but gradually progresses to hypoxemia at rest. Hypercapnia develops as air trapping worsens and the work of breathing increases. Chest x-ray may reveal changes in thoracic diameter, distended lung fields, and flattening of the diaphragm. In individuals for whom chest x-ray and pulmonary function testing are not definitive for the diagnosis, high-resolution CT scanning is indicated.

Prevention of COPD is the best treatment because pathologic changes are not reversible. By the time an individual seeks medical care for symptoms, considerable airway damage is present. If the individual stops smoking, disease progression can be slowed. Influenza and pneumococcal vaccination should be kept up to date.

COPD is not reversible; therefore management is focused on symptom control ([Box 36.2](#)). Treatment is based on clinical stage as determined by the Global Strategy for the Diagnosis, Management and Prevention of COPD.⁸³ Bronchodilators (long-acting inhaled anticholinergics or long-acting inhaled beta agonists) and expectorants are prescribed to reduce dyspnea. Mucolytics, such as *N*-acetylcysteine, reduce cough and have been found to have antiinflammatory and antioxidant effects.⁸⁴ The addition of inhaled corticosteroids has been found to diminish the number of acute exacerbations, slow the rate of decline in quality of life, and reduce the rate of decline in FEV₁; however, their use must be weighed against the potential side effects (oropharyngeal candidiasis and hoarseness,

risk of pneumonia). Phosphodiesterase-4 (PDE4) inhibitors have been shown to reduce inflammation, cough, and sputum production. Chronic oral corticosteroids should be considered a last resort. During acute exacerbations (infection and bronchospasm), individuals require treatment with antibiotics and corticosteroids and may need mechanical ventilation. Macrolides are antiinflammatory and reduce neutrophil-elastase–induced mucous stasis in addition to their antibiotic properties.⁸⁵

Box 36.2

Pharmacologic Management of COPD

- Short-acting anticholinergic (e.g., ipratropium)
- Short-acting beta₂ agonist (e.g., levalbuterol)
- Long-acting anticholinergic (e.g., tiotropium)
- Long-acting beta₂ agonist (e.g., salmeterol)
- Phosphodiesterase-4 inhibitor (e.g., roflumilast)
- Inhaled corticosteroid (e.g., fluticasone)
- Mucolytics and antioxidants (e.g., *N*-acetylcysteine)
- Methylxanthine (e.g., theophylline)
- Antibiotics (e.g., erythromycin)

Data from Global Initiative for Chronic Obstructive Lung Disease (GOLD): *Update 2016*. Available at: <http://www.goldcopd.org/>.

Chest physical therapy may be helpful and includes deep breathing and postural drainage. Teaching includes nutritional counseling, respiratory hygiene, recognition of the early signs of infection, and techniques that relieve dyspnea, such as pursed-lip breathing, all of which may be useful in the treatment of COPD in selected individuals⁸⁶ (see [Nutrition & Disease: Chronic Obstructive Pulmonary Disease](#)). Progressive pulmonary dysfunction with hypoxemia and hypercapnia may require long-term oxygen therapy and ventilation.

Oxygen is titrated with care to individuals with severe hypoxemia and CO₂ retention. If titration of oxygen therapy cannot be achieved without significant hypercapnia, the individual's lungs must be mechanically ventilated.⁸⁷ In selected individuals with emphysema, lung volume reduction surgery, endoscopic techniques, or transplantation can be considered.⁸⁸ α_1 -Antitrypsin augmentation may be indicated for primary emphysema.⁸⁹ In addition, many comorbidities accompany COPD and require monitoring and therapy, including bronchiectasis, cardiovascular disorders, metabolic diseases, bone disease, stroke, lung cancer, cachexia and muscle weakness, anemia, depression, and cognitive decline.

Nutrition & Disease

Chronic Obstructive Pulmonary Disease

Diet and nutrition have been linked to the development and progression of chronic obstructive pulmonary disease (COPD). For example, a high intake of omega-3 fatty acids has been linked to a decreased risk of COPD, whereas obesity and low levels of vitamin D are linked to an increased risk for COPD. Once the diagnosis of COPD has been established, and as the disease progresses, weight and muscle loss are common and are associated with reduced survival. The impact of poor nutrition on individuals with COPD is exacerbated by the fact that these individuals have increased work of breathing and elevated energy expenditure. Specifically, malnutrition (1) limits muscle strength and oxygen uptake, thus reducing exercise capacity; (2) decreases ventilatory capacity, contributing to hypercapnia; (3) limits surfactant production, negatively impacting lung function; (4) reduces cell-mediated immune responses, contributing to infection; and (5) decreases protein synthesis, contributing to widespread effects on cellular function. The goals of medical nutrition therapy are to maintain an acceptable and stable weight and supply adequate calories, minerals, vitamins, and antioxidants to promote optimal exercise

capacity. However, dyspnea and fatigue, as well as the presence of inflammatory cytokines in COPD, impair appetite. Other nutrition impact symptoms (NISs) include dry mouth, stomachache, pain, and constipation or diarrhea. Consumption of high-energy foods, provision of oral nutritional support, promotion of frequent snacking that includes soft foods and beverages, and assistance with shopping and meal preparation can help overcome these barriers. Increasing omega-3 fatty acid supplementation and antioxidant intake may modulate the effects of systemic inflammation. Vitamin D and calcium supplementation is indicated to improve bone health. Serum phosphate levels also should be monitored to prevent hypophosphatemia, which can contribute to muscle weakness.

Respiratory Tract Infections

Respiratory tract infections are the most common cause of short-term disability in the United States. Most of these infections—the common cold, pharyngitis (sore throat), and laryngitis (inflammation of the larynx [voice box])—involve only the upper airways. Infections of the lower respiratory tract occur most often in the very young, the very old, or individuals with impaired immunity or underlying disease.

Acute Bronchitis

Acute bronchitis is acute infection or inflammation of the large airways or bronchi and is usually self-limiting. More than 90% of cases of acute bronchitis are caused by viruses.⁹⁰ Many of the clinical manifestations are similar to those of pneumonia (i.e., cough, fever, chills, malaise), but physical examination does not reveal signs of pulmonary consolidation and chest radiographs do not show infiltrates. Individuals with viral bronchitis usually have a

nonproductive cough that occurs in paroxysms and is aggravated by cold, dry, or dusty air. However, purulent sputum may be produced with some viral infections. Chest pain often develops from the effort of coughing. Treatment consists of antitussive agents and beta₂ agonists for wheezing (especially in individuals with underlying asthma or COPD).⁹¹

Individuals with bacterial bronchitis have a productive cough, fever, and pain behind the sternum (breast bone) that is aggravated by coughing. It is rare in previously healthy adults except after viral infection, but is common in those with COPD. Bacterial bronchitis is treated with antitussive agents. Antibiotics have shown no difference in follow-up examinations compared with placebo, and potential side effects, antibiotic resistance, and cost need to be considered.^{90,92}

Pneumonia

Pneumonia is infection of the lower respiratory tract caused by bacteria, viruses, fungi, protozoa, or parasites. It is the eighth leading cause of death in the United States and is responsible for more disease and death than any other infection.⁹³ The incidence and mortality of pneumonia are highest in the elderly. Risk factors for pneumonia include advanced age; compromised immunity; underlying lung disease, particularly COPD; alcoholism; altered consciousness; chest trauma; impaired swallowing; smoking; endotracheal intubation; malnutrition; immobilization; underlying cardiac or liver disease; and residence in a nursing home.⁹⁴

Pneumonia can be categorized as community-acquired (CAP), or healthcare-associated (HCAP), including hospital-acquired (HAP), or ventilator-associated (VAP). CAP is one of the most common reasons for hospitalization in the United States. HCAP is defined as occurring in individuals with recent hospitalization, residence in a nursing home or extended care facility, home infusion therapy, chronic dialysis, home wound care, nonambulatory status, and the use of tube feedings or gastric acid suppressive agents.⁹⁵ It is estimated that nearly one-third of all hospital admissions for pneumonia are now considered HCAP. HAP is the second most common nosocomial

infection (urinary tract infection [UTI] most common), but has the greatest mortality (overall 20% to 50% mortality). VAP occurs in 9% to 27% of individuals who require intubation and mechanical ventilation.⁹⁶⁻⁹⁸ The microorganisms that most commonly cause CAP are different from those infections that cause HCAP, HAP, and VAP (Box 36.3). In addition, the characteristics of the individual are important in determining which etiologic microorganism is likely; for example, immunocompromised persons tend to be susceptible to opportunistic infections that are uncommon in normal adults (see Box 36.3). Bacterial pneumonia can occur secondary to respiratory viral infection and is a cause of influenza deaths.⁹⁹ Mechanisms of viral and bacterial infection are reviewed in Chapter 10.

Box 36.3

Etiologic Microorganisms for Pneumonia in Adults

CAP	HCAP/HAP/VAP	IMMUNOCOMPROMISED INDIVIDUALS

CAP, Community-acquired pneumonia; *HAP*, hospital-acquired pneumonia; *HCAP*, healthcare-associated pneumonia; *VAP*, ventilator-associated pneumonia.

◆Pathophysiology.

Aspiration of oropharyngeal secretions is the most common route of lower respiratory tract infection; thus the nasopharynx and oropharynx constitute the first line of defense for most infectious agents. Another route of infection is through the inhalation of microorganisms that have been released into the air when an infected individual coughs, sneezes, or talks, or from aerosolized water, such as that from contaminated respiratory therapy equipment. This route of infection is most important in viral and mycobacterial pneumonias and in *Legionella* outbreaks. Endotracheal tubes become colonized with bacteria that form biofilms (protected colonies of bacteria that are resistant to host defenses and treatment with antibiotics) and can seed the lung with microorganisms, especially during endotracheal suctioning.¹⁰⁰ Pneumonia also can occur when bacteria are spread to the lungs in the blood from bacteremia that can result from infection elsewhere in the body or from intravenous drug use.

In healthy individuals, pathogens that reach the lungs are expelled or controlled by mechanisms of self-defense (see [Chapters 7, 8, and 10](#)). If a microorganism overcomes the upper airway defense mechanisms, such as the cough reflex and mucociliary clearance, the next line of defense is the airway epithelial cell. Airway epithelial cells can recognize some pathogens directly (e.g., *Pseudomonas aeruginosa* and *Staphylococcus aureus*). However, the most important guardian cell of the lower respiratory tract is the alveolar macrophage, which recognizes pathogens through its pattern-recognition receptors (e.g., Toll-like receptors). Macrophages present infectious antigens to the adaptive immune system, activating T cells and B cells with the induction of cellular and humoral immunity. Release of TNF- α and IL-1 from macrophages and chemokines and chemotactic signals from mast cells and fibroblasts contributes to widespread inflammation in the lung with recruitment of neutrophils from the capillaries of the

lungs into the alveoli.

Neutrophils are critical phagocytes that kill microbes through the formation of phagolysosomes filled with degradative enzymes, antimicrobial proteins, and toxic oxygen free radicals.¹⁰¹ Neutrophils have also been found to extrude a meshwork of proteins called a *neutrophil extracellular trap (NET)* that can capture any bacteria that have not yet been phagocytosed. Unfortunately, many pathogens, such as the pneumococcus, can release a deoxyribonuclease (DNase) that cleaves the NET and thus escapes neutrophil defense.¹⁰² The release of inflammatory mediators and immune complexes can damage bronchial, mucosal, and alveolocapillary membranes, causing the terminal bronchioles and acini to fill with infectious debris and exudate. In addition, some microorganisms release toxins from their cell walls that can cause further lung damage. Obstruction of bronchioles and accumulation of exudate in the acinus lead to V/Q mismatching, hypoxemia, and dyspnea.

Pneumococcal Pneumonia.

The pathogenesis of pneumococcal pneumonia (*Streptococcus pneumoniae*) is the most common cause of bacterial pneumonia and serves as a model for understanding other forms of bacterial pneumonia (Fig. 36.17). *S. pneumoniae* microorganisms initiate innate and adaptive immune responses (see Chapters 7 and 8). The immune response includes complement activation and the production of antibodies, which are crucial for opsonizing the encapsulated bacterium. Rapid lysis of pneumococcal bacteria (as occurs with antibiotic treatment) results in the release of intracellular bacterial proteins that can be toxic. The best known of these proteins is pneumolysin, which is cytotoxic to virtually every cell in the lung and is partially responsible for the worsening in clinical symptoms sometimes seen in individuals immediately after they begin antibiotic treatment.¹⁰³ Inflammatory cytokines and cells are released that cause alveolar edema. Edema creates a medium for the multiplication of bacteria and aids in the spread of infection into adjacent portions of the lung. The involved lobe undergoes consolidation, which alveoli fill

with blood cells, fibrin, edematous fluid, and pneumococci, giving lung tissue a red appearance. This passes into the stage in which affected tissues become gray because of fibrin deposition over the pleural surfaces and the presence of fibrin and neutrophils in the consolidated alveoli, where phagocytosis is rapidly taking place. With resolution, increasing numbers of macrophages appear in the alveolar spaces, the neutrophils degenerate, and the fibrin threads and remaining bacteria are digested by macrophages and removed by lymphatic vessels. Usually infection is limited to one or two lobes.

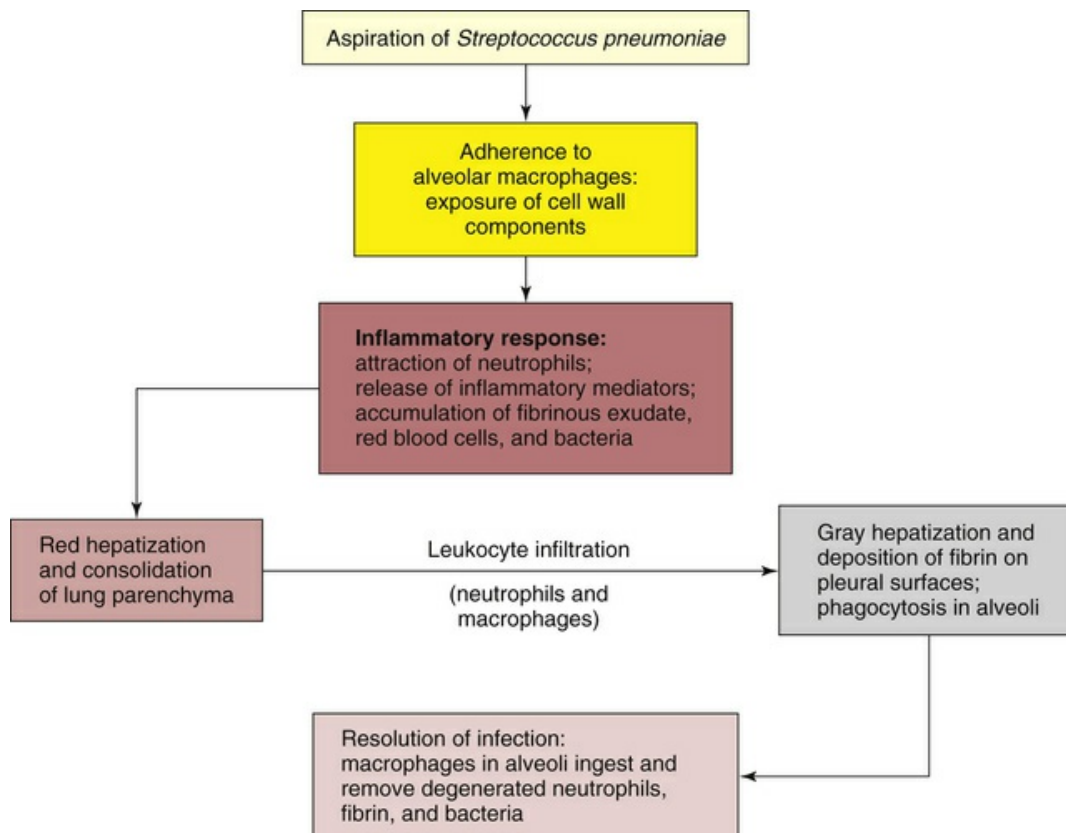

FIGURE 36.17 Pathophysiologic Course of Pneumococcal Pneumonia (*Streptococcus pneumoniae*).

Viral Pneumonia.

Viral pneumonia is seasonal, usually mild and self-limiting, but it can set the stage for a secondary bacterial infection (especially by *S. aureus*

and *Streptococcus pneumoniae*) by providing an ideal environment for bacterial growth and by damaging ciliated epithelial cells, which normally prevent pathogens from reaching the lower airways. Viral pneumonia can be a primary infection (e.g., influenza pneumonia) or a complication of another viral illness (e.g., chickenpox, measles). Influenza virus is the most common viral cause of pneumonia. Influenza viruses impair antibacterial defense mechanisms by increasing neutrophil apoptosis and neutrophil and monocyte dysfunction, depressing chemotaxis, and suppressing phagocytosis. The virus not only destroys the ciliated epithelial cells but also invades the goblet cells and bronchial mucous glands. Sloughing of destroyed bronchial epithelium occurs throughout the respiratory tract, preventing mucociliary clearance and promoting attachment of bacteria. Bronchial walls become edematous and infiltrated with leukocytes, and viruses can evade the protective effect of surfactant proteins in the alveoli.¹⁰⁴

Some forms of viral pneumonia can progress to severe systemic illness and sepsis with many complications and a high morbidity and mortality. Severe viral pneumonia can include common types of influenza that can be fatal, especially in older adults.¹⁰⁵ Other severe viral infections are considered opportunistic infections, such as cytomegalovirus pneumonia in immunocompromised individuals. New or atypical forms of viral infection, such as swine influenza A (H1N1) virus, avian influenza A (H5N1 and H7N9) viruses, enterovirus D68 (EV-D68), and the coronavirus that causes severe acute respiratory syndrome (SARS), can affect previously healthy populations and pose a considerable threat for pandemics.^{106,107}

◆Clinical Manifestations.

Most cases of pneumonia are preceded by an upper respiratory tract infection, which is usually viral. This is then followed by the onset of cough, dyspnea, and fever. The cough is often productive, but may be nonproductive, especially in viral pneumonia. Other symptoms include chills, malaise, and pleuritic chest pain. Physical examination may reveal signs of pulmonary consolidation, such as inspiratory

crackles, increased tactile fremitus (palpable chest vibrations), egophony (a voice sound heard on auscultation as a prolonged “a” over consolidated lung tissue when a person says “e”), and whispered pectoriloquy (the sound of whispering heard on auscultation over consolidated lung tissue, which is abnormal). Individuals also may demonstrate symptoms and signs of underlying systemic disease or sepsis.

◆Evaluation and Treatment.

Diagnosis is made on the basis of history, physical examination (tachypnea, tachycardia, crackles, bronchial breath sounds, and findings of pleural effusion), white blood cell count, measurement of procalcitonin or C-reactive protein level, and chest x-ray. Stains and cultures of blood and respiratory tract secretions are completed in more severe and hospitalized cases and before the start of antibiotic therapy. The white blood cell count is usually elevated, although it may be low if the individual is debilitated, is immunocompromised, or has overwhelming infection.¹⁰⁸ Serum procalcitonin or C-reactive protein levels can be used to help differentiate bacterial from viral infection in order to guide therapy. Chest imaging shows infiltrates that may involve a single lobe of the lung or may be more diffuse. Once the diagnosis of pneumonia has been made, the pathogen is identified by means of sputum characteristics (Gram stain, color, odor) and cultures or, if sputum is absent, blood cultures. Because many pathogens exist in the normal oropharyngeal flora, the specimen may be contaminated with pathogens from oral secretions. If sputum studies fail to identify the pathogen, the individual is immunocompromised, or the individual's condition worsens, further diagnostic studies may include molecular testing of blood or urine, thoracentesis, bronchoscopy, or lung biopsy.¹⁰⁹ Prevention of pneumonia includes prevention of aspiration, respiratory isolation of immunocompromised individuals, vaccination for appropriate populations, and reduction of ventilator-associated pulmonary infections through a variety of oral hygiene and endotracheal tube interventions.

The first step in the management of pneumonia is establishing adequate ventilation and oxygenation. Most individuals have hypoxemia and a respiratory alkalosis, although persons with underlying lung disease may require ventilation. Adequate hydration and good pulmonary hygiene (e.g., deep breathing, coughing, chest physical therapy) are also important. Severe pneumonia is a common cause of sepsis and septic shock (see [Chapter 49](#)) and requires intensive care.

Antibiotics should be given within 4 hours of presentation to treat bacterial pneumonia. When a specific microorganism is not identified, empirical antibiotics are chosen based on the likely causative microorganism and whether the individual has CAP, HCAP, HAP, or VAP.¹¹⁰ The 2014 National Institute for Health and Care Excellence (NICE) guidelines recommend antibiotics only when the C-reactive protein level is greater than 20 mmol/L and positive clinical findings are evident.¹¹¹ Resistant strains of *Pneumococcus*, *Pseudomonas aeruginosa*, Enterobacteriaceae extended-spectrum β -lactamase (ESBL+), and methicillin-resistant *Staphylococcus aureus* (MRSA) are becoming more prevalent and require secondary antibiotics.¹¹² HCAP, HAP, and VAP require broad-spectrum empirical antibiotics, and sputum or blood cultures may indicate the need for additional therapies (e.g., antifungals).¹¹³ Viral pneumonia is usually treated with supportive therapy alone (unless secondary bacterial infection is present); however, antivirals may be needed in severe cases. Infections with opportunistic microorganisms may be polymicrobial and require multiple drugs, including antifungals.

Tuberculosis

Tuberculosis (TB) is an infection caused by *Mycobacterium tuberculosis*, an acid-fast bacillus that usually affects the lungs, but may invade other body systems. TB is the leading cause of death from a curable infectious disease throughout the world. Since the 1992 peak resurgence in TB occurred (attributable to AIDS), the incidence of TB has declined every year and the death rate has declined by 67%. The highest number of reported cases is among foreign-born individuals,

accounting for 67.9% of cases in the United States in 2016. The highest number of cases among racial and ethnic groups occurs among Asians and American Indian/Alaska Natives, Native Hawaiians and other Pacific Islanders.¹¹⁴ In 2015 worldwide, 10.4 million people were diagnosed with TB and 1.8 million died from the disease, including 170,000 children primarily in low- and middle-income countries. One in three HIV deaths occurred in 2015 because of TB.¹¹⁵ Crowded institutional settings or living environments, homelessness, substance abuse, and lack of access to screening and medical care contribute to the spread of TB. Over the past decade, there has been a rapid emergence of multidrug-resistant TB (MDR-TB) and extensively drug-resistant TB (XDR-TB) around the world (see [What's New? Multidrug-Resistant and Extensively Drug-Resistant Tuberculosis](#)).¹¹⁶

What's New?

Multidrug-Resistant and Extensively Drug-Resistant Tuberculosis

Multidrug-resistant tuberculosis (MDR-TB) refers to strains of *Mycobacterium tuberculosis* that are resistant to both isoniazid and rifampin. Extensively drug-resistant TB (XDR-TB) refers to strains that also are resistant to fluoroquinolones and at least one of three injectable second-line drugs (amikacin, kanamycin, or capreomycin). MDR-TB has been reported in hundreds of countries around the world, resulting in increased transmission and mortality. XDR-TB remains relatively rare, but concern is increasing, especially since the recognition of several cases of totally drug-resistant TB (TDR-TB). Mechanisms of drug resistance include mutations in ribonucleic acid (RNA) polymerase and the catalase peroxidase gene, especially in individuals exposed to inconsistent drug treatment (noncompliance) for TB infection. Other risk factors include prolonged hospitalization, HIV infection, and lack of directly observed therapy regimens or lack of consistently available drugs. The diagnosis of MDR-TB and XDR-TB combines culture

and drug sensitivity testing with nucleic acid amplification assays that detect specific gene mutations associated with drug resistance. Second-line drugs for MDR-TB include aminoglycosides and fluoroquinolones. Drugs for XDR-TB include alanine analogs, thioamide drugs, salicylate antifolate, diarylquinoline, and oxazolidinone; however, these drugs have significant side effects. The CDC reports that only 30% to 50% of people with XDR-TB can be successfully treated with these medications and the estimated cost of treatment exceeds \$400,000. New medications are being explored in an attempt to improve success rates. One emerging approach is host-directed therapeutics, such as therapeutic vaccines and monoclonal antibodies, which seek to improve the immune response while reducing lung injury.

Data from Dheda K, Barry CE 3rd, Maartens G: *Lancet* 387(10024):1211–1226, 2016; Engstrom A: *Infect Dis (Lond)* 48(1):1–17, 2016; Wallis RS et al: *Lancet Infect Dis* 16(4):e34–e46, 2016; Wilson JW, Tsukayama DT: *Mayo Clinic Proc* 91(4):482–495, 2016; Yin J et al: *PLoS One* 11(3):e0150511, 2016.

◆Pathophysiology.

TB is highly contagious and is transmitted from person-to-person by inhalation of airborne droplets. Host susceptibility to infection is influenced by host and parasite genetic polymorphisms, including those that affect macrophages, tumor necrosis factor, and interleukins.¹¹⁷ In immunocompetent individuals, the microorganism usually is contained by the inflammatory and immune response systems, resulting in asymptomatic latent tuberculosis infection.¹¹⁸

After inhalation of *M. tuberculosis*, the bacilli lodge in the lung periphery, are phagocytized by resident macrophages, and cause nonspecific pneumonitis (lung inflammation). Some bacilli migrate through the lymphatics and become lodged in the lymph nodes, where they encounter lymphocytes and initiate the immune response. Inflammation in the lung causes neutrophils and macrophages to migrate to the area. These phagocytes engulf the bacilli and begin the process by which the body's defense mechanisms isolate the bacilli,

preventing their spread. However, the bacterium is successful as a pathogen because it can survive within macrophages, resist lysosomal killing, multiply within the cell, and transit into a stage of dormancy rendering itself extremely resistant to host defense and drug treatment.¹¹⁹ In defense, macrophages and lymphocytes release interferon, which inhibits the replication of the microorganisms and stimulates more macrophages to attack the bacterium. Apoptotic infected macrophages also can activate cytotoxic T cells (CD8). Neutrophils, lymphocytes, and macrophages seal off the colonies of bacilli, forming a granulomatous lesion called a *tubercle*. Infected tissues within the tubercle die, forming cheeselike material called *caseation necrosis*. (Necrosis is described in [Chapter 2](#).) Collagenous scar tissue then grows around the tubercle, completing isolation of the bacilli. The immune response is complete after about 10 days, preventing further multiplication of the bacilli.

Once the bacilli are isolated in tubercles and immunity develops, TB may remain dormant for life. There is a range of tuberculosis infections that include individuals with effective immune responses that eradicate all viable bacilli; individuals who contain the infection but continue to maintain populations of bacilli that intermittently replicate in macrophages, granulomas, and other tissues as their immune system tries to control the bacilli; and individuals with no effective immunity, resulting in rapid progression to active disease. Liquefaction of the caseous center can occur, with extracellular bacterial growth and cavity formation. TB may spread through the blood and lymphatics and cause extrapulmonary disease. Coinfection with human immunodeficiency virus (HIV) is the single greatest risk factor for primary infection or reactivation of latent or controlled infection because the two diseases (i.e., HIV and TB) potentiate each other, accelerating the decline of immune function.¹²⁰ Cancer, diabetes mellitus, immunosuppressive medications, poor nutritional status, renal failure, and other debilitating diseases can reactivate disease.^{121,122}

◆Clinical Manifestations.

Latent TB infection is asymptomatic with no radiologic evidence of disease. Symptoms of active disease develop gradually and may not be noticed until the disease is advanced. However, symptoms can appear in immunosuppressed individuals within weeks of exposure to the bacillus. Common clinical manifestations include fatigue, weight loss, lethargy, anorexia (loss of appetite), a low-grade fever that usually occurs in the afternoon, and night sweats. (These are common signs and symptoms of all chronic infections.) A cough that produces purulent sputum develops slowly and becomes more frequent over several weeks or months. Dyspnea, chest pain, and hemoptysis also may occur as the disease progresses. Extrapulmonary TB disease is common in HIV-infected individuals and may cause neurologic deficits, meningitis symptoms, bone pain, and urinary symptoms.

◆Evaluation and Treatment.

Screening for TB consists of obtaining a tuberculin skin test (TST; purified protein derivative [PPD]), immunoassays, and chest radiographs.¹²³ A positive tuberculin skin test indicates the need for yearly chest radiographs to detect active disease. The skin test does not differentiate between past, latent, or active forms of the disease. In addition, individuals who have received the TB vaccine with bacille Calmette-Guérin (BCG) will have a positive TST even if they have never had TB. Two immunoassays (enzyme-linked immunospot and quantitative blood interferon-gamma assay) are available. These newer tests are more sensitive and specific for the diagnosis of latent TB and are not confounded by previous BCG vaccination.

Sputum microscopy, culture, and indirect drug susceptibility testing (DST) remain the “gold standard” for diagnosing TB. When active pulmonary disease is present, sputum staining (using an acid-fast stain) and culture are positive for the tubercle bacillus. However, sputum culture can take up to 6 weeks to become positive. Current generation tuberculosis-specific nucleic acid amplification tests (NAATs) are important supplementary tests for the rapid direct detection of multidrug-resistant TB.¹²⁴ Chest radiographs of

individuals with current or previous active disease demonstrate characteristic changes. Nodules, calcifications, cavities, and hilar enlargement (enlarged mediastinal lymph nodes) commonly are seen in the upper lobes. Screening and treatment of positive cases prevent transmission of the disease. Isolating individuals with active tuberculosis, limiting use of immunosuppressive medications, and treating underlying immunocompromising diseases, such as AIDS, are all critical steps.¹²⁵ Treatment consists of combinations of antibiotics (isoniazid, rifampin, pyrazinamide, and ethambutol) to control drug-sensitive disease or prevent reactivation of latent TB infection. The choice of drugs and the duration of treatment depend on the individual's health history, the likelihood of bacterial resistance to certain drugs, and the presence of active disease.¹²⁶

The waxy coat of *M. tuberculosis* renders it impermeable to many common drugs. For drug-resistant bacilli, the recommended treatment is administration for an 18-month timeframe of a combination of at least four drugs to which the microorganism is susceptible, including injectable drugs, with intermittent review of drug effectiveness. New drugs and drug combinations, including drugs purposed for other infections, are being tested to overcome drug resistance, including immune modulators.¹²⁷ New vaccines are in clinical trials.¹²⁵

Abscess Formation and Cavitation

An **abscess** is a circumscribed area of suppuration and destruction of lung parenchyma and is a type of liquefactive necrosis. Abscess formation follows **consolidation** of lung tissue, in which inflammation causes alveoli to fill with fluid, pus, and microorganisms. The development of a lung abscess may be acute (less than 6 weeks) or chronic (more than 6 weeks). Necrosis of consolidated tissue may progress proximally until it communicates with a bronchus. If this occurs, the abscess empties into the bronchus, leaving a cavity that has a radiographic appearance similar to that of a lesion of tuberculosis.

Pneumonia caused by aspiration or by exposure to *Klebsiella* or *Staphylococcus* is the most common cause of abscess formation. Aspiration abscess is usually associated with alcohol abuse, seizure

disorders, general anesthesia, and swallowing disorders. Immunocompromised individuals also are at greater risk for lung abscesses and may be infected with opportunistic microorganisms, such as fungi and mycobacteria. The clinical manifestations of abscess formation are similar to those of pneumonitis: fever, cough, chills, excessive sputum production, and pleural pain. Abscess communication with a bronchus causes a severe cough, copious amounts of often foul-smelling sputum, and occasionally hemoptysis. **Cavitation** is the process of abscess emptying and cavity formation. Diagnosis is made by radiography.¹²⁸ Treatment includes the administration of appropriate antibiotics and chest physical therapy, including chest percussion and postural drainage. Bronchoscopy may be performed to drain the abscess.¹²⁹

Pulmonary Vascular Disease

Blood flow through the lungs can be disrupted by a number of disorders that result in occlusion of the vessels, an increase in pulmonary vascular resistance, or destruction of the vascular bed. The consequences of altered pulmonary blood flow may be of little functional significance or can result in severe and life-threatening changes in ventilation-perfusion ratios. Major disorders that result from pulmonary vascular diseases include pulmonary embolism, pulmonary hypertension, and cor pulmonale.

Pulmonary Embolism

Pulmonary embolism (PE) is occlusion or partial occlusion of the pulmonary artery or its branches by an embolus. PE most commonly results from embolization of a clot from deep venous thrombosis (DVT) involving the lower leg (see [Chapter 33](#)). Other less common nonthrombotic emboli include tissue fragments, lipids (fats), a foreign body, an air bubble, or amniotic fluid ([Fig. 36.18](#)). Risk factors for PE include conditions and disorders that promote blood clotting as a result of *venous stasis* (immobilization, heart failure), *hypercoagulability* (inherited coagulation disorders, malignancy, hormone replacement,

oral contraceptives, pregnancy), and *endothelial injury* to the cells that line the vessels (trauma, infection, caustic intravenous infusions). Increased risk for thrombosis associated with hemodynamic stasis, hypercoagulability, and endothelial injury is known as *triad of Virchow*¹³⁰ (see [Chapter 33](#)). Genetic risks include factor V Leiden mutation, antithrombin II deficiency, protein S deficiency, activated protein C deficiency, and prothrombin 20210 gene mutations. No matter its source, a blood clot becomes an embolus when all or part of it breaks away from the site of formation and begins to travel in the bloodstream. Thromboembolism is described further in [Chapter 33](#).

FIGURE 36.18 Pulmonary Embolus. The embolus extends into major branches of the pulmonary artery. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.)

◆Pathophysiology.

The effect of the embolus depends on the extent of pulmonary blood flow obstruction, the size of the affected vessels, the nature of the embolus, and the secondary effects. Pulmonary emboli can result in any of the following:

1. Embolus with infarction: an embolus that causes infarction (death) of a portion of lung tissue

2. Embolus without infarction: an embolus that does not cause permanent lung injury (perfusion of the affected lung segment is maintained by the bronchial circulation)
3. Massive occlusion: an embolus that occludes a major portion of the pulmonary circulation (i.e., main pulmonary artery embolus)
4. Multiple pulmonary emboli: multiple emboli that may be chronic or recurrent

As a result of the thrombus lodging in the pulmonary circulation, there is a release both of neurohumoral substances, such as serotonin, histamine, catecholamines, and angiotensin II, and of inflammatory mediators, such as endothelin, leukotrienes, thromboxanes, and toxic oxygen free radicals. This causes widespread vasoconstriction that further impedes blood flow to the lung. Hemodynamically, this results in increased pulmonary artery pressures (pulmonary hypertension) and can lead to right ventricular dilation and increased afterload.¹³¹ Absent blood flow to a lung segment causes a ventilation-perfusion mismatch (increased dead space) and a decrease in surfactant production. The resulting atelectasis of the affected lung segments further contributes to hypoxemia. If the thrombus is large enough, infarction of lung tissue, dysrhythmias, decreased cardiac output, shock, and death are possible. The pathogenesis of pulmonary embolism is summarized in [Fig. 36.19](#).

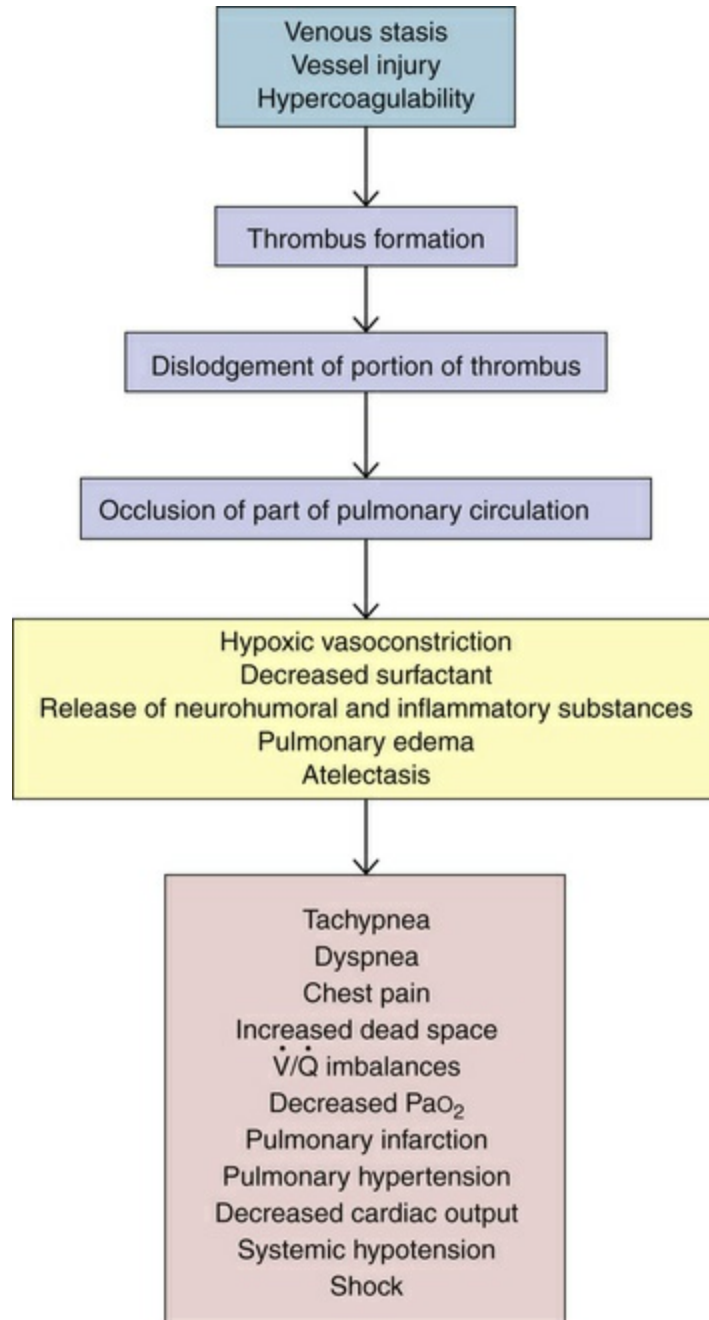

FIGURE 36.19 Pathogenesis of Massive Pulmonary Embolism Caused by a Thrombus (Pulmonary Thromboembolism).

If the embolus does not cause infarction, the clot is dissolved by the fibrinolytic system (see [Chapter 28](#)) and pulmonary function returns to normal. If pulmonary infarction occurs, shrinking and scarring develop in the affected area of the lung.

◆Clinical Manifestations.

In most cases the clinical manifestations of PE are nonspecific; therefore evaluation of risk factors and predisposing factors is an important aspect of diagnosis. Consequently, the recognition of individuals at high risk for PE is crucial to assessing the clinical presentation. In suspected PE, assessment for DVT may indicate the presence of a lower extremity source for the thromboembolism. Calf pain and tenderness and also calf asymmetry (when documented with a tape measure) are some of the most important findings in DVT. Unfortunately, DVT is often asymptomatic and clinical examination has low sensitivity for the presence of a clot, especially in the thigh and pelvis. Therefore the lack of clinical indicators for DVT does not rule out the possibility for PE.

An individual with PE usually presents with the sudden onset of pleuritic chest pain, cough, dyspnea, tachypnea, tachycardia, and unexplained anxiety. Occasionally syncope (fainting) or hemoptysis occurs. With large emboli, a pleural friction rub, pleural effusion, fever, and leukocytosis may be noted. Recurrent pulmonary emboli occur in individuals with a history of previous emboli. Recurrent small emboli may not be detected until progressive incapacitation, precordial pain, anxiety, dyspnea, and right ventricular enlargement are exhibited. Massive occlusion causes severe pulmonary hypertension and shock.

◆Evaluation and Treatment.

The evaluation of individuals suspected of having acute venous thromboembolism is based on the use of Clinical Decision Rules, such as the Well's score, which guide the sequence of diagnostic modalities based on pretest risk assessments.¹³² Routine chest radiographs and pulmonary function tests are not definitive for pulmonary embolism in the first 24 hours. Oximetry and arterial blood gas analyses usually demonstrate hypoxemia. The ECG may show evidence of strain on the right side of the heart. The serum D-dimer level measures products of thrombus degradation (fibrinogen and fibrin) by the fibrinolytic system and, if normal, makes the presence of a PE highly unlikely. When D-dimer is positive, further evaluation may be conducted using

single or multidetector spiral CT arteriography.¹³³ Magnetic resonance arteriography (MRA) is used in some centers. In rare cases, a pulmonary angiogram is necessary to confirm the diagnosis of PE. The measurement of elevated serum troponin I levels has been useful in stratifying the risk and severity of PE because it increases with right ventricular dysfunction and serious adverse events.¹³⁴ Diagnostic algorithms guide diagnosis and treatment.¹³¹

The ideal treatment of PE is prevention through risk factor recognition and elimination of predisposing factors. Venous stasis in hospitalized individuals is minimized by bed exercises, frequent position changes, early ambulation, and pneumatic calf compression. Most at-risk individuals also will receive prophylactic anticoagulation with low-molecular-weight heparin, warfarin, or fondaparinux. Oral anticoagulants that are not dependent on vitamin K levels, such as rivaroxaban, apixaban, and dabigatran, have been approved for the prevention and treatment of PE and DVT and do not require long-term anticoagulation monitoring.^{135,136} Once venous thromboembolism has occurred, rapid assessment of hemodynamic stability and oxygenation is essential. Low-molecular-weight heparin, unfractionated heparin, fondaparinux, or one of the new anticoagulants not dependent on vitamin K levels are indicated for stable individuals.¹³¹ In those with unstable hemodynamics, thrombolytic therapy, either intravenously provided or catheter directed, reduces mortality.¹³² Oxygen and hemodynamic stabilization with fluids may be needed for life-threatening complications. Surgical embolectomy is indicated in massive PE. After stabilization, anticoagulation therapy is continued for several months. In individuals who have contraindications to anticoagulation therapy, the placement of a filter in the inferior vena cava can prevent emboli from reaching the lungs.^{137,138}

Pulmonary Artery Hypertension

Pulmonary artery hypertension (PAH) is defined as a mean pulmonary artery pressure greater than 25 mmHg at rest (normal is 15 to 18 mmHg). [Box 36.4](#) contains the World Health Organization

(WHO) 2014 clinical categories for PAH. Left heart disease is the most common cause of PAH overall, and COPD is the most common lung disease associated with PAH. Idiopathic PAH is rare.

Box 36.4

Clinical Classification of Pulmonary Hypertension*

1. Pulmonary artery hypertension (PAH)
 - 1.1 Idiopathic (IPAH) (rare)
 - 1.2 Heritable
 - 1.2.1 *BMPR2*
 - 1.2.2 *ALK1, endoglin* (with or without hereditary hemorrhagic telangiectasia), *SMAD9, CAV-1, KCNK3*
 - 1.2.3 Unknown
 - 1.3 Drug- and toxin-induced PAH
 - 1.4 Associated with PAH (APAH)
 - 1.4.1 Connective tissue disease

HIV, Human immunodeficiency virus.

*Pulmonary arterial hypertension (PAH) refers to group 1 PAH. Pulmonary hypertension (PH) refers to any of group 2 through group 5 PH, and also is used when referring to all five groups collectively.

Data from Lau EM, Humbert M: *Can J Cardiol* 31(4):367–374, 2015.

◆Pathophysiology.

Idiopathic PAH usually occurs in women between the ages of 20 and 40. It is characterized by endothelial dysfunction with overproduction of vasoconstrictors, such as thromboxane and endothelin-1, and decreased production of vasodilators, such as nitric oxide and prostacyclin-1.¹³⁹ Proinflammatory cytokines, abnormal calcium signaling (vasoconstriction), abnormal potassium channels (vasoconstriction), phosphodiesterases (modulate cellular proliferation), serotonin (vasoconstrictor), and adrenomedullin (vasodilator) also play a role in the pathogenesis of PAH. Release of growth factors causes proliferation of endothelial cells, smooth muscle cells, and fibroblasts, resulting in patchy intimal and medial hypertrophy, intimal fibrosis, abnormal angiogenesis, and in situ thrombosis in the small precapillary pulmonary arteries (resistance vessels). In individuals with *BMPR2* gene mutations (a member of the transforming growth factor-beta family), intracellular signaling abnormalities result in vascular proliferation. These processes result in *vascular remodeling* with luminal narrowing and abnormal vasoconstriction. The combined changes cause resistance to pulmonary artery blood flow, thus increasing the pressure in the pulmonary arteries.¹⁴⁰ As resistance and pressure increase, the workload of the right ventricle increases and subsequent right ventricular hypertrophy, followed by failure, may occur (cor pulmonale). Gas exchange is reduced with restriction in lung volumes. Eventually death results in most individuals with PAH. The pathogenesis of pulmonary artery hypertension and cor pulmonale, resulting from disease of the respiratory system or hypoxia, is shown in [Fig. 36.20](#).

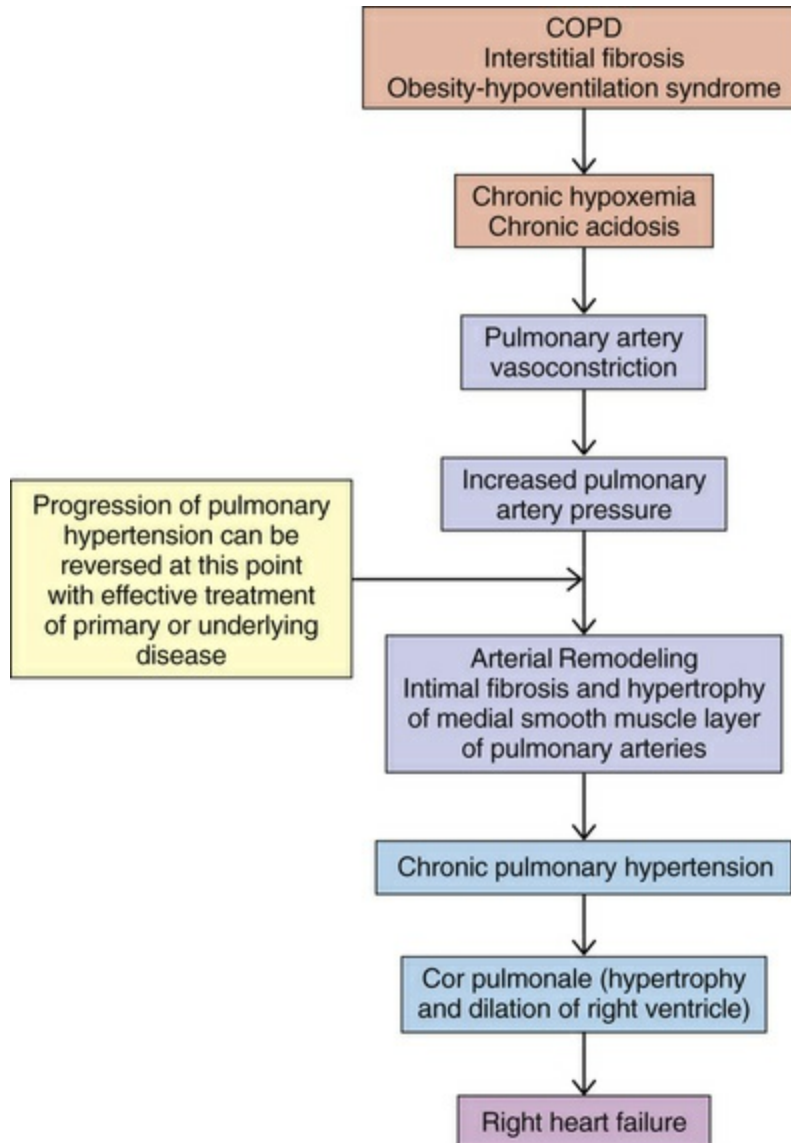

FIGURE 36.20 Pathogenesis of Pulmonary Hypertension and Cor Pulmonale Caused by Disease of the Respiratory System or Hypoxia. *COPD*, Chronic obstructive pulmonary disease.

Pulmonary hypertension associated with hypoxia is a serious complication of many acute and chronic pulmonary disorders, such as COPD and hypoventilation associated with obesity. These conditions are complicated by hypoxic pulmonary vasoconstriction, which further increases pulmonary artery pressures.

◆Clinical Manifestations.

Pulmonary artery hypertension may not be detected until it is quite severe. The symptoms are often masked by underlying pulmonary or

cardiovascular disease. The first indication of pulmonary hypertension is often an abnormality seen on a chest radiograph (enlarged pulmonary arteries and right heart border) or an electrocardiogram that shows right ventricular hypertrophy. Symptoms of fatigue, progressive shortness of breath with exertion, chest discomfort, tachypnea, palpitations, and cough are common. Examination may reveal peripheral edema, jugular venous distention, a right parasternal lift from an enlarged right ventricle, and splitting of the second heart sound with a loud pulmonic valve component as a result of forced closure of the pulmonic valve secondary to elevated pulmonary pressures.¹³⁹

◆Evaluation and Treatment.

Definitive diagnosis and accurate assessment of pulmonary artery pressure can be made only with right-sided heart catheterization. Common diagnostic modalities used to determine the cause include chest x-ray, echocardiography (to estimate right ventricular systolic pressures), and computed tomography. Other diagnostic studies to detect underlying causes of PAH can include arterial blood gas testing, liver function testing, HIV serology, electrocardiography, pulmonary function testing, polysomnography, and ventilation-perfusion scanning. The diagnosis of idiopathic PAH (IPAH) is made when all other causes of pulmonary hypertension have been eliminated. Disease severity is quantified using the New York Heart Association or WHO classification of functional status of patients with pulmonary artery hypertension.¹⁴¹

General therapies for PAH include administration of oxygen, diuretics, and anticoagulants and avoidance of contributing factors such as air travel, decongestant medications, nonsteroidal antiinflammatory medications, pregnancy, and tobacco use. Medications used in the treatment of PAH include prostacyclin analogs (epoprostenol, beraprost, iloprost), endothelin receptor antagonists (bosentan, ambrisentan), phosphodiesterase-5 inhibitors, and calcium channel blockers.^{139,140} Those who fail medical therapy may be candidates for lung transplantation.

The most effective treatment for secondary pulmonary artery hypertension is treatment of the primary disorder. However, once pulmonary hypertension has persisted long enough for hypertrophy of the medial smooth muscle layer to develop (as it does with chronic hypoxemia), it is no longer reversible. Treatment relies on the use of supplemental oxygen to reverse hypoxic vasoconstriction.

Cor Pulmonale

Cor pulmonale is secondary to pulmonary artery hypertension and consists of right ventricular enlargement (hypertrophy, dilation, or both).¹⁴²

◆Pathophysiology.

Cor pulmonale develops as pulmonary artery hypertension creates chronic pressure overload in the right ventricle. Pressure overload increases the work of the right ventricle, causes hypertrophy of the normally thin-walled heart muscle, and compromises right ventricular myocardial perfusion. The increased pressure decreases perfusion of the right coronary arteries, resulting in ischemia, decreased contractility, and right ventricular overload.¹⁴³ Acute hypoxemia, such as might occur with pneumonia, can exaggerate pulmonary hypertension and further stress the ventricle as well. Right ventricular filling pressures are normal until failure occurs. The right ventricle usually fails when pulmonary artery pressure equals systemic blood pressure.

◆Clinical Manifestations.

The clinical manifestations of cor pulmonale may be obscured by primary respiratory disease and appear only during exercise testing. The heart appears normal at rest, but with exercise, cardiac output falls. The electrocardiogram shows right ventricular hypertrophy. Chest pain is common. The pulmonary component of the second heart sound, which represents closure of the pulmonic valve, may be accentuated, and a pulmonic valve murmur also may be present. Tricuspid valve murmur may accompany the development of right

ventricular failure. Increased pressure in the systemic venous circulation causes jugular venous distention, hepatosplenomegaly, and peripheral edema.

◆Evaluation and Treatment.

Diagnosis is made on the basis of physical examination, radiographic imaging, and electrocardiogram or echocardiogram, or both. The goal of treatment for cor pulmonale is to decrease the workload of the right ventricle by lowering pulmonary artery pressure. Treatment is the same as that for pulmonary artery hypertension, and its success depends on reversal of the underlying lung disease.

Malignancies of the Respiratory Tract

Laryngeal Cancer

Laryngeal cancer represents less than 1% of all cancers in the United States. There were an estimated 13,360 new cases and 3660 deaths in 2017.¹⁴⁴ The highest incidence is in men between 50 and 75 years of age. The primary risk factor for laryngeal cancer is tobacco smoking; risk is further heightened with the combination of smoking and alcohol consumption. The human papillomavirus (HPV types 6 and 11) also has been linked to both benign and malignant disease of the larynx.¹⁴⁵

◆Pathophysiology.

Carcinoma of the true vocal cords (glottis) is more common than that of the supraglottic structures (epiglottis, aryepiglottic folds, arytenoids, and false cords). Tumors of the subglottic area are rare. Squamous cell carcinoma is the most common cell type, although small cell carcinomas also occur (Fig. 36.21). Laryngeal dysplasia has a high risk of progressing to malignancy. Metastasis develops by spreading to the draining lymph nodes, and distant metastasis, usually to the lung, is rare.

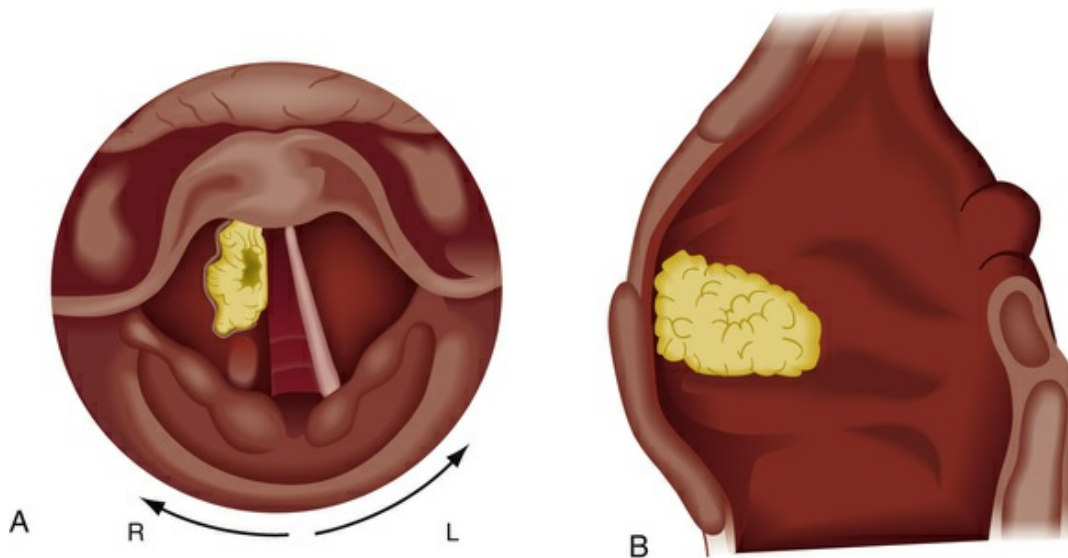

FIGURE 36.21 Laryngeal Cancer. A, Mirror view of carcinoma of right false cord partially hiding true cord. B, Lateral view. (From del Regato JA, Spjut HJ, Cox JD: *Ackerman and del Regato's cancer*, ed 2, St Louis, 1985, Mosby.)

◆Clinical Manifestations.

The presenting symptoms of laryngeal cancer include hoarseness, dyspnea, and cough. Progressive hoarseness is the most significant symptom and can result in voice loss. Dyspnea is rare in the case of supraglottic tumors, but can be severe in subglottic tumors. Cough occurs less commonly and may follow swallowing. Laryngeal pain or a sore throat is likely to be present with supraglottic lesions.

◆Evaluation and Treatment.

Evaluation of the larynx includes external inspection and palpation of the larynx and the lymph nodes in the neck. Indirect laryngoscopy provides a stereoscopic view of the structure and movement of the larynx. A biopsy also can be obtained during this procedure. Direct laryngoscopy provides specific visualization of the tumor. Imaging procedures facilitate the identification of tumor boundaries and the degree of extension to surrounding tissue.

Combined chemotherapy and radiation therapy can result in cure in early-stage disease. Partial laryngectomies followed by combined chemotherapy and radiation therapy can result in local tumor control.

For metastatic disease, combined chemotherapy and radiation therapy before surgery can reduce disease burden. Total laryngectomy is required when lesions are extensive and involve the cartilage. Swallowing and speech therapy after treatment can significantly improve recovery. Voice restoration after total laryngectomy includes instruction in esophageal speech, use of an electrolarynx, and tracheoesophageal puncture with voice prosthesis placement (the gold standard).¹⁴⁶ An artificial larynx is in development.¹⁴⁷

Lung Cancer

Lung cancers (bronchogenic carcinomas) are tumors that arise from the epithelium of the respiratory tract. Other pulmonary tumors, including sarcomas, lymphomas, blastomas, and mesotheliomas (associated with asbestos exposure), occur less commonly. Lung cancer is the second most common cancer in the United States and the most common cause of cancer deaths. Important trends in lung cancer are summarized in [Box 36.5](#).

Box 36.5

Important Trends for Lung Cancer

Incidence

The incidence of lung cancer has been declining since the mid-1980s in men but only since the mid-2000s in women. There will be an estimated 222,500 new cases in 2017: 116,990 in men and 105,510 in women.

Mortality

Death rates have declined by 38% in men since 1990 and by 12% in women since 2002 because of the drop in smoking prevalence; however, lung cancer remains by far the greatest cancer killer in the United States. There will be an estimated 155,870 deaths in 2017: 84,590 in men and 71,280 in women.

Risk Factors

Cigarette smoking is the number one risk factor and accounts for 80% of lung cancer deaths in the United States. Environmental smoke exposure (exposure to someone else's cigarette smoke) increases the risk of lung cancer. Occupational risk factors include exposure to asbestos dust, arsenic, chromium, nickel, ionizing radiation, chloromethyl methyl ether, coal products, mustard gas, and vinyl chloride. Genetic susceptibility plays a role in the development of lung cancer.

Warning Signs

Warning signs include a persistent cough, sputum streaked with blood, chest pain, recurring attacks of pneumonia or bronchitis, weight loss, and hard nodes in the neck or axilla.

Early Detection and Prevention

Lung cancer is very difficult to detect early. Periodic chest x-ray films and sputum cytologic analysis are often used to screen for lung cancer; however, low-dose spiral computed tomography has been shown to reduce lung cancer mortality by 20% compared to standard chest x-ray in at-risk adults.

Treatment

Surgical resection of the entire tumor is the only treatment that results in cure; however, the disease is often too advanced by the time of diagnosis for surgery to be indicated. Radiation therapy and chemotherapy can be used as adjunctive or palliative treatment modalities. New treatments include gene therapy and immunotherapy.

Survival

Although the stage of cancer progression at the time of diagnosis greatly affects prognosis, the typical 1- and 5-year survival rates are 44% and 17%, respectively. The 5-year survival rate for small cell

lung cancer is only 7%.

Data from American Cancer Society: *Cancer facts and figures 2017*. Available at: <https://www.cancer.org/research/cancer-facts-statistics/all-cancer-facts-figures/cancer-facts-figures-2017.html>.

The most common cause of lung cancer is tobacco smoking, and approximately 10% to 15% of active smokers will develop lung cancer. Smokers with obstructive lung disease (low FEV₁ measurements) are at even greater risk. About 10% to 25% of lung cancers occur in persons who have never smoked, and it is estimated that 20% of lung cancer cases among never-smokers could be attributed to exposure to environmental tobacco smoke.¹⁴⁸ Environmental or occupational risk factors associated with lung cancer include exposure to benzopyrene, radon gas, metals (chromium, cadmium, arsenic), asbestos fibers, diesel exhaust, nitrogen and mustard gases, nickel, silica, vinyl chloride, and chloromethyl methyl ether. Genetic risks include polymorphisms of the genes responsible for growth factor receptors, angiogenesis, apoptosis, DNA repair, and detoxification of inhaled smoke.¹⁴⁹ Theories of carcinogenesis are discussed in [Chapter 12](#). Currently there are no specific tools for predicting risk for or rate of progression of lung cancer.

Types of Lung Cancer.

Primary lung cancers arise from cells that line the bronchi and are therefore called *bronchogenic carcinomas*. The development of lung cancer involves a multistep process of genetic, epigenetic, and environmental interactions resulting in the dysregulation of oncogenes and tumor-suppressor genes with activation of cancer-related signaling pathways. Although there are many types of lung cancer, they are divided into two major categories based on cell histology: nonsmall cell lung carcinoma (NSCLC, about 85% of all lung cancers) and neuroendocrine tumors. NSCLC can be subdivided into three common types of lung cancer: squamous cell carcinoma, adenocarcinoma, and large cell undifferentiated carcinoma, and they

each have cellular subtypes. Neuroendocrine tumors of the lung arise from the bronchial mucosa and include small cell carcinoma, large cell neuroendocrine carcinoma, typical carcinoid, and atypical carcinoid tumors. Small cell carcinoma is the most common of these neuroendocrine tumors, accounting for about 10% to 15% of all lung cancers. Characteristics of these tumors are illustrated in [Fig. 36.22](#) and described in [Table 36.4](#). Many cancers that arise in other organs of the body metastasize to the lungs; however, these are not considered lung cancers and are categorized by their primary site of origin.

FIGURE 36.22 Lung Cancer. A, Squamous (epidermoid) cell carcinoma. B, Squamous cell carcinoma. This hilar tumor originates from the main bronchus. C, Adenocarcinoma. D, Peripheral adenocarcinoma. The tumor shows prominent black pigmentation, suggestive of having evolved in an anthracotic scar. E, Small cell (oat cell) carcinoma. F, Large cell carcinoma. (A, C, E, F, from Des Jardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease*, ed 3, St Louis, 1995, Mosby. B and D from Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

TABLE 36.4**CHARACTERISTICS OF LUNG CANCERS**

TUMOR TYPE	GROWTH RATE	METASTASIS	MEANS OF DIAGNOSIS	CLINICAL MANIFESTATIONS AND TREATMENT
Non-Small Cell Carcinoma				
Squamous cell carcinoma	Slow	Late; mostly to hilar lymph nodes	Biopsy, sputum analysis, bronchoscopy, electron microscopy, immunohistochemistry	Cough, hemoptysis, sputum production, airway obstruction, hypercalcemia; treated surgically, chemotherapy and radiation as adjunctive therapy
Adenocarcinoma	Moderate	Early; to lymph nodes, pleurae, bone, adrenal glands, and brain	Radiography, fiberoptic bronchoscopy, electron microscopy	Pleural effusion; treated surgically, chemotherapy as adjunctive therapy
Large cell carcinoma	Rapid	Early and widespread	Sputum analysis, bronchoscopy, electron microscopy (by exclusion of other cell types)	Chest wall pain, pleural effusion, cough, sputum production, hemoptysis, airway obstruction resulting in pneumonia; treated surgically
Neuroendocrine Tumors of the Lung				
Small cell carcinoma	Very rapid	Very early; to mediastinum, lymph nodes, brain, and bone marrow	Radiography, sputum analysis, bronchoscopy, electron microscopy, immunohistochemistry	Cough, chest pain, dyspnea, hemoptysis, localized wheezing, airway obstruction, signs and symptoms of excessive hormone secretion; treated by chemotherapy and ionizing radiation to thorax and central nervous system
Other Pulmonary Tumors				
Malignant pleural	Rapid	Early; to lymph nodes, lungs,	Radiography, thoracentesis	Chest pain, chronic cough, signs of

mesothelioma (MPM)		heart, and bone		pleural effusion
--------------------	--	-----------------	--	------------------

Nonsmall Cell Lung Cancer (NSCLC).

Squamous cell carcinoma (SCC) accounts for about 30% of bronchogenic carcinomas and is associated with smoking and COPD. These tumors are typically located centrally near the hila and project into bronchi (Figs. 36.22, A and B). Because of this central location, nonproductive cough or hemoptysis is common. Pneumonia and atelectasis are often associated with squamous cell carcinoma. Chest pain is a late symptom associated with large tumors. These tumors are often fairly well localized and tend not to metastasize until late in the course of the disease.

Adenocarcinoma (tumor arising from glands) of the lung constitutes about 35% to 40% of all bronchogenic carcinomas (Figs. 36.22, C and D). Adenocarcinoma occurs more frequently in women, in nonsmokers, and in Asians. Environmental tobacco smoke, occupational carcinogens, viruses, hormones, and positive family history are associated with this tumor type.¹⁵⁰ *Epidermal growth factor receptor (EGFR)* mutations and *anaplastic lymphoma kinase (ALK)* gene rearrangements, as well as other tyrosine kinase inhibitors, are common in this type of lung cancer and are targets for therapy.¹⁵¹ These tumors, which are usually smaller than 4 cm, more commonly arise in the peripheral regions of the pulmonary parenchyma. Pulmonary adenocarcinoma develops in a stepwise fashion through atypical adenomatous hyperplasia, adenocarcinoma in situ, and minimally invasive adenocarcinoma to invasive carcinoma. These tumors may be asymptomatic and discovered by routine chest x-ray in the early stages, or the individual may seek treatment for pleuritic chest pain and shortness of breath from pleural involvement by the tumor.

Included in the category of adenocarcinoma is bronchoalveolar cell carcinoma. These tumors arise from the terminal bronchioles and alveoli and are now being referred to as *adenocarcinoma in situ* or *minimally invasive adenocarcinoma*. They are slow-growing tumors with

an unpredictable pattern of metastasis through the pulmonary arterial system and mediastinal lymph nodes.

Diagnosis of NSCLC requires cytologic analysis from biopsy, and treatment is based on histologic and molecular markers (e.g., EGFR tyrosine kinase inhibitors for adenocarcinoma) for a targeted approach to therapy. Surgical resection is possible in a high proportion of adenocarcinoma cases, but because metastasis occurs early (70% of lung cancers present in advanced stages), the 5-year survival rate remains less than 20%.¹⁴⁴ Clinical trials are in progress to develop immunotherapies/vaccines for NSCLC.¹⁵²

Large cell carcinomas (undifferentiated) constitute about 10% to 15% of bronchogenic carcinomas (Fig. 36.22, *F*). These transformed epithelial cells have lost all evidence of differentiation. Recent studies have confirmed that these tumors arise from squamous, glandular, or neuroendocrine precursor cells, and molecular analyses have made it possible to target some of these aggressive cancers for immunologic therapy.¹⁵³ These tumors commonly arise centrally and can grow to distort the trachea and cause widening of the carina.

Once metastasis has occurred, surgical therapy is limited to palliative procedures (comfort measures) designed to relieve obstructive pneumonitis or prevent recurrence of pleural effusion. Neither radiation therapy nor chemotherapy has been successful in increasing survival.

Neuroendocrine Lung Tumors.

Small cell lung carcinomas (SCLCs) are the most common type of neuroendocrine lung tumors and constitute about 15% of lung cancers but cause 25% of lung cancer deaths. Most tumors arise from the central part of the lung (see Fig. 36.22, *E*). Cell sizes range from 6 to 8 μm . This cell type has the strongest correlation with tobacco smoking. Because these tumors show a rapid rate of growth and tend to metastasize early and widely, this type of carcinoma has the worst prognosis of all lung cancers. Survival time for untreated small cell carcinoma is about 8% at 5 years.

Small cell carcinoma arises from neuroendocrine cells that contain

neurosecretory granules and exist throughout the tracheobronchial tree. Thus small cell carcinoma is often associated with tumor-derived hormone production. Hormone production is important to the clinician because resultant signs and symptoms called *paraneoplastic syndromes* (see [Table 12.4](#)) may be the first manifestations of the underlying cancer. Examples include hyponatremia (antidiuretic hormone), Cushing syndrome (adrenocorticotrophic hormone), hypocalcemia (calcitonin), gynecomastia (gonadotropins), carcinoid syndrome (serotonin), and Lambert-Eaton myasthenic syndrome.¹⁵⁴

Bronchial carcinoid tumors are rare, represent about 1% of all lung tumors, are not related to smoking, are slow growing, and have a low potential to metastasize. Carcinoid tumors can occur from childhood through older age. They arise more commonly in the main or segmental bronchi, are easily visualized bronchoscopically, and are found on routine chest radiographs. The tumor cells have dense granules containing neuroendocrine-like hormones, but they rarely produce endocrine symptoms. Fifty percent of individuals with bronchial carcinoid tumors are asymptomatic. Local surgical resection is curative if metastasis has not occurred; this can often be done by bronchoscopic resection. Histologic features determine typical and atypical characteristics and guide further treatment.¹⁵⁵

Other Lung Cancers.

Adenocystic tumors (cylindromas) and **mucoepidermoid carcinomas** are rare bronchial gland tumors. They arise predominantly in the trachea or large airways and cause obstruction. They can be malignant and metastasize early, although distal pulmonary metastases are usually slow growing. Thus it is not unusual for an individual to survive 10 to 15 years after diagnosis.

Mesotheliomas are rare tumors associated with asbestos exposure (80%) up to 40 years prior to diagnosis. Most tumors are aggressive malignant tumors arising from mesothelial cells that line the pleural cavities. A long latent interval between exposure to asbestos and the appearance of mesothelioma usually occurs, and the onset of symptoms may take 20 to 40 years. Clinical manifestations include

dyspnea and chest pain that result from tumor-derived pleural fluid and invasion of the chest wall. Early detection is difficult because radiologic studies do not reveal the tumor at an early stage. Diagnosis is made by chest x-ray, CT scan, and thoracentesis with cytologic examination of the pleural fluid. Thoracoscopy also may be used for biopsy. Osteopontin and mesothelin are being explored as potential tumor markers for early diagnosis. Current management of malignant mesothelioma includes a combination of pleuropneumectomy, chemotherapy, radiation, and hyperthermia. Molecular targeted approaches include vascular endothelial growth factor inhibition, monoclonal antibody immunotherapy, vaccination, and oncoviruses. Aspirin inhibition of asbestos-induced inflammation may decrease or delay mesothelioma onset or growth, or both.¹⁵⁶

◆Pathogenesis.

Environmental carcinogens found in tobacco smoke and asbestos are associated with malignant transformations. Tobacco smoke contains as many as 30 lung carcinogens and is responsible for the vast majority of lung cancers. These carcinogens, along with inherited genetic predisposition to cancers and epigenetic mechanisms, result in tumor formation and the development of a microenvironment that promotes tumor progression.^{157,158} Once lung cancer is initiated by these carcinogen-induced mutations, further tumor development is promoted by growth factors that alter cell growth and differentiation, and by cells and products of inflammation that promote immune suppression, neoangiogenesis and lymphangiogenesis, remodeling of extracellular matrix, invasion, and metastasis.¹⁵⁹ The bronchial mucosa suffers multiple carcinogenic “hits” because of repetitive exposure to tobacco smoke, and eventually epithelial cell changes begin to be visible on biopsy. These changes progress from metaplasia to carcinoma in situ to finally invasive carcinoma. Tumor progression includes invasion of surrounding tissues and, finally, metastasis to distant sites, including the brain, bone marrow, and liver.

◆Clinical Manifestations.

[Table 36.4](#) summarizes the characteristic clinical manifestations according to tumor type. Symptoms are often nonspecific and are likely to be attributed by the individual to the effects of smoking. By the time manifestations are severe enough to motivate the individual to seek medical advice, the disease is usually advanced with signs and symptoms of metastatic disease (e.g., bone pain or alteration in liver function) or paraneoplastic syndromes (see [Chapter 12](#)).

◆Evaluation and Treatment.

Diagnosing and treating lung cancer early in its development are crucial for long-term survival. Screening with a low-dose spiral CT scan promotes early detection and decreases the risk of dying from lung cancer by 20% in persons who are heavy smokers.¹⁶⁰ Diagnostic tests for the evaluation of lung cancer include sputum cytologic studies, chest imaging, virtual bronchoscopy, radial probe endobronchial ultrasound, electromagnetic navigational bronchoscopy, and biopsy. Biopsy determines the cell type. The evaluation of lymph nodes and other organ systems is used to determine the stage of the cancer. The histologic cell type, the genotype, and the stage of the disease are major factors that influence choice of therapy. The currently accepted system for the staging of NSCLC uses the **TNM classification system** in which *T* denotes the extent of the primary tumor, *N* indicates nodal involvement, and *M* describes the extent of metastasis (illustrated in [Fig. 36.23](#)). Staging for small cell carcinoma is divided into only two categories: limited disease (TNM stages I to III: 20% to 30%) and extensive disease (TNM stage IV: 70% to 80%).

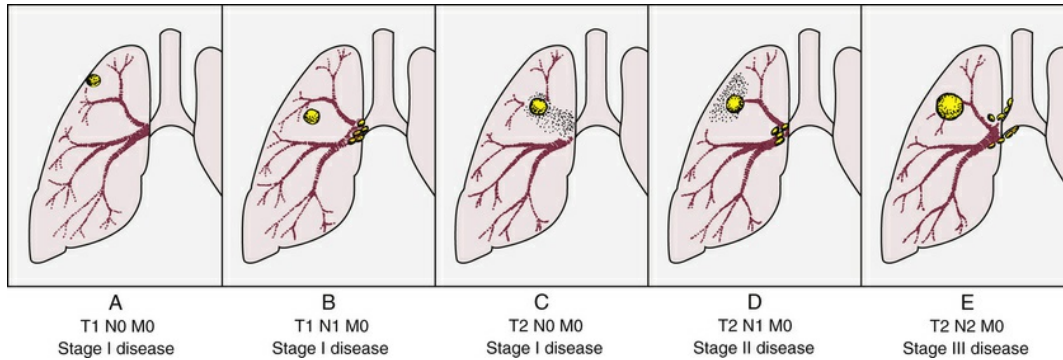

FIGURE 36.23 Staging of Lung Cancer by the TNM Classification System.

A, B, Stage I disease includes tumors classified as T1, with or without metastasis to the lymph nodes in the ipsilateral hilar region. C, Also included in stage I are tumors classified as T2 but having no nodal or distant metastases. D, Stage II disease includes those tumors classified as T2, with metastasis only to the ipsilateral hilar lymph nodes. E, Stage III includes all tumors more extensive than T2 or any tumor with metastasis to the lymph nodes in the mediastinum or adjacent organs. Stage IV (not shown) involves spread to other organs.

For all types of early stage lung carcinoma, the preferred treatment is surgical resection. Once metastasis has taken place, total surgical resection is more difficult and survival rates dramatically decrease. NSCLC is less responsive to chemotherapy than is small cell carcinoma, but chemotherapy (e.g., platinum) and radiation are commonly used as adjuvant or palliative care. Targeted approaches based on histology and molecular markers guide the management of advanced stage NSCLC, and methodologies are being developed for all stages of the disease.¹⁶¹ Small cell carcinoma is poorly differentiated and usually widely metastasized by the time of diagnosis. Palliative chemotherapy and radiation can initially improve survival, but mortality is high at 5 years primarily because of extreme genomic instability. Dose-intensified radiation radiofrequency ablation, microwave ablation, cryotherapy, and brachytherapy may be available as primary or palliative treatment for those for whom surgical removal is not an option. Antiangiogenic therapy, growth factor inhibitors, proapoptotic agents, epigenetic modulators, cancer stem cell targets, gene therapy, and immunotherapy continue to be evaluated for targeted treatment.¹⁶² Prevention of lung cancer relies primarily on reduction of exposure to carcinogens. For most individuals this means smoking cessation.

Summary Review

Clinical Manifestations of Pulmonary Alterations

1. Dyspnea is a feeling of breathlessness and increased respiratory effort; it is associated with respiratory and cardiac diseases and causes distress. Orthopnea is dyspnea when a person is in the recumbent position and is associated with heart failure. Paroxysmal nocturnal dyspnea occurs at night and requires the person to sit or stand for relief.
2. Coughing is a protective reflex that expels secretions and irritants from the lower airways; the cough reflex is mediated by the vagus nerve.
3. Abnormal sputum is a change in the amount, consistency, color, and odor of sputum.
4. Hemoptysis is expectoration of bloody mucus that can be caused by bronchitis, TB, abscess, neoplasms, and other conditions that cause hemorrhage from damaged vessels.
5. Abnormal breathing patterns are adjustments made by the body to minimize the work of respiratory muscles. They include Kussmaul, obstructed, restricted, gasping, and/or Cheyne-Stokes respirations, and sighing.
6. Hypoventilation is decreased alveolar ventilation caused by airway obstruction, chest wall restriction, or altered neurologic control of breathing. Hypoventilation causes increased PaCO₂.
7. Hyperventilation is increased alveolar ventilation produced by anxiety, head injury, or severe hypoxemia. Hyperventilation causes decreased PaCO₂.
8. Cyanosis is a bluish discoloration of the skin caused by desaturation of hemoglobin, polycythemia, or peripheral vasoconstriction.
9. Clubbing of the fingertips is associated with diseases that disrupt the normal pulmonary circulation and cause chronic hypoxemia.

10. Chest pain can result from inflamed pleurae, the trachea, bronchi, or respiratory muscles.
11. Hypercapnia is increased PaCO₂ caused by a decrease in minute volume (respiratory rate × tidal volume).
12. Hypoxemia is a reduced PaO₂ caused by (a) decreased oxygen content of inspired gas, (b) hypoventilation, (c) diffusion abnormality, (d) ventilation-perfusion mismatch, or (e) shunting.
13. Acute respiratory failure is caused by inadequate gas exchange or ventilation (PaO₂ ≤50 mmHg or PaCO₂ ≥50 mmHg and pH ≥7.25).

Disorders of the Chest Wall and Pleura

1. If the chest wall is deformed, traumatized, immobilized, or made heavy by fat, the work of breathing is increased and ventilation is compromised by a decrease in tidal volume from compression of the lungs or impaired chest wall muscle function.
2. Flail chest results from rib or sternal fractures that disrupt the mechanics of breathing.
3. Pneumothorax is the accumulation of air in the pleural space. It can be caused by spontaneous rupture of weakened areas of the pleura or can be secondary to pleural damage caused by disease, trauma, or mechanical ventilation.
4. Tension pneumothorax is a life-threatening condition caused by trapping of air in the pleural space.
5. Pleural effusion is the accumulation of fluid in the pleural space, usually resulting from disorders that promote transudation or exudation from capillaries underlying the pleura but occasionally resulting from blockage or injury that causes lymphatic vessels to drain into the pleural space.
6. Empyema is the presence of pus in the pleural space (infected pleural effusion). The source of the pus is usually lymphatic drainage from sites of bacterial pneumonia.

Pulmonary Disorders

1. Aspiration is passage of fluid and solid particles into the lung, usually from impaired swallowing and coughing. It frequently results in pneumonitis and pulmonary infection.
2. Atelectasis is the collapse of alveoli resulting from compression of the lung tissue, absorption of gas from obstructed alveoli, or impairment of surfactant.
3. Bronchiectasis is abnormal dilation of the bronchi usually secondary to another pulmonary disorder, usually infection or chronic inflammation.
4. Bronchiolitis is the inflammatory obstruction of small airways. It is most common in children.
5. Bronchiolitis obliterans organizing pneumonia is a complication of bronchiolitis obliterans in which the alveoli and bronchioles become filled with plugs of connective tissue.
6. Bronchiolitis obliterans syndrome is an inflammatory, fibrotic process that occurs as a complication of lung transplantation.
7. Pulmonary fibrosis is an excessive amount of connective tissue in the lung. It diminishes lung compliance and may be idiopathic or caused by disease; it results in decreased oxygen diffusion and hypoxemia.
8. Inhalation of noxious gases or prolonged exposure to high concentrations of oxygen can damage the bronchial mucosa or alveolocapillary membrane and cause inflammation or acute respiratory failure.
9. Pneumoconiosis is caused by inhalation of dust particles in the workplace, including coal dust (anthracosis), silica (silicosis), or asbestos. It causes chronic inflammation, pulmonary fibrosis, and susceptibility to lower airway infection and tumor formation.
10. Hypersensitivity pneumonitis (extrinsic allergic alveolitis) is an allergic or hypersensitivity reaction to many allergens.
11. Pulmonary edema is the presence of excess water in the lung caused by disturbances of capillary hydrostatic pressure,

capillary oncotic pressure, or capillary permeability. A common cause is left-sided heart failure, which increases the hydrostatic pressure in the pulmonary circulation.

12. ALI/ARDS results from an acute, diffuse inflammatory injury to the alveolocapillary membrane and decreased surfactant production, which increases membrane permeability and causes pulmonary edema and atelectasis.
13. Obstructive pulmonary disease is characterized by airway obstruction that causes difficult expiration. Obstructive disease can be acute or chronic and includes asthma, chronic bronchitis, and emphysema.
14. Asthma is a chronic inflammatory disorder of the bronchial mucosa that causes bronchial hyperresponsiveness, mucosal edema, airway constriction, and variable obstruction to airflow that is reversible. Obstruction is caused by episodic airway epithelial exposure to antigen with attacks of bronchospasm, bronchial inflammation, mucosal edema, and increased production of mucus.
15. COPD is the coexistence of two primary phenotypes, chronic bronchitis and emphysema, which frequently overlap each other.
16. The asthma-COPD overlap syndrome is a phenotype of chronic respiratory disease where there is an overlap of the clinical symptoms of asthma and COPD.
17. Chronic bronchitis is chronic inflammation of the bronchi that causes airway obstruction resulting from bronchial smooth muscle hypertrophy, increases in the size and number of epithelial mucous glands and goblet cells, and increased production of thick, tenacious mucus.
18. Emphysema results from destruction of elastin in the alveolar septa and loss of passive elastic recoil, leading to airway collapse, obstruction to gas flow during expiration, and air trapping.
19. Emphysema in which septal deterioration is caused by α_1 -antitrypsin deficiency or old age tends to be panacinar.

20. Emphysema in which septal deterioration results from smoking tends to be centriacinar.
21. Paraseptal emphysema is associated with large bullae formation.
22. Upper respiratory tract infections are the most common cause of short-term disability in the United States and include rhinitis (the common cold), pharyngitis, and laryngitis.
23. Serious lower respiratory tract infections, which occur most often in older adults and individuals with impaired immunity or underlying disease, include pneumonia and tuberculosis.
24. Acute bronchitis is acute infection or inflammation of the large airways or bronchi; it is usually self-limiting and caused by viruses.
25. Pneumonia is an infection of the lower respiratory tract and can be categorized as community-acquired (CAP), healthcare-associated (HCAP), hospital-acquired (HAP), or ventilator-associated (VAP).
26. Pneumococcal pneumonia is an acute lung infection resulting in an inflammatory response with four phases: (a) consolidation, (b) red hepatization, (c) gray hepatization, and (d) resolution.
27. Viral pneumonia is an acute, self-limiting lung infection usually caused by the influenza virus.
28. TB is a lung infection caused by *M. tuberculosis* (tubercle bacillus) and can also invade other organs. The bacterium is successful as a pathogen because it can survive within macrophages, resist lysosomal killing, multiply within the cell, and transit into a stage of dormancy rendering itself extremely resistant to host defense and drug treatment.
29. Bacilli may remain dormant within the tubercles for life; or if the immune system becomes compromised, they may cause recurrence of active disease.
30. Abscesses are circumscribed areas of destruction of lung parenchyma with suppuration usually resulting from aspiration pneumonia.

31. Acute bronchitis is acute infection or inflammation of the airways or bronchi usually caused by a virus.
32. Pulmonary vascular diseases are caused by embolism or hypertension in the pulmonary circulation.
33. PE is occlusion of a portion of the pulmonary vascular bed by a thrombus (most common), a tissue fragment, or an air bubble. Depending on its size and location, the embolus can cause hypoxic vasoconstriction, pulmonary edema, atelectasis, pulmonary hypertension, shock, and even death.
34. Pulmonary artery hypertension (pulmonary artery pressure) is defined as a mean pulmonary artery pressure greater than 25 mmHg at rest. It is caused by (a) elevated left ventricular pressure, (b) increased blood flow through the pulmonary circulation, (c) obliteration or obstruction of the vascular bed, or (d) active constriction of the vascular bed produced by hypoxemia or acidosis.
35. Cor pulmonale is right ventricular enlargement caused by chronic pulmonary hypertension. Cor pulmonale progresses to right ventricular failure if the pulmonary hypertension is not reversed.
36. Laryngeal cancer occurs primarily in men and represents less than 1% of all cancers. Squamous cell carcinoma of the true vocal cords is most common and manifests with a clinical symptom of progressive hoarseness.
37. Lung cancer, the most frequent cause of cancer death in the United States, is commonly caused by smoking of cigarettes or tobacco.
38. Cancer cell types include non–small cell lung cancer (squamous cell carcinoma, adenocarcinoma, large cell undifferentiated carcinoma) and neuroendocrine tumors (small cell carcinoma and bronchial carcinoid tumors). Other tumors include small cell (oat cell) carcinoma, bronchial adenoma, adenocystic tumors (cylindromas), mucoepidermoid carcinomas (bronchial tumors), and mesothelioma. Each type arises in a characteristic site or type

of tissue, causes distinctive clinical manifestations, and differs in likelihood of metastasis and prognosis.

Key Terms

Abscess, 1189
Absorption atelectasis, 1170
Acute cough, 1164
Acute lung injury (ALI), 1174
Acute respiratory distress syndrome (ARDS), 1174
Adenocarcinoma, 1194
Adenocystic tumor (cylindroma), 1195
Air trapping, 1184
Alveolar dead space, 1167
Asbestos exposure, 1173
Asbestosis, 1173
Aspiration, 1170
Asthma, 1177
Atelectasis, 1170
Bronchial carcinoid tumor, 1195
Bronchiectasis, 1170
Bronchiolitis, 1172
Bronchiolitis obliterans organizing pneumonia (BOOP), 1172
Bronchiolitis obliterans syndrome (BOS), 1172
Cavitation, 1190
Centriacinar (centrilobular) emphysema, 1183
Cheyne-Stokes respiration, 1164
Chronic bronchitis, 1181
Chronic cough, 1164
Chronic obstructive pulmonary disease (COPD), 1181
Clubbing, 1165
Coal worker pneumoconiosis (coal mine lung disease, anthracosis), 1173
Compression atelectasis, 1170

Consolidation, 1189
Cor pulmonale, 1192
Cough, 1164
Cyanosis, 1165
Cylindrical bronchiectasis, 1170
Dyspnea, 1163
Dyspnea on exertion, 1164
Emphysema, 1181
Empyema (infected pleural effusion), 1169
Flail chest, 1167
Hemoptysis, 1164
Hypercapnia, 1165
Hypersensitivity pneumonitis (extrinsic allergic alveolitis), 1173
Hyperventilation, 1165
Hypocapnia, 1165
Hypoventilation, 1164
Hypoxemia, 1166
Hypoxia (ischemia), 1166
Idiopathic pulmonary fibrosis (IPF), 1172
Kussmaul respiration (hyperpnea), 1164
Large cell carcinoma (undifferentiated), 1195
Laryngeal cancer, 1193
Lung cancer, 1194
Mesothelioma, 1195
Mucoepidermoid carcinoma, 1195
Obstructive pulmonary disease, 1176
Orthopnea, 1164
Oxygen toxicity, 1172
Pain, 1165
Panacinar emphysema, 1183
Paraseptal emphysema, 1183
Paroxysmal nocturnal dyspnea (PND), 1164
Pleural effusion, 1169
Pneumoconiosis, 1173
Pneumonia, 1186

Pneumothorax, 1168
Pulmonary artery hypertension (PAH), 1191
Pulmonary edema, 1173
Pulmonary embolism (PE), 1190
Pulmonary fibrosis, 1172
Pulsus paradoxus, 1179
Respiratory (lung) failure, 1167
Saccular bronchiectasis, 1170
Shunting, 1167
Silicosis, 1173
Small cell lung carcinoma (SCLC), 1195
Sputum, 1164
Squamous cell carcinoma (SCC), 1194
Status asthmaticus, 1179
Surfactant impairment, 1170
TNM classification system, 1196
Tuberculosis (TB), 1188
Varicose bronchiectasis, 1170

Acute Lung Injury/Acute Respiratory Distress Syndrome, 1220

Alterations of respiratory function in children are influenced by age, development, gender, race, genes, and environmental conditions. Structural differences in infants and children render them less competent to tolerate conditions that cause increased work of breathing. Newborns, premature newborns in particular, are especially vulnerable to a variety of upper and lower airway infections caused by immaturity of the airways, circulation, chest wall, and the immune system. Access to health care and timeliness of immunizations influence the incidence and severity of pulmonary disorders.

Structure and Function

A number of structural characteristics of the pulmonary system influence the way in which infants and children respond to respiratory disturbances. These include structural characteristics of the upper and lower respiratory tracts, chest wall and lung dynamics, metabolic requirements, immunologic immaturity, and physiologic control of respiration. Alterations in pulmonary blood flow that occur at birth are described in [Chapter 35](#).

Upper Airway

All conducting airways (the portions of airway that do not participate in gas exchange) are present at birth and change only in size throughout childhood. Branching of the bronchial tree is in fact complete by the sixteenth week of fetal life.

Because infants and children naturally have smaller-diameter airways than adults, they suffer more obstruction for a given degree of

mucosal edema or secretion accumulation. The relative sizes of tonsils, adenoids, and the epiglottis likewise are proportionately greater in the young child, and the presence of swelling can impose a significant site of obstruction. Infants up to 2 to 3 months of age are “obligatory nose breathers” and have difficulty inhaling through their mouths. Nasal congestion is therefore a serious threat to a young infant, especially during sleep.

Lower Airways and Lung Parenchyma

During fetal development the lung is transformed from a somewhat dense organ to one that is more delicately structured to facilitate air exchange. Beginning in the second trimester of pregnancy, there is loss of interstitial (mesenchymal) tissue with concomitant expansion of the future air spaces. Capillaries grow into the distal respiratory units that keep subdividing (alveolarization) to maximize the surface area for gas exchange. The number of alveoli continues to increase during the first 5 to 8 years of life, after which the alveoli increase in size and complexity. In addition to the structural development of the lung in utero, there is accompanying functional maturation during which specialized cell types, such as type II cells, manifest. (Fig. 37.1 contains a summary of alveolar development and stages of fetal lung development.)

FIGURE 37.1 Prenatal Development of the Alveolar Unit and Stages of Lung Development. A, Epithelial cells differentiate into type II and type I cells. Mature type II cells are cuboidal, have apical microvilli, and contain lamellar bodies for surfactant storage and secretion. Type I cells are derived from type II cells and consist of flattened epithelium overlying capillaries, thus forming part of the desired thin air-blood barrier. During fetal development the pulmonary capillaries initially are randomly distributed in mesenchyme. They progressively arrange around the epithelial tubes and establish close contacts to the lining epithelium. Overall the volume of mesenchyme decreases and that of the potential air space increases. B, Stages of fetal lung development. (B adapted from Gleason CA, Devaskar S: *Avery's diseases of the newborn*, ed 9, Philadelphia, 2012, Saunders.)

Surfactant is a lipid-protein mixture that is produced by type II alveolar cells and is critical for maintaining alveolar expansion (thus allowing normal gas exchange, see [Chapter 35](#)). Surfactant is

produced by 20 to 24 weeks' gestation and is secreted into the fetal airways by 30 weeks. Surfactant deficiency syndrome is often seen in premature infants and causes respiratory distress syndrome (RDS), previously known as *hyaline membrane disease*. The risk of acquisition of RDS escalates with increasing prematurity of the infant.

Chest Wall Dynamics

Chest wall compliance is high in infants, particularly premature infants. The cartilaginous structures of the thoracic cage are not yet well ossified (ossification continues to occur throughout childhood), and the chest wall is easily collapsible. During inspiration in the young child, air is drawn in by the downward movement of the diaphragm, but the resulting negative pressure causes the “soft” chest wall to be drawn *inward* (Fig. 37.2); this produces so-called *paradoxical breathing*, or *diaphragmatic breathing*. Paradoxical breathing is especially seen during rapid eye movement (REM) sleep of premature infants. With pulmonary compromise the accessory muscles are drawn inward, creating retraction of the intercostal and supraclavicular spaces (Fig. 37.3).

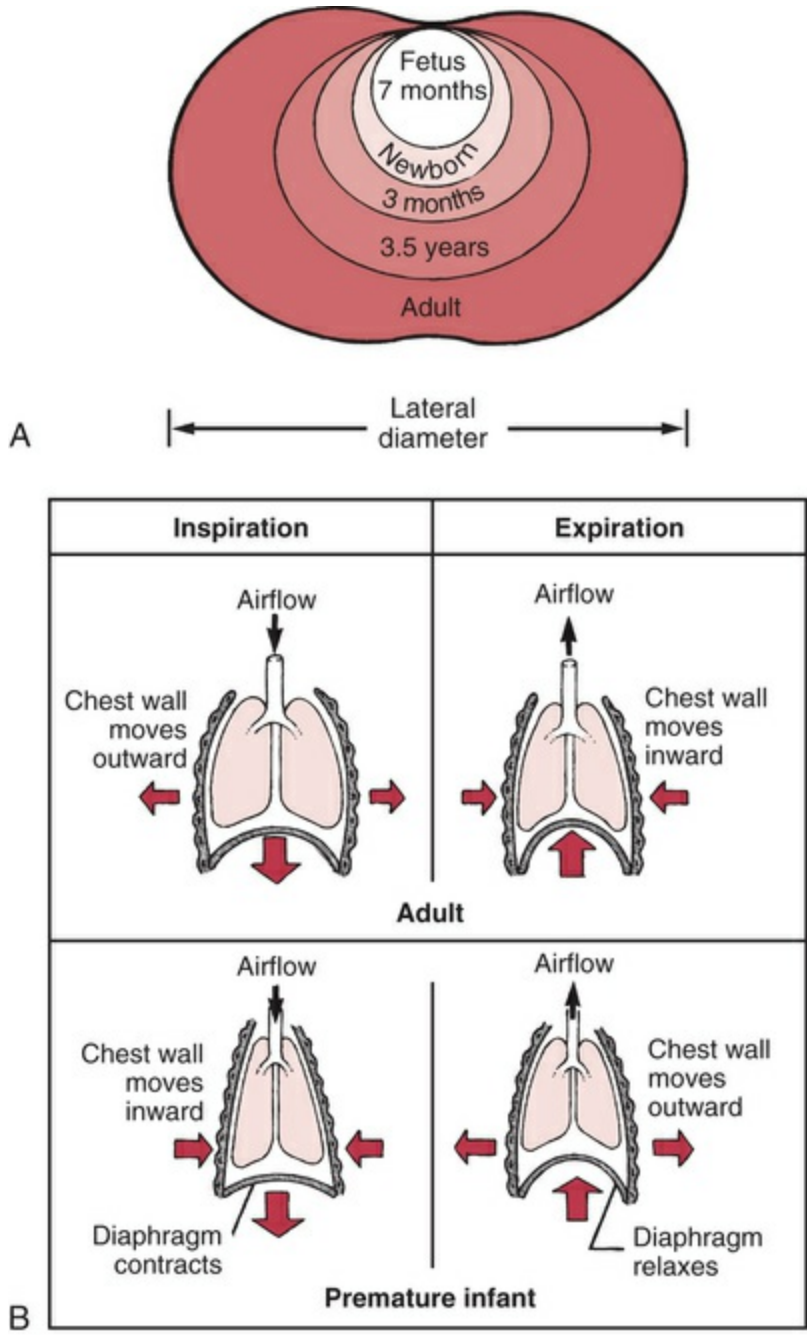

FIGURE 37.2 Developmental Differences in the Chest Wall and Lung Mechanics. A, Changes in chest wall shape with age. B, Differences in lung mechanics caused by differences in chest wall compliance (degree of rigidity) in premature infants and adults. (Arrows indicate direction of airflow, chest wall movement, and diaphragm movement.)

FIGURE 37.3 Areas of Chest Muscle Retraction.

Resting lung volume, or **functional residual capacity (FRC)**, represents the balance point between the natural elastic recoil of the lungs (to collapse) and the elastic recoil of the chest wall (to expand). In the face of an overly compliant chest wall, infants up to about 1 year of age are thought to maintain their FRC and avoid atelectasis by muscular “braking” of their expiration. This may occur either by active glottic narrowing or by increased activity of the inspiratory intercostal muscles.

Metabolic Characteristics

The basal metabolic rate of a child is greater than that of an adult, and thus oxygen consumption (VO_2) is greater per unit of body weight. The VO_2 of the child's normal work of breathing accounts for up to 25% of the total VO_2 . Respiratory distress increases the work of breathing and VO_2 exponentially. Children have less muscle glycogen reserve, which limits the efficiency of accessory muscles, such that fatigue with lactic acidosis can occur quickly. Children also have a high proportion of extracellular fluid and therefore more quickly lose

fluid and become dehydrated from fever, from environmental heat, or in association with tachypnea (which causes evaporation from the respiratory tract).

Immunologic Incompetence

Passive immunity with immunoglobulin G (IgG) is normally conveyed transplacentally from the mother to the fetus beginning at 20 weeks' gestation; thus IgG levels are lower in preterm than term infants. Breast-feeding allows transfer of secretory IgA, IgG, and IgM after birth. Because IgG has a half-life of approximately 21 days, the placentally transferred antibodies are depleted after just a few months. Infants are able to synthesize IgG, IgM, and IgA, and the levels of these immunoglobulins increase slowly with age. Cell-mediated immunity is also not fully developed in the neonate, which creates a situation of enhanced susceptibility to viral and fungal infections.

Physiologic Control of Respiration

Respiratory control in the neonate is immature compared to that in older children and adults, including respiratory responses to hypoxia and hypercapnia and an exaggerated apneic response to laryngeal stimulation. The mechanisms for this are not well understood but may reflect reduced activity of the peripheral chemoreceptors (in the carotid body) and nonadaptive responses or inhibitory influences on the respiratory center (in the brainstem). There is increased risk for apnea and hypoxia.¹ Congenital or acquired lesions of the central nervous system also may cause hypoventilation or apnea. Exposure to maternal smoking both during and after fetal development can have significant deleterious effects on lung development and subsequent susceptibility to pulmonary disorders. Exposure to environmental air pollution after birth also is associated with increased risk for childhood respiratory disease (see [What's New? Environmental Air Pollution and Childhood Respiratory Disease](#)).

What's New?

Environmental Air Pollution and Childhood Respiratory Disease

Environmental exposures, such as tobacco smoke, air pollution (particulate matter, polycyclic aromatic hydrocarbons, and nitrogen dioxide), mold, respiratory viral infections, and medications, may contribute to pediatric pulmonary diseases, including increased asthma incidence and prevalence, risk of bronchitis and wheezing, susceptibility to infection, immune dysfunction, and deficits of lung growth and function. In the United States, 10.7% of pregnant mothers smoked during the last 3 months of pregnancy, which disturbs lung development in utero. Exposure to secondhand (environmental) tobacco smoke affects alveolar maturation during infancy and childhood. “Thirdhand smoke” results from tobacco chemicals that deposit on surfaces in the home. These tobacco products can react with chemicals in the environment, becoming even more toxic, and then can be inhaled or ingested by young children. In addition to smoke exposure, air pollution is increasingly recognized as a major contributor to pediatric pulmonary disease throughout the world. The impact of these exposures is mediated through changes in epigenetic controls on lung tissue genes and on immune cytokine synthesis and function. For example, both tobacco smoke and air pollution have been found to shift immune cytokine profiles toward allergy, increase airway inflammation, and increase expiratory airway obstruction, all of which are key components of asthma pathophysiology. Other epigenetic changes include increased airway fibroblast activation and disruption of normal respiratory center and peripheral chemoreceptor function. Clinicians, public health experts, and policy makers are expanding efforts to reduce prenatal, infant, and childhood exposure to these environmental risks.

Data from Chen Z et al: *J Thorac Dis* 7(1):46–58, 2015; Dick S et al: *BMJ Open* 4(11):e006554, 2014; Gibbs K, Collaco JM, McGrath-Morrow SA: *Chest* 149(2):552–561, 2016; Viera SE: *Int J*

Disorders of the Upper Airways

Pulmonary dysfunction can be categorized into disorders of either the upper airway or the lower airway. Signs of acute respiratory failure are the same regardless of etiology. These include the following:

- Increased respiratory effort with retractions (see [Fig. 37.3](#)) or gasping (apnea in some conditions)
- Cyanosis or pallor
- Agitation
- Decreased level of consciousness
- Cardiovascular signs: tachycardia, mottled color, or bradycardia
- Physiologic compromise reflected by hemoglobin desaturation, hypoxemia, hypercarbia, and acidosis

Upper Airway Obstruction

The crucial issue in the upper airways is patency. The most common causes of *acute-onset* **upper airway obstruction (UAO)** in children are infections, foreign body aspiration, angioedema, obstructive sleep apnea, and trauma. *Chronic UAO* has many etiologies, including congenital malformations affecting the airway, cartilaginous weakness, vocal cord paralysis, and subglottic stenosis. Chronic upper airway symptoms should prompt referral to a pediatric pulmonologist or an otolaryngologist because specialized diagnostic studies may be needed. A summary of causes of pediatric UAO can be found in [Box 37.1](#).

Box 37.1

Causes of Upper Airway Obstruction and Stridor in Children According to Site of Obstruction

Nose and Pharynx

- Choanal atresia
- Lingual thyroid or thyroglossal cyst
- Macroglossia
- Micrognathia
- Hypertrophic tonsils/adenoids
- Retropharyngeal or peritonsillar abscess

Larynx

- Laryngomalacia
- Laryngeal web, cyst, or laryngocele
- Laryngotracheobronchitis (viral croup)
- Acute spasmodic laryngitis (spasmodic croup)
- Epiglottitis
- Vocal cord paralysis
- Laryngotracheal stenosis
- Intubation trauma
- Foreign body
- Cystic hygroma
- Subglottic hemangioma
- Laryngeal papilloma
- Angioneurotic edema
- Laryngospasm (hypocalcemic tetany)
- Psychogenic stridor

Trachea

Tracheal stenosis
Tracheomalacia
Bacterial tracheitis
External compression

Data from Ida JB, Thompson DM: *Otolaryngol Clin North Am* 47(5):795–819, 2014; Mandal A, Kabra SK, Lodha R: *Indian J Pediatr* 82(8):737–744, 2015; Pflieger A, Eber E: *Paediatr Respir Rev* 18:64–72, 2016.

The site and nature of the obstruction are often discernible by assessing the noise or sounds associated with breathing, the quality of the voice or cry, and the presence of feeding difficulties (Fig. 37.4). This assessment often can be made without even touching the child. Likewise, the severity of the problem often can be judged by visual observation of signs, including retractions, nasal flaring, gasping or obstructed breaths, anxiety, restlessness, or need to maintain a specific head or body position. Agitation should be regarded as a likely sign of hypoxemia or obstruction. In acute UAO, increasing the child's anxiety by excessive physical examination can worsen the condition. The child should be kept as calm as possible. The clinician should never attempt a pharyngeal examination if there is any suspicion of epiglottitis or retropharyngeal abscess because this maneuver may precipitate acute obstruction of the airway.

FIGURE 37.4 Listening Can Help Locate the Site of Airway Obstruction. A loud, gasping snore suggests enlarged tonsils or adenoids. Stridor during inspiration suggests the airway is compromised at the level of the supralaryngeal structures (epiglottis and arytenoid cartilages), vocal cords, and glottic region. With forced inspiration, intrathoracic pressure becomes quite negative and is less than atmospheric pressure, promoting collapse at or just above the site of obstruction. Expiratory stridor or central wheeze results from narrowing or collapse of the lower trachea or bronchi. During forced exhalation, rising pleural pressure may exceed intratracheal pressure. Airway noise during both inspiration and expiration often represents a fixed obstruction of the vocal cords or subglottic space. Hoarseness or a weak cry is a byproduct of obstruction at the vocal cords. Hoarseness or a weak cry is a byproduct of obstruction at the vocal cords. If a cough is croupy or low pitched, suspect tracheal pathology. (Redrawn from Eavey RD: *Contemp Pediatr* 3[6]:78, 1986; used with permission; original illustration by Paul Singh-Roy.)

The sounds of the child's breathing can provide key clues (see [Fig. 37.4](#)). A sonorous, snoring noise is typical for nasopharyngeal obstruction, such as adenotonsillar hypertrophy. A common sign of pediatric UAO is **stridor**, a harsh, vibratory sound of variable pitch caused by turbulent flow through the partially obstructed airway.² A diagnostic approach to stridor is outlined in [Fig. 37.5](#). Whether it is present in inspiration, expiration, or both reflects the site of the problem. In general, *inspiratory* stridor is generated with obstruction

of the *extrathoracic* airway (above the thoracic inlet), which includes the supraglottic structures, the larynx, the subglottic space, and the upper trachea. *Expiratory* stridor or a monophonic wheeze may be generated by an obstruction in the *intrathoracic* airway (the middle to lower trachea and central bronchi). Biphasic stridor typically reflects obstruction at the glottis (e.g., vocal cord paralysis) itself or a *fixed* rather than a *dynamic* lesion in the subglottic space (e.g., hemangioma or subglottic stenosis). Biphasic noise may sometimes mean abnormalities of both the extrathoracic and intrathoracic trachea (long-segment stenosis or malacia).

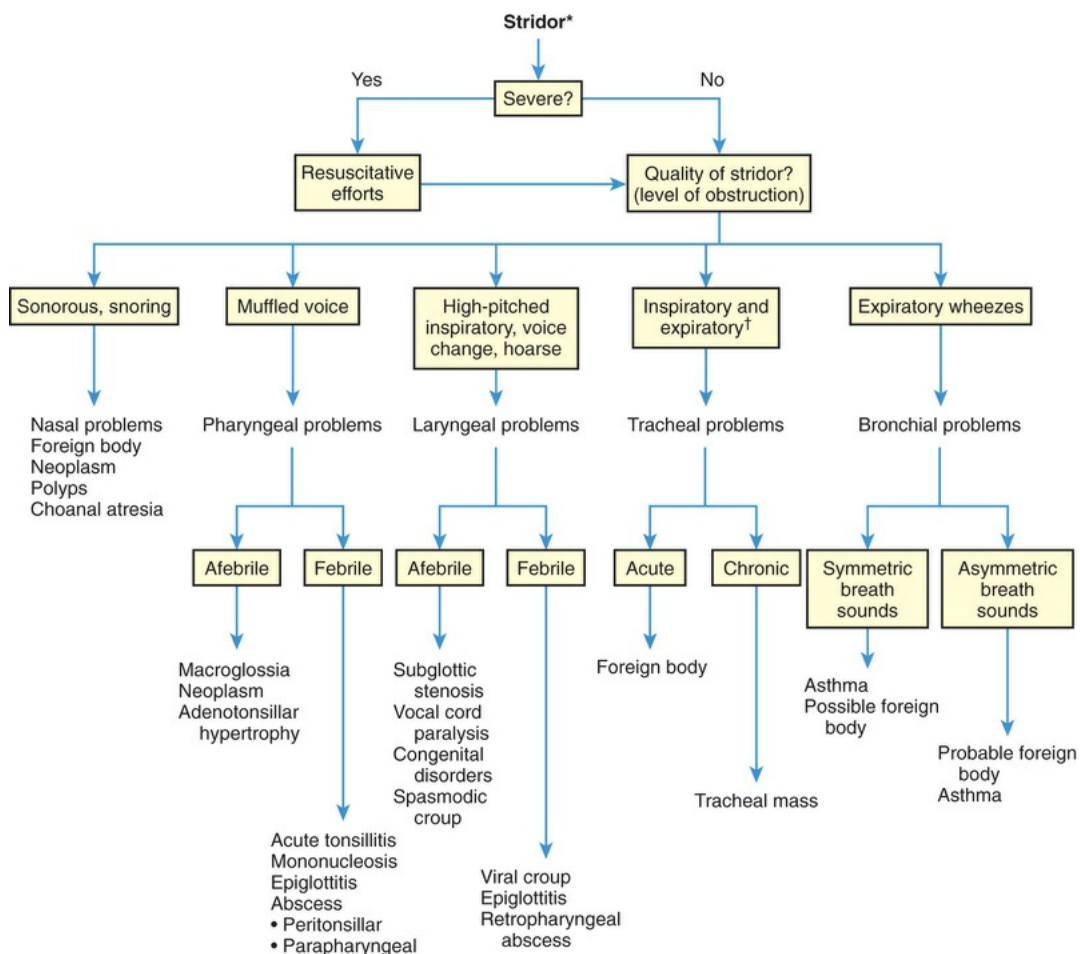

FIGURE 37.5 Diagnostic Approach to Stridor. *The age of the patient must be considered in making a specific diagnosis. †Laryngeal problems are frequently associated with inspiratory and expiratory stridor. (Adapted from Handler SD: Stridor. In Fleisher GR, Ludwig S, editors: *Textbook of pediatric emergency medicine*, Baltimore, 1993, Williams & Wilkins.)

Abnormalities of voice or cry (weak or hoarse) suggest problems at the larynx, such as vocal cord paralysis. Muffling of the voice, especially in an acute condition, suggests supralaryngeal obstruction, such as epiglottitis or retropharyngeal abscess. Pronounced cough may be an irritative symptom, such as that produced by an aspirated foreign body, or may be a sign of tracheal obstruction. The cough associated with croup or a tracheal foreign body is usually harsh and barking.

Airway obstruction occurs sooner in infants than in older children. Obviously, airway luminal size is smaller in accordance with smaller body size, but any decrease in luminal diameter will be much more significant. This is because airway resistance is proportional to the inverse of the *fourth* power of the radius; thus a decrease to half the original diameter increases resistance 16-fold. Furthermore, an infant's cartilaginous structures are more collapsible and thus are prone to creating or contributing to UAO.

Infections

Infections of the upper airway (Table 37.1) are common in children; some have the potential to cause life-threatening emergencies. Recognition and rapid evaluation of these problems are crucial pediatric care skills.

TABLE 37.1

COMPARISON OF UPPER AIRWAY INFECTIONS

CONDITION	AGE	ONSET	ETIOLOGY	PATHOPHYSIOLOGY	SIGNS AND SYMPTOMS
Acute laryngotracheobronchitis (croup)	6 mo–3 yr	Usually gradual	Viral (parainfluenza 1 and 3, influenza A, respiratory syncytial virus)	Inflammation from vocal cords to bronchial lumina	Hoarse cry, stridor
Acute tracheitis	1–12 yr	Abrupt or following	<i>Staphylococcus aureus</i> /methicillin-resistant	Inflammation of upper trachea	High-pitched stridor

		viral illness	resistant <i>S. aureus</i> (MRSA) <i>Haemophilus influenzae</i> type B Group A streptococci		
Epiglottitis	2-6 yr	Abrupt	<i>H. influenzae</i> type B (Hib) Group A streptococci	Inflammation of supraglottic structures	Se
Retropharyngeal abscess	>6 yr	Gradual, 2-5 days; may follow oral trauma	<i>S. aureus</i> /MRSA <i>Streptococcus pyogenes</i> Anaerobes Group A beta-hemolytic streptococci Often polymicrobial	Abscess in posterior pharyngeal wall	Sii
Peritonsillar abscess	>9 yr	May be abrupt	<i>S. pyogenes</i> <i>S. aureus</i> /MRSA	Abscess within or around tonsil	Sii

Croup.

Croup illnesses include viral croup (laryngotracheitis), recurrent croup (spasmodic croup), laryngotracheobronchitis, and laryngotracheobronchopneumonitis. Viral and recurrent croup are the most common. Diphtheria can be considered a croup illness but is now rare because of vaccinations. Croup illnesses are characterized by infection and obstruction of the upper airways.

Recurrent croup (spasmodic croup, also described as atypical croup) is two or more episodes of croup with symptoms similar to croup except it recurs without symptoms of respiratory tract infection. It often resolves as quickly as it develops and usually occurs in older children. The etiology is unknown but in some cases it is associated with an underlying congenital obstruction or airway narrowing (i.e.,

laryngomalacia or tracheomalacia). There also may be other associated illnesses such as gastroesophageal reflux disease or asthma.^{3,4} Acute **laryngotracheitis (croup)** most commonly occurs in children from 6 months to 5 years of age, with peak incidence at about 2 years of age.⁵

◆Pathophysiology.

The pathophysiology of viral croup is caused primarily by subglottic edema from the infection. The mucous membranes of the larynx are tightly adherent to the underlying cartilage, whereas those of the subglottic space are looser and thus allow accumulation of mucosal and submucosal edema (Fig. 37.6). Furthermore, the cricoid cartilage is structurally the narrowest point of the airway, making edema in this area critical. As illustrated in Fig. 37.7, increased resistance to airflow leads to increased work of breathing, which generates more negative intrathoracic pressure, which in turn may exacerbate dynamic collapse of the upper airway.

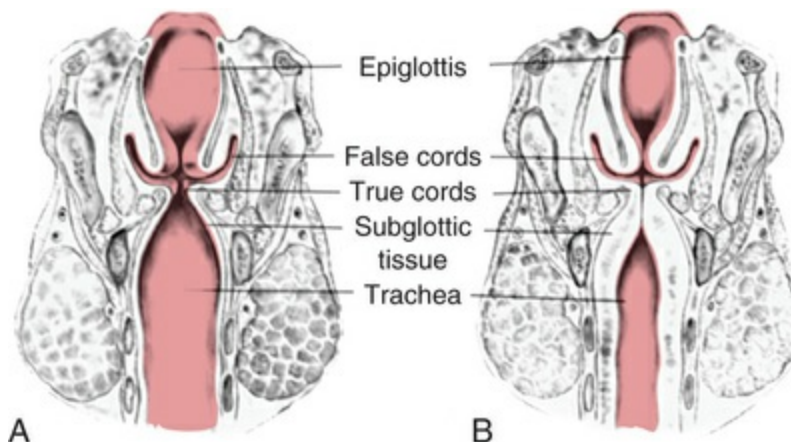

FIGURE 37.6 The Larynx and Subglottic Trachea. A, Normal. B, Narrowing and obstruction from edema caused by croup. (From Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 10, St Louis, 2015, Mosby.)

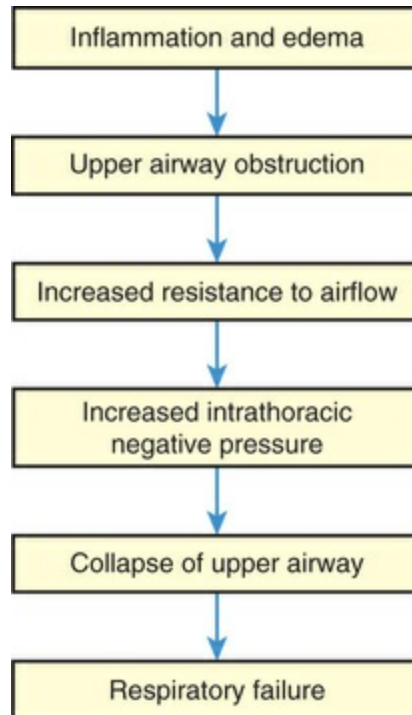

FIGURE 37.7 Upper Airway Obstruction with Croup.

◆Clinical Manifestations.

Typically there is a prodrome of rhinorrhea, sore throat, and low-grade fever for a few days. The child then develops the characteristic harsh (seal-like) barking cough, hoarse voice, and inspiratory stridor. Most cases are mild and resolve spontaneously after several more days. Occasionally, however, UAO becomes severe and requires urgent management.

◆Evaluation and Treatment.

The degree of symptoms determines the level of treatment. Most children have a barking cough and viral symptoms and may need no specific treatment. However, the presence of stridor (especially at rest), retractions, or agitation suggests a sicker child. The tool most often used for estimating croup severity is the Westley croup score, which provides a cumulative score for the degree of stridor, retractions, air entry, cyanosis, dyspnea, and level of consciousness in the child.⁶

The degree of seriousness of croup also is classified as mild,

moderate, and severe. Most children with croup require no treatment. Inhalation of humidified air does not improve symptoms in mild to moderate croup. Glucocorticoids, either injected or oral (dexamethasone) or nebulized (budesonide), have been shown to improve symptoms within 6 hours. The use of nebulized racemic epinephrine improves outcomes with moderate to severe croup.^{5,7} Epinephrine stimulates α - and β -adrenergic receptors and is thought to decrease airway secretions and mucosal edema. It is a temporizing measure until concomitantly given corticosteroids begin to take effect. Thus children who are given nebulized epinephrine should be closely observed for 2 to 3 hours to ensure that they will remain stable. Oxygen also should be administered. Heliox (helium/oxygen mixture of 80:20 or 70:30) may be used for severe cases of croup, although there is lack of scientific evidence to establish use in routine clinical practice.⁸ In rare cases, croup and recurrent croup may require placement of an endotracheal tube. Children with recurrent croup require evaluation for anatomic abnormalities and the presence of associated diseases.⁹

Acute Epiglottitis.

Historically, **acute epiglottitis** was caused by *Haemophilus influenzae* type B (Hib). Since the advent of Hib immunization, the overall incidence of acute epiglottitis in children has decreased significantly. However, up to 25% of epiglottitis cases are still caused by HiB.¹⁰ Current pediatric cases usually represent vaccine failures or are caused by other pathogens. Infants less than 1 year of age are at greater risk.¹¹ Noninfectious causes include trauma from foreign body inhalation and chemical burns.

◆Pathophysiology.

The epiglottis arises from the posterior tongue base and covers the laryngeal inlet during swallowing. It has a rich blood and lymphatic circulation. Bacterial invasion of the mucosa and associated inflammation lead to the rapid development of edema causing severe, life-threatening obstruction of the upper airway.¹²

◀Clinical Manifestations.

In the classic form of the disease, a child between 2 and 6 years of age suddenly develops high fever, irritability, sore throat, a “hot potato voice,” inspiratory stridor, and severe respiratory distress. The child appears ill and classically will adopt a forward-leaning position (tripod position) with drooling and dysphagia (inability to swallow). Examination of the throat may trigger laryngospasm and cause respiratory collapse. Death may occur in a few hours. Pneumonia, cervical lymph node inflammation, otitis, and, rarely, meningitis or septic arthritis may occur during the course of epiglottitis.

◀Evaluation and Treatment.

Acute epiglottitis is a life-threatening emergency. The essentials are recognizing the presence of the disease, being careful not to disturb the child (which could worsen the obstruction), and securing the airway. Examination of the throat should not be attempted because it may trigger laryngospasm and cause respiratory collapse. With severe airway obstruction, the airway is secured with endotracheal intubation and anesthesia. Subsequent culture of the airway is obtained and intravenous broad-spectrum antibiotics are administered promptly. Therapy is reevaluated after culture results return. Corticosteroids also are generally used in treatment regimens.^{13,14} Resolution with treatment is usually rapid. When Hib epiglottitis is diagnosed, the American Academy of Pediatrics (AAP) recommends that postexposure prophylaxis with rifampin be administered to household contacts of the infected child if they have not been fully vaccinated or are immunocompromised. Rifampin is given once daily for 4 days and eradicates *H. influenzae* type B in approximately 95% of carriers.¹⁵

Tonsillar Infections.

Tonsillar infections (tonsillitis) are occasionally severe enough to cause UAO. As with other infections of the upper airway, the incidence of tonsillitis secondary to group A beta-hemolytic *Streptococci* (GABHS) and methicillin-resistant *Staphylococcus aureus*

(MRSA) has risen in the past 15 years.¹⁶ Significant swelling of the tonsils and pharynx occurs, and a tenacious membrane may cover the mucosa. UAO because of tonsillitis is a well-known complication of infectious mononucleosis, especially in a young child. The development of UAO in tonsillar infections requires the administration of appropriately selected antibiotics and the use of corticosteroids.¹⁷ Some children with recurrent tonsillitis benefit from adenotonsillectomy. Tonsillitis may be complicated by formation of a **tonsillar abscess**, which can further contribute to airway obstruction. **Peritonsillar abscess** is usually unilateral and is most often a complication of acute tonsillitis.¹⁸ The most common causative microorganism is GABHS. Symptoms in children include fever, sore throat, dysphagia, trismus, pooling of saliva, and muffled voice. Peritonsillar bulging ([Fig. 37.8](#)) and cervical adenopathy on the same side are usually visible. The abscess must be drained and the child given antibiotics. Death can occur from spontaneous abscess rupture with aspiration or airway obstruction.¹⁹

FIGURE 37.8 Peritonsillar Abscess. If the tonsils are inflamed and appear asymmetrical with unilateral palatal swelling (*black arrow*) and uvular deviation (*white arrow*), a peritonsillar abscess should be suspected. (From Goldman L, Schafer AI: *Goldman's Cecil medicine*, ed 24, Philadelphia, 2012, Saunders.)

Bacterial Tracheitis.

Bacterial tracheitis (pseudomembranous croup) is the most common, potentially life-threatening upper airway infection in children. It is most often caused by *S. aureus* (including methicillin-resistant [MRSA] strains), *H. influenzae*, GABHS (*Streptococcus pyogenes*), or *Moraxella catarrhalis* virus. A fungus is more likely to be seen as the source of tracheitis in immunocompromised children.

The presence of airway edema and copious purulent secretions leads to airway obstruction that can be worsened by the formation of a tracheal pseudomembrane and mucosal sloughing. Increased morbidity can occur because of respiratory and cardiopulmonary arrest, respiratory failure, pneumonia, septic shock, toxic shock syndrome, acute respiratory distress syndrome (ARDS), and multiple organ dysfunction syndrome (MODS).²⁰ The onset of symptoms may be sudden or may be preceded by a preexisting viral upper respiratory tract infection or croup. The acute clinical presentation frequently includes tachypnea, stridor, hoarse voice, fever, cough, and/or increased secretions from the mouth and nose. There may be evidence of concurrent infections, such as sinusitis, otitis, pneumonia, or pharyngitis. Management requires the rapid administration of broad-spectrum intravenous antibiotics and endotracheal intubation in order to prevent airway obstruction.²¹

Retropharyngeal Abscess.

Retropharyngeal abscess can be caused by aerobic, anaerobic, or polymicrobial infection. There has been an increase in GABHS strains associated with this condition, and the emergence of MRSA as the offending microorganism is increasingly noted.²²

Retropharyngeal abscess usually occurs more commonly in children about 4 years of age and as a consequence of either nasopharyngeal infection or penetrating local injury.²³ Clinical signs include fever, dysphagia, drooling, stridor, respiratory distress, and neck pain. This condition requires emergency treatment with intravenous antibiotics targeted at the suspected microorganism, and sometimes incision and drainage.²⁴

Aspiration of Foreign Bodies

Aspiration of foreign bodies into the airways is most common in children 1 to 4 years of age. More than 100,000 cases and 100 deaths occur each year.²⁵ Most objects are expelled by the cough reflex, but some objects may lodge in the larynx, trachea, or bronchi. Large objects (e.g., nuts, seeds, hard candy, a bite of hot dog, popcorn, grapes, beans, toy pieces, fragments of popped balloons, or coins) may occlude the airway and become life-threatening. Items of particular concern are batteries and multiple magnets. The aspiration event is often not witnessed or not recognized when it happens because the coughing, choking, wheezing, or gagging symptoms may resolve quickly. Foreign bodies lodged in the larynx or upper trachea cause cough, stridor, hoarseness or inability to speak, decreased breath sounds, respiratory distress, and agitation or panic; the presentation is often dramatic and frightening.²⁶ Foreign bodies in the intrathoracic airways more commonly produce wheezing. Symptoms are determined by the size of the object and the site where it is located, as well as the child's age and size (see Fig. 37.4). If the child is acutely hypoxic and unable to move air, immediate action, such as sweeping the oral airway or performing abdominal thrusts (formerly called the *Heimlich maneuver*), may be required to prevent tragedy. Otherwise, bronchoscopic removal should be performed urgently. If an aspirated foreign body is small enough, it will be transferred to a bronchus before becoming lodged. If the foreign body is lodged in the airway for a notable period of time, local irritation, granulation, obstruction, and infection will ensue. Thus children may present with cough or wheezing, atelectasis, pneumonia, lung abscess, or blood-streaked sputum. Many objects are not radiopaque and will not be visible on a chest radiograph. Occasionally, air will accumulate distal to the obstruction if the object is causing a ball-valve effect. This effect can sometimes be documented by inspiratory and expiratory chest films (Fig. 37.9). These children are treated by prompt bronchoscopic removal of the object and administration of antibiotics as necessary. Children with an unexplained persistent cough and refractory parenchymal infiltrates also should be considered for unrecognized

foreign body aspiration.²⁷

FIGURE 37.9 Foreign Body Aspiration. Anteroposterior inspiratory (A) and expiratory (B) chest radiographs. Air trapping in the left lung is caused by a peanut in the left mainstem bronchus. (From Taussig LM, Landau LI: *Pediatric respiratory medicine*, ed 2, St Louis, 2008, Mosby.)

Angioedema

Angioedema is a localized edema involving the deep, subcutaneous layers of skin or mucous membranes. Generally, angioedema causes facial swelling first, particularly around the eyes and lips, and may progress to airway swelling. Angioedema is usually secondary to mast cell-mediated allergic phenomena (e.g., allergy to peanuts, cow's milk, chicken eggs). Increased levels of bradykinin mediate this adverse effect by causing vasodilation, increased vascular permeability, and histamine release. An occasional cause of pediatric angioedema is use of angiotensin-converting enzyme inhibitors for treatment of hypertension or heart disease. If airway compromise is apparent, standard treatment includes epinephrine (subcutaneous), antihistamines, and corticosteroids.²⁸

An inherited deficiency of the plasma protein C-1 inhibitor (C-1 INH) causes *hereditary angioneurotic edema (HAE)*, a rare but serious problem in children. About 50% of cases occur during childhood.²⁹

The mean age of onset of initial symptoms is 8 to 19 years but it also may occur as early as the first year of life. This condition is characterized by nonallergic, recurring attacks of angioedema involving subcutaneous tissues (especially limbs, genitalia, and face); abdominal and pelvic viscera; and, much less often, the airway. Laryngeal attacks in these individuals may be life-threatening and do not respond reliably to standard measures for airway edema. Laboratory evaluation of complement and C-1 INH levels usually provides an accurate diagnosis.³⁰ The mortality of undiagnosed HAE can be as high as 50%. The mainstays of supportive care are airway monitoring, hydration, pain relief, and control of nausea. Treatments include concentrates of C-1 INH, ecallantide/kallikrein inhibitor, and icatibant/bradykinin receptor antagonist.^{31,32}

Congenital Malformations

Congenital malformations can occur at multiple sites from the nasal openings to the subglottis. Anatomic or functional obstruction can cause severe respiratory distress.

Laryngomalacia and Tracheomalacia.

Laryngomalacia results from abnormally soft laryngeal cartilages and is the most common cause of chronic stridor in infants. Boys are more likely than girls to present with symptoms. In laryngomalacia, the epiglottis or arytenoids, or both, fold inward with inspiration, partially covering the glottis (Fig. 37.10). The pathophysiology of these abnormalities is still not completely understood. A neuromuscular hypothesis suggests there is immaturity or an abnormality of the sensorimotor integrative function of the brainstem, and peripheral reflexes are responsible for laryngeal tone and airway patency. Laryngeal nerve hypertrophy also has been documented.³³ Gastroesophageal reflux disease (GERD) and other comorbidities are associated with laryngomalacia.³⁴

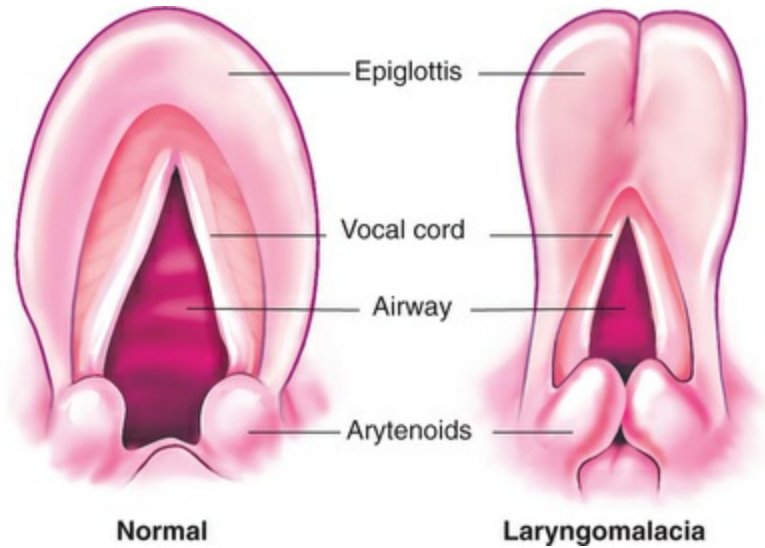

FIGURE 37.10 Laryngomalacia. In the normal larynx (*left*), supralaryngeal structures maintain their upright orientation during inspiration. In contrast, in infants with laryngomalacia (*right*), there is inward prolapse of the arytenoid masses, which include the prominent cuneiform tubercles and the arytenoid cartilages. The glottis becomes partially covered, and airflow is impeded. Sometimes the edges of the epiglottis curl inward, further exacerbating the obstruction. In expiration, these structures are “blown” aside passively.

Typical signs of laryngomalacia include inspiratory stridor beginning in the first days or weeks of life that is accentuated with activity, and sometimes with positional changes (worse in supine or head-flexed positions). Feeding difficulties may be noted, but they are usually mild. Cry is normal. Laryngoscopy is used to confirm the diagnosis. Laryngomalacia is usually mild and improves spontaneously over the first year of life as the supralaryngeal cartilage structures stiffen; thus most cases are managed with watchful waiting. Supraglottoplasty is the surgery of choice for severe symptoms, including breathing and eating difficulties with weight loss or failure to thrive. A late-onset variant of this disease has been noted in the literature and should be suspected if the following occur: potential cause of feeding difficulties in toddlers, sleep apnea in children, and exercise intolerance in teenagers.^{35,36}

In **tracheomalacia**, or **tracheobronchomalacia**, the tracheobronchial cartilages are flaccid and tend to collapse during the expiratory cycle, causing stridor. This may be classified as primary (idiopathic) or secondary. When malacia is caused by a secondary source, it is

usually related to extrinsic compression of the trachea from a vascular malformation (congenital tracheomalacia). Tracheobronchomalacia involves the mainstem bronchi and presents clinically as a spectrum of respiratory illnesses that range from life-threatening conditions to chronic cough and wheeze conditions. In some cases symptoms may be more subtle than those associated with laryngomalacia. Low-pitched inspiratory stridor may be a sign of malacia of the upper trachea or a centrally located, single-pitch (monophonic) wheeze may be present in malacia of the middle to distal trachea. Tracheomalacia can be suspected clinically, usually by 2 to 3 months of age, and confirmed by bronchoscopy and imaging. Depending on the type and severity of the lesion, surgical approaches for repair may be indicated.³⁷

Vocal Cord Paralysis.

Vocal cord paralysis is second to laryngomalacia as a cause of stridor and is a relatively uncommon congenital disorder. The vocal cords should move apart to facilitate inspiration and move together to facilitate vocalization. Paralysis of one or both vocal cords may affect breathing, swallowing, and speech. The etiology of the congenital abnormality is unclear but may be caused by immaturity of the vagus nerve or brainstem, or both. Iatrogenic injury is frequently cited as the major secondary cause of vocal cord paralysis, such as surgical trauma to the recurrent laryngeal nerve during cardiac surgery. Other secondary causes include Arnold-Chiari malformation (the region of the brainstem in which the nucleus ambiguus acts as the “relay station” for laryngeal function), cerebral palsy, hydrocephalus, myelomeningocele, spina bifida, or hypoxia.³⁸ Other associations include infectious and neoplastic causes, trauma, and inflammatory conditions.³⁹ In older children and adolescents, exercise can result in inducible laryngeal obstruction (previously known as *vocal cord dysfunction* [VCD]).⁴⁰

Clinical findings of vocal cord paralysis in children younger than 1 year include dysphonia, glottic incompetence, GERD, and stridor.³⁹ It sometimes resolves spontaneously (most often during the first year of

life) or with correction of the underlying problem. Flexible laryngoscopy and chest x-ray are common evaluative tools that may help determine the cause. In some individuals, inducible laryngeal obstruction may be misdiagnosed as asthma.⁴¹ Medical therapy may include the use of corticosteroids, proton pump inhibitors, and speech therapy. Recurrent pulmonary infections secondary to aspiration may occur and require treatment until the cords are repaired. Surgical treatment of unilateral vocal cord paralysis includes injection laryngoplasty, thyroplasty, and laryngeal reinnervation.⁴² Tracheostomy may be used until the vocal cords are surgically repaired.

Subglottic Stenosis.

Congenital **subglottic stenosis** is the third most common laryngeal anomaly and is defined as a subglottic airway diameter of less than 4 mm at the cricoid region (just below the vocal folds extending to the lower border of the cricoid cartilage) in a full-term infant, and less than 3 mm in a premature infant. Incomplete recanalization of the laryngotracheal tube during the third month of gestation results in this defect. The overall rate of symptomatic subglottic stenosis (stridor, intercostal retractions, and barking cough) in neonates is 0.2%.⁴³ Subglottic stenosis also is associated with eosinophilic esophagitis, Wegener granulomatosis, and neurofibromatosis.⁴⁴⁻⁴⁶ Because of the rapid growth of the lumen of the trachea and cricoid cartilage in the first year (which triples in size), infants may outgrow the obstruction, particularly if it is mild or moderate. An endotracheal tube is placed in severe cases. Traumatic injury to the upper airway with development of secondary subglottic stenosis is a well-described complication of endotracheal intubation. Factors that contribute to secondary subglottic stenosis include utilization of long-term assisted ventilation, use of an endotracheal tube that is too large, excessive movement of the tube, and susceptibility of the individual. Neonates can tolerate long periods of endotracheal intubation and subglottic stenosis can be minimized by ensuring that the tube size allows a small air leak during inspiration (at a peak inspiratory force of

approximately 25 mmHg) and that the tube is securely taped. Because of the rapid growth of the lumen of the trachea and cricoid cartilage in the first year (which triples in size), infants may outgrow the obstruction, particularly if mild or moderate. Serial balloon dilation can be effective. For severe subglottic stenosis, laryngotracheal reconstruction (LTR) along with cricotracheal resection and thyrotracheal anastomosis may be required.⁴⁷

Other Congenital Malformations.

Congenital malformations of the upper airways, trachea, and bronchial tree are rare and cause airway obstruction. Lesions include choanal atresia; laryngeal atresias, webs, cysts, clefts, and subglottic hemangiomas; and tracheal stenosis. **Choanal atresia** can be unilateral or bilateral and causes lack of patency of the nasal cavity within the nasopharynx. Bilateral choanal atresia can be life-threatening in newborns because they are obligate nasal breathers. **Laryngeal atresias** and webs are caused by failure of the larynx to recanalize during embryogenesis. Most of these disorders are in the area of the glottis with extension into the subglottis. **Tracheal stenosis** is a rare malformation characterized by inspiratory and expiratory stridor within the first few weeks of birth. It is usually associated with pulmonary, cardiovascular, and gastrointestinal malformations.⁴⁸ Structural abnormalities such as pectus excavatum or abnormalities involving the great vessels also can result in tracheal compression. For example, absent pulmonary valve syndrome dilates the pulmonary artery, which can compress the trachea and bronchi.⁴⁹ Tracheal or bronchial compression results in airway symptoms or feeding difficulties, or both, ranging from dysphagia, recurrent respiratory tract infections, wheezing, and stridor to acute respiratory distress or “dying spells.” Many older children are first thought to have gastroesophageal reflux or asthma as the principal problem. Surgical management is usually required for these conditions, and some infants may require mechanical ventilation while awaiting surgery.⁵⁰

Obstructive Sleep Apnea Syndrome

Obstructive sleep apnea syndrome (OSAS) is a form of sleep-disordered breathing (SDB) defined by partial or intermittent complete UAO during sleep with disruption of normal ventilation and sleep patterns. Childhood OSAS is common with an estimated prevalence of 2% to 3% of children 12 to 14 years of age, up to 13% of children ages 3 to 6 years, and about 60% of obese children.⁵¹ Prevalence is estimated to be two to four times higher in vulnerable populations (blacks, Hispanics, and preterm infants) and there may be a family history of OSAS.⁵² Possible influences early in life may include passive smoke inhalation, socioeconomic status, and snoring together with genetic modifiers that promote airway inflammation.

◆Pathophysiology.

The pathophysiology of childhood OSAS is likely to be multifactorial in origin, involving the central nervous, cardiovascular, metabolic, and immune systems. Airway narrowing and increased upper airway collapsibility are the common causes of OSAS. Obstruction of the upper airway during sleep results in cyclic episodes of increasing respiratory effort and changes in intrathoracic pressures with oxygen desaturation, hypercapnia, and arousal. The child goes back to sleep and the cycle repeats. Adenotonsillar hypertrophy, gastroesophageal reflux, obesity, and craniofacial anomalies are associated with airway narrowing. Infants are at risk because they have both anatomic and physiologic predispositions toward airway obstruction and gas-exchange abnormalities, including a superiorly placed larynx, increased chest wall compliance, ventilation-perfusion mismatching, and ventilatory control instability.

Reduced motor tone of the upper airways may be seen in neurologic disorders, such as cerebral palsy and Down syndrome. Upper airway inflammation and altered neurologic reflexes involving respiratory control of upper airway muscles are significant factors in reducing airway diameter. Allergy and asthma may contribute to inflammation, and children who have a history of a clinically significant episode of respiratory syncytial virus (RSV) bronchiolitis in infancy may exhibit altered neuroimmunomodulatory pathways

toward inflammation in the upper airway. In obese children, current research links OSAS with airway inflammation and elevated levels of C-reactive protein, which also contribute to increased risk for cardiovascular and metabolic diseases.⁵³

◆Clinical Manifestations.

Common manifestations of OSAS include snoring and failure to thrive in infants, labored breathing, restlessness, sweating during sleep (which can be continuous or intermittent), and sleepiness in children and adolescents. There may be episodes of increased respiratory effort but no audible airflow, often terminated by snorting, gasping, repositioning, or arousal. Affected children are often chronic mouth breathers and have large tonsils and adenoids. They also may exhibit nocturnal enuresis. Untreated OSAS can cause cardiovascular disease (particularly left ventricular hypertrophy and pulmonary hypertension) and insulin resistance as well as upper and lower respiratory tract infections. Cognitive and neurobehavioral impairment (e.g., inattention, hyperactivity, aggression, conduct problems, attention-deficit/hyperactivity disorder [ADHD]/emotional [mood]), impaired school performance, and poor quality of life are consequences of OSAS.⁵⁴

◆Evaluation and Treatment.

All parents should be asked if their child exhibits snoring and labored breathing, sweating, and restlessness during sleep, which may be continuous or intermittent. Screening tools and sleep questionnaires are helpful in evaluating the presence of SDB.⁵⁵ Imaging of the upper airway may be used to rule out adenoidal hypertrophy or upper airway narrowing. The most definitive evaluation (“gold standard”) is the polysomnographic sleep study, which documents obstructed breathing and physiologic impairment and may be combined with nocturnal oximetry studies. If obstructive sleep apnea caused by tonsillar enlargement is documented or strongly suspected clinically, children are most often referred for tonsillectomy and adenoidectomy (T&A). For severely affected children who do not respond to T&A or

who have different problems, such as obesity that cannot be rapidly remedied, use of continuous positive airway pressure (CPAP), antiinflammatory medications, dental treatments, or a high-flow nasal cannula as well as weight loss can be considered. Treatment is important to minimize associated morbidities.^{56,57}

Disorders of the Lower Airways

Lower airway disease is one of the leading causes of morbidity in the first year of life and continues to be an important component of other illnesses. Infants may have respiratory distress from immature lungs and surfactant deficiency, or from aspiration of amniotic fluid or meconium. Other disorders include congenital malformations, asthma, cystic fibrosis, infections, and acute respiratory distress syndrome (ARDS).

Surfactant Deficiency Disorder (Respiratory Distress Syndrome of the Newborn)

Surfactant deficiency disorder (SDD) (respiratory distress syndrome [RDS] of the newborn), previously known as **hyaline membrane disease (HMD)**, is a significant cause of neonatal morbidity and mortality. It occurs almost exclusively in premature infants, and the incidence has increased in the United States over the past two decades. Preterm births accounted for about 9.50% of all births in 2014 (about 8.0% for white mothers, about 13.23% for black mothers, and about 9.03% for Hispanic mothers).⁵⁸ The major predisposing factor is prematurity because the immature lung is not well structured for gas exchange and has not yet developed adequate surfactant production and secretion. SDD (RDS) occurs in 50% to 60% of infants born at 29 weeks' gestation and decreases significantly by 36 weeks. Infants of diabetic mothers and those with cesarean delivery (especially elective C-section) are more likely to develop SDD (RDS) because the labor-associated catecholamine and steroid surges do not occur, causing decreased pulmonary surfactant release.⁵⁹ It is more common in boys

than girls, and in one cohort it was more common in black infants.^{60,61} Death rates have declined significantly since the introduction of antenatal steroid therapy and postnatal surfactant therapy. The epidemiology, pathophysiology, and clinical presentation of SDD (RDS) are summarized in [Box 37.2](#).

Box 37.2

Surfactant Deficiency Disorder (Respiratory Distress Syndrome of the Newborn)

Epidemiology

- Worldwide
- Prematurity predisposes
- Cesarean section without labor predisposes
- Perinatal asphyxia predisposes
- Meconium aspiration predisposes
- Male > female
- White > black
- Second-born twin at greater risk
- PROM spares
- IUGR spares
- Advanced maternal age predisposes
- Maternal stress spares
- Maternal diabetes predisposes if less than 37 weeks
- Maternal hemorrhage predisposes

Etiology

- Surfactant deficiency
- Probable inadequate hormonal (corticoid) stimulus in utero
- DPL synthesis impaired and/or destruction increased

Autonomic dysfunction

Pathophysiology

Reduced lung compliance

Reduced FRC

Poor lung distensibility

Poor alveolar stability

Right-to-left shunts

Reduced effective pulmonary blood flow

If hypotensive and hypoxic, poor peripheral perfusion, poor renal perfusion, myocardial malfunction

Patent ductus arteriosus contributes

Clinical Signs

Onset near the time of birth

Tachypnea

Increased work of breathing:

 Nasal flaring

 Retractions of respiratory muscles

Expiratory grunt

Cyanosis

Systemic hypotension

Characteristic chest film

Course to death or improvement in 3 to 5 days

Fine inspiratory rales

Hypothermia

Peripheral edema

Pulmonary edema

Pathobiochemistry

Respiratory acidosis

Decreased saturated phospholipids
Low amniotic fluid L/S ratio
Low surfactant-associated proteins
Decreased total serum proteins
Decreased fibrinolysis
Low thyroxine levels

Pathology

Atelectasis
Injury to epithelial cells, edema
Membrane contains fibrin and cellular products
No tubular myelin
Osmiophilic lamellar bodies decreased early, increased later

Prevention

Prenatal glucocorticoids for more than 24 hours
Prevention of asphyxia
Surfactant replacement:
 Prophylactically—within 15 minutes after birth
 Early rescue—within 60 minutes after birth
 Established RDS—within 12 hours after birth
Continuous positive airway pressure
Lower tidal volumes

DPL, Dipalmitoyl lecithin; *FRC*, functional residual capacity; *IUGR*, intrauterine growth restriction; *L/S*, lecithin/sphingomyelin; *PROM*, prolonged rupture of membranes (>16 hours); *RDS*, surfactant deficiency disorder (respiratory distress syndrome).

Data from Jackson JC: Respiratory distress in the preterm infant. In Gleason CA, Devaskar SU, editors: *Avery's disease of the newborn*, ed 9, Philadelphia, 2011, Saunders; Jobe AH: Pathophysiology of respiratory distress syndrome. In Polin RA et al, editors: *Fetal and neonatal physiology*, ed 5, Philadelphia, 2017, Saunders.

◆Pathophysiology.

SDD (RDS) is caused by surfactant deficiency. Surfactant lipoproteins have a detergent-like effect that separates the liquid molecules inside the alveoli, thereby decreasing alveolar surface tension. Without surfactant, alveoli collapse at the end of each exhalation, which decreases the alveolar surface area available for gas exchange.⁶² Surfactant normally is not secreted by the alveolar cells until approximately 20 to 24 weeks' gestation (see [Fig. 37.1](#)). Premature infants also are born with underdeveloped and small alveoli that are difficult to inflate. Additionally, the alveoli have thick walls and an inadequate capillary blood supply such that gas exchange is significantly impaired. The infant's chest wall is weak and highly compliant and, thus, the rib cage tends to collapse inward with respiratory effort. The net effect is *atelectasis* ([Fig. 37.11](#)), resulting in significant hypoxemia. Atelectasis is difficult for the neonate to overcome because it requires a significant negative inspiratory pressure to open the alveoli with each breath. The increased work of breathing and a decrease in tidal volume cause alveolar hypoventilation and hypercapnia. Hypoxia and hypercapnia cause pulmonary vasoconstriction and increase intrapulmonary resistance and shunting. This results in hypoperfusion of the lung and a decrease in effective pulmonary blood flow. Increased pulmonary vascular resistance may even cause a partial return to fetal circulation (see [Chapter 35](#)) with right-to-left shunting of blood through the ductus arteriosus and foramen ovale. Inadequate perfusion of tissues and hypoxemia contribute to metabolic acidosis.

FIGURE 37.11 Patchy Atelectasis of Neonatal Lungs with Surfactant Deficiency Disorder (Respiratory Distress Syndrome). (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Inadequate alveolar ventilation can be further complicated by increased pulmonary capillary permeability. Many premature infants with SDD (RDS) require positive pressure mechanical ventilation with high oxygen content, which damages the alveolar epithelium (e.g., barotrauma and oxygen toxicity). Together these conditions result in the leakage of plasma proteins into the alveoli and pulmonary edema. Fibrin deposits in the air spaces create the appearance of *hyaline membranes* for which the disorder was originally named. The plasma proteins leaked into the air space have the additional adverse effect of inactivating any surfactant that may be present. The pathogenesis of SDD (RDS) is summarized in [Figs. 37.11](#) and [37.12](#).

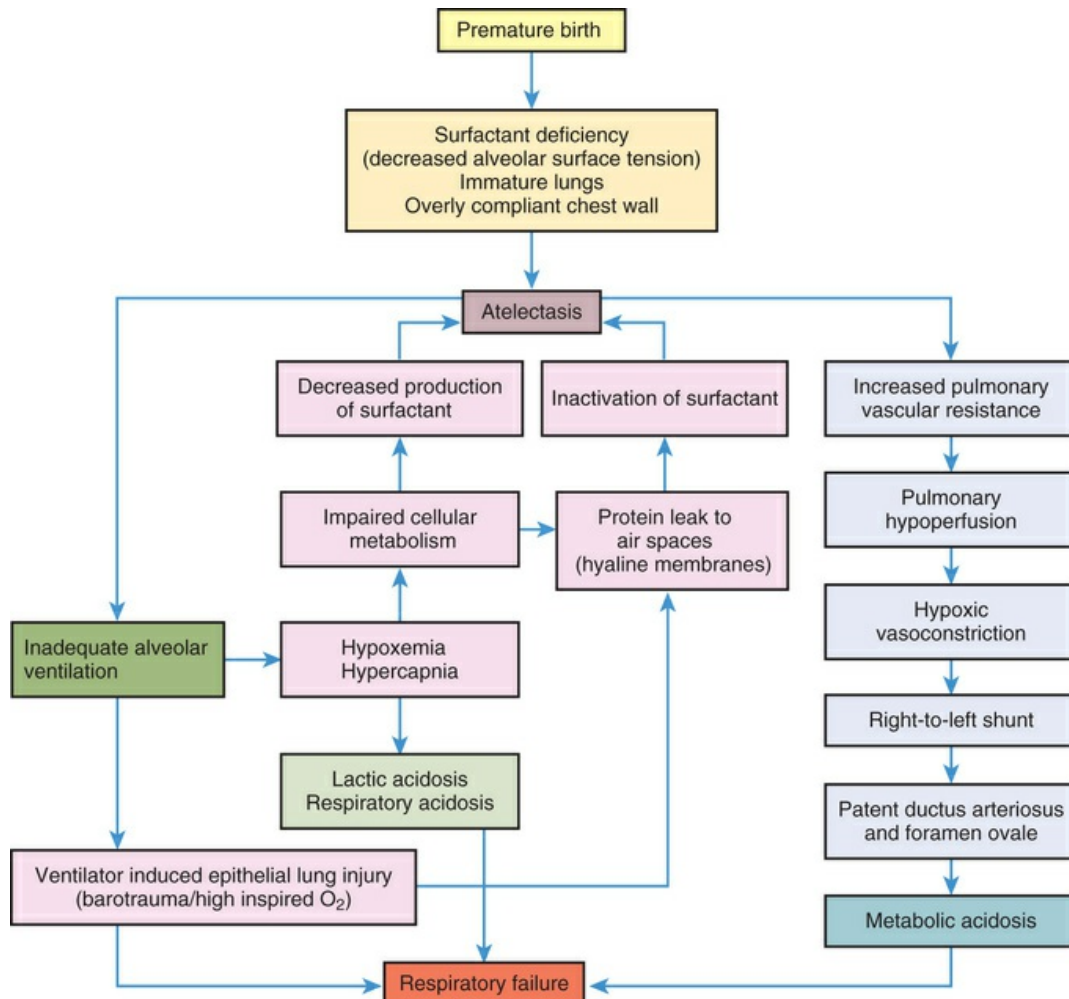

FIGURE 37.12 Pathogenesis of Surfactant Deficiency Disorder (Respiratory Distress Syndrome) of the Newborn.

◆Clinical Manifestations.

Signs of SDD (RDS) appear within minutes of birth and include tachypnea (respiratory rate more than 60 breaths per minute), expiratory grunting, intercostal and subcostal retractions, nasal flaring, and cyanosis. The natural course is characterized by progressive hypoxemia and dyspnea with severity progressing over the first hours after birth. Apnea and irregular respirations occur as the infant tires. The severity of the hypoxemia and the difficulty in providing adequate supplemental oxygenation result in the Vermont Oxford Network definition of RDS as a PaO₂ less than 50 mmHg in room air, central cyanosis in room air, or a need for supplemental

oxygen to maintain a PaO₂ greater than 50 mmHg, as well as chest film appearance.⁶³ Typically, a chest radiograph shows diffuse, fine granular densities within the first 6 hours of life. This “ground glass” appearance is associated with alveolar flooding. In most cases the clinical manifestations reach a peak within 3 days, after which there is gradual improvement with appropriate treatment.

◆Evaluation and Treatment.

Diagnosis is made on the basis of clinical manifestations, chest radiographs, and, if needed, analysis of amniotic fluid or tracheal aspirates to estimate lung maturity (lecithin/sphingomyelin ratio [L/S ratio]). The ultimate treatment for SDD (RDS) would be prevention of premature birth. There is extensive evidence that when there is risk of preterm labor, antenatal corticosteroid therapy given between 24 and 34 weeks' gestation reduces the incidence of SDD (RDS) and death. Repeated courses of corticosteroids may be safe in this setting.⁶⁴ Glucocorticoids induce a significant and rapid acceleration of lung maturation, particularly type 1 and type 2 pneumocytes, with stimulation of surfactant production and improved lung compliance and gas exchange in the fetus. There is extensive evidence that maternal steroid therapy significantly reduces the incidence of SDD (RDS), bronchopulmonary dysplasia, central nervous system hemorrhage, and neonatal mortality. Efforts are in progress to determine the long-term effects on infant neurodevelopment with strategies to personalize dosage recommendations.⁶⁵ The American Congress of Obstetricians and Gynecologists recommends that administration of betamethasone may be considered in women with a singleton pregnancy between 34 0/7 and 36 6/7 weeks' gestation at imminent risk of preterm birth within 7 days.⁶⁶ Efforts are in progress to determine the long-term effects on infant development with personalization of dosage recommendations.⁶⁷

Administration of exogenous surfactant (either synthetic or natural) is recommended as a prophylactic or preventive treatment for infants weighing between 500 and 2000 g with prophylaxis beginning within 15 to 30 minutes of birth through a thin catheter (minimally invasive

surfactant administration) or nebulizer or by nasal continuous positive airway pressure (CPAP) ventilation. Rescue surfactant therapy is given only to preterm infants with established SDD (RDS) and is most often administered within the first 12 hours after birth, when specified threshold criteria of severity of SDD (RDS) are met.⁶⁸ There is usually a dramatic improvement in oxygenation, as well as a decreased incidence of SDD (RDS) death, pneumothorax, and pulmonary interstitial emphysema. Surfactant therapy also can be considered complementary to antenatal glucocorticoids. The two therapies together appear to have an additive effect on improving lung function. Supplemental inositol also may promote maturation of surfactant and prevent adverse neonatal outcomes.⁶⁹

Supportive care includes oxygen administration and mechanical ventilation. Mechanical ventilation can result in a proinflammatory state that may contribute to the development of chronic lung disease, such as bronchopulmonary dysplasia (BPD). Strategies that are lung protective, such as greater reliance on nasal continuous positive airway pressure (NCPAP) to prevent lung injury, permissive hypercapnia, lower oxygen saturation targets, modulation of tidal volume (V_T) settings, and use of high-frequency oscillation or jet ventilation, are being evaluated.^{70,71} Mechanical ventilation with mixtures of oxygen and nitric oxide or helium may improve gas exchange and reduce airflow resistance and have improved outcomes.^{72,73}

Most infants survive SDD (RDS) and, in many cases, recovery may be complete within 10 to 14 days. However, the incidence of subsequent chronic lung disease (i.e., bronchopulmonary dysplasia) is significant among very low birth weight infants.⁷⁴

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD), also known as *chronic lung disease of prematurity*, is a chronic inflammatory lung disease associated with arrested pulmonary development and a need for supplemental oxygen. It is the major cause of pulmonary disease in infants and is associated with premature birth (usually before 28

weeks' gestation and birth weights less than 1500 g), SDD (RDS), perinatal supplemental oxygen, and positive pressure ventilation. Annually in the United States, approximately 10,000 to 15,000 infants are affected, including about 50% of infants weighing less than 1000 g. Up to 30% of very low and extremely low birth weight infants develop BPD.^{75,76} The widespread use of antenatal glucocorticoids, postnatal surfactant, and NCPAP has lessened the incidence and severity of SDD (RDS) and thus also reduced the incidence of BPD. Surprisingly, some of the tiny infants who develop BPD have shown few or no clinical signs of SDD (RDS) at birth or have initially received only low levels of supplemental oxygen or ventilatory support for apnea. The presence of antenatal chorioamnionitis, preeclampsia, inflammation and postnatal sepsis, patent ductus arteriosus, hyperoxia and genetic susceptibility confers additive risk of developing BPD. Numerous biomarkers associated with immunity, inflammation, and oxidative stress also have been identified and are being used to develop risk factors and guidelines for diagnosis and treatment.⁷⁷

BPD is a multisystem condition and is associated with developmental disorders in other systems, such as growth retardation, pulmonary hypertension, neurodevelopmental delays (e.g., cerebral palsy), hearing defects, and retinopathy of prematurity.⁷⁸

◆Pathophysiology.

Lung immaturity and inflammation contribute to the development of BPD. In preterm infants born at less than 28 weeks' gestation, the fetal lung is in the *canalicular stage* of development (16 to 28 weeks), a critical period during which type II epithelial cells appear, capillaries grow into the future distal alveolar regions, and the interstitium begins to condense (see Fig. 37.1). Ultimately the alveoli must have a very thin interface between the air space and the capillary for appropriate gas exchange. The extensive network of alveoli develops by septation within the terminal respiratory unit, beginning in the *saccular stage*, starting at approximately 26 to 28 weeks. The alveoli are vulnerable to inflammation and impaired growth during this stage.

Before the widespread use of surfactant therapy, BPD was a disease characterized by airway injury, inflammation, and parenchymal fibrosis (*classic BPD*). Now, after the initiation of surfactant therapy, what is called *new BPD* is most often a form of arrested lung development with poor formation of the alveolar architecture. Alveoli are large and fewer in number, thereby presenting decreased surface area for gas exchange. There is abnormal vascular endothelial growth factor that results in hypoplastic pulmonary capillary development and mild fibrosis accompanied by persistent inflammation contributing to ventilation-perfusion mismatch, pulmonary hypertension, and lasting pulmonary vascular disease.⁷⁹

Levels of proinflammatory cytokines, such as tumor necrosis factor-alpha (TNF- α), interleukin-1 β (IL-1 β), interleukin 6 (IL-6), and interleukin 8 (IL-8), are all elevated in the amniotic fluid or tracheal aspirates, or both, of preterm infants who later develop BPD. Inflammation invites neutrophils and macrophages to release reactive oxygen species and proteolytic enzymes, initiating oxidative and immune injury. The predominant mediators of *new BPD* are profibrotic and angiogenic cytokines, which contribute to pulmonary hypertension.⁸⁰ Fig. 37.13 illustrates the pathophysiology of BPD.

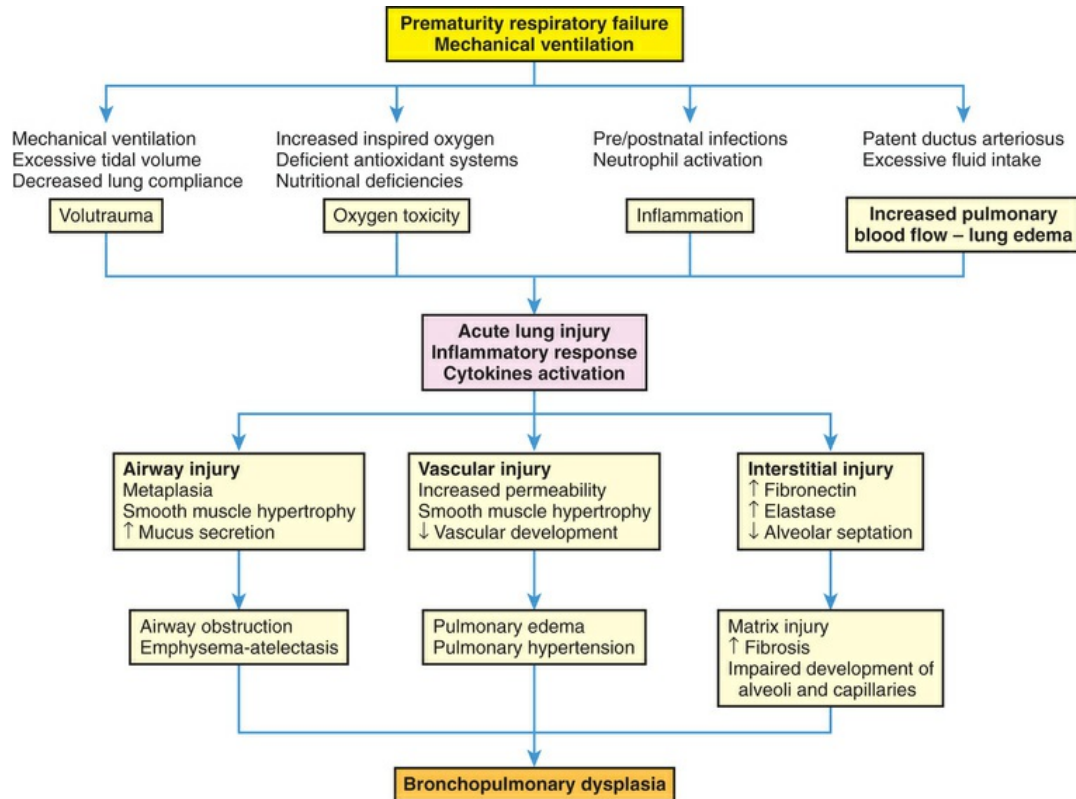

FIGURE 37.13 Pathophysiology of Bronchopulmonary Dysplasia (BPD).

◀Clinical Manifestations.

The clinical definition of BPD includes the need for supplemental oxygen at 36 weeks' postmenstrual age, which is also known as *gestational age* (the time elapsed between the first day of the last normal menstrual period and the day of birth) and for at least 28 days after birth. It also details graded severity dependent on required respiratory support at term (divided into mild, moderate, and severe based on oxygen requirements and ventilatory needs). Clinically, the infant exhibits hypoxemia caused by ventilation-perfusion mismatch and diffusion defects. Work of breathing is elevated, resulting in hypercapnia. The ability to feed may be impaired. Intermittent bronchospasm with wheezing, mucus plugging, and pulmonary hypertension characterizes the clinical course of the most severely affected babies. Of the most severely affected infants, dusky spells may occur with agitation, feeding, or gastroesophageal reflux. Infants with mild BPD may demonstrate only mild tachypnea and difficulty

handling respiratory tract infections.

◆Evaluation and Treatment.

Infants with severe BPD require prolonged, assisted ventilation. Prevention of lung damage with noninvasive respiratory support (see [Evaluation and Treatment](#) section under [Surfactant Deficiency Disorder \[Respiratory Distress Syndrome of the Newborn\]](#)) or early nasal intermittent CPAP, or both, is used in clinical situations when permitted. When compared to mechanical ventilation, use of CPAP has resulted in fewer days of oxygen and ventilator requirement by reducing the amount of lung injury. Additionally, oxygen supplementation at lower than previously accepted values (89% to 94% saturations) is a means to reduce oxidant injury to the lungs and retinal vasculature. Diuretics are used to control pulmonary edema. Bronchodilators reduce airway resistance. Inhaled corticosteroids improve the rate of extubation and reduce the time that mechanical ventilation is required. Prophylactic caffeine citrate is used to prevent apnea and for neuroprotection. Supplementation with vitamin A provides antioxidant protection and stimulates lung growth and surfactant production.⁸¹ New treatments are under consideration.⁸² Careful nutritional and fluid and electrolyte support is routinely used and has resulted in improved outcomes.

Respiratory Tract Infections

Respiratory tract infections are common in children and are a frequent cause for emergency department visits and hospitalizations. Clinical presentation, age of the child, season of the year, and environmental exposures can often provide clues to the etiologic agent, even when the agent cannot be proven.

Bronchiolitis

Bronchiolitis is a common, viral-induced respiratory tract infection of the small airways that occurs almost exclusively in infants and young toddlers. There are distinct regional differences in the United States

depending on geographic variation in the viral season. The most commonly associated pathogen is respiratory syncytial virus (RSV), but bronchiolitis also may be associated with rhinovirus (older children), adenovirus, influenza, parainfluenza virus (PIV), human metapneumovirus, and bocavirus. There are distinct regional differences in the United States depending on variation in the viral season based on geography. Healthy infants usually make a full recovery from RSV bronchiolitis, but infants who are premature (birth weight <2500 g) or who have underlying BPD, heart disease, or immune deficiency may have a much more severe or even deadly course. Their respiratory systems are immature, and maternal immunoglobulins do not protect against RSV infection.⁸³ Bronchiolitis has been linked to an increased risk for asthma later in childhood, particularly in those with a family history of asthma.⁸⁴

◆Pathophysiology.

Viral infection causes inflammation and necrosis of the bronchial epithelium with destruction of ciliated epithelial cells. There is infiltration with lymphocytes around the bronchioles and a cell-mediated hypersensitivity to viral antigens with release of lymphokines causing inflammation, as well as activation of eosinophils, neutrophils, and monocytes. The submucosa becomes edematous, and cellular debris and fibrin form plugs within the bronchioles. Edema of the bronchiolar wall, accumulation of mucus and cellular debris, and possibly bronchospasm narrow or occlude many peripheral airways. Airway obstruction leads to atelectasis and uneven ventilation leads to ventilation-perfusion mismatch and hypoxemia. Airway narrowing causes obstruction of airflow that is worse with expiration. This leads to air trapping, hyperinflation, and an increase in FRC. Airway resistance and hyperinflation result in decreased lung compliance and increased work of breathing and may cause hypercapnia in severe cases.

◆Clinical Manifestations.

Symptoms usually begin with significant rhinorrhea followed by a

tight, dry cough over the next several days, along with systemic signs of decreased appetite, lethargy, and fever. Infants may have tachypnea, expiratory wheezing, cough, rhinorrhea, mild fever, varying degrees of respiratory distress, and abnormal auscultatory findings of the chest. Wheezing is most common, but rales or rhonchi also may be present. Chest radiographs often show hyperexpanded lungs, patchy or peribronchial infiltrates, and atelectasis of the right upper lobe. With overexpansion of the lungs, the diaphragm is flattened, causing downward displacement of the liver and spleen. Abdominal distention results from air swallowing. Very young infants may present with severe apnea before lower respiratory tract symptoms appear, and these apneas frequently require mechanical ventilation.⁸³ Many children also may present with conjunctivitis or otitis media.

◆ Evaluation and Treatment.

Guidelines from the American Academy of Pediatrics are available for the evaluation, treatment, and prevention of bronchiolitis.⁸⁵ Diagnosis of bronchiolitis is made by review of history, signs, and symptoms (e.g., rhinitis, cough, wheezing, crackles, chest retractions and/or hyperinflation, tachypnea). Laboratory studies and radiologic or ultrasound examination are not routinely performed. Nasal washings/swabbings may be tested for specific viral agents, such as RSV. RSV swabs are positive in 70% of cases of bronchiolitis.

Treatment is determined by the severity of the disease and the age of the child. Most cases are mild and require no specific treatment, and affected children may be monitored as outpatients with supportive care. In more severe cases, supplemental oxygen with high-flow nasal cannula and increased hydration are commonly used. Nebulized 3% hypertonic saline has shown heterogeneous outcomes. Continuous positive airway pressure (CPAP) increases positive end-expiratory pressure (PEEP) and warm humidified oxygen helps to overcome airway resistance.⁸⁶ Preventive treatment or prophylaxis with RSV-specific options includes immunotherapy with palivizumab an RSV-specific recombinant monoclonal antibody, although it is

costly.⁸⁷ Other preventive measures include use of handwashing and alcohol-based decontamination, prevention of exposure to tobacco smoke, and promotion of infant breast-feeding. No licensed vaccine is currently available to protect against RSV.

Pneumonia

Pneumonia is infection and inflammation in the terminal airways and alveoli. **Community-acquired pneumonia (CAP)** is a major cause of morbidity and mortality in children, particularly in developing countries. The incidence of viral and bacterial pneumonia varies according to age, time of year, and geographic location. The most common agents are viruses, followed by bacteria and atypical microorganisms (e.g., mycoplasma); clinical symptoms often do not differentiate viral from bacterial or atypical pneumonia. Risk factors for developing CAP include age younger than 2 years, overcrowded living conditions, winter season, recent antibiotic treatment, attendance at daycare centers, and passive smoke exposure. Nutritional status, age, and underlying disease process influence morbidity and mortality related to CAP.

◆Pathophysiology and Clinical Manifestations.

Viral pneumonia is two to three times more likely in children than in adults, and incidence generally follows a seasonal pattern. Bacterial coinfections are common. The most common cause in infants and young children is respiratory syncytial virus (RSV). A number of other viruses are important, including parainfluenza, influenza, human rhinovirus, human metapneumovirus, adenoviruses, and *Mycoplasma pneumoniae*.⁸⁸ Acquisition of viruses is by direct contact, droplet transmission, or aerosol exposure. There is initial destruction of the ciliated epithelium of the distal airway with sloughing of cellular material. A mononuclear-predominant inflammatory response initially occurs in the interstitium and may later involve the alveoli. It is often difficult to determine whether the pneumonia is viral or bacterial early in the course of the disease. The clinical presentation of viral pneumonia often consists of cough and no fever, and the white

blood count is often normal. In bacterial pneumonia, the degree of elevated temperature, absolute neutrophil counts, and percent of bands are consistently higher than in those cases of viral etiology.⁸⁹ Diagnosis of a viral etiology requires laboratory confirmation (immunofluorescence tests). Antiviral therapy may prevent development of influenza-associated CAP. Development of safe agents to treat and prevent viral pneumonias continues to be a priority, as is development of more effective vaccines.⁹⁰

Bacterial pneumonia beyond the neonatal period is most commonly the result of infection with *Streptococcus pneumoniae*. It is the predominant bacteria isolated from bacterial CAP in children. Other causative microorganisms include *S. aureus* and atypical bacteria (e.g., *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*) (Table 37.2). Childhood immunization with polyvalent pneumococcal conjugate vaccine is recommended to decrease the incidence of pneumococcal pneumonia in children younger than 2 years of age. *Haemophilus influenzae* pneumonia has become rare because of widespread immunization.⁹¹

TABLE 37.2

COMMON TYPES OF PNEUMONIA IN CHILDREN

TYPE	CAUSAL AGENT	AGE	ONSET	SIGNS/SYMPTOMS	PA
Viral pneumonia	Respiratory syncytial virus (RSV), influenza (A and B), adenovirus, parainfluenza, human metapneumovirus (hMPV)	Infants for RSV All ages for others	Acute or gradual, winter and early spring	Mild to high fever, cough, rhinorrhea, malaise, rales, rhonchi, or wheezing; variable radiographic pattern	Ede a 1
Pneumococcal pneumonia	Pneumococci (<i>Streptococcus pneumoniae</i>)	1–4 yr	Acute, follows an upper respiratory tract infection, winter and early spring	High fever, productive cough, pleuritic pain, increased respiratory rate, decreased breath sounds in area of consolidation; lobar pattern or “round	1 1 1

				pneumonia" on radiograph	
Staphylococcal pneumonia	<i>Staphylococcus aureus</i> Methicillin-resistant <i>S. aureus</i> (MRSA)	1 wk–2 yr	Acute, winter months	High fever, cough, respiratory distress, toxic appearance, sepsis, empyema, pneumatoceles are common; multilobar consolidation	Nec
Streptococcal pneumonia	Group A streptococci	All ages	Acute, any season	High fever, chills, respiratory distress, sepsis or shock; empyema, pneumatoceles	Trac
<i>Mycoplasma</i> and <i>Chlamydophila</i> pneumonia	<i>M. pneumoniae</i> <i>C. pneumoniae</i>	School age and adolescents	Gradual	Low-grade fever; cough	Infl:

RBCs, Red blood cells; *WBCs*, white blood cells.

Bacterial pneumonia usually begins with aspiration of one's own nasopharyngeal bacteria. A preceding viral infection sometimes sets the stage for bacterial infection by causing a damaged epithelium, reduced mucociliary clearance in the trachea and major bronchi, and a reduced immune response.⁹² Once in the alveolar region, bacteria encounter local host defenses, such as antibodies, complement, phagocytes, and cytokines, that prepare bacteria for ingestion by alveolar macrophages. Alveolar macrophages recognize bacteria with their surface receptors and phagocytose them. If these mechanisms fail, macrophages will release numerous inflammatory cytokines, neutrophils will be recruited, and an intense cytokine-mediated inflammation will ensue. Vascular engorgement, edema, and a fibrinopurulent exudate with tissue damage occur. Alveolar filling precludes gas exchange and, if extensive, can lead to respiratory failure. If sepsis occurs at the same time, shock and end-organ hypoperfusion will cause metabolic acidosis. Staphylococcal and

group A streptococcal pneumonia can be particularly fulminant and necrotizing, with a high incidence of accompanying empyema, pneumatoceles, and sepsis. Empyema is associated with pneumococcal infections and antibiotic-resistant microorganisms.⁹³

The clinical presentation of bacterial pneumonia, particularly pneumococcal, may include a preceding viral illness followed by fever with chills and rigors, shortness of breath, and an increasingly productive cough. Occasionally there is blood streaking of the sputum. Respiratory rate and oxygen saturation are important clinical indicators. Auscultation usually reveals such abnormalities as crackles or decreased breath sounds. Other less specific findings may include malaise, emesis, abdominal pain, and chest pain. Chest films will usually present with a lobar pattern in older children and adolescents but may appear patchier with a bronchopneumonic pattern in younger children.

Atypical pneumonia (*Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*) is the most common cause of CAP for school-age children and young adults. *Chlamydophila pneumoniae* is clinically indistinguishable from and is typically grouped with *Mycoplasma* as “atypical pneumonia.” Transmission is from person-to-person with a 2- to 3-week incubation period.

Mycoplasma is known to cause a wide spectrum of disease and has more extensive complications than previously recognized. Studies reveal that macrolide-resistant *Mycoplasma pneumoniae* is seen increasingly in infants and younger children.⁹⁴ Children experiencing recurrent respiratory tract infections often have been found to be infected with atypical bacteria.

Mycoplasma microorganisms lack cell walls but have a limiting membrane and a specialized tip for attaching to ciliated respiratory epithelial cells. Local sloughing of cells occurs. Peribronchial lymphocytic infiltration develops, along with neutrophil recruitment to the airway lumen. The pattern resembles bronchitis or bronchopneumonia.

Onset of symptoms is usually gradual, resembling a typical upper respiratory tract infection with low-grade fever and prominent cough.

There may be accompanying wheezing, sore throat, myalgia, and headache. Cases are not usually clinically severe, and full recovery should be expected without complications. When complications do occur, they can include bronchopneumonia, parapneumonic effusions, and necrotizing pneumonitis.⁹³

◆Evaluation and Treatment.

Guidelines have been developed to improve and aid assessment and management of pediatric pneumonia.⁹⁵ Diagnosis of pneumonia is based on clinical and laboratory findings. The etiologic agent can sometimes be inferred from the age of the child and clinical scenario. Chest x-ray in bacterial pneumonia initially shows an alveolar infiltrate and later reveals a segmental or lobar disease. A viral infection is more likely to be associated with an interstitial pattern. Identifying etiologic pathogens can be very difficult in children, especially because there is often overlap between bacterial and viral pathogens. Biomarkers facilitate more rapid diagnosis, and procalcitonin is most specific to bacterial infection and can guide antibiotic therapy. The highly sensitive C-reactive protein (hs-CRP) is less specific and its level is elevated in both viral and bacterial infections.⁹⁶ Other laboratory tests that may be helpful include a white cell–granulocyte count or erythrocyte sedimentation rate (ESR) but do not indicate a specific etiology. Several microbiologic tests are available, such as polymerase chain reaction (PCR) and nucleic acid amplification tests (NAATs).

Some pneumonias may be treated on an outpatient basis; however, some children require oxygen supplementation and, occasionally, assisted ventilation. This is particularly true with infants who have a viral interstitial pneumonia like that caused by RSV. In addition, adequate hydration, nutrition, and supportive pulmonary therapy are required to reduce the duration and severity of illness. Many infants are markedly tachypneic and unable to coordinate their breathing with swallowing such that they may require enteral feeding. Aspiration is always a risk with infants in respiratory distress.

Appropriate antibiotic administration for bacterial pneumonias is

dependent on age and severity assessment. Local patterns of drug resistance must be considered when choosing appropriate antibiotics. Pneumococcal and mycoplasmal pneumonias present some unique treatment obstacles and may need a multifaceted approach to care, including vaccine antigens and immunoadjuvant therapies.⁹⁷ Treatment of *Mycoplasma pneumoniae* with antibiotics is controversial.⁹⁸ Children should be vaccinated against influenza and pneumococcus.

Aspiration Pneumonitis

Aspiration pneumonitis is caused by a foreign substance, such as meconium, food, secretions (saliva or gastric secretions), or environmental compounds entering the lung and causing inflammation of lung tissue. The aspiration of meconium from amniotic fluid can occur at birth. Meconium contains bile salts and other constituents from the fetal intestinal tract that cause inflammation.⁹⁹ Neurologically compromised children or children with chronic lung disease may have chronic pulmonary aspiration (CPA), which can cause progressive lung disease, bronchiectasis, and respiratory failure. This is the leading cause of death in children who are neurologically compromised because of failure of protective reflexes and difficulty swallowing.^{100,101} Children undergoing sedation or administration of an anesthetic also may aspirate oral secretions contaminated with anaerobic bacteria or stomach contents.

The severity of lung injury after an aspiration incident is determined by the volume of material aspirated, the pH of the aspirated material, and the presence of pathogenic bacteria. Very low pH or very high pH causes a significant inflammatory response. With hydrocarbon ingestions, lung injury is determined by the volatility and viscosity of the aspirated substance. A low-viscosity substance, such as gasoline or lighter fluid, is the most toxic; high-viscosity hydrocarbons, such as petroleum jelly or mineral oil, are much less likely to cause a pneumonitis. Treatment for aspiration pneumonitis depends on the material aspirated but generally can include broad-spectrum antibiotics with failure to improve after 48 hours. Children with CPA and a large amount of upper respiratory tract secretions

may benefit from salivary gland injection with botulinum toxin A (BTX-A) to suppress secretion.¹⁰²

Bronchiolitis Obliterans

Bronchiolitis obliterans (BO) is fibrotic obstruction of the respiratory bronchioles and alveolar ducts secondary to intense inflammation. It is relatively rare in children. Two types are noted in the literature—proliferative and constrictive (obstructive)—with the latter being the more common form. BO most often occurs as a sequela of a severe viral pulmonary infection (e.g., adenovirus [most common], influenza, pertussis [whooping cough], or measles). Other cases may be secondary to parainfluenza, RSV, human immunodeficiency virus (HIV), or *M. pneumoniae* infection. It may occur after allograft transplantation (lung, heart-lung, and bone marrow) as a manifestation of graft-vs.-host disease. BO also is associated with collagen vascular disease, toxic fume inhalation, chronic hypersensitivity pneumonitis, Crohn disease, and Stevens-Johnson syndrome.^{103,104} Cough, respiratory distress, and cyanosis initially occur, followed by a brief period of improvement. The progression of disease is then reflected by increasing tachypnea, sputum production, crackles, wheezing, increased anterior/posterior diameter, and hypoxemia.

There is no specific treatment for BO and, because it is so rare, there have been no randomized clinical trials. Therapeutic options include inhaled corticosteroids, bronchodilators, antibiotics (long-term azithromycin), and oxygen supplementation. Mechanical ventilation may contribute to the progression of the disease. Use of antiviral agents may be warranted in managing those with viral infection. For transplant recipients, augmentation of immunosuppressive therapies without increasing risk for infection and treatment with antiinflammatory agents are showing promise in reducing airway inflammation, thus improving pulmonary function.¹⁰⁵ Clinical progression can be quite variable depending on the predisposing condition. Some children experience partial recovery, whereas others follow a course of steady decline in lung function. Lung

transplantation may be considered.¹⁰⁶

Asthma

Asthma is a chronic inflammatory disease characterized by bronchial hyperreactivity and reversible airflow obstruction, usually in response to an allergen. It is the most prevalent chronic disease in childhood, affecting about 8.4% of U.S. children between birth and 17 years of age, and prevalence is increasing. Populations most affected include black and Puerto Rican children and those below 100% of poverty status.¹⁰⁷

Childhood asthma and its severity result from a complex interaction between *genetic* susceptibility and *environmental* factors. Genetic studies have led to the identification of many candidate genes or chromosomal regions that are associated with asthma.¹⁰⁸ Included in the long list of asthma-associated genes are those that code for increased levels of immune and inflammatory mediators (e.g., IL-4, IL-5, IL-6, IL-13, IgE, and leukotrienes), adrenergic receptors, nitric oxide, and transmembrane proteins in the endoplasmic reticulum.¹⁰⁹ Various genotypes are associated with multiple phenotypes of asthma, including early-onset mild allergic asthma, asthma with severe exacerbations, later-onset asthma associated with obesity, atopic or nonatopic asthma, eosinophilic or noneosinophilic asthma, asthma associated with aspirin sensitivity or insensitivity, and asthma dependent or resistant to corticosteroids. Linking specific genes to specific asthma phenotypes is leading to targeted therapies and personalized approaches to asthma treatment¹¹⁰ (see [What's New? Asthma Phenotypes and Endotypes in Children](#)).

What's New?

Asthma Phenotypes and Endotypes in Children

The severity and clinical course of asthma in children can vary from mild and transient to severe and lifelong. Research is emerging that suggests genetically influenced differences in inflammatory and

immune mechanisms may explain much of this variability. A phenotype is the observable characteristics (i.e., clinical manifestation, cell types, treatment response) of a disease without a link to a specific underlying pathology or pathophysiologic mechanism. Phenotypic heterogeneity in asthma includes the severity of airway obstruction, type of airway immune cells and inflammation, presence of airway remodeling, and response to medication. Inflammatory phenotypes include eosinophilic and neutrophilic asthma. The majority of asthmatic children have the well-described allergic (type I hypersensitivity) phenotype of asthma that is characterized by the presence of high levels of T helper2 (Th2) cytokines (interleukin [IL]-4, IL-5, and IL-13), synthesis of immunoglobulin E (IgE), and activation of eosinophils (therefore also called *eosinophilic asthma*), resulting in episodic bronchospasm that is responsive to inhaled bronchodilators and antiinflammatory medications, including corticosteroids. Children whose asthma phenotype is characterized by more severe symptoms and relative unresponsiveness to treatment with inhaled corticosteroids most often have *neutrophilic asthma*, or nonatopic asthma, in which the presence of Th1 cytokines and activation of large numbers of neutrophils appear to dominate lung injury. Neutrophilic asthma especially involves the cytokines tumor necrosis factor-alpha (TNF- α), interferon-gamma (IFN- γ), leukotriene B₄ (LTB₄), IL-17a, IL-6, and IL-8, and is corticosteroid resistant. *Endotypes* are subgroups that share an underlying disease pathobiology and explain the characteristic of the phenotype. At the molecular level, endotypes describe gene profiles of the airways that affect the development of airway remodeling and the response to treatment. For example, variation in candidate genes is associated with variability of response to leukotriene modifiers, glucocorticoids, inhaled corticosteroids, β_2 -adrenergic receptor agonists and anticholinergics, theophylline, mast cell stabilizers, and monoclonal antibodies to immunoglobulin E. Increased understanding of different asthma phenotypes and underlying endotypes is leading to drugs that target specific molecules and

pathways that may provide significant improvements in personalized management of severe and drug-resistant asthma.

Data from Bostantzoglou C et al: *Breathe (Sheff)* 11(3):186–193, 2015; Desai M, Oppenheimer J: *Ann Allergy Asthma Immunol* 116(5):394–401, 2016; Landgraf-Rauf K, Anselm B, Schaub B: *Mol Cell Pediatr* 3(1):27, 2016; Panettieri RA Jr: *Immunol Allergy Clin North Am* 36(3):569–579, 2016.

Important environmental risk factors include early exposure to allergens (e.g., air pollution, dust mites, molds, cockroach antigen, and tobacco smoke), respiratory tract infections, gastroesophageal reflux, preterm birth, and childhood obesity. Additional confounding variables that affect disparity in asthma morbidity and therapy are social stress in the home (e.g., violence and depressed housing conditions), lack of health insurance, poor access to asthma specialists, inappropriate utilization of healthcare resources, and inadequate medical care.^{111,112} Vitamin D insufficiency may be a risk factor for wheezing in children because vitamin D suppresses Th2-mediated allergic disease, suppresses inflammatory Th17 cells, inhibits IgE expression in B cells, is important for lung development, and suppresses infection.¹¹³ Epigenetic mechanisms of asthma pathogenesis are being evaluated¹¹⁴ (see [What's New? Environmental Air Pollution and Childhood Respiratory Disease](#)). Individual risk factors may overlap and vary in strength of association.¹¹⁵ The *hygiene hypothesis* proposes that infants and children who are exposed to a highly hygienic environment, who receive vaccinations to prevent certain infections, or who are treated with antibiotics lack adequate exposure to common pathogens and therefore do not achieve balanced immune responses as they mature.¹¹⁶ Consequently, this increases their risk for Th2-predominant allergic disease.¹¹⁷ Early exposure to microbial products also may promote a microbiome that promotes Th1 immunity necessary to balance Th2 immune responses.¹¹⁸

◆ Pathophysiology.

The pathophysiology of asthma in children is similar to that for adults

and is described in [Chapter 36](#); see [Asthma](#) under Obstructive Pulmonary Disease). Early-onset allergic asthma is initiated by a type I hypersensitivity reaction primarily mediated by Th2 lymphocytes whose cytokines activate mast cells and eosinophils, increase leukocyte synthesis, and enhance B-cell IgE production (see [Figs. 36.10, 36.11, and 36.12](#)). As in adults, inflammation, bronchospasm, and mucus production in the airways lead both to ventilation-perfusion mismatch with hypoxemia and to expiratory airway obstruction with air trapping and increased work of breathing. In young children, airway obstruction can be more severe because of the smaller diameter of their airways.

◆Clinical Manifestations.

Clinical manifestations of an acute asthma attack include coughing, wheezing, and shortness of breath. Expiratory wheezing is often described as high pitched and musical, along with prolongation of the expiratory phase of the respiratory cycle. Breath sounds may become faint when air movement is poor. The child may speak in clipped sentences or not at all because of dyspnea. Respiratory and heart rates are elevated. Nasal flaring and accessory muscle use are evident, with retractions in the substernal, subcostal, intercostal, suprasternal, or sternocleidomastoid areas. Infants may appear to be “head bobbing” because of sternocleidomastoid muscle use. Pulsus paradoxus (decrease in systolic blood pressure of more than 10 mmHg during inspiration) may be present. The child may appear anxious or diaphoretic, important signs of respiratory compromise. About 70% to 80% of acute wheezing episodes are associated with viral respiratory tract infections.¹¹⁹ As a result, there may be signs of a preceding upper respiratory tract infection, such as rhinorrhea or low-grade fever. The most common of these is RSV in infants and toddlers younger than 2 years of age and rhinovirus in older children.

Findings in chronic asthma may include hyperinflation of the thorax (barrel chest) or pectus excavatum. Clubbing should not be seen in those with asthma and, if present, should trigger evaluation for other conditions, such as cystic fibrosis. Exercise intolerance may

indicate underlying asthma.

◆Evaluation and Treatment.

Currently, asthma cannot be prevented or cured, but it can be controlled. Asthma is often underdiagnosed and untreated, especially in preschool-age children because asthma symptoms overlap with other respiratory illness, such as bronchitis or upper respiratory tract infections. Diagnosis is based on episodes of wheezing, as well as a variety of risk factors including parental history of asthma, atopic dermatitis, sensitization to aeroallergens or foods, blood eosinophilia, increased IgE levels, or wheezing not associated with upper respiratory tract illnesses. The Modified Asthma Predictive Index (mAPI) can be used to help with asthma diagnosis and is recommended by the National Institutes of Health (NIH) guidelines.¹²⁰ Confirmation of the diagnosis of asthma relies on pulmonary function testing using spirometry, which can be accomplished only after the child is 5 to 6 years of age. Characteristic abnormalities of spirometry testing would be reduced expiratory flow rates that are reversible in response to an inhaled bronchodilator. For younger children, an empirical trial of asthma medications is commonly initiated. Many children with less severe asthma outgrow the disease by adulthood and may reflect a particular genetic phenotype of asthma.¹²¹

The goal of asthma therapy is to achieve long-term control by reduction in impairment and risk. Child and family education and appropriate allergen avoidance techniques should begin immediately. Care providers must periodically assess asthma control in children. Key features for assessment include nighttime awakenings, interference with normal activities, use of short-acting beta₂ agonists, pulmonary function testing, and exacerbations requiring corticosteroids. Peak flowmeters are often used to help guide treatment. Before therapy is augmented, care providers need to assess medication administration techniques, environmental controls, and comorbidities. Stepwise reduction in therapy can begin after the child's asthma has been well controlled for a minimum of 3 months.¹²⁰

The pharmacologic treatment of asthma in children is essentially the

same as that for adults and is initiated in a stepwise sequence based on asthma severity and response to treatment (see [Chapter 36](#)). Management of asthma medications in children is often difficult because there is commonly fluctuation in severity of symptoms.

Acute Lung Injury/Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) occurs in children of all ages and is a dramatic, life-threatening condition resulting from a direct acute lung injury (ALI), such as pneumonia, aspiration, near drowning, or smoke inhalation; or from a systemic insult, such as sepsis or multiple trauma. ALI activates an inflammatory response that causes alveolocapillary injury and results in ARDS. ARDS accounts for approximately 10% of total admissions to pediatric intensive care units. Mortality in pediatric ARDS varies from 18% to 35%.¹²²

◆Pathophysiology.

The pathophysiology of ARDS in children is the same as that described for adults in [Chapter 36](#) (see [Acute Lung Injury/Acute Respiratory Distress Syndrome](#) in [Chapter 36](#) and also see [Fig. 36.8](#)).

◆Clinical Manifestations.

The Pediatric Acute Lung Injury Consensus Conference¹²³ has developed a definition for pediatric ARDS (pARDS) that has some different elements than the definition for adults:

1. All pediatric age groups are affected from the neonatal period through adolescence. Perinatal causes of acute hypoxemia are excluded (i.e., lung disease related to prematurity, perinatal lung injury [meconium aspiration syndrome, pneumonia, and sepsis acquired during delivery], and congenital abnormalities [congenital diaphragmatic hernia or alveolar capillary dysplasia]).

2. Onset of hypoxemia and radiologic changes occur within 7 days after a known clinical insult.
3. Chest radiographs show new infiltrates (either unilateral or bilateral) consistent with parenchymal lung disease.
4. Children with left ventricular dysfunction presenting with acute-onset hypoxemia and new changes on chest radiographs not explained by left ventricular failure or fluid overload and who meet all other pARDS criteria are included in the definition.
5. The degree of hypoxemia used to define the severity of pARDS uses the oxygenation index (OI) ($OI = \text{mean airway pressure} [M_{PAW}] \times FiO_2 / PaO_2$) rather than the PaO_2 / FiO_2 ratio (recommended in the Berlin consensus for adults). In the event that the PaO_2 is unavailable, the oxygen saturation index ($OSI = MAP \times FiO_2 / SatO_2$) can be used under the same conditions proposed for the OI.

Initially, hyperventilation occurs but CO_2 retention may ultimately develop because of inadequate functional air space, atelectasis, decreased pulmonary compliance, and respiratory muscle fatigue. The severity of the overall picture is modified by comorbid factors, such as the presence of sepsis or multisystem organ failure, and the development of complications, such as nosocomial pneumonia. More research is needed regarding the long-term outcomes of pediatric ARDS.¹²²

◆ Evaluation and Treatment.

ARDS in older children and adolescents is similar to that in adults. However, infants have more compliant chest walls, lower hematocrit levels, higher baseline airway resistance, and lower functional residual capacity. The maturing lung may be at greater risk for ventilator-induced lung injury.¹²⁴ These factors have implications for management strategies that are different than those for older children and adolescents. Few randomized controlled trials have been completed to guide the clinical management of ALI/ARDS in infants

and very young children.

Treatment of ARDS remains supportive in nature, including maintenance of fluid balance and nutrition. The goals of therapy are to maintain adequate tissue oxygenation, minimize acute lung injury, and avoid iatrogenic pulmonary complications. Most children with ARDS require mechanical ventilation and relatively high levels of positive end-expiratory pressure (PEEP) to promote alveolar ventilation and stabilization, and redistribution of alveolar edema fluid into the interstitium. Lung-protective ventilation strategies may include low tidal volumes, permissive hypercapnia, permissive hypoxemia to prevent oxygen toxicity, and airway pressure release ventilation. Use of corticosteroids in children with ARDS is controversial. One study reported fewer ventilator-free days and longer duration of ventilation in survivors.¹²⁵ Extracorporeal membrane oxygenation (ECMO) is used for reversible causes of pediatric ARDS and considers quality of life.¹²⁶

Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive inherited disease that results from defective epithelial chloride ion transport. The CF gene is located on chromosome 7. More than 2000 different variants of this gene are known to produce CF.¹²⁷ They are divided into six classes with varying severity of disease expression. Classes 1 through 3 are associated with more severe disease and classes 4 through 6 with milder pulmonary disease (generally pancreatic sufficient). Mortality correlates respectively with the aforementioned classes, and therapy is currently being directed at specific gene classes.¹²⁸

The incidence varies by race and is higher in whites.¹²⁹ Approximately 28,680 individuals in the United States and 70,000 worldwide manifest the disease. In the United States approximately 853 new cases of CF were diagnosed in 2015; the median age at diagnosis was 4 months and more than half of the CF population was age 18 years or older. The median predicted age at death was 30.1 years.^{129,130}

◆Pathophysiology.

CF is a multiorgan disease that affects the airways, digestive tract, and reproductive organs (see [Table 43.1](#)). The *cystic fibrosis transmembrane conductance regulator (CFTR) gene* mutation results in the abnormal expression of **cystic fibrosis transmembrane conductance regulator (CFTR) protein**. There are many *CFTR* variants and they are grouped into six classes. The most common mutation is called *F508delCFTR*. The CFTR protein is an activated chloride channel present on the surface of many types of epithelial cells, including those lining airways, bile ducts, the pancreas, sweat ducts, paranasal sinuses, and the vas deferens. The most important effects are on the lungs, and respiratory failure is almost always the cause of death. The typical features of CF lung disease are mucus plugging, chronic inflammation, and chronic infection of the small airways. The mucus plugging results from increased production of mucus from increased numbers and size of goblet cells, altered physicochemical properties of the mucus, and impaired mucociliary clearance. CF mucus is dehydrated and viscous because of defective chloride secretion and excess sodium absorption. The periciliary fluid layer is depleted in volume, impairing the mobility of the cilia and, thereby, allowing mucus to adhere to the airway epithelium along with bacteria and injurious byproducts from neutrophils. Neutrophils are present in great excess in the airways and release damaging oxidants and proteases (e.g., elastase) that cause direct damage to lung structural proteins, resulting in remodeling of the airway and, ultimately, development of bronchiectasis. Neutrophils promote inflammation and induce airway cells to produce interleukin-8 (IL-8), which attracts more neutrophils and stimulates mucus secretion, and destroys immunoglobulin G (IgG) and complement components important for opsonization and phagocytosis of pathogens.¹³¹ Bacteria then form biofilms promoting chronic endobronchial infection. Progressive bronchiectasis becomes widespread. Parenchymal involvement occurs much later and includes microabscess formation, patchy consolidation and pneumonia, peribronchial fibrosis, and cyst formation ([Fig. 37.14](#)). The pathophysiology for these changes is outlined in [Fig. 37.15](#).

Airway obstruction and weakening of the airway wall can lead to the development of peripheral bullae, which may rupture and cause pneumothorax. Hemoptysis, sometimes life-threatening, may occur because of erosion of enlarged bronchial arteries that develop in response to the inflammation associated with bronchiectasis. Over a long period of time, pulmonary vascular remodeling occurs because of localized hypoxia and arteriolar vasoconstriction; pulmonary hypertension and cor pulmonale may develop with end-stage disease.

FIGURE 37.14 Pathology of the Lung in End-Stage Cystic Fibrosis. Key features are widespread mucus impaction of airways and bronchiectasis (especially in upper lobe, *U*), with hemorrhagic pneumonia in the lower lobe (*L*). Small cysts (*C*) are present at the apex of the lung. (From Kleinerman J, Vauthy P: *Pathology of the lung in cystic fibrosis*, Atlanta, 1976, Cystic Fibrosis Foundation.)

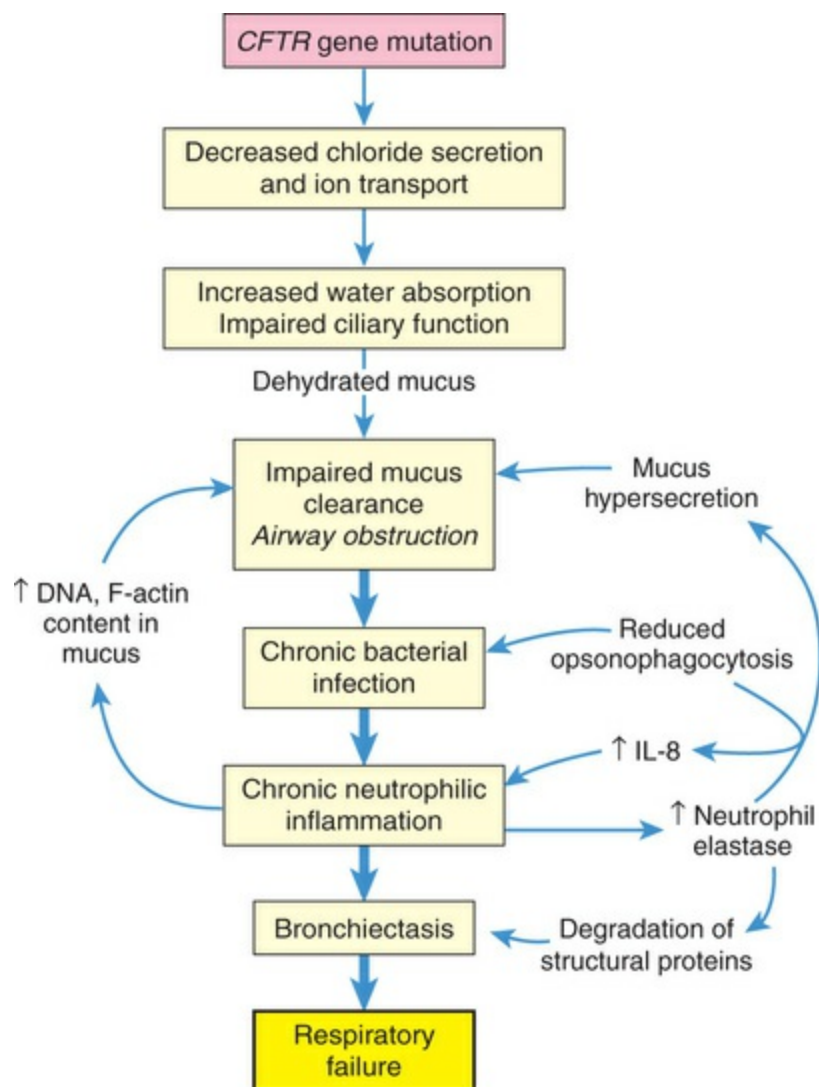

FIGURE 37.15 Pathogenesis of Cystic Fibrosis Lung Disease. *CFTR*, Cystic fibrosis transmembrane conductance regulator; *IL-8*, interleukin-8.

◆Clinical Manifestations.

The most common manifestations involve the respiratory and gastrointestinal systems (see [Chapter 43](#)). Respiratory symptoms include persistent cough or wheeze, excessive sputum production, and recurrent or severe pneumonia. More subtle respiratory tract presentations of CF include chronic sinusitis and nasal polyps. Digital clubbing may appear quite early even in the absence of significant

pulmonary impairment. Development of barrel chest or persistent crackles occurs much later in the course of the disease.

The overall severity of CF lung disease is highly variable. Even affected siblings may have disparate courses and different clinical phenotypes despite identical *CFTR* mutations, environment, and treatment strategy. The *CFTR* genotype is expressed differently in epithelial cells of different organs (airways, sinuses, gastrointestinal [GI] tract, pancreas, biliary system, sweat glands, and genitourinary system), and results in phenotypic variation in clinical manifestations with influences on disease progression and survival.¹³²

◆ Evaluation and Treatment.

According to the Cystic Fibrosis Foundation, guidelines for the diagnosis of CF include one or more clinical features, history of CF in a sibling, or a positive newborn screen plus laboratory evidence of an abnormality in the *CFTR* gene or protein. The standard laboratory methods of diagnosis (screening) are the immunoreactive trypsinogen (IRT) blood test and the sweat chloride test, which reveal sweat chloride concentration in excess of 60 mEq/L. Alternative or supplemental methods include genotyping for *CFTR* mutations. Newborn screening for CF is universal in the United States.¹³³ Genetic counseling of CF gene carriers is important so they understand risk assessment in relation to disease.¹³⁴

Treatment is primarily focused on pulmonary health and nutrition. Because the pulmonary decline in CF is slow and insidious, and because of the early onset of chronic inflammation and infection, treatment strategies begin immediately at diagnosis and are modified over time as disease progresses. Pulmonary therapies include techniques to promote mucus clearance, such as chest physical therapy and related mechanical devices (such as the high-frequency chest wall oscillation vest) and an assortment of hand-held positive expiratory pressure (PEP) devices. Aerosol therapy includes bronchodilators, dornase alfa, and hypertonic saline, which liquefy mucus.^{133,135} Different classes of antibiotics and routes of administration (oral, inhaled, and intravenous) are used to treat

different pathogens (e.g., *Pseudomonas aeruginosa*, *S. aureus*, *Burkholderia cepacia* nontuberculous mycobacteria) and to overcome antibiotic resistance.^{136,137} Targeted therapy with oral *CFTR* modulators is available to treat specific *CFTR* mutation dysfunction. Ivacaftor has been approved in the United States, Canada, Australia, and the European Union for individuals 2 years of age and older for the *G551D CFTR* gating mutation. The corrector–potentiator pair lumacaftor–ivacaftor has been approved in the United States for individuals 12 years of age and older who are homozygous for the *CFTR* mutation *F508del* (34% of the U.S. CF population). The drugs are effective in the lung, GI tract, and sweat glands but are very expensive. Further research is in progress to target the other common genotypes.^{138,139} Recombinant human growth hormone has been shown to improve lung function, height, and weight in children with severe CF.¹⁴⁰ Azithromycin, ibuprofen, and corticosteroids can reduce airway inflammation and improve lung function. New antiinflammatory drugs are under investigation.¹⁴¹ Individuals with end-stage lung disease may consider lung transplantation.¹⁴²

Nutritional problems are extremely common in CF, and poor nutrition is correlated with worse outcomes including progression of lung disease; onset of additional complications, such as decreased bone mineral density; and growth failure. Elements of aggressive nutritional support include meticulous monitoring of growth parameters, controlling fat malabsorption, maintaining adequate protein and caloric intake, and keeping overall health stable. Approximately 90% of children with CF have pancreatic insufficiency. This is the result of abnormal ion transport causing decreased fluid and bicarbonate secretion from the pancreatic acinar cells, which leads to thickened secretions plugging the smaller pancreatic ducts, and eventual autodigestion or atrophy of the acinar cells. Therefore, individuals must take exogenous pancreatic enzymes with meals and snacks in order to absorb nutrients and control malabsorptive symptoms (see *Nutrition & Disease: Cystic Fibrosis [CF]*).¹⁴³ Diabetes mellitus can develop as a secondary complication of pancreatic involvement.¹⁴⁴

Nutrition & Disease

Cystic Fibrosis (CF)

Chronic inflammation, increased work of breathing, reduced nutrient absorption from pancreatic enzyme deficiency, and inadequate nutrient intake contribute to growth failure, poor clinical outcomes, and reduced life expectancy in CF. Adequate nutritional status is achieved when the weight-for-length value is greater than the 50th percentile in children younger than 2 years of age and the body mass index (BMI) is greater than the 50th percentile in children older than 2 years. Assessment of free fat mass assists evaluation of nutritional status. Energy requirements needed to meet normal growth and weight gain in children with CF necessitate a diet composed of 35% to 40% of calories from fat. Breast-feeding for the first 4 to 6 months has shown to be protective for the infant with CF, and then supplemental formula fortified with additional fat increases energy content. Oral pancreatic enzyme replacement is important in maintaining adequate nutritional status, particularly for fat absorption. The Food and Drug Administration now requires approval for the marketing of these products. Selection of dose and preparations is based on weight gain and individual response. High doses of lipase can be associated with fibrosing colonopathy, and new products are being tested in clinical trials. Fecal pancreatic elastase-1 is a common diagnostic test for evaluating pancreatic insufficiency. Yearly monitoring of fat-soluble vitamins (A, D, E, and K) is recommended with supplementation as needed. Vitamin D supplements are needed to maintain minimum serum concentrations at 30 ng/mL. Enteral feedings should be considered when weight gain and growth are inadequate. Current recommendations are to follow the Cystic Fibrosis Foundation nutrition care guidelines available at www.cff.org/treatments/CFCareGuidelines/Nutrition/. The management of CF-related diabetes mellitus is a particular challenge and occurs in up to 30% of CF individuals who are 18

years and older. Guidelines have been published by the American Diabetes Association. Nutritional guidelines and counseling are a necessary component of care for all individuals with CF.

Data from Lusman S, Sullivan J: *Pediatr Clin North Am* 63(4):661–678, 2016; Solomon M, Bozic M, Mascarenhas MR: *Clin Chest Med* 37(1):97–107, 2016; Wolfe SP, Collins C: *J Cyst Fibros* 16(4):436–438, 2017.

There is a growing contingent of adults with CF living into their forties and fifties. Care for these individuals shifts away from a pediatric focus because their care needs are unique and often extremely complex. Pregnancy also has become possible with advances in in vitro fertilization for men and women with fertility problems.¹⁴⁵

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS)/sudden unexpected infant death remains a disease of unknown cause and is the most common cause of unexplained infant death in Western countries.^{146,147} It is defined as “sudden death of an infant under 1 year of age which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history.”¹⁴⁸

The incidence of SIDS is low during the first month of life but sharply increases in the second month of life, peaks at 2 to 4 months of age, and is unusual after 6 months of age. In 2014 about 3500 infants died a sudden unexpected death in the United States, of which 1500 were attributed to SIDS (44%). Other causes were accidental suffocation and strangulation in bed (25%) and unknown (31%). SIDS is more common among non-Hispanic blacks and American Indian/Alaskan Natives.¹⁴⁹ It almost always occurs during nighttime sleep, when infants are least likely to be observed. A seasonal variation has been noted, with higher frequencies during the winter months. This has been related to a higher rate of respiratory tract

infection during those months, and such infections are often reported to have preceded the death. The sleeping room also may be overheated or the infant overwrapped.

Clinical risk groups are summarized in [Box 37.3](#). About 75% of all SIDS victims have no known predisposing clinical risk factor. Epidemiologic studies have shown that SIDS rates decreased where massive public campaigns warned against prone sleeping for infants (e.g., the Back-to-Sleep Campaign).¹⁵⁰

Box 37.3

Sudden Infant Death Syndrome (SIDS)

- Prone and side-lying sleeping positions
- Sleeping on soft bedding
- Overheated sleeping environment
- Lower socioeconomic status
- Mothers younger than 20
- Mothers with less education
- Native American, Alaskan Native, Non-Hispanic blacks
- Low birth weight or growth-restricted infants
- Viral respiratory tract infection
- Male infants
- Preterm delivery
- Multiple gestations
- Sibling who died of SIDS
- Substance abuse during pregnancy (smoking, illicit drugs, alcohol)
- Exposure to tobacco smoke
- Lack of prenatal care
- Larger family size
- Polymorphism serotonin transporter gene (affects autonomic

nervous system)

Data from Carlin RF, Moon RY: *JAMA Pediatr* 171(2):175-180, 2017; Jhun I et al: *Epidemiology* 2017 Jun 28 [Epub ahead of print]; Moon RY: *Pediatrics* 138(5), 2016.

The etiology of SIDS remains unknown, but probably involves a combination of predisposing factors including a vulnerable infant in a critical developmental period for homeostatic control with altered cardiorespiratory, circulatory, and arousal characteristics, and environmental stressors (e.g., prone or side-resting position, soft bedding, or in utero or environmental tobacco exposure). There has been long-standing interest in hypotheses involving impaired autonomic regulation and failure of cardiovascular, ventilatory, and arousal responses.^{151,152} Other theories involve immune dysregulation, airway inflammation, and responses to either bacterial pathogens from the nasopharynx or viral respiratory tract infections.¹⁵³ Finally, there is growing evidence that genetic factors may predispose certain individuals to SIDS. The most important risk factor genes include those involved in the regulation of the immune system and inflammation, cardiac function, and brainstem function.^{152,154,155}

Currently, the best strategy to reduce SIDS and sudden unexpected infant death occurring during sleep is avoidance of risk factors as described by the American Academy of Pediatrics.¹⁵⁶ Breast-feeding has been identified as a specific risk reduction measure. Parents of infants with clinical risk should be taught cardiopulmonary resuscitation as a precaution. Some infants at risk for episodes of apnea and bradycardia may warrant cardiorespiratory monitoring after careful consideration of the individual situation.¹⁵⁷

Summary Review

Structure and Function

1. The airways of infants and children are narrower than those of

- adults, thus making them more prone to obstruction.
2. Infants and young children continue to form new alveoli for several years after birth.
 3. Surfactant production is an important marker of developmental maturity of the fetal lung and is secreted into the airways by 30 weeks' gestation.
 4. The immature chest wall is soft and compliant, contributing to inefficient mechanisms of breathing.
 5. Children have greater oxygen consumption than adults per unit of body weight.
 6. Immune mechanisms are not fully developed at birth, making young infants more susceptible to infection.
 7. Newborns have a blunted ventilatory response to hypoxia compared with older children and adults, increasing their risk for apnea and hypoxemia.
 8. Neonatal exposure to air pollution increases the risk for respiratory disease.

Disorders of the Upper Airways

1. Physical examination can provide important clues in assessing the location and nature of UAO and stridor.
2. Upper airway infections can pose serious threats because of inflammatory edema and airway obstruction, including bacterial tracheitis, retropharyngeal abscess, and peritonsillar infections. Recognition and rapid evaluation are crucial.
3. Viral croup (laryngotracheobronchitis) is the most common cause of acute upper airway inflammatory obstruction in children ages 6 months to 5 years. Subglottic edema may be mild to severe. Parainfluenza is the most common cause.
4. Acute epiglottitis is a life-threatening emergency that is now rarely seen because of vaccination against *H. influenzae*, which had been the primary causative microorganism. Current cases usually represent vaccine failure or are caused by other bacteria, such as group A streptococci.

5. Tonsillar infections may be severe enough to cause UAO, and they are treated with appropriate antibiotics and corticosteroids. Complications can include tonsillar abscess.
6. Bacterial tracheitis causes airway edema and copious purulent secretions with UAO and requires administration of antibiotics and maintenance of the airway.
7. Retropharyngeal abscess is associated with nasopharyngeal infection or penetrating local injury and requires immediate antibiotic treatment.
8. Aspiration of a foreign body should be considered whenever there is a sudden onset of stridor, coughing, wheezing, or hoarseness. This usually occurs in children ages 1 to 3 years. Occasionally diagnosis is delayed and symptoms may be attributed to asthma, bronchitis, or pneumonia without recognition of the underlying cause.
9. Angioedema is a mast cell–mediated allergy to certain foods, causing edema of mucous membranes or subcutaneous layers of the skin; it can result in mucosal swelling and airway obstruction.
10. Chronic UAO may be manifested by stridor, abnormal cry, wheezing, or dyspnea. Causes of stridor in infants include laryngomalacia, tracheomalacia, subglottic stenosis, laryngeal atresias, tracheal stenosis, vocal cord paralysis, and vascular rings.
11. Obstructive sleep apnea syndrome usually occurs in older children rather than infants and is underdiagnosed. Typical symptoms are related to airway narrowing and include snoring, gasping, and restless sleep. OSAS is associated with airway narrowing and increased upper airway collapsibility. Adenotonsillar hypertrophy, gastroesophageal reflux, obesity, and craniofacial anomalies are common causes of OSAS.

Disorders of the Lower Airways

1. SDD (RDS) of the newborn usually occurs in premature infants

- who are born before surfactant production and alveolocapillary development are complete. Atelectasis and hypoventilation cause shunting, hypoxemia, and hypercapnia.
2. BPD is a chronic lung disease of infancy that is usually the consequence of acute respiratory disease in premature infants who required oxygen and positive pressure ventilatory support. Contributing factors include structural immaturity, inflammation, and disordered lung repair processes.
 3. Bronchiolitis occurs in infants and toddlers, usually in the winter and early spring. It is caused by viruses, most commonly RSV. There is extensive edema, inflammation, and damage to the bronchiolar epithelium with airway obstruction and wheezing. Injection of monoclonal antibody against RSV or immunotherapy is recommended as a preventive measure for high-risk infants.
 4. Childhood pneumonia is infection and inflammation in the terminal airways and alveoli usually caused by community-acquired viruses (most common), bacteria, or *Mycoplasma*. Lobar pneumonia is usually bacterial. Certain bacteria, such as *S. aureus* and group A streptococci, can cause particularly fulminant disease, as well as abscesses and empyema.
 5. Aspiration pneumonitis can occur because of lung inflammation from entry of any foreign substance, including food, drink, or chemicals. Aspiration of oropharyngeal bacteria can occur because of loss of protective reflexes in neurologically impaired children, or during induction of anesthesia.
 6. Bronchiolitis obliterans is fibrotic obstruction of the respiratory bronchioles and alveolar ducts usually secondary to severe respiratory viral infection or graft-versus-host disease after allograft transplantation. It is rare in children.
 7. Asthma is a chronic inflammatory disease characterized by bronchial hyperreactivity and reversible airflow obstruction; it usually occurs in response to an allergen and has episodes of acute respiratory symptoms (cough, wheeze, dyspnea) and

intermittent or chronic subacute symptoms. It is the most common chronic condition in children and results from genetic susceptibility and environmental factors with varying phenotypes. Environmental triggers cause inflammatory cell infiltration, mucosal edema, mucus plugging of airways, and epithelial damage with obstruction to airflow and long-term remodeling of airways.

8. ARDS is an acute life-threatening condition characterized by severe hypoxemia, poor lung compliance, atelectasis, and diffuse densities on chest radiographs. It can be triggered by direct acute lung injury (ALI), such as pneumonia, aspiration, near drowning, or smoke inhalation; or from a systemic insult, such as sepsis or multiple trauma. High-level ventilatory support is required, and mortality is significant.
9. CF is an autosomal recessive disease caused by the *cystic fibrosis transmembrane conductance regulator (CFTCR)* gene mutation. Defective chloride secretion and excess sodium absorption cause production of thick, tenacious mucus, plugging of airways, chronic pulmonary infection, and bronchiectasis related to airway epithelial chloride and sodium transport. The other major manifestations are digestive and nutritional, related to pancreatic insufficiency.

Sudden Infant Death Syndrome

1. SIDS is a diagnosis of exclusion after thorough investigation and autopsy following sudden death of an infant younger than 1 year of age. Usually the event occurs during nighttime sleep.
2. The cause is unknown. However, some known risk factors are avoidable, such as maternal smoking, prone sleeping, using soft bedding surfaces, and overheating of the infant. The incidence of SIDS has decreased significantly since public health campaigns have encouraged the supine sleeping position for babies.

The primary function of the kidney is to maintain a stable internal environment for optimal cell and tissue metabolism. The kidneys accomplish these life-sustaining tasks by balancing solute and water transport, excreting metabolic waste products, conserving nutrients, and regulating acids and bases. The kidney also has an endocrine function, secreting the hormones renin, erythropoietin, and 1,25-dihydroxy-vitamin D₃ for regulation of blood pressure, erythrocyte production, and calcium metabolism, respectively. The kidney also can synthesize glucose from amino acids, performing the process of gluconeogenesis (see [What's New? The Kidney and Glucose Regulation](#)). The formation of urine is achieved through the processes of glomerular filtration, tubular reabsorption, and secretion within the kidney. The bladder stores the urine that it receives from the kidney by way of the ureters. Urine is then removed from the body through the urethra.

What's New?

The Kidney and Glucose Regulation

The human kidney contributes to the regulation of glucose concentration by making glucose through gluconeogenesis, by taking up glucose from the circulation, and by reabsorbing glucose from the glomerular filtrate. The human liver and kidneys release approximately equal amounts of glucose through gluconeogenesis in the postabsorptive state (4 to 12 hours after meal ingestion). Other tissues lack the enzyme necessary for gluconeogenesis (glucose-6-phosphatase) and cannot participate in gluconeogenesis. In the postprandial state (up to 4 hours after meal ingestion), although overall endogenous glucose release decreases substantially, renal gluconeogenesis accounts for 40% of glucose formed by gluconeogenesis.

About 180 grams of glucose are normally filtered each day by the kidneys. Almost all of this is actively reabsorbed by means of sodium-glucose cotransporter 2 (SGLT2), a transmembrane protein

expressed in the luminal border of the proximal tubule. This ensures sufficient energy is available during fasting periods. When plasma glucose concentrations exceed a threshold, the SGLT2 becomes saturated and glucose appears in the urine. Individuals with diabetes mellitus have an increased transport maximum (T_m) for glucose from enhanced expression of SGLT2 and this contributes to hyperglycemia when there is poor glucose control. SGLT2 inhibitors are used for reducing hyperglycemia associated with diabetes mellitus.

Renal glucose release is stimulated by epinephrine and is inhibited by insulin. Insulin suppresses glucose release in both the liver and the kidney. The kidneys do not synthesize glycogen and, therefore, do not release glucose through glycogenolysis. In the postabsorptive state, the kidneys utilize about 10% of all glucose used by the body. When there is hypoglycemia, the liver initially releases glucose through glycogenolysis and then increases gluconeogenesis. The kidney also counter-regulates hypoglycemia through gluconeogenesis, which may explain in part why individuals with renal failure tend to develop hypoglycemia.

Data from Solini A: *Acta Diabetol* 53(6):863-870, 2016; Moen MF, et al: *Clin J Am Soc Nephrol* 4(6):1121-1127, 2009; White JR Jr: *Med Clin North Am* 2015 99(1):131-143, 2015.

Structures of the Renal System

Structures of the Kidney

The **kidneys** are paired organs located in the posterior region of the abdominal cavity behind the peritoneum ([Fig. 38.1](#)). They lie on either side of the vertebral column with their upper and lower poles extending from approximately the twelfth thoracic to the third lumbar vertebrae. The right kidney is slightly lower than the left and is displaced downward by the overlying liver. Each kidney is approximately 11 cm long, 5 to 6 cm wide, and 3 to 4 cm thick. A tightly adhering capsule (the **renal capsule**) surrounds each kidney,

and the kidney then is embedded in a mass of fat. The capsule and fatty layer are covered with a double layer of **renal fascia**, composed of fibrous tissue that attaches the kidney to the posterior abdominal wall.

FIGURE 38.1 Organs of the Urinary System. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

The cushion of fat and the position of the kidney between the abdominal organs and muscles of the back protect it from trauma. The **hilum** is a medial indentation in the kidney and is the location of the entry and exit for the renal blood vessels, nerves, lymphatic vessels, and ureter.

The structures of the kidney are summarized in [Fig. 38.2](#). The outer layer of the kidney is called the **cortex** and contains all of the glomeruli, most of the proximal tubules, and some segments of the distal tubule. The **medulla** forms the inner part of the kidney and consists of regions called the **pyramids**. **Renal columns** are an extension of the cortex and lie between the pyramids and extend to the renal pelvis. The apexes of the pyramids project into **minor calyces** (cup-shaped cavities) that unite to form **major calyces**. The

minor calyces receive urine from the collecting ducts through the renal papilla. The major calyces join to form the **renal pelvis**, which connects with the proximal end of the ureter. The walls of the calyces, pelvis, and ureter are lined with epithelial cells and contain smooth muscle cells that contract to move urine to the bladder. The structural unit of the kidney is the lobe. Each lobe is composed of a pyramid and the overlying cortex. On average, there are 14 lobes in each kidney.

FIGURE 38.2 Kidney Structure. (From Solomon E: *Introduction to human anatomy and physiology*, ed 4, St Louis, 2016, Saunders.)

Nephron

The **nephron** is the functional unit of the kidney. Each kidney contains approximately 1.2 million nephrons. The nephron is a tubular structure with subunits that include the renal corpuscle, proximal convoluted tubule, loop of Henle (nephron ansa), distal convoluted tubule, and collecting duct, all of which contribute to the formation of urine (Fig. 38.3). The different epithelial cells lining various segments

of the tubule facilitate the special functions of reabsorption and secretion (Fig. 38.4).

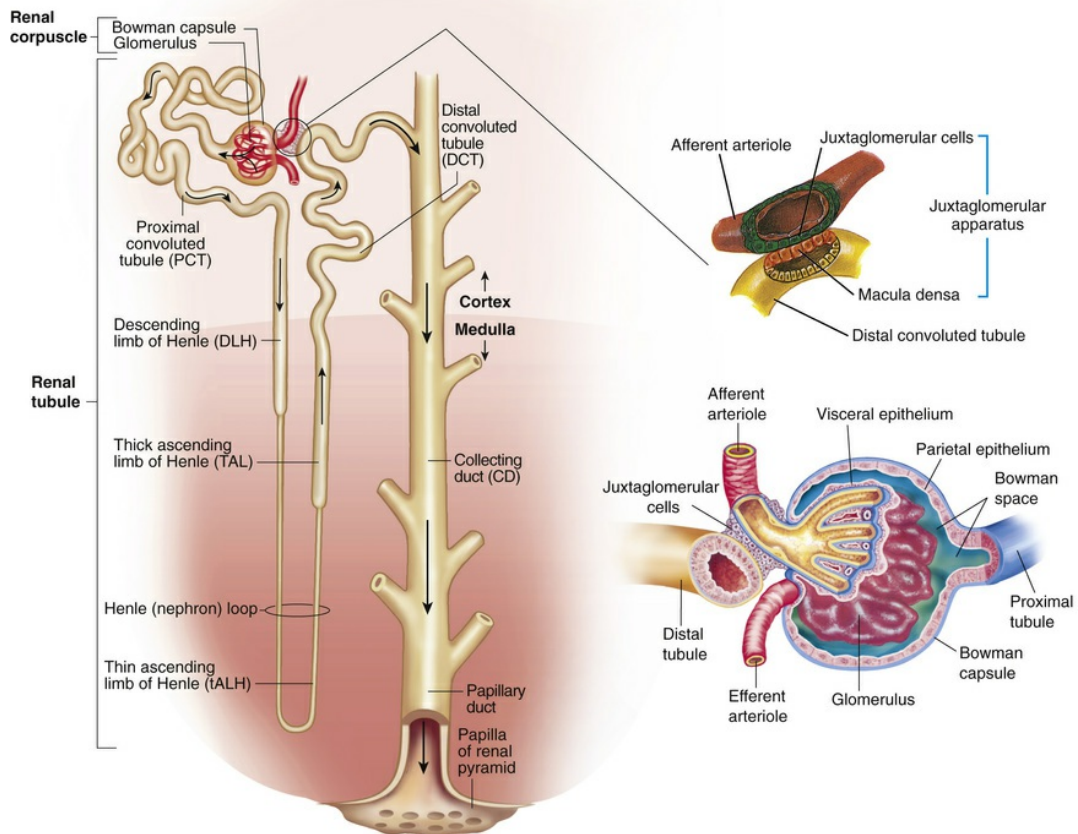

FIGURE 38.3 Components of the Nephron. (From Patton KT, Thibodeau GA, Dougllass MM: *Essentials of anatomy & physiology*, St Louis, 2012, Mosby; Damjanov I: *Pathology for health professions*, ed 4, St Louis, 2012, Mosby.)

FIGURE 38.4 Epithelial Cells of the Various Segments of Nephron Tubules. The brush border and high number of mitochondria in the cells of the proximal convoluted tubule permit reabsorption of 60% of the glomerular filtrate. *Intercalated cells* (blue text) secrete either H^+ (reabsorb HCO_3^-) or HCO_3^- and reabsorb K^+ . *Principal cells* (magenta text) reabsorb Na^+ and water and secrete K^+ .

The kidney has three kinds of nephrons: (1) **superficial cortical nephrons** (85% of all nephrons), which extend partially into the medulla; (2) **midcortical nephrons** with short or long loops; and (3) **juxtamedullary nephrons**, which lie close to and extend deep into the medulla and are important for the concentration of urine (Fig. 38.5). The **glomerulus** (Fig. 38.6; see also Fig. 38.3) is a tuft of capillaries that loop into the circular Bowman capsule, like fingers pushed into bread dough. **Bowman capsule** is composed of a **visceral epithelium** (visceral layer) forming podocytes. The visceral epithelium is reflected back at the vascular pole to become the outer **parietal epithelium** (parietal layer) (see Fig. 38.3). **Mesangial cells** (shaped

like smooth muscle cells) and the **mesangial matrix** (a type of connective tissue), secreted by mesangial cells, lie between and support the glomerular capillaries. Different mesangial cells contract like smooth muscle cells to regulate glomerular capillary blood flow. They also have phagocytic properties similar to monocytes and release inflammatory cytokines and growth factors.¹ Together, the glomerulus, Bowman capsule, and mesangial cells are called the **renal corpuscle**.

FIGURE 38.5 The Nephron Unit with Its Blood Vessels. Blood flows through nephron vessels as follows: interlobular artery, afferent arteriole, glomerulus, efferent arteriole, peritubular capillaries (around the tubules), venules, interlobular vein. (From Patton KT, Thibodeau GA, Douglass MM:

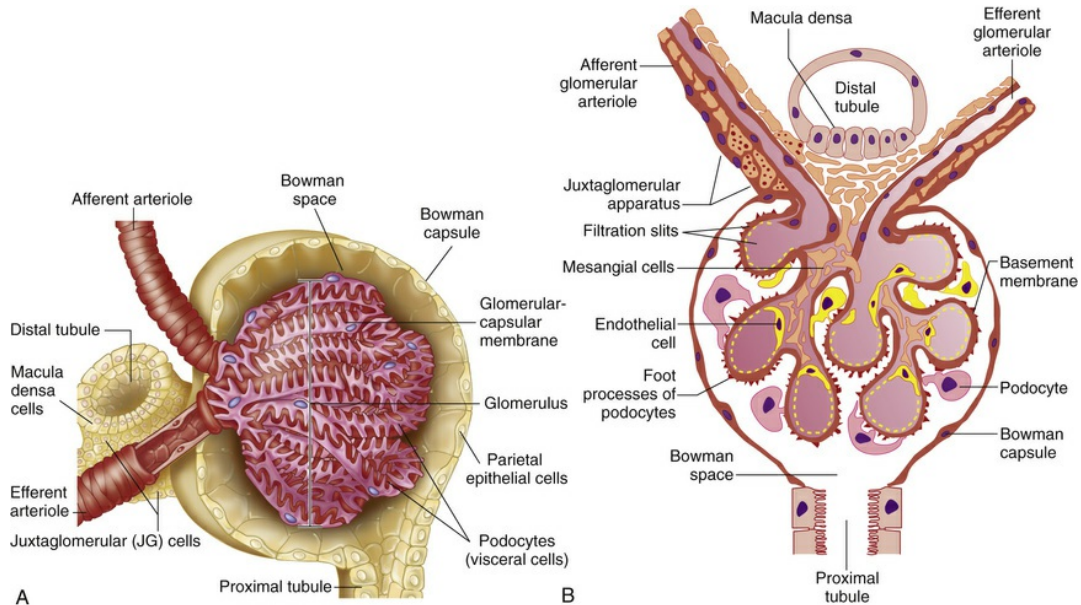

FIGURE 38.6 Anatomy of the Glomerulus and Juxtaglomerular Apparatus. **A**, Longitudinal cross section of glomerulus and juxtaglomerular apparatus. **B**, Longitudinal cross section illustrating detail of glomerular structures. (B from Goldman L, Schafer AI: *Goldman-Cecil medicine*, ed 25, Philadelphia, 2016, Elsevier.)

The **glomerular filtration membrane** filters blood components through its three layers: (1) an inner capillary endothelium; (2) a middle glomerular basement membrane (GBM); and (3) an outer layer, the visceral epithelium, which forms the inner layer of Bowman capsule (Fig. 38.7; see also Fig. 38.6). The capillary endothelium is composed of cells in continuous contact with the basement membrane and contains pores. The pores are maintained by vascular epithelial growth factor (VEGF) produced by the visceral epithelium. The endothelial cells synthesize nitric oxide (a vasodilator) and endothelin-1 (a vasoconstrictor) that help regulate glomerular blood flow. The middle basement membrane is composed of a selectively permeable network of proteoglycans (type IV collagen) secreted and maintained by the epithelial cells.² The visceral epithelium is composed of specialized cells called **podocytes** from which pedicles (foot projections) radiate and adhere to the basement membrane. The

pedicles of one podocyte interlock with the pedicles of adjacent podocytes, forming an elaborate network of intercellular clefts (**filtration slits** or **slit membranes**) (see [Fig. 38.7](#)) and modulate filtration. *Nephrin*, *podocin*, *CD2-associated protein*, and other transcellular protein molecules ensure proper function of the filtration slits and, when altered, cause glomerular disease.³

FIGURE 38.7 Glomerular Capillary. A, Scanning electron micrograph of normal glomerular capillary (C). B, Glomerular capillary wall (filtration membrane) ($\times 40,000$). Black arrow indicates direction of urine flow. (From Kissane JM, editor: *Anderson's pathology*, ed 9, St Louis, 1990, Mosby.)

The space between the visceral and parietal epithelia is the **Bowman space (urinary space)**, which is continuous with the lumen of the renal tubules. The endothelium, basement membrane, and podocytes are covered with protein molecules bearing anionic (negative) charges that retard the filtration of anionic proteins and prevent proteinuria. The glomerular filtration membrane separates the blood of the glomerular capillaries from the fluid in Bowman space and allows all components of the blood to be filtered, with the exception of blood cells and plasma proteins with a molecular weight greater than 70,000. The glomerular filtrate passes through the three layers of the glomerular membrane and forms the primary urine.

The glomerulus is supplied by the afferent arteriole and drained by the efferent arteriole. A group of specialized cells known as **juxtaglomerular cells** (renin-releasing cells) are located around the afferent arteriole where it enters the glomerulus (see [Figs. 38.3](#) and

38.6). Between the afferent and efferent arterioles is the **macula densa** (sodium-sensing cells) of the distal convoluted tubule. Together the juxtaglomerular cells and macula densa cells form the **juxtaglomerular apparatus (JGA)** (see Fig. 38.6). Control of renal blood flow, glomerular filtration, and renin secretion occurs at this site.

The **proximal convoluted tubule** continues from the Bowman capsule and has an initial convoluted segment (pars convoluta) and then a straight segment (pars recta) that descends toward the medulla (see Fig. 38.3). The wall of the tubule consists of one layer of cuboidal epithelial cells with a surface layer of microvilli (a brush border) that increases reabsorptive surface area. This is the only surface inside the nephron where the cells are covered with microvilli (see Fig. 38.4). The proximal convoluted tubule joins the hairpin-shaped **loop of Henle**. The loop is composed of a thin descending segment, a thin ascending segment, and a thick ascending segment. The thin descending segment is composed of squamous cells, has no active transport functions, and is highly permeable to water. The thin ascending segment is permeable to ions but not to water. The thick ascending segment actively transports ions into the interstitium and passes urine into the distal convoluted tubule (see Fig. 38.14). *Cortical nephrons* are more numerous and have glomeruli originating close to the surface of the cortex or in the midcortex. *Juxtamedullary nephrons* have glomeruli located deep in the cortex close to the medulla. The major structural difference between the two types of nephrons is the length of the loop of Henle. In cortical nephrons the loop is short and may not extend into the medulla. The loop of Henle for the juxtamedullary nephrons, however, may extend the whole length of the medulla (approximately 40 mm). Juxtamedullary nephrons represent about 12% of the total number of nephrons and are important for the concentration and dilution of urine.

The **distal tubule** has straight and convoluted segments. It extends from the macula densa to the **collecting duct**, a large tubule that descends down the cortex and through the renal pyramids of the inner and outer medullae, draining urine into the minor calyx. The

distal tubule is composed of two epithelial cell types: **principal cells** that reabsorb sodium and water and secrete potassium, and **intercalated cells** that secrete hydrogen and reabsorb potassium (see [Fig. 38.4](#)).

Blood Vessels of the Kidney

The blood vessels of the kidney closely parallel nephron structure. The major vessels are as follows:

1. **Renal arteries** arise as the fifth branches of the abdominal aorta, divide into anterior and posterior branches at the renal hilum, and then subdivide into lobar arteries supplying blood to the lower, middle, and upper thirds of the kidney.
2. **Interlobar artery** subdivisions travel down renal columns and between pyramids and form afferent glomerular arteries (see [Fig. 38.5](#)).
3. **Arcuate arteries** consist of branches of interlobar arteries at the cortical-medullary junction; they arch over the base of the pyramids and run parallel to the surface.
4. **Glomerular capillaries** consist of four to eight vessels and are arranged in a fistlike structure; they arise from the **afferent arteriole** and empty into the **efferent arteriole**, which carries blood to the peritubular capillaries. They are the major resistance vessels for regulating intrarenal blood flow (see under Autoregulation of Intrarenal Blood Flow).
5. **Peritubular capillaries** surround convoluted portions of the proximal and distal tubules and the loop of Henle; they are adapted for cortical and juxtamedullary nephrons.
6. **Vasa recta** is a network of capillaries that forms loops and closely follow the loops of Henle; it is the only blood supply to the medulla (important for formation of concentrated urine).
7. **Renal veins** follow the arterial path in reverse direction and have the same names as the corresponding arteries; they eventually empty into the inferior vena cava. The lymphatic vessels also tend to follow the distribution of the blood vessels.

Urinary Structures

Ureters

The urine formed by the nephrons flows from the distal tubules and collecting ducts through the ducts of Bellini and the **renal papillae** (projections of the ducts) into the calyces, where it is collected in the renal pelvis (see [Fig. 38.2](#)) and then funneled into the **ureters**. Each adult ureter is approximately 30 cm long and is composed of long, intertwining smooth muscle bundles. The close approximation of smooth muscle cells permits the direct transmission of electrical stimulation from one cell to another. The lower ends of the ureters pass obliquely through the posterior aspect of the bladder wall. The resulting downward peristaltic activity propels urine into the bladder. Contraction of the bladder during **micturition** (urination) compresses the lower end of the ureter, preventing reflux. Peristalsis is maintained even when the ureter is denervated, so ureters can be transplanted.

Sensory innervation for the upper part of the ureter arises from sympathetic inputs from the tenth thoracic nerve roots, with referred pain to the umbilicus. The innervation of lower segments arises from parasympathetic sacral nerves with referred pain to the vulva or penis. The ureters have a rich blood supply. The upper part of the ureter is supplied by the renal arteries, the middle part by the common iliac arteries and branches from the abdominal aorta and gonadal arteries, and the lower part mainly by branches from the internal iliac and vesical arteries.

Bladder and Urethra

The **bladder** is a bag composed of a basketweave of smooth muscle fibers that forms the **detrusor muscle** and its smooth lining of **uroepithelium (transitional epithelium)**. As the bladder fills with urine, it distends and the layers of uroepithelium within the lining slide past each other and become thinner as the volume of the bladder increases. The uroepithelium forms the interface between the urinary space and underlying vasculature and connective, nervous, and

muscle tissue. Uroepithelium also lines the urinary tract from the renal pelvis to the urethra. The uroepithelium maintains an important barrier function to prevent movement of water and solutes between the urine and the blood. It communicates information about luminal pressure and urine composition to surrounding nerve and muscle cells.⁴ The **trigone** is a smooth triangular area lying between the openings of the two ureters and the urethra (Fig. 38.8). The position of the bladder varies with age and sex. In infants and young children the bladder rises above the symphysis pubis, providing easy access for percutaneous aspiration. In adults it lies in the true pelvis, in front of the rectum and in front of the uterus in women. Inferiorly, the bladder sits on the prostate in men and on the anterior vagina in women. The bladder has a profuse blood supply, accounting for the bleeding that readily occurs with trauma, surgery, or inflammation.

FIGURE 38.8 Structure and Location of the Urinary Bladder. Frontal view of a dissected urinary bladder (male) in a fully distended position. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

The **urethra** extends from the inferior side of the bladder to the outside of the body. A ring of smooth muscle forms the **internal urethral sphincter** at the junction of the urethra and bladder. The **external urethral sphincter** is composed of striated skeletal muscle and is under voluntary control. The entire urethra is lined with mucus-secreting glands. The female urethra is short (3 to 4 cm). The male urethra is long (18 to 20 cm) and has three main segments: prostatic, membranous, and penile. The prostatic urethra is closest to the bladder. It passes through the prostate gland and contains the openings of the ejaculatory ducts. The membranous urethra is the segment that passes through the floor of the pelvis. The penile segment forms the remainder of the tube. The penile segment is surrounded by the corpus spongiosum erectile tissue and contains the openings of the bulbourethral glands.

The innervation of the bladder and internal urethral sphincter is supplied by parasympathetic fibers of the autonomic nervous system that arise from the sacral levels of the spinal cord (S2 to S4) and contribute to bladder contraction and urine emptying. Sympathetic fibers originate from T11-L2 and inhibit the bladder body and excite the lower bladder and proximal urethral sphincter to retain urine. Sensory fibers from the bladder and urethra may extend as high as the T6 portion of the spinal cord. Somatic motor neurons in the pudendal nerve innervate the striated external urethral sphincter. The reflex arc required for micturition is stimulated by mechanoreceptors that respond to stretching of tissue sensing bladder fullness and sending impulses to the sacral level of the spinal cord. When the bladder accumulates 250 to 300 mL of urine, the bladder contracts and the internal urethral sphincter relaxes through activation of the spinal reflex arc (known as the *micturition reflex*). At this time a person feels the urge to void. The reflex can be inhibited or facilitated by impulses coming from the brain, resulting in voluntary control of micturition.

Renal Blood Flow

The kidneys are highly vascular organs and receive about 20% to 25% of the cardiac output, which in adults is equivalent to 1000 to 1200 mL of blood per minute. With a normal hematocrit of 45%, about 600 to 700 mL of blood flowing through the kidney per minute is plasma. From the renal plasma flow (RPF), 20% (approximately 120 to 140 mL/min) is filtered at the glomerulus and passes into the Bowman capsule. The filtration of the plasma per unit of time is known as the **glomerular filtration rate (GFR)**, which is directly related to the perfusion pressure in the glomerular capillaries.

The remaining 80% (about 480 mL/min) of plasma flows through the efferent arterioles to the peritubular capillaries. The ratio of glomerular filtrate to RPF per minute ($120/600 = 0.20$) is called the *filtration fraction*. Normally all but 1 to 2 mL per minute of the glomerular filtrate is reabsorbed and returned to the circulation by the peritubular capillaries.

The GFR is directly related to renal blood flow (RBF), which is regulated by intrinsic autoregulatory mechanisms, neural regulation, and hormonal regulation. In general, blood flow to any organ is determined by the arteriovenous pressure differences across the vascular bed. If mean arterial pressure decreases or vascular resistance increases, RBF declines and urinary output decreases. Normal urinary output is about 30 mL/hour minimum in adults or 0.5 to 1.0 mL/kg/hr.

Autoregulation of Renal Blood Flow

In the kidney a local mechanism tends to keep the rate of glomerular perfusion and therefore the GFR fairly constant over a range of arterial pressures between 80 and 180 mmHg (Fig. 38.9). Changes in afferent arteriolar pressure and resistance occur in the same direction. Therefore, intrarenal blood flow and GFR are relatively constant independent of renal perfusion pressure, a relationship maintained by an intrinsic autoregulatory myogenic mechanism of contraction when blood vessels are stretched. The purpose of **autoregulation of intrarenal blood flow** is to keep RBF and GFR constant when there are increases or decreases in systemic blood pressure. Solute and water excretion, and thus blood volume, are regulated despite arterial

pressure changes, and barotrauma is prevented in states of high systemic blood pressure.⁵

FIGURE 38.9 Autoregulation of Renal Blood Flow. Blood flow and glomerular filtration rate are stabilized with changes in mean arterial pressure between about 80 and 180 mmHg. *GFR*, Glomerular filtration rate; *RBF*, renal blood flow. (From Koeppen BM, Stanton BA: *Berne and Levy physiology* [updated], ed 6, St Louis, 2010, Mosby.)

A second mechanism of autoregulation of RBF and GFR is **tubuloglomerular feedback**. Because the glomerular filtration rate in an individual nephron increases or decreases in relation to changing arterial pressure, the macula densa cells of the juxtaglomerular apparatus in the distal tubule sense the increasing or decreasing amounts of filtered sodium. When GFR and sodium concentration decrease, the macula densa cells stimulate afferent arteriolar vasodilation and increase GFR. At the same time, juxtaglomerular cells secrete renin which results in angiotensin II release causing vasoconstriction of the efferent arterioles increasing glomerular hydrostatic pressure and GFR. The opposite occurs with increases in GFR and sodium concentration at the macula densa (Fig. 38.10). This mechanism prevents large fluctuations in body water and sodium.⁵

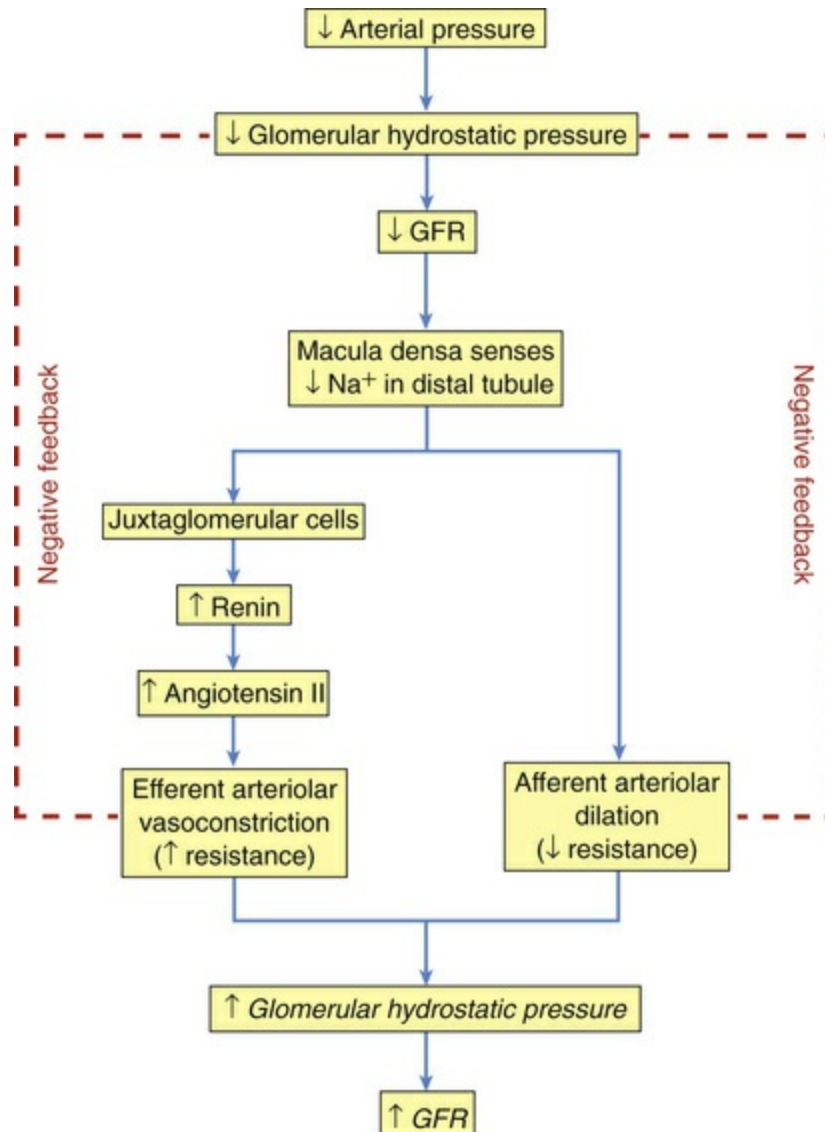

FIGURE 38.10 Tubuloglomerular Feedback. See text for details. *GFR*, Glomerular filtration rate.

Neural Regulation of Renal Blood Flow

The blood vessels of the kidney are innervated by sympathetic nerve fibers located primarily on afferent arterioles. When systemic arterial pressure decreases, increased renal sympathetic nerve activity is mediated reflexively through the carotid sinus and the baroreceptors of the aortic arch. The sympathetic nerves release catecholamines. This stimulates afferent renal arteriolar vasoconstriction and decreases RBF and GFR, increases renal tubular sodium and water reabsorption, and

increases blood pressure. Decreased afferent renal sympathetic nerve activity produces the opposite effects. The integrated response regulates water and sodium balance. **Renalase** is a hormone released by the kidney and heart that may promote the metabolism of catecholamines and in this way participate in blood pressure regulation.⁶ The sympathetic nervous system also participates in hormonal (i.e., angiotensin II) regulation of renal blood flow. There is no significant parasympathetic innervation. The innervation of the kidney arises primarily from the celiac ganglion and greater splanchnic nerve.

Hormones and Other Factors Regulating Renal Blood Flow

Hormones and other mediators can alter the resistance of the renal vasculature by stimulating vasodilation or vasoconstriction. A major hormonal regulator of renal blood flow is the renin-angiotensin-aldosterone system (RAAS), which can increase systemic arterial pressure and change RBF. Renin is an enzyme formed and stored in granular cells of the afferent arterioles of the JGA⁷ (see Fig. 38.3). Renin release is triggered by decreased blood pressure in the afferent arterioles, decreased sodium chloride concentrations in the distal convoluted tubule, sympathetic nerve stimulation of β -adrenergic receptors on the juxtaglomerular cells, and release of prostaglandins.

When renin is released, it cleaves an α -globulin (angiotensinogen produced by liver hepatocytes) in the plasma to form angiotensin I, which is physiologically inactive. In the presence of angiotensin-converting enzyme (ACE) produced from the pulmonary and renal endothelium, angiotensin I is converted to angiotensin II. **Angiotensin II** stimulates secretion of aldosterone by the adrenal cortex, is a potent vasoconstrictor, and stimulates antidiuretic hormone secretion and thirst (see Chapter 3, Fig. 3.4; and Chapter 21, Fig. 21.20).

Numerous physiologic effects of the RAAS stabilize systemic blood pressure and preserve extracellular fluid volume during hypotension or hypovolemia. Actions include sodium reabsorption, potassium

excretion, systemic vasoconstriction, sympathetic nerve stimulation, and thirst stimulation with increased drinking. The effects of aldosterone combine with those of antidiuretic hormone in regulating blood volume.

Natriuretic peptides are a group of peptide hormones, including **atrial natriuretic peptide (ANP)** secreted from myocardial cells in the atria and **brain natriuretic peptide (BNP)** secreted from myocardial cells in the cardiac ventricles. They are natural antagonists to the renin-angiotensin-aldosterone system. When the heart dilates during volume expansion or heart failure, ANP and BNP inhibit sodium and water absorption by kidney tubules, inhibit secretion of renin and aldosterone, vasodilate the afferent arterioles, and constrict the efferent arterioles. The result is increased urine formation, leading to decreased blood volume and blood pressure. **C-type natriuretic peptide** is secreted from vascular endothelium and in the nephron and causes vasodilation.⁸ **Urodilatin** is a renal natriuretic peptide secreted by the distal convoluted tubules and collecting ducts and causes vasodilation, increased renal blood flow, and diuretic effects. Other hormones and mediators that influence renal blood flow are summarized in [Table 38.1](#).

TABLE 38.1

HORMONES, MEDIATORS, AND RENAL BLOOD FLOW

HORMONE OR MEDIATOR	EFFECT ON RENAL BLOOD FLOW
Adenosine	Produced within kidney; causes vasoconstriction of afferent arteriole; decreases RBF and GFR
Angiotensin II	Produced systemically and within kidneys; constricts afferent and efferent arterioles; decreases RBF and GFR
Atrial and brain natriuretic peptides	Produced by atria and ventricles of the heart with hypertension and increased blood volume; cause vasodilation of afferent arteriole and vasoconstriction of efferent arteriole; modest increase in GFR with little change in RBF
Bradykinin	Produced in kidney from kininogen and causes vasodilation by release of nitric oxide and prostaglandins; increases RBF and GFR
Dopamine	Produced by the proximal tubule; increases RBF; inhibits renin secretion

Endothelin	Produced by renal vessel endothelial cells, mesangial cells, and distal tubule cells in response to bradykinin, angiotensin II, epinephrine, and stretch; most active with renal disease; profound vasoconstriction of afferent and efferent arterioles; decreases RBF and GFR
Histamine	Produced locally within the kidney; modulates RBF in basal state and during inflammation; increases RBF by decreasing afferent and efferent arteriolar resistance and does not decrease GFR
Nitric oxide	Produced by renal vessel endothelial cells with increased stretch and by stimulation of acetylcholine, histamine, bradykinin, ATP; increases vasodilation of afferent and efferent arterioles
Prostaglandins, PGI ₂ , PGE ₂	Produced locally within kidney with decreased RBF; dampen vasoconstriction caused by sympathetic nerves and angiotensin II; prevent harmful vasoconstriction and renal ischemia
Urodilatin (a natriuretic peptide)	Produced by distal tubule and collecting duct when there is increased circulating volume and increased blood pressure; inhibits sodium and water reabsorption from medullary part of collecting duct, thereby producing diuresis

ATP, Adenosine triphosphate; *GFR*, glomerular filtration rate; *PGE2*, prostaglandin E2; *PGI2*, prostaglandin I2; *RBF*, renal blood flow.

Kidney Function

Nephron Function

The nephron can perform many functions simultaneously ([Fig. 38.11](#)) as follows:

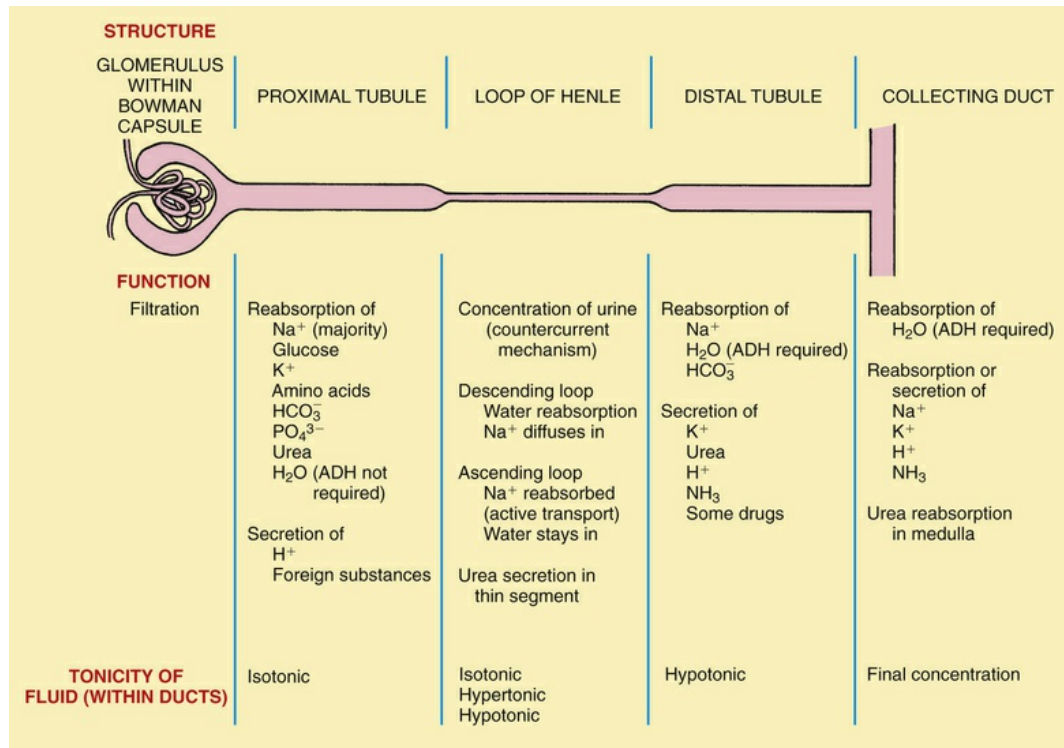

FIGURE 38.11 Major Functions of Nephron Segments. *ADH*, Antidiuretic hormone. (Modified from Hockenberry MJ: *Wong's nursing care of infants and children*, ed 8, St Louis, 2007, Mosby.)

1. Filters plasma at glomerulus.
2. Reabsorbs and secretes different substances along tubular structures.
3. Forms a filtrate of protein-free fluid (ultrafiltration).
4. Regulates the filtrate to maintain body fluid volume, electrolyte composition, and pH within narrow limits.

Glomerular filtration is the movement of fluid and solutes across the glomerular capillary membrane into the Bowman space. **Tubular reabsorption** is the movement of fluids and solutes from the tubular lumen to the peritubular capillary plasma. **Tubular secretion** is the transfer of substances from the plasma of the peritubular capillary to the tubular lumen. The transport mechanisms are active as well as passive. **Excretion** is the elimination of a substance in the final urine (Fig. 38.12).

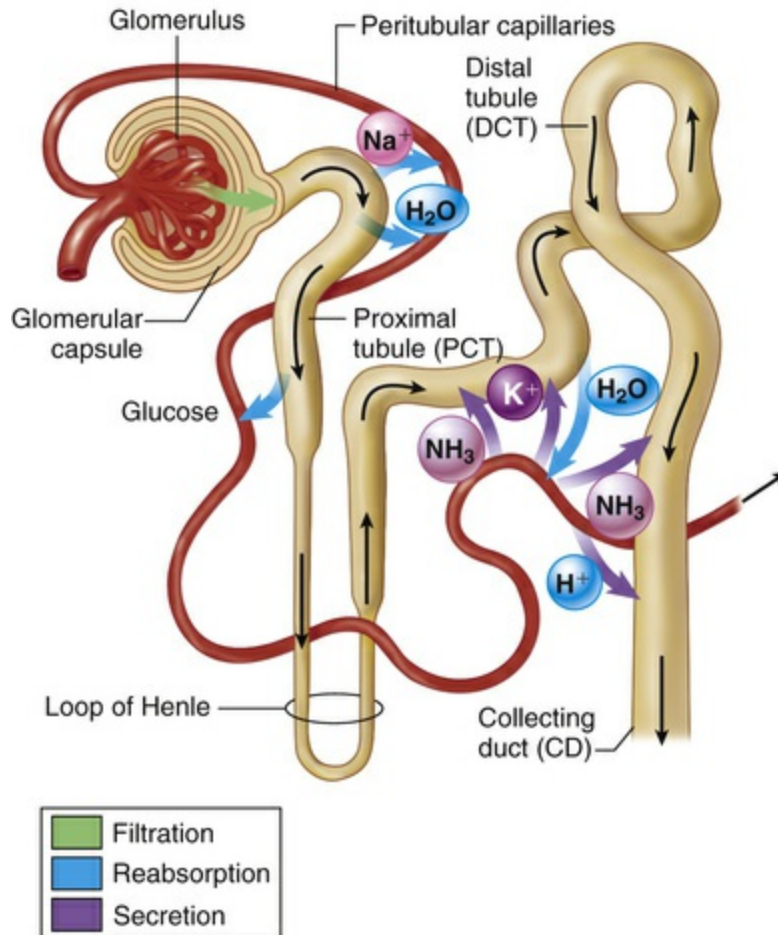

FIGURE 38.12 Urine Formation: Glomerular Filtration, Tubular Reabsorption, and Tubular Secretion. The three processes by which the kidneys excrete urine. Water, electrolytes, glucose, and organic molecules are filtered at the glomerulus. Sodium and glucose are reabsorbed into peritubular capillaries by active transport from the proximal convoluted tubules, and water reabsorption follows by osmosis. Sodium is reabsorbed by active transport from distal convoluted tubules; more sodium is conserved when aldosterone is secreted. Osmotic reabsorption of water from them occurs when antidiuretic hormone (ADH) is present. Secretion of ammonia (NH_3), hydrogen, and potassium occurs from peritubular capillaries into distal tubules by active transport. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

Glomerular Filtration

The fluid filtered by the glomerular capillary filtration membrane and released into the proximal convoluted tubule is protein-free but contains electrolytes (such as sodium, chloride, and potassium) and organic molecules (such as creatinine, urea, and glucose) in the same

concentrations as found in plasma. Like other capillary membranes, the glomerulus is freely permeable to water and relatively impermeable to large colloids such as plasma proteins. The molecule's size and electrical charge are important factors, and the small size of the filtration slits in the glomerular epithelium restricts the passage of proteins and other macromolecules. The negative charge along the filtration membrane further impedes the passage of negatively charged macromolecules (because like forces repel each other). Positively charged macromolecules therefore permeate the membrane more readily than neutrally charged particles.

Capillary pressures also affect glomerular filtration. The hydrostatic pressure within the capillary is the major force for moving water and solutes across the filtration membrane into Bowman capsule. This pressure is determined by the systemic arterial pressure and the resistances to blood flow in the afferent and efferent arterioles. Two forces oppose the filtration effects of the glomerular capillary hydrostatic pressure (P_{GC}): (1) the hydrostatic pressure in Bowman space (P_{BC}), and (2) the effective oncotic pressure of the glomerular capillary blood (π_{GC}). Because the fluid in Bowman space normally contains only minute amounts of protein, it usually does not have an oncotic influence on the plasma of the glomerular capillary (Fig. 38.13).

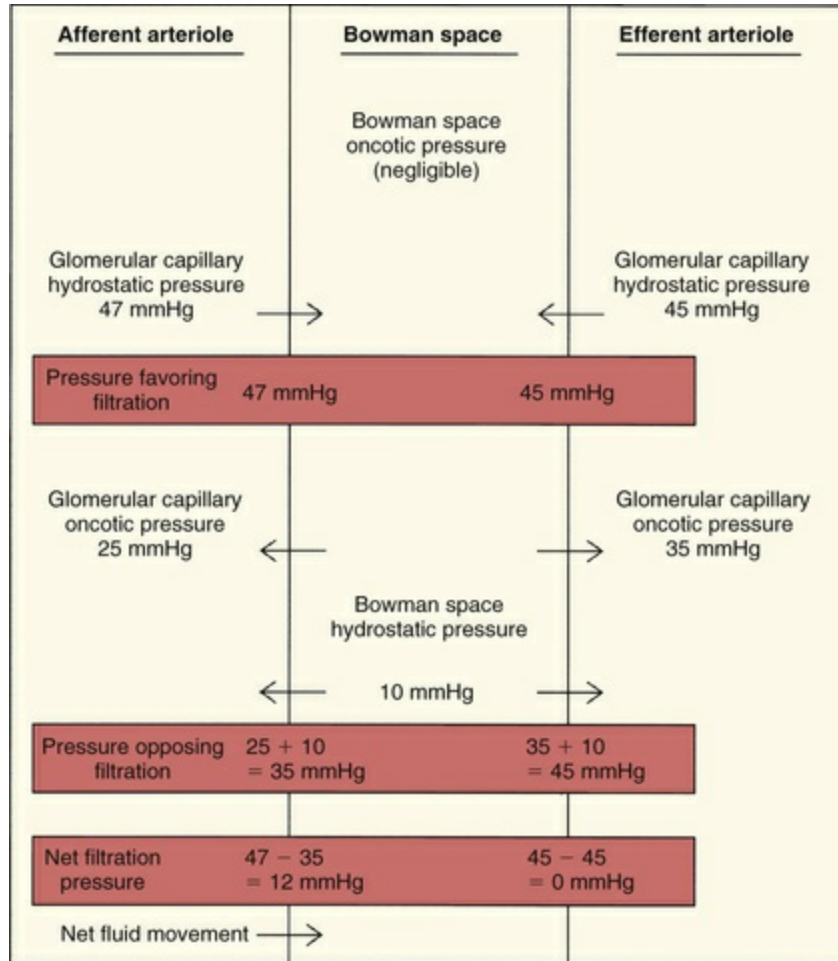

FIGURE 38.13 Glomerular Filtration Pressures.

The combined effect of forces favoring and forces opposing filtration determines the filtration pressure. The **net filtration pressure (NFP)** is the sum of forces favoring and opposing filtration and is expressed by the following equation:

$$\text{NFP} = (P_{GC} + \pi_{BC})(\text{forces favoring filtration}) - (P_{BC} + \pi_{GC})(\text{forces opposing filtration})$$

The estimated values contributing to the forces of net filtration are presented in [Fig. 38.13](#).

As the protein-free fluid is filtered into Bowman capsule, the plasma oncotic pressure increases and the hydrostatic pressure decreases. The increase in glomerular capillary oncotic pressure is

great enough to reduce the net filtration pressure to zero at the efferent end of the capillary and to stop the filtration process effectively. The low hydrostatic pressure and increased oncotic pressure in the efferent arteriole then are transferred to the peritubular capillaries and facilitate reabsorption of fluid from the proximal convoluted tubules.

Filtration Rate.

The total volume of fluid filtered by the glomeruli averages 180 L/day, or approximately 120 mL/min, a phenomenal amount considering the size of the kidneys. Because only 1 to 2 L of urine is excreted per day, 99% of the filtrate is reabsorbed into the peritubular capillaries and thus is returned to the blood. The factors determining the GFR are directly related to the pressures that favor or oppose filtration.

Obstruction to the outflow of urine (caused by strictures, stones, or tumors along the urinary tract) can cause a retrograde increase in pressure at Bowman capsule and a decrease in GFR. Low levels of plasma protein in the blood from severe malnutrition or liver disease result in a decrease in the effective oncotic pressure of the glomerular capillary blood (π_{CC}), which increases GFR. Excessive loss of protein-free fluid from vomiting, diarrhea, use of diuretics, or excessive sweating can increase glomerular capillary oncotic pressure and decrease the GFR. Renal disease also can cause changes in pressure relationships by altering capillary permeability and the surface area available for filtration (see [Chapter 39](#)).

Tubular Transport.

At the end of the proximal convoluted tubule, approximately 60% to 70% of filtered sodium and water and about 50% of urea have been reabsorbed, along with 90% or more of potassium, glucose, bicarbonate, calcium, phosphate, amino acids, and uric acid. Chloride, water, and urea are reabsorbed passively but are linked to the active transport of sodium (a cotransport mechanism). For some molecules, active transport in the renal tubules is limited as carrier molecules become saturated, a phenomenon known as **transport maximum**

(T_m). For example, when the carrier molecules for glucose reabsorption in the proximal convoluted tubule become saturated (i.e., with the development of hyperglycemia and serum glucose values of 180 mg/dL or greater), the excess will be excreted in the urine.

Proximal Convoluted Tubule.

Active reabsorption of sodium is the primary function of the proximal convoluted tubule. Water, most other electrolytes, and organic substances are cotransported with sodium. The osmotic force generated by active sodium transport promotes the passive diffusion of water out of the tubular lumen and into the peritubular capillaries. Passive transport of water is further enhanced by the elevated oncotic pressure of the blood in the peritubular capillaries, which is created by the previous filtration of water at the glomerulus. The reabsorption of water leaves an increased concentration of urea within the tubular lumen, creating a gradient for its passive diffusion to the peritubular plasma. As the positively charged sodium ions leave the tubular lumen, negatively charged chloride ions passively follow to maintain electroneutrality. Because the inner membrane of the proximal tubular cell has a limited permeability to chloride, chloride reabsorption lags behind that of sodium.

Hydrogen ions are actively exchanged for sodium ions in the tubular lumen. The hydrogen ions (H⁺) then combine with bicarbonate (HCO_3^-) in the tubular lumen to form carbonic acid (H₂CO₃).

Bicarbonate is completely filtered at the glomerulus, and approximately 90% is reabsorbed in the proximal tubule. In the tubular lumen, hydrogen and bicarbonate ions combine to form carbonic acid (H₂CO₃), which rapidly breaks down, or dissociates, to carbon dioxide (CO₂) and water (H₂O). CO₂ and H₂O then diffuse into the tubular cell, where carbonic anhydrase again catalyzes the CO₂ and H₂O to form HCO_3^- and H⁺. The H⁺ is secreted again and HCO_3^- combines with sodium and is transported to the peritubular capillary blood as NaHCO₃ (a sodium bicarbonate buffer). Bicarbonate is thus conserved, and the hydrogen is reabsorbed as water (see [Fig. 3.14](#)).

Therefore, these ions normally do not contribute to the urinary excretion of acid or the addition of acid to the blood.

In addition to the proximal tubular secretion of hydrogen ions, secretory Tms exist for creatinine, other organic bases, and endogenous and exogenous organic acids, including *para*-aminohippurate (PAH) and penicillin (Box 38.1). These secretory mechanisms are important for eliminating drugs and other exogenous chemical products from the body, often after first conjugating them with sulfate and glucuronic acid in the liver. Many drugs and their metabolites are eliminated from the body in this way. When the renal tubules are damaged, metabolic byproducts and drugs may accumulate, causing toxic levels in the body.

Box 38.1

Some Substances Transported by Renal Tubules

REABSORPTION	SECRETION
Albumin	Choline
Ascorbate	Creatinine
Fructose	Histamine Dopamine Catecholamines
Galactose	Methyl guanidine
Glucose	<i>para</i> -Aminohippurate
Glutamate	Penicillin
Phosphate	Steroid glucuronides
Sulfate	Thiamine Bile salts
Xylose	

Normally, 99% of the glomerular filtrate is reabsorbed. When the GFR spontaneously decreases or increases, the renal tubules and,

primarily, the proximal tubules, automatically adjust their rate of reabsorption of sodium and water to balance the change in GFR. Thus a constant fraction of filtered sodium and water is reabsorbed from the proximal tubule. This prevents wide fluctuations in sodium and water excretion into the urine and maintains sodium and water balance and is known as **glomerulotubular balance (GTB)**. GTB and tubuloglomerular feedback (see [Renal Blood Flow](#)) together regulate sodium and water balance.

Loop of Henle and Distal Convoluted Tubule.

Urine can be hypotonic, isotonic, or hypertonic. Urine concentration or dilution occurs principally in the loop of Henle, distal tubules, and collecting ducts. The structural features of the medullary hairpin loops allow the kidney to concentrate urine and conserve water for the body. The transition of the filtrate into the final urine reflects the concentrating ability of the loops. Final adjustments in urine composition are made by the distal tubule and collecting duct according to body needs.

Production of concentrated urine involves a **countercurrent exchange system**, in which fluid flows in opposite directions through the parallel tubes of the loop of Henle. A concentration gradient in the medulla causes fluid to be exchanged across the parallel pathways. The concentration gradient increases from the cortex to the tip of the medulla. The longer the loops of Henle, the greater their extension into the concentration gradient. The loops multiply the concentration gradient, and the vasa recta blood vessels act as a countercurrent exchanger for maintaining the gradient. The process is initiated in the thick ascending limb of the loop of Henle with the active transport of chloride and sodium out of the tubular lumen and into the medullary interstitium ([Fig. 38.14](#)). Because the lumen of the ascending limb is impermeable to water, water cannot follow the sodium chloride transport. This causes the ascending tubular fluid to become hypoosmotic and the medullary interstitium to become hyperosmotic. The descending limb of the loop, which receives fluid from the proximal tubule, is highly permeable to water, but it is the only place

in the nephron that does not actively transport either sodium or chloride. Sodium and chloride may, however, diffuse into the descending tubule from the interstitium. The hyperosmotic medullary interstitium causes water to move out of the descending limb, and the remaining fluid in the descending tubule becomes increasingly concentrated while it flows toward the tip of the medulla. While the tubular fluid rounds the loop and enters the ascending limb, sodium and chloride are removed and water is retained. The fluid then becomes more and more dilute as it encounters the distal tubule.

FIGURE 38.14 Countercurrent Mechanism for Diluting and Concentrating Urine. **A**, Urine dilution; **B**, urine concentration. 1, Filtrate isotonic to plasma. 2, Descending thin limb permeable to water. 3, Ascending thin limb impermeable to water; permeable to ions. 4, Ascending thick limb actively transports NaCl; impermeable to water and urea. 5, Distal tubule actively resorbs NaCl; resorbs water in presence of ADH and adjusts the final concentration of the urine. 6, Medullary CD actively resorbs NaCl, and slightly permeable to water and urea. 7, Urine is dilute or concentrated depending on concentration of urea and other nonreabsorbed solutes (NOTE: Numbers under "Interstitial fluid osmolality" represent milliosmoles [mOsm/kg H₂O] of interstitial fluid.). See text for details. ADH, Antidiuretic hormone; CD, collecting duct, NaCl, sodium chloride, H₂O, water. (Adapted from: Koeppen BM, *Renal physiology*, ed 5, St Louis, 2013, Mosby.)

The slow rate of blood flow and the hairpin structure of the vasa recta blood vessels allow blood to flow through the medullary tissue without disturbing the osmotic gradient. When blood flows into the descending limb of the vasa recta, it encounters the increasing osmotic concentration gradient of the medullary interstitium. Water moves out and sodium and chloride diffuse into the descending vasa recta. The plasma becomes increasingly concentrated as it flows toward the tip of the medulla.

As blood flows away from the tip of the medulla and toward the cortex, the surrounding interstitial fluid becomes comparatively more dilute. Water then moves back into the vasa recta, and sodium and chloride diffuse out and the plasma again becomes more dilute. The net result is a preservation of the medullary osmotic gradient. If blood were to flow rapidly through the vasa recta, as occurs in some renal diseases, the medullary concentration gradient would be washed away and the ability to concentrate urine and conserve water would be lost. The efficiency of water conservation is related to the length of the loops of Henle: the longer the loops, the greater the ability to concentrate the urine.

Urea is the major constituent of urine along with water. The glomerulus freely filters urea, and tubular reabsorption depends on urine flow rate, with less reabsorption at higher flow rates. Approximately 50% of urea is excreted in the urine, and 50% is recycled within the kidney. This recycling contributes to the osmotic gradient within the medulla and is necessary for the concentration and dilution of urine (see [Fig. 38.14](#)). Because urea is an end product of protein metabolism, individuals with protein deprivation cannot maximally concentrate their urine.⁹

Another function of the loop of Henle is the production of uromodulin (also known as *Tamm-Horsfall protein [THP]*), the most abundant protein in human urine. This protein is produced in the thick ascending loop and binds to uropathogens to prevent urinary tract infection, protects the uroepithelium from injury, protects against kidney stone formation, and is associated with progression of kidney disease.¹⁰

The convoluted portion of the distal tubule is poorly permeable to water but readily absorbs ions and contributes to the dilution of the tubular fluid. The later, straight segment of the distal tubule and the collecting duct are permeable to water as controlled by antidiuretic hormone released from the posterior pituitary gland. Sodium is readily absorbed by the later segment of the distal tubule and collecting duct under the regulation of the hormone aldosterone (see [Chapter 21](#)). Potassium is actively secreted by principal cells and is

reabsorbed in lesser amounts by intercalated cells in these segments. Potassium secretion is controlled by aldosterone and other factors related to the concentration of potassium in body fluids.

Hydrogen also is secreted by the distal tubule and combines with non-bicarbonate buffers (i.e., ammonium and phosphate) for the elimination of excess acids in the urine. The distal tubule thus contributes to the regulation of acid-base balance by excreting hydrogen ions into the urine and by adding new bicarbonate to the plasma (see [Fig. 3.14](#)). The mechanism is similar to the conservation of bicarbonate by the proximal tubule, except that the hydrogen ion is excreted in the urine. (The specific mechanisms of acid-base balance and acid excretion are described in [Chapter 3](#).)

Urine Composition

Urine is normally clear yellow or amber in color. Cloudiness may indicate the presence of bacteria, cells, or high solute concentration. The pH ranges from 4.6 to 8.0, but it is normally acidic, providing protection against bacteria. Specific gravity ranges from 1.001 to 1.035. Normal urine does not contain glucose or blood cells and only occasionally contains traces of protein, usually in association with rigorous exercise.

Hormones and Nephron Function

Antidiuretic Hormone

The distal tubule in the cortex receives the hypoosmotic urine from the ascending limb of the loop of Henle. The concentration of the final urine is controlled by **antidiuretic hormone (ADH)**, which is secreted from the posterior pituitary, or neurohypophysis. ADH increases water permeability in the last segment of the distal tubule and along the entire length of the collecting ducts, which pass through the inner and outer zones of the medulla. The water diffuses into the ascending limb of the vasa recta and returns to the systemic circulation. The excreted urine can have a high osmotic concentration, up to 1400 mOsm. The volume is normally reduced to about 1% of the

amount that was filtered at the glomerulus.

Excess ADH secretion is therefore one cause of **oliguria**, or diminished excretion of urine, clinically defined as less than 400 mL/day or 30 mL/hr. The syndrome of inappropriate secretion of ADH occurs when the posterior pituitary hypersecretes ADH, resulting in excess water reabsorption and water excess in the plasma (see [Chapters 3](#) and [22](#)). Inadequate secretion of ADH results in diabetes insipidus, and causes the distal tubules and collecting ducts to become impermeable to water. Water remains in the tubular lumen and is excreted as a dilute and large volume of urine. (The mechanism for the regulation of ADH and plasma osmolality is described in [Chapters 3](#) and [21](#).)

Natriuretic Peptides

The natriuretic peptides (urodilatin, ANP, and BNP) promote diuresis and were described under Hormones and Other Factors Regulating Renal Blood Flow.

Diuretics as a Factor in Urine Flow

A **diuretic** is any agent that enhances the flow of urine. Clinically, diuretics interfere with renal sodium reabsorption and reduce extracellular fluid volume. Diuretics are commonly used to treat hypertension and edema caused by heart failure, cirrhosis, and nephrotic syndrome.

Diuretics are divided into five general categories: (1) osmotic diuretics, (2) carbonic anhydrase inhibitors (inhibitors of urinary acidification), (3) inhibitors of loop sodium or chloride transport, (4) potassium sparing (i.e., aldosterone receptor antagonists), and (5) aquaretics. (The physiologic mechanism related to each category is summarized in [Table 38.2](#).)

TABLE 38.2

ACTION OF DIURETICS

DIURETIC	SITE OF ACTION	ACTION	SIDE EFFECTS
Osmotic Diuretic			
Mannitol Glycerol Urea	Proximal tubule	Freely filtered but not reabsorbed; osmotically attracts water and diminishes sodium reabsorption	Hypokalemia, dehydration
Carbonic Anhydrase Inhibitors			
Acetazolamide	Proximal tubule	Inhibits carbonic anhydrase; blocks hydrogen ion secretion and reabsorption of sodium and bicarbonate	Hypokalemia, systemic acidosis, alkaline urine
Inhibitors of Sodium/Chloride Reabsorption (Loop Diuretics)			
Thiazides	Between end of ascending loop and beginning of distal tubule	Blocks sodium and chloride reabsorption; mildly suppresses carbonic anhydrase	Hypokalemia, metabolic alkalosis
Furosemide Ethacrynic acid Torsemide	Thick ascending limb of Henle loop	Blocks active transport of chloride, sodium, and potassium	Hypokalemia, uric acid retention
Bumetanide	Cortical vasodilation	Increased rate of urine formation	Hypokalemia, uric acid retention
Potassium Sparing			
Spirolactone Eplerenone	Distal tubule	Inhibits aldosterone, blocks sodium reabsorption, and results in potassium retention	Hyperkalemia, nausea, confusion, gynecomastia
Triamterene Amiloride	Distal tubule	Blocks sodium reabsorption and inhibits potassium excretion	Nausea, vomiting, headache, and amiloride granulocytopenia, skin rash
Aquaretics			
Vasopressin (V2 receptor) blockers (e.g., conivaptan)	Distal tubule and collecting ducts	Blocks action of antidiuretic hormone	Dehydration

Renal Hormones

The kidneys activate or synthesize hormones that have systemic

effects. These hormones include the active form of vitamin D, erythropoietin, renin-angiotensin-aldosterone, and natriuretic hormones.

Vitamin D

Vitamin D is a hormone that can be obtained in the diet or synthesized by the action of ultraviolet radiation (sun exposure) on cholesterol in the skin. These forms of vitamin D₃ (cholecalciferol) are inactive and require two hydroxylations to establish a metabolically active form. The first step occurs in the liver with hydroxylation at carbon-25 (calcifediol), and the second hydroxylation occurs at the first carbon position in the kidneys and is stimulated by parathyroid hormone. The end product is 1,25-dihydroxycholecalciferol, or 1,25-dihydroxy-vitamin D₃ (1,25-OH₂D₃) (calcitriol), the active form of vitamin D.

Calcitriol (1,25-dihydroxy-vitamin D₃) is necessary for the absorption of calcium and phosphate by the small intestine. A decreased plasma calcium level (less than 10 mg/dL) stimulates the secretion of parathyroid hormone. Parathyroid hormone then stimulates a sequence of events that help restore plasma calcium level back toward normal including:

1. Calcium mobilization from bone
2. Synthesis of 1,25-dihydroxy-vitamin D₃
3. Absorption of calcium from the intestine
4. Increased renal calcium reabsorption
5. Decreased renal phosphate reabsorption

Serum phosphate concentration fluctuations also influence the renal hydroxylation of vitamin D. Decreased levels stimulate active 1,25-dihydroxy-vitamin D₃ formation, and increased levels inhibit formation. This results in compensatory changes in phosphate absorption from bone and the intestine. Individuals with renal disease have a deficiency of 1,25-dihydroxy-vitamin D₃ and manifest

symptoms of disturbed calcium and phosphate balance (see [Chapters 3 and 39](#)).

Erythropoietin

Erythropoietin is produced by the fetal liver and the adult kidney and is essential for normal erythropoiesis. With decreased oxygen delivery in the kidneys, oxygen-sensing peritubular fibroblasts in the juxtamedullary cortex release erythropoietin, which stimulates the bone marrow to increase the rate of red blood cell production (see [Chapter 28](#)). Individuals with chronic renal failure develop anemia related to reduced erythropoietin secretion. Erythropoietin also affects the endothelium and promotes angiogenesis, mitogenesis, and antiapoptosis. It is also antiinflammatory, cytoprotective, and neurotrophic.¹¹

Tests of Renal Function

Renal Clearance

A number of specific renal functions can be measured by renal clearance. Renal clearance techniques determine how much of a substance can be cleared from the blood by the kidneys per given unit of time. The application of this principle permits an indirect measure of GFR, tubular secretion, tubular reabsorption, and renal blood flow.

Clearance and Glomerular Filtration Rate

The GFR provides the best estimate of functioning renal tissue. Damage to the glomerular membrane or loss of nephrons leads to a corresponding decrease in GFR. The measurement of GFR requires use of a substance that has a stable plasma concentration, is not protein bound, is freely filtered at the glomerulus, does not influence GFR, and is not secreted, reabsorbed, or metabolized by the tubules and is easy to measure. *Inulin* (a fructose polysaccharide) is one substance that meets the criteria for measurement of GFR.

The kidney “clears” inulin from the plasma by filtering it at the glomerulus, reabsorbing nearly all of the fluid, and excreting the inulin left behind in the urine. The amount of inulin filtered is equal to the volume of plasma filtered (GFR) multiplied by the plasma concentration of inulin (P_{IN}). The amount of inulin in the urine is equal to a volume of urine per unit of time \dot{V} (usually 24 hours) multiplied by the inulin concentration of urine (U_{IN}). Because all the inulin filtered is excreted in the urine,

$$GFR \times P_{IN} = U_{IN} \times \dot{V}$$

GFR can be calculated by rearranging the formula:

$$GFR \text{ (mL/min)} = \frac{U_{IN} \times \dot{V}}{P_{IN}}$$

The accurate determination of **insulin clearance** requires constant infusion to maintain a stable plasma level. This is time consuming, inconvenient, and prone to error. Therefore, the clearance of *creatinine*, a natural substance produced by muscle and released into the blood at a relatively constant rate, is commonly used as an estimate clinically. It is freely filtered at the glomerulus and is not reabsorbed by the renal tubules, but a small amount is secreted by the renal tubules. Therefore, creatinine clearance overestimates the GFR but within tolerable limits. **Creatinine clearance** provides a good estimate of GFR because only one blood sample is required in addition to a 24-hour volume of urine. The GFR estimated by creatinine clearance is calculated as follows:

$$GFR \text{ (mL/min)} = \frac{U_{CR} \times \dot{V}}{P_{CR}}$$

Cystatin C is a stable protein in serum filtered at the glomerulus and metabolized in the tubules. Serum levels of cystatin C also are a marker for estimating GFR, particularly for mild to moderate impaired renal function. A combined creatinine and cystatin C estimate of GFR was developed in 2012 and considers age, race, and gender.¹² Formulas are used to estimate GFR.¹³ The Cockcroft and Gault creatinine-based formula is commonly used and considers age, body weight, and plasma creatinine (P_{CR}) values, and the National Kidney Foundation recommends the Modification of Diet in Renal Disease (MDRD) equation.¹⁴ The Chronic Kidney Disease Epidemiology Collaboration (2009 CKD-EPI) equation has been developed as a more precise estimate of GFR than the MDRD and considers age, gender, and race.¹⁵ In 2012, cystatin C and combined creatinine and cystatin C equations were developed. Calculators for estimates of GFR using these formulas are readily available on the Internet (see example at http://touchcalc.com/ip_epi_gfr/ip_ckd_epi). Normal values are 90 to 120 mL/min.

Plasma Creatinine Concentration

A chronic decline in GFR over weeks or months is reflected in the **plasma creatinine (P_{CR}) concentration** (normal value = 0.7 to 1.2 mg/dL). The P_{CR} concentration has a stable value when the GFR is stable because creatinine has a constant rate of production as a product of muscle metabolism. The amount filtered is approximately equal to the amount excreted. When the GFR declines, the P_{CR} increases proportionately. Thus the GFR and P_{CR} are inversely related. If the GFR were to decrease by 50%, the filtration and excretion of creatinine would be reduced by 50% and creatinine would accumulate in plasma to twice the normal value. Therefore, elevated P_{CR} values represent decreasing GFR. In the new steady state, however, the total amount of creatinine excreted in the urine would remain the same because of the proportionate decrease in GFR and increase in P_{CR} .

The application of this principle is simple and useful for monitoring progressive changes in renal function. The test is most valuable for

monitoring the progress of chronic rather than acute renal disease because it takes 7 to 10 days for the plasma creatinine level to stabilize when GFR declines. Serial measures can be obtained over a long time and plotted as a curve of glomerular function. Normal P_{CR} value decreases with advanced age, since older adults experience a decrease in lean muscle mass. The P_{CR} value becomes elevated during trauma or breakdown of muscle tissue. In such instances the value is then not useful for estimating GFR.

Blood Urea Nitrogen

The concentration of urea nitrogen in the blood reflects glomerular filtration and urine-concentrating capacity. Because urea is filtered at the glomerulus, **blood urea nitrogen (BUN)** levels increase as glomerular filtration drops. Because urea is reabsorbed by the blood through the permeable tubules, the BUN value rises in states of dehydration and acute and chronic renal failure when passage of fluid through the tubules is slowed. BUN value also varies as a result of altered protein intake and protein catabolism and therefore is a poor measure of GFR. The normal range for BUN value in the adult is 10 to 20 mg/dL of blood.

Clearance and Renal Blood Flow

A clearance formula also can be used to estimate renal plasma flow (RPF) and RBF using a molecule called *para*-aminohippuric acid (PAH). Some PAH is filtered at the glomerulus, and most of the remainder is secreted into the tubules in one circulation through the kidney. If all the PAH were removed from the plasma during a single pass through the kidney, total RPF could be determined. Because the supporting and nonsecreting structures of the kidney receive 10% to 15% of **effective renal blood flow (ERBF)**, clearance of PAH measures only what is known as the **effective renal plasma flow (ERPF)**, which is 85% to 90% of the true renal plasma flow:

$$\text{ERPF} = \frac{U_{\text{PAH}} \times \dot{V}}{P_{\text{PAH}}}$$

where U_{PAH} = concentration of PAH in urine, and P_{PAH} = concentration of PAH in plasma.

The estimation of ERBF can then be calculated by considering the hematocrit in the following formula:

$$\text{ERBF} = \frac{\text{ERPF}}{1 - \text{Hematocrit}} \\ (1.0 - 0.45)$$

Evaluation of the biochemical components of the blood and urine provides valuable information regarding renal function.

Urinalysis

Urinalysis is a noninvasive and relatively inexpensive diagnostic procedure. The best results are obtained from a fresh, cleanly voided specimen because decay permits changes in the composition of urine. Urinalysis includes evaluation of color, turbidity, protein, pH, specific gravity, sediment, and supernatant.

Urine color is normally a clear, light yellow because of urochrome and other pigments. When formed substances (crystals, blood cells, or casts) are in the urine, it appears turbid. Protein in the urine creates marked foaming when shaken, and the foam is yellow or orange when the urine contains bile pigments. Urine does not normally contain protein or bile.

Urine pH normally ranges between 5 and 6.5, but it may vary from 4.5 to 8. Urine is more alkaline after eating and then becomes less alkaline before the next meal. Because sleep is accompanied by intermittent hypoventilation, urine is more acidic on awakening.

Specific gravity is an estimated measure of the solute concentration of the urine. The specific gravity of any solution is measured by comparing the weight of the solution with an equal volume of

distilled water. Hence specific gravity is not a true measure of the number or concentration of particles, but it correlates well with osmolality and is a useful clinical tool. Specific gravity usually is measured with a hydrometer in a cylinder of urine; the normal value is 1.016 to 1.022. Dipstick evaluations may be falsely high when urine pH is less than 6 and falsely low when the pH is more than 7.

The final urine osmolality is primarily a function of ADH, which controls water reabsorption in the collecting ducts. If the kidney is unable to concentrate or dilute urine, given a stimulus, the cause is usually a malfunction of the renal tubules or inappropriate ADH secretion by the posterior pituitary gland. The state of hydration also affects the urine specific gravity, so hydration status should be evaluated before making a diagnosis. This determination is helpful for differentiating oliguria caused by intrinsic renal disease from hypovolemia as a result of dehydration.

Urine Sediment

The urine sediment is examined microscopically and may contain cells, casts, crystals, and bacteria. Epithelial cells may be seen in the microscopic field because they are shed naturally throughout the urinary tract.

Red Blood Cells.

Normal urine contains few or no red blood cells. If a large number of red cells are present, this is known as **hematuria**, and the sediment may be red or brown. An alkaline or hypotonic urine causes lysis of red cells, however, so that the cells will not be seen. Urine then will be positive for hemoglobin, and the specific gravity will be elevated. Hematuria can occur with the administration of anticoagulants and with several renal diseases.

Casts.

Casts (accumulations of cellular precipitates) originate in the renal tubules, from which they take their shape. They are cylindrical with distinct borders. All casts have a precipitated microprotein matrix and

arise primarily from the ascending limb of the distal tubule. Red cell casts indicate bleeding into the tubules or escape of red blood cells through the glomerulus; white cell casts are associated with an inflammatory process. Epithelial cell casts indicate degeneration of the tubular lumen or necrosis of the renal tubules. The type of cast identified suggests the disease process occurring in the kidney.

Crystals.

Numerous kinds of **crystals** can be observed in the urine. They may be composed of cystine, uric acid, calcium oxalate, or phosphate. They may not be initially observable, but as the urine cools, crystals will form. Crystals tend to form in a concentrated acidic or alkaline urine. Generally they are not clinically significant. Crystal formation is diagnostically significant, usually indicating inflammation, infection, or a metabolic disorder.

White Blood Cells.

White blood cells (WBCs) in the urine (a condition termed **pyuria**) are indicative of urinary tract infection, particularly when bacteria are present. Glomerulonephritis and nephrotic syndrome also may demonstrate pyuria but usually in combination with proteinuria, red cells, and casts. The finding of WBC casts reflects a kidney infection because these casts are not formed in the bladder or prostate. If WBCs are present in the urine, a culture should be done for specific identification of bacteria and sensitivity of bacteria to antibiotics.

Other Measures

Dipsticks and reagent strips are available for detecting other substances in the urine, including glucose, bilirubin, urobilinogen, leukocyte esterase and nitrates, ketones, proteins, hemoglobin, and myoglobin.

Aging and Renal Function

Throughout life the kidney responds to an increased workload by compensatory hypertrophy. This hypertrophy is marked in individuals who have donated a kidney for transplant or have lost functioning nephrons from trauma or disease. The glomeruli increase in diameter, and the tubules enlarge effectively to maintain the regulatory functions of the kidney. Hypertrophy occurs more rapidly and with a larger size increase in younger individuals and in those with high protein intake.

Changes in the kidneys occur throughout life, resulting in a reduction in size and a linear decrease in renal blood flow and GFR; however, it is less pronounced in healthy individuals. Reference values for estimated GFR are available by age group.¹⁶

The number and size of nephrons decrease with aging, possibly related to oxidative stress, inflammation, and associated clinical conditions (e.g., hypertension and diabetes mellitus). The primary mechanism appears to be a change in the renal vasculature and perfusion patterns related to atherosclerosis that leads to a reduction in numbers of nephrons and nephrosclerosis. Tubular atrophy also occurs. The rate of nephron loss accelerates after 50 years of age. By about 75 years of age, the nephron population is reduced by 30% to 50% with loss of renal mass occurring primarily in the cortex.¹⁷ Degenerative changes within nephrons also occur with aging. The glomerular capillaries become sclerotic, and remaining glomeruli become hypertrophic. The glomeruli may disappear completely. The arcuate and interlobular arteries become tortuous, contributing to ischemia. The loss of the glomerular tuft may cause a shunt between the afferent and efferent arterioles. Although loss of juxtaglomerular nephrons still allows the vasa recta to be perfused, the combination of events contributes to a reduced ability to excrete a concentrated urine.^{18,19} Thus the specific gravity of the urine in older individuals tends to be on the low side of normal.

Tubular transport changes with aging, although under normal conditions the tubules function adequately. Adaptation to stressful conditions is more difficult. Glucose, bicarbonate, and sodium are not as efficiently reabsorbed, and hyperkalemia is more common because

of decreased secretion. Response to acid or base loads is delayed and prolonged. Sudden or large changes in pH or fluid load may lead to serious imbalances with increased risk of hypervolemia or hypovolemia. Acute losses or chronic fluid deficits can lead to renal insufficiency in the older adult. Administration of drugs eliminated by renal processes may require dose modifications and more astute observations for toxic side effects. Contrast agents and nonsteroidal antiinflammatory drugs should be used with caution.

The T_m for glucose reabsorption decreases with age, contributing to a greater amount of glucose in the urine. This is an important consideration when glycosuria is used for screening or monitoring the process of diabetes mellitus in older adults. These changes occur independently of disease, however, indicating a normal process of aging. An age-related decline in renal activation of vitamin D decreases intestinal absorption of calcium, and older adults need more vitamin D to overcome diminishing renal function.²⁰ Previous or concurrent renal disease or urinary tract obstruction may amplify age-related changes in function.

Bladder symptoms are common among older adults and include frequency, urgency, and nocturia. Ischemic-induced neurogenic and myogenic changes in bladder structure and function may contribute to some symptoms as well as influences outside the urinary tract (i.e., cardiovascular disease, prostatic disease, uterine prolapse, stool impaction and hormonal changes). Changes in neurotransmission influence the micturition reflex and may lead to an overactive or underactive bladder.^{21,22}

Summary Review

Structures of the Renal System

1. The primary functions of the kidney are to maintain fluid, electrolyte, acid-base, and blood pressure balance; excrete wastes; secrete the hormones renin and erythropoietin; and activate vitamin D.

2. The kidneys are paired structures lying in the retroperitoneal space between the twelfth thoracic and third lumbar vertebrae.
3. The kidney is composed of a capsule, an outer cortex containing the glomeruli, and an inner medulla containing the tubules and collecting ducts that drain into the calyces.
4. The calyces join to form the renal pelvis and are continuous with the upper end of the ureter.
5. The nephron is the urine-forming unit of the kidney and is composed of the glomerulus, proximal tubule, hairpin loops of Henle, distal tubule, and collecting duct.
6. The glomerulus contains loops of capillaries contained in the Bowman capsule. The capillary walls serve as a filtration membrane for the formation of the primary urine. The layers of the glomerular capillary include the endothelium, basement membrane, and epithelium. The epithelium is composed of podocytes that interlock to provide filtration slits. An anion charge across the filtration membrane restricts filtration of negatively charged molecules such as proteins.
7. Mesangial cells and matrix lie between and support the glomerular capillaries in the Bowman capsule.
8. Juxtaglomerular cells secrete renin and are located around the afferent arteriole. They are contiguous with the sodium-sensing macula densa cells of the distal convoluted tubule.
9. The Bowman capsule is the space between the visceral and parietal epithelium.
10. The proximal tubule is lined with microvilli to increase surface area and enhance reabsorption.
11. The hairpin-shaped loops of Henle selectively transport solutes and water, contributing to the hypertonic state of the medulla important for the concentration of urine.
12. The distal tubule adjusts acid-base balance by excreting acid into the urine and forming new bicarbonate ions.
13. The collecting duct contains principal cells that resorb sodium and water and excrete potassium and intercalated cells that secrete hydrogen or bicarbonate and potassium.

14. The ureters extend from the renal pelvis to the posterior wall of the bladder. Urine flows through the ureters by means of peristaltic contraction of the ureteral muscles.
15. The bladder is a bag composed of the detrusor and trigone muscles and innervated by branches of parasympathetic (contracts the bladder and relaxes the urethra), sympathetic (relaxes the bladder and contracts the proximal urethral sphincter), and somatic (striated urethral sphincter) pathways. When accumulation of urine reaches 250 to 300 mL, mechanoreceptors, which respond to stretching of tissue, stimulate the micturition reflex.

Renal Blood Flow

1. Renal blood flows at about 1000 to 1200 mL/min, or 20% to 25% of the cardiac output.
2. Blood flow through the glomerular capillaries is maintained at a constant rate in spite of a wide range of systemic arterial pressures (autoregulation).
3. The GFR is the filtration of plasma per unit of time and is directly related to the perfusion pressure of renal blood flow.
4. The renal blood vessels are innervated by the sympathetic noradrenergic nerves that regulate vasoconstriction.
5. Autoregulation of RBF and sympathetic neural regulation of vasoconstriction maintain a constant GFR.
6. Renin is an enzyme secreted from juxtaglomerular cells in the afferent arteriole; it causes the generation of angiotensin I, which is converted to angiotensin II by the action of ACE. Angiotensin II is a potent vasoconstrictor and also stimulates release of aldosterone from the adrenal cortex. Thus the renin-angiotensin-aldosterone system is a regulator of renal blood flow and blood pressure.
7. Natriuretic peptides from the myocardium antagonize the renin-angiotensin-aldosterone system and promote sodium chloride and water excretion.

Kidney Function

1. The major function of the nephron is urine formation, which involves the processes of glomerular filtration, tubular reabsorption, and tubular secretion and excretion.
2. Glomerular filtration is favored by capillary hydrostatic pressure and opposed by oncotic pressure in the capillary and hydrostatic pressure in the Bowman capsule. The balance of favoring and opposing filtration forces is the net filtration pressure (NFP).
3. The GFR is approximately 120 mL/min, and 99% of the filtrate is reabsorbed.
4. The proximal convoluted tubule reabsorbs about 60% to 70% of the filtered sodium and water and 90% of other electrolytes.
5. Because most molecules are reabsorbed by active transport, the carrier mechanism can become saturated at the T_m . Molecules not reabsorbed are excreted with the urine.
6. The distal tubules actively reabsorb sodium and water and secrete potassium and hydrogen for the regulation of fluid, electrolyte, and acid-base balance.
7. The concentration of the final urine is a function of the level of ADH that stimulates the distal tubules and collecting ducts to reabsorb water. The countercurrent exchange system of the long loops of Henle and their accompanying capillaries establishes a concentration gradient within the renal medulla to facilitate the reabsorption of water from the collecting duct.
8. The distal nephron regulates acid-base balance by excreting hydrogen ions and forming new bicarbonate.
9. The kidney secretes or activates a number of hormones that have systemic effects, including vitamin D_3 (1,25- OH_2D_3) which promotes calcium absorption in the gut, and erythropoietin, which stimulates erythropoiesis when there is hypoxia.

Tests of Renal Function

1. Tests that measure renal clearance indicate how much of a substance can be cleared from the blood by the kidneys per given amount of time.
2. Creatinine, a substance produced by muscle, is measured in plasma and urine to calculate a commonly used clinical estimate of GFR (creatinine clearance).
3. The plasma creatinine concentration, cystatin C plasma concentration, and BUN levels estimate glomerular function. Plasma creatinine and cystatin C are measured to monitor progressive renal dysfunction; BUN is an indicator of hydration status.
4. PAH clearance is used to determine renal plasma flow and blood flow.
5. Urinalysis involves evaluation of color, turbidity, protein, pH, specific gravity, sediment, and supernatant.
6. Presence of bacteria, red blood cells, white blood cells, casts, or crystals in the urine sediment may indicate a renal disorder.

Aging and Renal Function

1. As a person ages, a decrease occurs in the number and size of nephrons. Renal blood flow and glomerular filtration rate decline.
2. Tubular transport and reabsorption decrease with age. Response to acid-base changes and reabsorption of glucose are delayed. Drugs eliminated by the kidney can accumulate in the plasma, causing toxic reactions.
3. Neurogenic and myogenic changes in the bladder may lead to symptoms of urgency and frequency or urine retention.

Renal and urinary function can be affected by a variety of disorders. The most common type of urinary dysfunction is infection. Stones, tumors, or the associated inflammatory edema also can obstruct the urinary tract. Renal function can be impaired by disorders of the kidney itself or by many other systemic diseases and ultimately may result in acute kidney injury or chronic kidney disease. Because the kidney filters the blood, it is directly linked to every other organ system. Renal failure, whether acute or chronic, is a life-threatening condition.

Urinary Tract Obstruction

Urinary tract obstruction is an interference with the flow of urine at any site along the urinary tract (Fig. 39.1). An obstruction may be anatomic or functional. The obstruction impedes urine flow, increases hydrostatic pressure and dilates structures proximal to the obstruction, increases risk for infection, and compromises renal function. Anatomic changes in the urinary system caused by obstruction are referred to as **obstructive uropathy**. The severity of an obstructive uropathy is determined by (1) the location of the obstructive lesion, (2) the involvement of one or both upper urinary tracts (ureters and renal pelvis), (3) the completeness of the obstruction, (4) the duration of the obstruction, and (5) the nature of the obstructive lesion. Obstructions may be relieved or partially alleviated by correction of the obstruction, although permanent impairments occur if a complete or partial obstruction persists over weeks to months or longer.

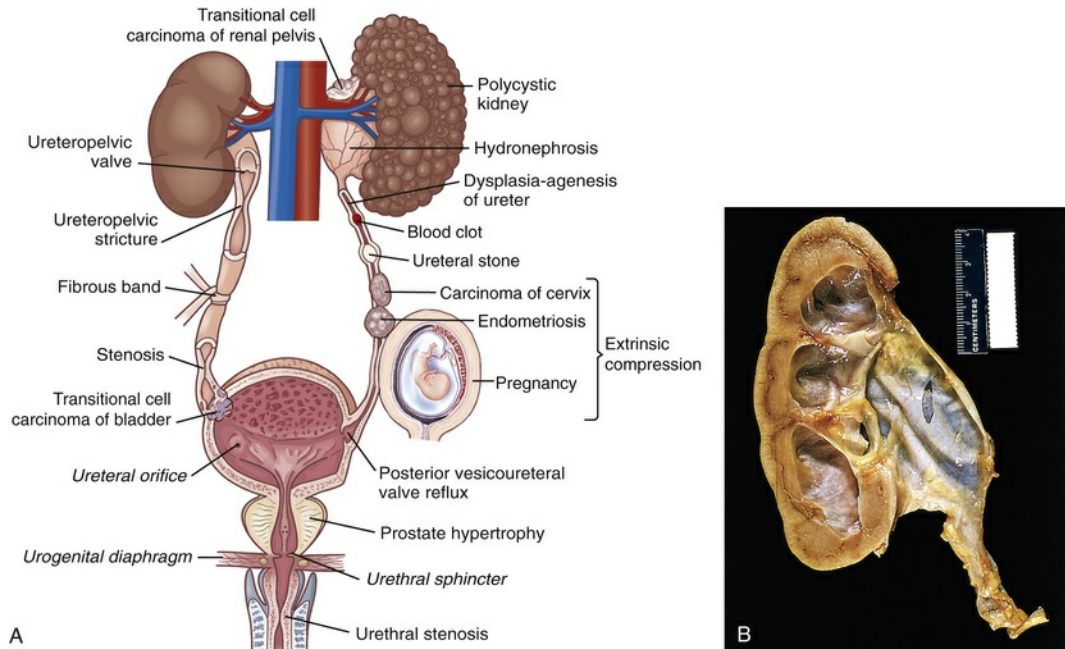

FIGURE 39.1 Urinary Tract Obstruction and Hydronephrosis. **A**, Causes of urinary tract obstruction. Terms in *italics* are normal structures. **B**, Hydronephrosis, marked dilation of renal pelvis and calyces with thinning of parenchyma. (B from Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

Upper Urinary Tract Obstruction

Common causes of upper urinary tract obstruction include stricture or congenital compression of a calyx or the ureteropelvic or ureterovesical junction (e.g., stones [calculi]); ureteral compression from an aberrant vessel, tumor, or abdominal inflammation and scarring (retroperitoneal fibrosis); or ureteral blockage from stones or a malignancy of the renal pelvis or ureter.

Obstruction of the upper urinary tract causes increased hydrostatic pressure, dilation of the ureter, renal pelvis, calyces, and renal parenchyma proximal to the site of urinary blockage. The increased pressure is transmitted to the glomerulus, which decreases glomerular blood flow and, ultimately, decreases glomerular filtration rate (GFR). Dilation of the ureter is referred to as **hydroureter** (accumulation of urine in the ureter), and dilation of the renal pelvis and calyces proximal to a blockage leads to **hydronephrosis** (enlargement of the renal pelvis and calyces) or **ureterohydronephrosis** (dilation of both

the ureter and the pelvicaliceal system) (see [Fig. 31.1, B](#)). Dilation of the upper urinary tract is an early response to obstruction and includes smooth muscle hypertrophy and accumulation of urine above the level of blockage (urinary stasis/retention). Unless the obstruction is relieved, this dilation leads to enlargement with tubulointerstitial fibrosis and apoptosis affecting the renal nephrons and can lead to chronic kidney disease.

Tubulointerstitial fibrosis is the deposition of excessive amounts of extracellular matrix (collagen and other proteins) by activated fibroblasts with associated areas of tubular atrophy. Deposition of extracellular matrix is a normal process of kidney repair and maintenance, and the deposition of extracellular matrix is normally balanced by its breakdown under the influence of metalloproteinases. The dysregulated repair of tubulointerstitial fibrosis results from activation of multiple cytokines, and growth factors have been implicated in the process of tubulointerstitial fibrosis and irreversible loss of kidney function, including transforming growth factor-beta-1 (TGF- β 1), angiotensin II, aldosterone, and various tumor necrosis factors.^{1,2} **Apoptosis** is a normal process that the body uses to replace damaged or senescent cells with new ones (see [Chapter 1](#)), but the imbalance in growth factors provoked by obstruction leads to excess cellular destruction and death, ultimately resulting in loss of functioning nephrons and kidney damage.

Tubulointerstitial fibrosis and apoptosis result in detectable damage to the distal renal tubules within approximately 7 days. By 14 days, obstruction has adversely affected both distal and proximal aspects of the nephron. Within 28 days the glomeruli of the kidney have been damaged and the renal cortex and medulla are reduced in size (thinned). Distal tubular damage occurs initially and decreases the kidney's ability to concentrate urine, causing an increase in urine volume despite a decrease in GFR. The affected kidney is unable to conserve sodium, bicarbonate, and water or to excrete hydrogen or potassium, leading to metabolic acidosis and dehydration. The magnitude of this damage, and the kidney's ability to recover normal homeostatic function, is affected by the severity and duration of the

obstruction. With complete obstruction, damage to the renal tubules and compression of the renal vasculature occur in a matter of hours, and irreversible damage occurs within 3 to 4 weeks. Nevertheless, even in the face of a complete obstruction, the human kidney may recover at least partial homeostatic function provided the blockage is removed within 56 to 69 days.³ This recovery requires approximately 4 months. Partial obstruction, in the absence of renal infection, leads to subtler but ultimately permanent impairments including loss of the kidney's ability to concentrate urine, reabsorb bicarbonate, excrete ammonia, or regulate metabolic acid-base balance if the obstruction is not relieved. Complete bilateral obstruction causes anuria because the retrograde increase in tubular hydrostatic pressure completely opposes glomerular filtration.

The body is able to partially counteract the negative consequences of unilateral obstruction by a process called **compensatory hypertrophy** and **hyperfunction**.⁴ The compensatory response is the result of **compensatory growth** that occurs under the influence of a hormone or hormones that have not yet been identified. Compensatory growth causes the contralateral (unobstructed) kidney to increase the size and function of individual glomeruli and tubules but not the total number of functioning nephrons. The ability of the body to engage in compensatory hypertrophy and hyperfunction diminishes with age, and the process is reversible when relief of obstruction results in recovery of function by the obstructed kidney. Unilateral obstruction may remain silent for a long time.

Relief of bilateral, partial urinary tract obstruction or complete obstruction of one kidney is usually followed by a brief period of diuresis (commonly called **postobstructive diuresis**).⁵ It is a physiologic response and is typically mild, representing a restoration of fluid and electrolyte imbalance caused by the obstructive uropathy. Alterations in tubular transport and water reabsorption and volume expansion contribute to the diuresis. Occasionally relief of obstruction will cause rapid excretion of large volumes of water, sodium, or other electrolytes, resulting in a urine output of 10 L/day or more (minimal normal daily urine output is approximately 720 mL/day). Rapid

postobstructive diuresis causes dehydration and fluid and electrolyte imbalances if not promptly corrected with fluid replacement. Risk factors for severe postobstructive diuresis include bilateral obstruction, impairment of one or both kidneys' ability to concentrate urine or reabsorb sodium (*nephrogenic diabetes insipidus*), hypertension, edema and weight gain, congestive heart failure, and uremic encephalopathy.

Kidney Stones

Renal calculi (nephrolithiasis), or **urinary stones (urolithiasis),** are masses of crystals, protein, or other substances that are a common cause of urinary tract obstruction in adults. Calculi can be located in the kidneys, ureters, and urinary bladder. The prevalence of stones in the United States is approximately 8.8% (10.6% among men and 7.1% among women) and is increasing. The recurrence rate is approximately 30% to 40% at 10 and 15 years. The risk of urinary calculus formation is influenced by a number of factors, including age, sex, race, geographic location, seasonal factors, fluid intake, diet, occupation, genetic predisposition, and other conditions including urinary tract infection, hypertension, atherosclerosis, metabolic syndrome, obesity, and type 2 diabetes.⁶ Most persons develop their first stone before age 50 years. Geographic location influences the risk of stone formation because of indirect factors, including average temperature, humidity, and rainfall and their influence on fluid intake and dietary patterns. Persons who regularly consume an adequate volume of water and those who are physically active are at reduced risk when compared with people who are inactive or consume lower volumes of water. Most kidney stones are unilateral and are a risk factor for chronic kidney disease and an increased risk for myocardial infarction.

Urinary calculi can be classified according to the primary minerals (salts) that make up the stones. The most common stone types include calcium oxalate or phosphate (70% to 85%), struvite (magnesium, ammonium, and phosphate) (1% to 5%), and uric acid (5% to 10%). Cystine stones are rare, less than 1%.⁶ Less common stone elements

include cystine, 2,8-dihydroxyadeninuria (a rare genetic disorder that increases risk of xanthine stones), triamterene (a diuretic), and indinavir (a protease inhibitor used in management of human immunodeficiency virus [HIV] infection). Urinary calculi also can be classified according to location and size. *Staghorn calculi* are large and fill the minor and major calyces. *Nonstaghorn calculi* are of variable size and are located in the calyces, in the renal pelvis, or at various sites along the ureter.

◆Pathophysiology.

Renal calculus formation is complex and related to (1) supersaturation of one or more salts in the urine, (2) precipitation of the salts from a liquid to a solid state (crystals), (3) growth through crystallization or agglomeration (sometimes called *aggregation*), and (4) the effect of stone inhibitors.⁷ *Supersaturation* is the presence of a higher concentration of a salt within a fluid (in this case, the urine) than the volume is able to dissolve to maintain equilibrium. Human urine contains many positively and negatively charged ions capable of *precipitating* from solution and forming a variety of salts. The salts form crystals that are retained and grow into stones. *Crystallization* is the process by which crystals grow from a small *nucleus* to larger stones in the presence of supersaturated urine. Although supersaturation is essential for free stone formation, the urine need not remain continuously supersaturated for a calculus to grow once its nidus has precipitated from solution. Intermittent periods of supersaturation after the ingestion of a meal or during times of dehydration are sufficient for stone growth in many individuals. The apical papillae have interstitial sites where hydroxyapatite deposits, known as *Randall plaque*, become exposed and serve as sites for calcium oxalate stone formation. Calcium phosphate stone formation is rare and found at the end of the collecting ducts.⁸ *Matrix* is an organic material (i.e., mucoprotein) in which the components of a kidney stone are embedded and form part of the stone and may protect the kidney from cellular injury.⁹

The pH of the urine also influences the risk of precipitation and

calculus formation. An alkaline urinary pH (pH >7.0) significantly increases the risk of calcium phosphate stone formation, whereas acidic urine (pH <5.0) increases the risk of a uric acid stone. Cystine and xanthine precipitate more readily in acidic urine.

Stone or crystal growth inhibiting substances, including potassium citrate, uromodulin, pyrophosphate, and magnesium, are capable of crystal growth inhibition if they are not overwhelmed by the rate of supersaturation.⁷ Thus they can reduce the risk of calcium phosphate or calcium oxalate precipitation in the urine and prevent subsequent stone formation.

Retention of *crystal particles* occurs primarily at the papillary collecting ducts. Although most crystals are flushed from the tract through antegrade urine flow, urinary stasis, anatomic abnormalities, or inflamed epithelium within the urinary tract may prevent prompt flushing of crystals from the system, thus increasing the risk of calculus formation.

The size of a stone determines the likelihood that it will pass through the urinary tract and be excreted through micturition. Stones smaller than 5 mm have about a 50% chance of spontaneous passage, whereas stones that are 1 cm have almost no chance of spontaneous passage.¹⁰ Nevertheless, a person with ureteral dilation from the previous passage of a stone may be able to excrete larger stones when compared with a person experiencing an initial obstructing calculus.

Calcium stones (urolithiasis) account for 70% to 80% of all stones requiring treatment. Calcium oxalate accounts for about 80% of these stones and calcium phosphate about 5%. Both genetic and environmental factors may increase susceptibility. Most affected individuals have *idiopathic calcium oxalate urolithiasis (ICOU)*, a condition whose exact etiology has not yet been defined. Stones can form freely in supersaturated urine or detach from interstitial sites of formation (i.e., from Randall plaque). Hypercalciuria, hyperoxaluria, hyperuricosuria, hypocitraturia, mild renal tubular acidosis, crystal growth inhibitor deficiencies, and alkaline urine are associated with calcium stone formation. Hypercalciuria and hyperoxaluria are usually attributable to intestinal hyperabsorption and less commonly

to a defect in renal calcium reabsorption. Hyperparathyroidism and bone demineralization associated with prolonged immobilization are also known to cause hypercalciuria.⁸

Struvite stones primarily contain magnesium ammonium phosphate as well as varying levels of matrix. Matrix forms in an alkaline urine and during infection with a urease-producing bacterial pathogen, such as a *Proteus*, *Klebsiella*, or *Pseudomonas*.¹¹ Struvite calculi may grow quite large and branch into a staghorn configuration (**staghorn calculus**) that approximates the pelvicaliceal collecting system. Women are at greater risk for struvite stones because they have an increased incidence of urinary tract infection.

Uric acid stones occur in persons who excrete excessive uric acid in the urine, such as those with gouty arthritis. Uric acid is primarily a product of biosynthesis of endogenous purines and is secondarily affected by consumption of purines (e.g., meat and beer) in the diet. A consistently acidic urine greatly increases this risk, including defective NH_4^+ excretion. Cystine and xanthine are amino acids that precipitate more readily in acidic urine.¹² *Cystinuria* and *xanthinuria* are genetic disorders of amino acid metabolism, and their excess in urine can cause **cystinuric** or **xanthine stone** formation in the presence of a low urine pH of 5.5 or less.

◆Clinical Manifestations.

Renal colic, described as moderate to severe pain often originating in the posterior hypochondrium (flank) and radiating to the groin, usually indicates obstruction of the renal pelvis or proximal ureter. Colic that radiates to the lateral flank or lower abdomen typically indicates obstruction in the midureter, and bothersome lower urinary tract symptoms (urgency, frequent voiding, urge incontinence) indicate obstruction of the lower ureter or ureterovesical junction. The pain can be severe and incapacitating and may be accompanied by nausea and vomiting. Gross (visible blood in the urine) or microscopic hematuria (three or more red blood cells per high power microscopic field) may be present.¹⁰

◆ Evaluation and Treatment.

The evaluation and diagnosis of urinary calculi are based on presenting symptoms and history combined with a focused physical assessment and imaging studies.¹³ The history queries dietary habits; the age of the first stone episode; stone analysis; and presence of complicating factors, including recurrent urinary tract infection, hyperparathyroidism, or recent gastrointestinal or genitourinary surgery. Urinalysis (including pH) is obtained and a 24-hour urine is completed to identify calcium oxalate, calcium citrate, and other significant constituents. In addition, every effort is made to retrieve and analyze calculi that are passed spontaneously or retrieved through aggressive intervention. Additional tests are obtained in selected individuals, such as those with suspected hyperparathyroidism (elevated serum calcium levels) or cystine or uric acid stones, in order to diagnose and manage underlying metabolic disorders. Imaging of kidney stones includes plain abdominal radiography, ultrasound, intravenous pyelography, computed tomography, and magnetic resonance imaging.¹⁴

The goals of treatment are to manage acute pain, promote stone passage, reduce the size of stones already formed, and prevent new stone formation.¹³ The components of treatment include (1) managing pain; (2) reducing the concentration of stone-forming substances by increasing urine flow rate with high fluid intake; (3) adjusting the pH of the urine (e.g., make it more alkaline with potassium citrate administration); (4) decreasing the amount of stone-forming substances in the urine by decreasing dietary intake or endogenous;¹⁵ and (5) removing stones using percutaneous nephrolithotomy, ureteroscopy, or ultrasonic or laser lithotripsy to fragment stones for excretion in the urine. Obstructing kidney stones with a suspected proximal urinary tract infection are urologic emergencies requiring emergent decompression, stone removal, and antibiotics.¹⁶ Prevention of recurrent stones includes increasing fluid intake to generate 2.5 L of urine per day; avoiding intake of colas and other soft drinks acidified with phosphoric acid; avoiding dietary oxalate (e.g., chocolate, beets, nuts, rhubarb, spinach, strawberries, tea, wheat bran); eating less

animal protein; limiting sodium intake; and, for calcium stone prevention, maintaining a dietary calcium intake of 1000 to 1200 mg/day.^{13,17}

Lower Urinary Tract Obstruction

Obstructive disorders of the lower urinary tract (LUT) are primarily related to storage of urine in the bladder or emptying of urine through the bladder outlet. The causes of the obstruction include neurogenic and anatomic alterations or, in some instances, a combination of both. Incontinence is a common symptom. Types of incontinence are reviewed in [Table 39.1](#).

TABLE 39.1

TYPES OF INCONTINENCE

TYPE	DESCRIPTION
Urge incontinence (most common in older adults)	Involuntary loss of urine associated with an abrupt and strong desire to void (urgency). Often associated with involuntary contractions of the detrusor (detrusor overactivity). When associated with a neurologic disorder, this is called <i>detrusor hyperreflexia</i> . When no neurologic disorder exists this is called <i>detrusor instability</i> . May be associated with decreased bladder wall compliance.
Stress incontinence (most common in women younger than 60 years and men who have had prostate surgery)	Involuntary loss of urine during coughing, sneezing, laughing, or other physical activity associated with increased abdominal pressure.
Overflow incontinence	Involuntary loss of urine with overdistention of the bladder. Associated with neurologic lesions below S1, polyneuropathies, and urethral obstruction (i.e., an enlarged prostate).
Mixed incontinence (most common in older women)	A combination of stress and urge incontinence.
Functional incontinence	Involuntary loss of urine caused by dementia or immobility.

Data from Agency for Healthcare Research and Quality: *Overview: urinary incontinence in adults, clinical practice guideline update*, Rockville, MD, 1996, Author. Available at: <https://archive.ahrq.gov/clinic/uioverview.htm>; MacLachlan LS,

Neurogenic Bladder

Neurogenic bladder is a general term for bladder dysfunction caused by neurologic disorders and involves problems with urine storage or voiding. The types of dysfunction are related to the sites in the nervous system that control sensory and motor bladder function (Fig. 39.2). Lesions that develop in upper motor neurons of the brain and spinal cord result in **dyssynergia** (loss of coordinated neuromuscular contraction) and overactive or hyperreflexive bladder function. Lesions in the sacral area of the spinal cord or peripheral nerves result in underactive, hypotonic, or atonic (flaccid) bladder function, often with loss of bladder sensation.

FIGURE 39.2 Causes of Neurogenic Bladder and Reflex Incontinence. (Adapted from Doughty DB, editor: *Urinary and fecal incontinence: current*

Neurologic disorders that develop above the pontine micturition center result in **detrusor hyperreflexia**, also known as an *uninhibited* or *reflex bladder*. This is an upper motor neuron disorder in which the bladder empties automatically when it becomes full and the external sphincter functions normally. Because the pontine micturition center remains intact, there is coordination between detrusor muscle contraction and the relaxation of the urethral sphincter. Stroke, traumatic brain injury, dementia, and brain tumors are examples of disorders that result in detrusor hyperreflexia. Symptoms include urine leakage and incontinence.

Neurologic lesions that occur below the pontine micturition center but above the sacral micturition center (between C2 and S1) are also upper motor neuron lesions and result in **detrusor hyperreflexia with detrusor sphincter dyssynergia**. There is loss of pontine coordination of detrusor muscle contraction and external sphincter relaxation, so both the bladder and the sphincter are contracting at the same time, causing a functional obstruction of the bladder outlet.¹⁸ Spinal cord injury, multiple sclerosis, Guillain-Barré syndrome, and intervertebral disk problems are causes of this disorder. There is diminished bladder relaxation during storage with small urine volumes and high intravesicular (inside the bladder) pressures. This results in an overactive bladder syndrome (see later discussion) with symptoms of urgency, frequency, urge incontinence, and increased risk for urethral turbulence and urinary tract infection.

Lesions that involve the sacral micturition center (below S1; may also be termed *cauda equina syndrome*) or peripheral nerve lesions result in **detrusor areflexia** (acontractile detrusor), a lower motor neuron disorder. The result is an acontractile detrusor or atonic bladder with retention of urine and distention. If the sensory innervation of the bladder is intact, the full bladder will be sensed but the detrusor may not contract. This is an *underactive bladder syndrome* and may have symptoms of stress and overflow incontinence. Myelodysplasia, multiple sclerosis, tabes dorsalis, and peripheral polyneuropathies are associated with this disorder.

Because the bladder neck consists of circular smooth muscle with adrenergic innervation, overactive bladder (OAB) syndrome and detrusor sphincter dyssynergia may be managed by α -adrenergic blocking (antimuscarinic) medications or botulinum toxin A. Obstruction that is not adequately managed by pharmacotherapy may require bladder neck incision. Detrusor sphincter dyssynergia may be managed by intermittent catheterization in combination with higher dose antimuscarinic drugs to prevent overactive detrusor contractions and associated dyssynergia while ensuring regular, complete bladder evacuation through catheterization. Alternatively, men with dyssynergia may be managed by condom catheter containment, supplemented by an α -adrenergic blocking drug or transurethral sphincterotomy (surgical incision of the striated sphincter) in order to relieve obstruction. Low bladder wall compliance may be managed by antimuscarinic drugs and intermittent catheterization; however, more severe cases may require augmentation enterocystoplasty (enlargement of the low compliant bladder wall using a detubularized piece of small bowel), urinary diversion, or long-term indwelling catheterization.¹⁸

Overactive and Underactive Bladder Syndromes

Overactive bladder (OAB) syndrome is a chronic syndrome of detrusor overactivity in the absence of infection. It is estimated that 29.8 million adults over the age of 40 have bothersome OAB symptoms with a prevalence of 11% to 19%.¹⁹ OAB is characterized by urgency with involuntary detrusor contractions during the bladder filling phase. The contraction may be spontaneous or provoked and associated with hyperexcitable nerves or involuntary reflexes. There is coordination between the contracting bladder and the external sphincter, but the detrusor is too weak to empty the bladder, resulting in urinary retention with overflow or stress incontinence. Overactive bladder is defined by the International Continence Society as a *symptom syndrome* of urgency, with or without urge incontinence and usually associated with frequency and nocturia.²⁰ Sexual dysfunction and bowel problems often accompany OAB. Diagnosis is usually

made by evaluation of symptoms. Urodynamic evaluation confirms the diagnosis. Treatment options include lifestyle modifications, behavioral therapy, pharmacotherapy (e.g., antimuscarinics), neuromodulation therapy, and surgical interventions.²¹ Adults are often reluctant to discuss this syndrome with their healthcare provider. When left untreated, OAB is costly, impairs health and quality of life, causes depression, and leads to social isolation. OAB is a risk for urinary tract infection and a risk for falls in older adults.

Underactive bladder (UAB) syndrome is defined by the International Continence Society (ICS) as bladder contraction of reduced strength and/or duration, resulting in prolonged bladder emptying or a failure to achieve complete bladder emptying, or both, within a normal time span.²⁰ Disruption of bladder innervation can occur with spinal cord injury, stroke, multiple sclerosis, Parkinson disease, and diabetic neuropathy. Aging can be a contributing factor. The symptoms may be indistinguishable from symptoms of lower urinary tract obstruction, including weak stream, intermittency, hesitancy, and straining to void. Urodynamic studies are required for evaluation. Treatment depends on the cause of the disorder and may include sacral neuromodulation, drugs that increase bladder contractility, and/or drugs that induce urethral relaxation.^{22,23}

Anatomic Obstructions to Urine Flow

Anatomic causes of resistance to urine flow include urethral stricture, prostatic enlargement in men, pelvic organ prolapse in women, and tumor compression. Symptoms of lower urinary tract obstruction are more common in men and include (1) frequent daytime voiding (urination more than every 2 hours while awake); (2) nocturia (awakening more than once each night to urinate for adults younger than 65 years of age or more than twice for older adults); (3) bothersome urgency, often combined with hesitancy; (4) poor force of stream; (5) intermittency of urinary stream; and (6) feelings of incomplete bladder emptying despite micturition.

A **urethral stricture** is a narrowing of its lumen and occurs when infection, injury, or surgical manipulation produces a scar that

reduces the caliber of the urethra. The vast majority of urethral strictures occur in men; they are less common in women. The severity of obstruction is influenced by its location within the urethra, its length, and the minimum caliber of urethral lumen within the stricture. Specifically, proximal urethral strictures cause more severe obstruction than do strictures of the distal urethra, longer strictures tend to be more obstructive, and the magnitude of blockage is in *reverse* proportion to the urethral caliber. Urethral stricture may be treated with urethral dilation. However, urethroplasty has become the first-line treatment of stricture disease, with long-term success for both men and women.^{24,25}

Prostate enlargement is caused by acute inflammation, benign prostatic hyperplasia, or prostate cancer (see [Chapter 26](#)). Each of these disorders can cause encroachment on the urethra with obstruction to urine flow and the symptoms summarized previously. Prostate enlargement is managed by treating the underlying cause of the prostate enlargement with medication or surgery. Acute prostatitis is initially managed by broad-spectrum antibiotics until the results of a urine culture are obtained. Urinary retention may require transient placement of a suprapubic catheter. The management of benign prostatic hyperplasia and treatment options for prostate cancer are presented in [Chapter 26](#).

Severe **pelvic organ prolapse (POP)** (see [Chapter 25](#)) in a woman causes bladder outlet obstruction when, most commonly, a cystocele (the downward protrusion of the bladder into the vagina) descends below the level of the urethral outlet. Rectoceles and prolapse of the uterus are additional causes of prolapse. Cystoceles (see [Fig. 25.11](#)) that reach or protrude beyond the vaginal introitus create the greatest risk for obstruction, particularly if the bladder neck (in females the bladder neck and proximal urethra constitute the internal sphincter of the bladder) has been surgically repaired without simultaneous repair of the cystocele. In men the bladder may rarely herniate into the scrotum, causing a similar type of obstruction.

Mild POP can be treated effectively with pelvic floor muscle training.²⁶ A pessary (rubber or silicone device designed to

compensate for vaginal wall prolapse) may be inserted to mechanically reverse severe pelvic organ (bladder, uterus, or rectum) prolapse. Depending on the device, the woman may be able to remove, cleanse, and replace the pessary, or it may be changed during a clinic visit. Intravaginal hormone replacement therapy may contribute to the long-term success of a pessary.²⁷ Alternatively, pelvic organ prolapse may be repaired surgically; the procedure may be combined with a urethral suspension to correct stress urinary incontinence or rectocele repair.²⁸

Partial obstruction of the bladder outlet or urethra initially causes an increase in the force of detrusor contraction. If the blockage persists, afferent nerves within the bladder wall are adversely affected, leading to urinary urgency and, in some cases, overactive detrusor contractions (a myogenic cause of overactive bladder). When obstruction persists, there is an increased deposition of collagen within the smooth muscle bundles of the detrusor muscle (*trabeculation*), possibly in an attempt to increase the force of its contraction strength. Ultimately, the bladder wall loses its ability to stretch and accommodate urine, a condition called **low bladder wall compliance**, and the detrusor loses its ability to contract efficiently. Low bladder wall compliance chronically elevates intravesicular pressure, greatly increasing the problems of hydronephrosis, hydroureter, and impaired renal function.

◆ **Evaluation of Lower Urinary Tract Disorders.**

Although the history and physical examination are critical to the evaluation of lower urinary tract disorders, it must be remembered that no symptom or cluster of symptoms has been identified that accurately differentiates the various causes of these disorders. For example, symptoms such as urgency, urge incontinence, frequent urination, and nocturia may develop because of overactive bladder or either increased or decreased bladder outlet resistance. Reduced resistance is associated with the symptom of stress incontinence (incontinence with coughing or sneezing), and symptoms of increased resistance are similar to those of bladder outlet obstruction, including

poor force of urinary stream, hesitancy, and feelings of incomplete bladder emptying.

Various diagnostic tests assist with evaluation.²⁹ A *cystometric test* uses a catheter and manometer to evaluate bladder urine volume and pressure in relation to involuntary bladder contraction (the leak point pressure) and the urge to void. The *postvoid residual urine* is measured by catheterization within 5 to 15 minutes of urination or through a bladder ultrasound machine that measures bladder height and width to provide an approximation of urine within the vesicle. This measurement may be combined with *uroflowmetry*, a graphic representation of the force of the urinary stream expressed as milliliters voided per second. Each of these measurements assesses the lower urinary tract's efficiency in evacuating urine through micturition but neither differentiates poor detrusor contraction strength from obstruction as a cause of urinary retention. Instead, *multichannel urodynamic testing* is used to identify obstruction, quantify its severity, and measure detrusor contraction strength (Fig. 39.3). *Video-urodynamic recordings* can also demonstrate overactive bladder and detrusor sphincter dyssynergia. An evaluation of renal function, including functional imaging studies and measurement of serum creatinine level, is completed particularly when obstruction is severe and associated with elevated residuals or urinary tract infection. *Electromyography* measures electrical activity in the bladder neck using surface or needle electrodes.

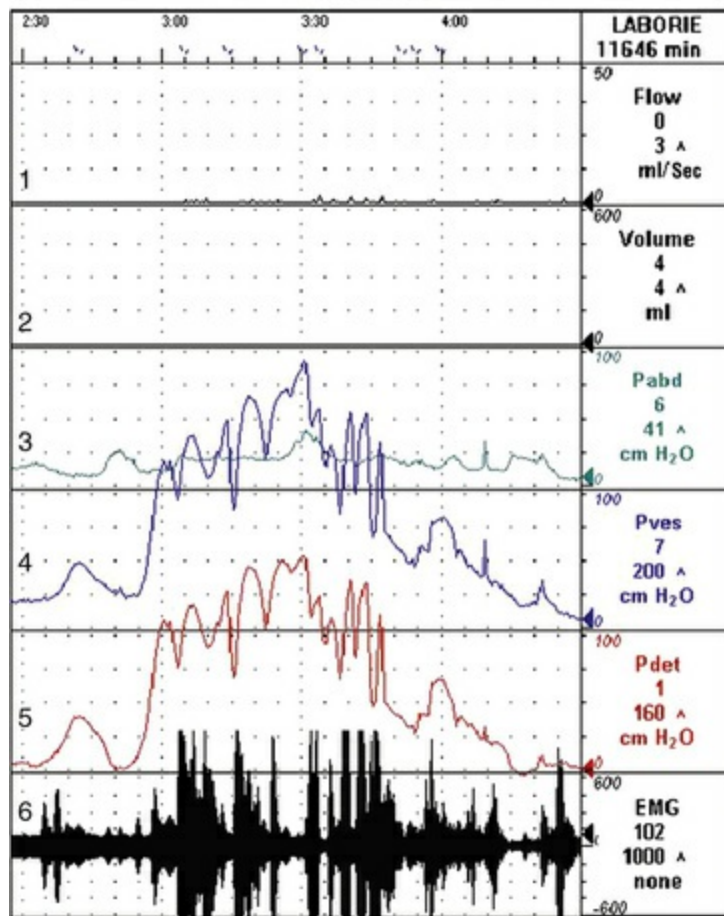

FIGURE 39.3 Neurogenic Detrusor Overactivity with Vesicosphincter. The arrow indicates narrowing of the striated sphincter consistent with electromyographic activity (*Line 6*) noted on the urodynamic tracing. Note the characteristic poor flow pattern (*Line 1*) with elevated voiding

pressures (*Lines 4 and 5*) indicating obstruction. *Line 1* = Urine flow rate; *Line 2* = urine volume; *Line 3* = abdominal pressure (*Pabd*); *Line 4* = intravesicular (inside bladder) pressure (*Pves*); *Line 5* = detrusor muscle pressure (*Pdet*); *Line 6* = bladder electromyogram (*EMG*).

Tumors

Renal Tumors

Renal tumors account for about 62,700 (3.7%) of new cancer cases and 14,240 (2.4%) of deaths in 2016.³⁰ There are a number of different histologic subtypes of kidney tumors.³¹ **Renal adenomas** (benign tumors) are uncommon but are increasing in number. The tumors are solid and encapsulated and are usually located near the cortex of the kidney. Because they can become malignant, they are usually surgically removed. **Renal cell carcinoma (RCC)** is the most common renal neoplasm (approximately 80% of all renal neoplasms) (Fig. 39.4). Renal cell carcinoma usually occurs in men (1.5 times more often than in women) between 50 and 60 years of age, and the incidence is increasing. Blacks have a higher incidence and mortality. Risk factors include cigarette smoking, obesity, hypertension, nonsteroidal antiinflammatory drug use, advanced-stage chronic renal failure (CRF), and occupational exposure to trichloroethylene.³² Several genes are associated with RCC. Five-year survival for stage I is about 80% and is about 8% for stage IV cancer (metastatic disease).³³

FIGURE 39.4 Renal Cell Carcinoma. Renal cell carcinomas usually are spheroidal masses composed of yellow tissue mottled with hemorrhage, necrosis, and fibrosis. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

◆Pathophysiology.

Renal cell carcinomas are adenocarcinomas and arise from tubular epithelium. The etiology is unknown. They are classified according to cell type and extent of metastasis. *Clear cell tumors*, the most common (80% of cases), are sporadic or hereditary dominated by mutations of the von Hippel-Lindau (*VHL*) gene located on chromosome 3p25. 3p mutations also can occur in sporadic tumors. They present a better prognosis than *non-clear cell renal cell carcinoma* (20%), which includes papillary (10%), chromophobe (5%), oncocytoma (3% to 4%), collecting duct tumors (1%), and unclassified (rare) tumors.³⁴ *Renal transitional cell carcinoma* is rare and primarily arises in the renal parenchyma and renal pelvis. Cortical tumors arise from proximal and distal convoluted tubular epithelium and have a growth pattern that pushes nonneoplastic nephrons to the periphery of the tumor. Medullary based tumors arise from the corticomedullary junction and typically invade the renal cortex. Renal pelvic tumors arise from the overlying urothelium with invasion through soft tissues and renal parenchyma, and retrograde growth up the collecting tubules.³⁵ Confinement within the renal capsule, together with treatment, is

associated with a better survival rate. The tumors usually occur unilaterally (see [Fig. 39.4](#)). About 25% to 30% of individuals with RCC present with metastasis (stage IV) because they are highly vascular. The most common sites of distant metastasis are the lung, lymph nodes, liver, bone, thyroid, and central nervous system.³⁶

◆Clinical Manifestations.

The classic clinical manifestations of renal tumors are hematuria, dull and aching flank pain, and palpable flank mass in thinner individuals. Systemic manifestations usually represent an advanced stage of disease and include weight loss, fatigue, intermittent fever from tumor cytokines, anemia from hematuria and lack of erythropoietin, polycythemia from tumor secretion of erythropoietin, hypertension from elevated renin levels, and alterations in liver function tests. All of these symptoms occur in less than 10% of cases. Further, they represent an advanced stage of disease, whereas earlier stages are often silent.

◆Evaluation and Treatment.

Diagnosis is based on the clinical symptoms; ultrasound; plain x-ray films of the abdomen; intravenous pyelography; renal angiography; chest, abdominal and pelvic computed tomography; and magnetic resonance imaging. Biopsy provides identification of histologic cell types, molecular markers, and information for staging ([Table 39.2](#)). Treatment for localized disease is surgical removal of the affected kidney (radical nephrectomy) or partial nephron-sparing nephrectomy for smaller tumors. Use of high-dose interleukin-2 is limited by significant toxicity (hypotension requiring vasopressor support, oliguria, pulmonary congestion, arrhythmias, and neurologic toxicity). Agents targeting the vascular endothelial growth factor pathway and the mammalian target of rapamycin (mTOR) (axitinib) have shown efficacy in randomized clinical trials for treatment of metastatic disease. Tyrosine kinase inhibitors, sunitinib and pazopanib, have been effective in phase III clinical trials for first-line treatment of clear cell carcinoma with good prognosis. Bevacizumab

or sorafenib, combined with interferon, are alternative options. Cabozantinib has been approved for advanced disease.³⁷ Non-clear cell renal cell carcinoma does not respond well to systemic therapy, and new treatment approaches are needed.³⁸ Techniques using stereotactic radiofrequency ablation, cryoablation, and laparoscopy are effective for lower grade tumors.³⁹ Tumor obstruction is relieved by placement of ureteral catheters or nephrostomy tubes or by completion of urinary diversion procedures. Survival is related to tumor grade, tumor cell type, and extent of metastasis.

TABLE 39.2

STAGING OF RENAL CELL CARCINOMA (TNM SYSTEM)

STAGE	METASTASIS
I	T1, N0, M0: The tumor is 7 cm across or smaller and is only in the kidney (T1). There is no spread to lymph nodes (N0) or distant organs (M0).
II	T2, N0, M0: The tumor is larger than 7 cm across but is still only in the kidney (T2). There is no spread to lymph nodes (N0) or distant organs (M0).
III	Either of the following: T3, N0, M0: The tumor is growing into a major vein (like the renal vein or the vena cava) or into tissue around the kidney, but it is not growing into the adrenal gland or beyond Gerota fascia (T3); there is no spread to lymph nodes (N0) or distant organs (M0). T1 to T3, N1, M0: The main tumor can be any size and may be outside the kidney, but it has not spread beyond Gerota fascia; the cancer has spread to nearby lymph nodes (N1) but has not spread to distant lymph nodes or other organs (M0).
IV	Either of the following: T4, any N, M0: The main tumor is growing beyond Gerota fascia and may be growing into the adrenal gland on top of the kidney (T4); it may or may not have spread to nearby lymph nodes (any N); it has not spread to distant lymph nodes or other organs (M0). Any T, Any N, M1: The main tumor can be any size and may have grown outside the kidney (any T); it may or may not have spread to nearby lymph nodes (any N); it has spread to distant lymph nodes and/or other organs (M1).

T, Tumor; N, node; M, metastasis.

<http://www.cancer.org/acs/groups/cid/documents/webcontent/003107-pdf.pdf>.

Bladder Tumors

Bladder tumors represent about 4.5% of all malignant tumors and are the fourth most common malignancy in white men over age 55 years. Approximately 76,960 people developed bladder cancer with 16,390 deaths (2.5% of all cancer deaths) in 2016. Risk factors include smoking; aromatic amines, such as benzidine and beta-naphthylamine; arsenic in drinking water; phenacetin; cyclophosphamide; and pioglitazone. *Schistosoma haematobium* is a risk factor in Asia and Africa.³⁰

◆Pathogenesis.

Urothelial (transitional cell) carcinoma is the most common bladder malignancy, appearing on the inner lining of the bladder. Oncogenes of the *ras* gene family and tumor-suppressor genes, including *TP53* mutations (more chemoresistant), and inactivation of *retinoblastoma gene (pRb)* are genomic subtypes of bladder cancer. Several other genes that are either deleted or amplified have been identified and contribute to tumorigenesis. Loss of heterozygosity at chromosome 9 has been found in all stages of urothelial cell carcinoma.^{40,41}

The tumor is usually composed of uroepithelial cells (cells lining the bladder, ureters, urethra, and renal pelvis). They may have a papillary growth pattern (a tuftlike lesion attached to a stalk) or are flat with a velvety appearance (Fig. 39.5). Flat tumors (10% to 30% of bladder tumors) are not as common as papillary tumors and occur as carcinoma in situ or invasive carcinoma. Carcinoma in situ also can present with papillary tumors. High-grade papillary tumors have a complex papillary architecture and a high degree of nuclear atypia, with high risk of recurrence and metastasis.⁴² Metastasis is usually to lymph nodes, liver, bones, lungs, and adrenal glands. Staging distinguishes between muscle invasive and nonmuscle invasive carcinoma and guides treatment and prognosis. Staging for bladder carcinoma is presented in Table 39.3. Secondary bladder cancer develops by invasion of cancer from bordering organs, such as cervical carcinoma in women or prostatic carcinoma in men.

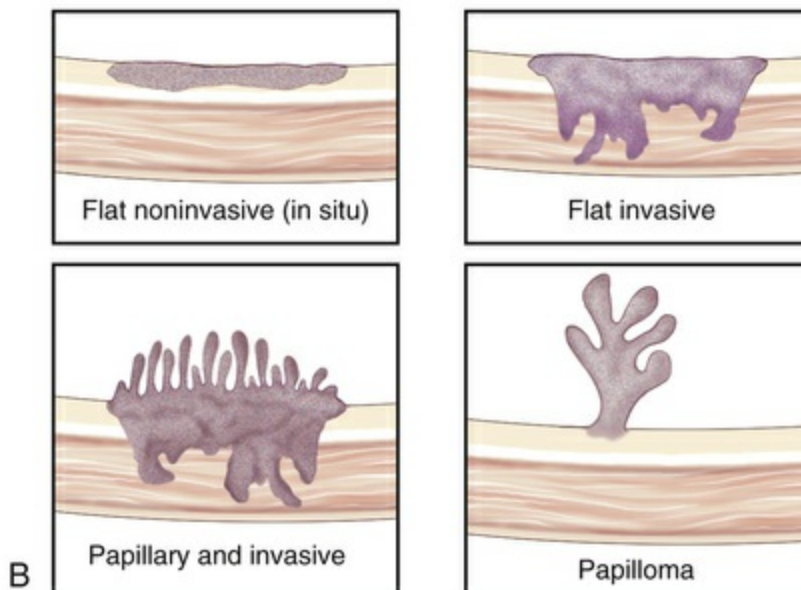

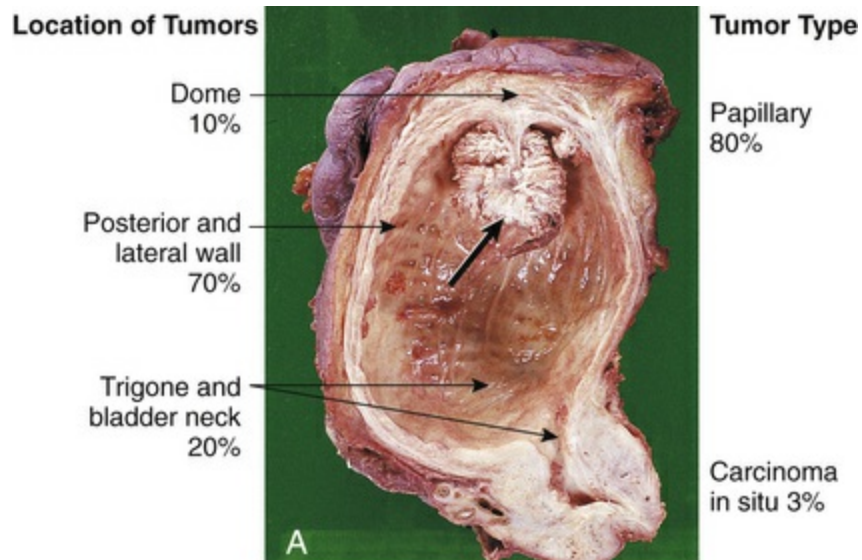

FIGURE 39.5 Carcinoma of the Bladder. A, Papillary transitional cell carcinoma arising in the dome of the bladder as a cauliflower-like lesion (*black arrow*); location and frequency of bladder tumor types noted. B, Bladder cancer with morphologic patterns of most common tumors. TABLE 39.3

STAGING OF BLADDER CARCINOMA (TNM SYSTEM)

STAGE	DESCRIPTION
-------	-------------

Primary Tumor	
T0	No primary tumor identified
Ta	Noninvasive papillary carcinoma—not in bladder muscle
Tis	Carcinoma in situ (CIS)
T1	Tumor invades connective tissue
T2	Tumor invades detrusor muscle
T3	Invasion of fatty tissue around bladder
T4	Tumor has invaded adjacent structures
Region of Lymph Nodes	
N0	No lymph node involvement
N1 to N3	Lymph node metastasis to pelvic or adjacent region
Distant Metastasis	
M0	No metastasis
M1	Distant metastasis

T, Tumor; *N*, node; *M*, metastasis.

Adapted from American Cancer Society: *Bladder cancer*, 2016. Available at: <http://www.cancer.org/cancer/bladdercancer/detailedguide/bladder-cancer-staging>.

◆Clinical Manifestations.

Gross painless microscopic hematuria is the common clinical manifestation of bladder cancer. Episodes of hematuria tend to recur, and they are often accompanied by other nonspecific lower urinary tract symptoms including daytime voiding frequency, dysuria, nocturia, urgency, and urge urinary incontinence. Flank pain may occur if tumor growth obstructs one or both ureterovesical junctions. Bothersome lower urinary tract symptoms are particularly intense in individuals with carcinoma in situ. Metastasis is the cause of death from bladder cancer, usually from high-grade muscle-invasive tumors.⁴³

◆Evaluation and Treatment.

Urinalysis for evidence of hematuria in the absence of infection provides a useful screening tool for high-risk patients. Urine cytology (pathologic analysis of sloughed cells within the urine) is completed in

individuals with evidence of hematuria from unknown causes; cystoscopy or fluorescence cystoscopy with tissue biopsy can confirm the diagnosis. Transurethral resection of the tumor determines staging and guides treatment. Biologic markers for the diagnosis, prognosis, and treatment of bladder cancer are under investigation (e.g., tyrosine kinase receptors, epidermal growth factor and estrogen receptor pathways, cell-cycle regulators, chromatin remodeling, and immune mediators).⁴⁴

Newer magnetic resonance techniques are helpful for local staging, and whole-body computed tomography detects metastasis. Transurethral resection or laser ablation, combined with intravesical chemotherapy (bacillus Calmette-Guerin [BCG]) or immunotherapy (according to guidelines), is effective for superficial tumors or carcinoma in situ. Radical cystectomy with urinary diversion and adjuvant chemotherapy is required for locally invasive tumors, and short-course radiation therapy may be used to support palliative or adjuvant treatment for muscle-invasive tumors. Cisplatin-based combination chemotherapy is currently the first-line therapy for advanced-stage carcinoma. Targeted therapies are under investigation and include fibroblast, epidermal and endothelial growth factors, antiangiogenesis agents (bevacizumab), tyrosine kinase inhibitors (cabozantinib), and immune checkpoint inhibitors (drugs that overcome tumor resistance to immune attack).⁴⁵ Individuals with bladder cancer require lifelong surveillance, as there is a high recurrence rate.⁴⁶

Urinary Tract Infection

Causes of Urinary Tract Infection

A **urinary tract infection (UTI)** is an inflammation of the urinary epithelium usually caused by bacteria from gut flora. A UTI can occur anywhere along the urinary tract including the urethra, bladder, ureter, or kidney. At risk are premature newborns; prepubertal children; sexually active and pregnant women; women treated with

antibiotics that disrupt vaginal flora; spermicide users; estrogen-deficient postmenopausal women; individuals with indwelling catheters; and persons with diabetes mellitus, neurogenic bladder, or urinary tract obstruction (see [What's New? Catheter-Associated Urinary Tract Infections \[CAUTI\]](#)). Cystitis is more common in women because of the shorter urethra and the closeness of the urethra to the anus (increasing the possibility of bacterial contamination). Up to 50% of women may have a lower UTI at some time in their life.^{47,48} *Uncomplicated UTIs* are generally mild and without complications, and they occur in individuals with a normal urinary tract. A *complicated (febrile) UTI* develops when there is an abnormality in the urinary system or a health problem that compromises host defenses, such as human immunodeficiency virus (HIV), renal transplant, diabetes, or spinal cord injury. UTI may occur alone or in association with pyelonephritis, prostatitis, or kidney stones. Up to 40% of cases of septic shock are caused by urosepsis that present in the emergency room.⁴⁸ *Recurrent UTI* is commonly defined as three or more UTIs within 12 months, or two or more occurrences within 6 months. It may occur as a *relapse* when there is a second UTI caused by the same pathogen within 2 weeks of the original treatment, or a *reinfection* that occurs more than 2 weeks after completion of treatment for the same or different pathogen. Mechanisms of UTI are summarized in [Fig. 39.6](#).

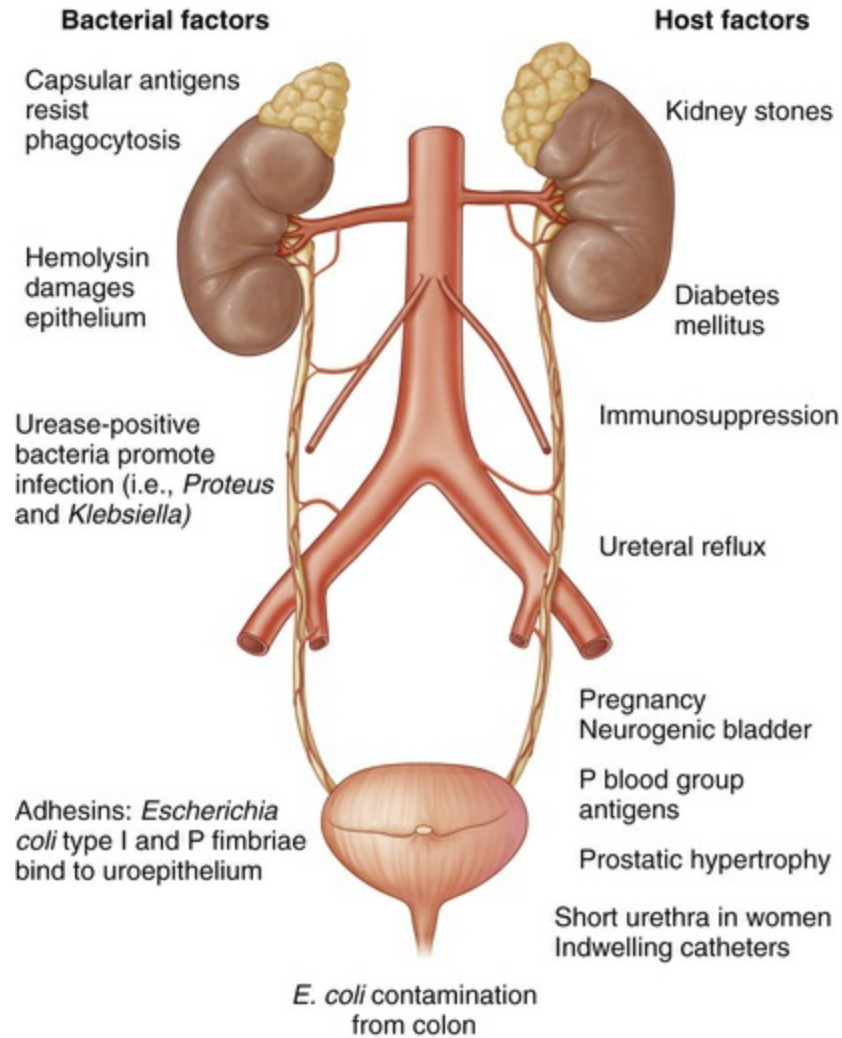

FIGURE 39.6 Mechanisms of Urinary Tract Infection.

What's New?

Catheter-Associated Urinary Tract Infections (CAUTI)

Catheter-associated urinary tract infections are the most common healthcare-associated infection worldwide, and most individuals are asymptomatic. *Escherichia coli* is the most common pathogen associated with short-term catheterization. Appropriate indications for use of catheters include acute urinary retention or obstruction; perioperative applications in select procedures; and the frequent,

accurate measurement of urine output in critically ill individuals. Other uses include sacral or perineal wound healing with incontinence and immobilization from unstable spine or pelvic fractures. The smallest bore catheter should be used and inserted under aseptic conditions and removed as soon as possible. Use of silver alloy or antimicrobial-impregnated/coated catheters has not resulted in reduced CAUTI during short-term catheterization. The system is maintained using a closed-drainage system that is replaced if the system is disconnected. The drainage bag is kept below the level of the bladder. Prophylactic antibiotics are not recommended except in special cases (e.g., before traumatic urinary tract interventions). Bacteriuria develops in several ways: periurethral microorganisms may be introduced at the time of catheterization; contaminated urine from the drainage bag or tubing may reflux back into the bladder; and microorganisms can be introduced when there is a break in the closed system. Additionally, bacterial biofilm develops along the inside and outside of the tubing, providing an environment that allows for bacterial colonization and spread with protection against host defenses and antibiotics. *Proteus mirabilis* and *Providencia stuartii* are known to produce greater amounts of crystalline biofilm, and their adhesion factors and motility allow them to block catheter drainage and ascend more rapidly in the urinary tract. Catheters with visual biofilm warning systems related to increases in pH are in evaluation.

Data from Agency for Healthcare Research and Quality National Guidelines Clearinghouse: Catheter-associated UTIs. In *Guidelines on urological infections*, updated December 23, 2011. Host Defense Mechanisms and Urinary Tract Infection

Host defense mechanisms maintain a sterile posterior urethra and bladder in a healthy individual. Even if bacteria manage to enter the bladder, these defense mechanisms prevent it from clinging to the walls of the bladder or ascending to the upper urinary tracts. Several factors normally combine to protect against UTI. Most bacteria are washed out of the urethra during micturition. The low pH and high osmolality of urea, the presence of uromodulin (Tamm-Horsfall protein, secreted by renal tubular cells in the distal loop of Henle), and secretions from the uroepithelium provide a bactericidal effect. The ureterovesical junction closes during bladder contraction, preventing reflux of urine to the ureters and kidneys. Periurethral mucus-secreting glands surround the distal two-thirds of the female urethra. Mucus from these glands traps bacteria before it can ascend from the proximal urethra to the bladder. In men, the length of the male urethra and secretions from the prostate and accessory periurethral glands combine to form a protective barrier against infection. In addition, the urethral sphincter mechanism acts as a mechanical barrier to bacterial ascent from the distal urethra.

Bacteria that successfully ascend the urethra face detection and destruction by components of the body's immune system, provided they come into contact with the bladder wall. Protective uroepithelial immune responses include Toll-like receptor (e.g., TLR4) recognition of pathogen-associated molecular patterns on the bacteria, neutrophil and macrophage recruitment, and phagocytosis. Susceptibility to infection also is influenced by genetic variation in the host immune response to bacterial virulence and by the virulence of the pathogen (see [Chapter 10](#)). Unfortunately, time is required for the immune system to respond to the potential threat, and this period may provide adequate time for bacteria or other pathogens to reproduce several times. The efficiency of the bladder's defenses is also influenced by the person's Lewis blood group. This taxonomy is based on recognition of inherited antigens associated with the ABO blood factors. Individuals with certain Lewis blood groups are more prone to UTIs because they secrete fewer antigens capable of resisting bacterial adherence by pilus formation.^{49,50}

Most people are able to rapidly rid the urinary tract of invading bacteria, but some show evidence of bacteria in the urine that does not provoke an infection. This condition, called **asymptomatic bacteriuria**, does not harm urinary function or require intervention except in pregnant women or individuals experiencing urinary tract surgery.⁵¹ A UTI occurs when a pathogen circumvents or overwhelms the host's defense mechanisms and rapidly reproduces.

Types of Urinary Tract Infection

Acute Cystitis

Acute cystitis is an inflammation of the bladder and the most common site of UTI. The morphologic appearance of the bladder through cystoscopy describes different types of cystitis. With mild inflammation, the mucosa is hyperemic (red). More advanced cases may show diffuse hemorrhage (termed *hemorrhagic cystitis*), pus formation, or suppurative exudates (termed *suppurative cystitis*) on the epithelial surface of the bladder. Prolonged infection may lead to sloughing of the bladder mucosa with ulcer formation (termed *ulcerative cystitis*). The most severe infections may cause necrosis of the bladder wall (termed *gangrenous cystitis*).

◆Pathophysiology.

Two factors account for the presence of a UTI: the efficiency of defense mechanisms within the host (individual) and the virulence of the pathogen (bacterium, fungus, or parasite). The most common infecting microorganisms are uropathic strains of *Escherichia coli* (80% to 85%), and the second most common is *Staphylococcus saprophyticus* (10%). Less common microorganisms include *Klebsiella*, *Proteus*, *Pseudomonas*, fungi, viruses, parasites, or tubercular bacilli. *Schistosoma haematobium* is the most common cause of parasitic invasion of the urinary tract on a global basis; it infects more than 200 million people and has a strong association with bladder cancer.⁵²

Bacterial contamination of the normally sterile urine usually occurs by retrograde movement of uropathic gram-negative bacilli (usually

Escherichia coli) from the gut into the urethra and bladder and then to the ureter and kidney. Strains of *E. coli* also produce *siderophores* for acquiring nutrient iron, are resistant to bactericidal effects of complement, and express toxins including *cytotoxin necrotizing factor-1* and *hemolysins*. Certain bacterial species also enhance their virulence by acting together to form a biofilm that enhances colonization and resists efficiency of innate host defense mechanisms and antimicrobial therapy, particularly in catheter-associated UTI. Uropathic strains of *E. coli* have *type-1 fimbriae* that bind to latex catheters and receptors on the uroepithelium. They resist flushing during normal micturition and have flagella that propel them upstream. These strains also have *P. fimbriae* (pyelonephritis-associated fimbriae) that bind to the uroepithelium of individuals with P blood group antigen and flagella that propel them upstream. Some women may be genetically susceptible to certain strains of *E. coli* attachment and may harbor pathogenic strains in their vaginal flora.⁵³ Fungal infections are comparatively uncommon. The most common pathogen is *Candida*, but multiple fungal species may colonize the urinary tract or urinary catheters and produce symptomatic UTIs, particularly in those who are immunosuppressed.⁵⁴ Hematogenous infections are uncommon and often preceded by septicemia. Infection initiates an inflammatory response and the symptoms of cystitis.

◆Clinical Manifestations.

Clinical manifestations of cystitis are related to the host inflammatory response and usually include frequency, urgency, dysuria (painful urination), and suprapubic and low back pain. The inflammatory edema in the bladder wall stimulates discharge of stretch receptors, initiating symptoms of bladder fullness with small volumes of urine and producing the urgency and frequency of urination associated with cystitis. Hematuria, cloudy and foul-smelling urine, and flank pain are more serious symptoms. Approximately 10% of individuals with bacteriuria have no symptoms,⁵⁵ and 30% of individuals with symptoms are abacteriuric. Older adults with cystitis may be asymptomatic or demonstrate confusion or vague abdominal

discomfort. Older adults with recurrent UTI and other concurrent illness have a higher risk of morbidity and mortality.⁵⁶

◆Evaluation and Treatment.

Infections in symptomatic individuals are diagnosed by urine culture of specific microorganisms with counts of 10,000/mL or more from freshly voided urine. Urine dipstick that is positive for leukocyte esterase or nitrite reductase can be used for the diagnosis of uncomplicated UTI. Risk factors, such as a urinary tract obstruction, should be identified and treated. Evidence of bacteria from urine culture and antibiotic sensitivity warrants treatment with a microorganism-specific antibiotic. Acute uncomplicated cystitis in nonpregnant women can be diagnosed without an office visit or urine culture. If a urine culture and sensitivity are ordered, the urine specimen must be obtained before the initiation of any antibiotic therapy; 3 to 5 days of treatment is most common.⁵⁷ Complicated UTI requires 7 to 14 days of treatment. From 20% to 25% of women have relapsing infection within 7 to 10 days requiring prolonged antibiotic treatment. Follow-up urine cultures should be obtained 1 week after initiation of treatment and at monthly intervals for 3 months. Clinical symptoms are frequently relieved, but bacteriuria may still be present. Repeat cultures should be obtained every 3 to 4 months until 1 year after treatment for evaluation and treatment of recurrent infection. Recurrent UTI is effectively treated with short courses of antibiotics, but antibiotic resistance is an emerging problem.⁵⁸ Urosepsis and septic shock are medical emergencies that usually demand parenteral, broad-spectrum antibiotic therapy and may require hospitalization.⁵⁹ A UTI caused by schistosomiasis is treated with praziquantel.⁶⁰ Noninfectious cystitis is associated with radiation or chemotherapy treatment for pelvic and urogenital cancers and is treated symptomatically.⁶¹

Interstitial Cystitis/Painful Bladder Syndrome

Interstitial cystitis/painful bladder syndrome (IC/PBS) is defined as an unpleasant sensation (pain, pressure, discomfort) perceived to be

related to the urinary bladder associated with lower urinary tract symptoms of more than 6 weeks' duration in the absence of infection or other identifiable causes.⁶² It occurs most commonly in women ages 20 to 40 years of age. Some individuals also experience fibromyalgia, irritable bowel syndrome, chronic fatigue syndrome, Sjögren syndrome, chronic headaches, and vulvodynia

The cause of IC/PBS is unknown, but an autoimmune reaction may be responsible for the inflammatory response, which includes mast cell activation, altered epithelial permeability, neuroinflammation, and increased sensory nerve sensitivity. The inflammation is associated with a derangement of the glycosaminoglycan layer of the bladder mucosa that makes it more susceptible to penetration by bacteria and noxious urinary solutes. Inflammation and fibrosis of the bladder wall are accompanied by the presence of hemorrhagic ulcers (Hunner ulcers) in some individuals, and bladder volume may decrease as a result of fibrosis, particularly in older individuals.⁶³ Antiproliferative factor (APF), a protein expressed by the bladder uroepithelium in those with IC, may be a biomarker. APF appears to block the normal growth of cells that line the inside wall of the bladder and indirectly increases bladder sensation.⁶⁴

Characteristic symptoms of IC include bladder fullness, frequency (including nocturia), small urine volume, and chronic pelvic pain with symptoms lasting longer than 6 months. Chronic pain and sleep deprivation can lead to depression. Diagnosis of IC requires a thorough history, physical examination and urinalysis, analysis of cystoscopic findings, and the exclusion of other diagnoses.⁶⁵ No single treatment is effective. Oral and intravesical therapies, sacral nerve stimulation, and onabotulinumtoxinA (Botox) are used for symptom relief. Surgery is used in refractory cases.⁶⁶ More research is needed to understand the pathogenesis and long-term treatment of this disease.

Acute Pyelonephritis

Pyelonephritis is an infection of one or both upper urinary tracts (ureter, renal pelvis, and kidney interstitium). Common causes are summarized in [Table 39.4](#). Urinary obstruction and reflux of urine

from the bladder (vesicoureteral reflux) are the most common underlying risk factors. Most cases occur in women.

TABLE 39.4

COMMON CAUSES OF PYELONEPHRITIS

PREDISPOSING FACTORS	PATHOLOGIC MECHANISMS
Kidney stones	Obstruction and stasis of urine contributing to bacteriuria and hydronephrosis; irritation of epithelial lining with entrapment of bacteria
Vesicoureteral reflux	Chronic reflux of urine up the ureter and into kidney during micturition, contributing to bacterial infection
Pregnancy	Dilation and relaxation of ureter with hydroureter and hydronephrosis; partly caused by obstruction from enlarged uterus and partly from ureteral relaxation caused by higher progesterone levels
Neurogenic bladder	Neurologic impairment interfering with normal bladder and urethral sphincter contraction with residual urine and ascending infection
Instrumentation	Introduction of organisms into urethra and bladder by catheters and endoscopes introduced into the urinary tract for diagnostic purposes
Female sexual trauma	Movement of organisms from the urethra into the bladder with infection and retrograde spread to kidney

◆Pathophysiology.

Microorganisms usually associated with acute pyelonephritis include *E. coli*, *Proteus*, and *Pseudomonas*. The latter two microorganisms are more commonly associated with infections after urethral instrumentation or urinary tract surgery. These microorganisms also split urea into ammonia, making alkaline urine that increases the risk of stone formation. The infection is probably spread by ascending uropathic microorganisms along the ureters. Dissemination also may occur by way of the bloodstream, and both kidneys are usually involved. The inflammatory process is usually focal and irregular, primarily affecting the pelvis, calyces, and medulla. The infection causes medullary infiltration of neutrophils with tubulointerstitial inflammation, renal edema, and purulent urine. In severe infections, localized abscesses may form in the medulla and extend to the cortex.

Primarily affected are the renal tubules; the glomeruli usually are spared. Necrosis of renal papillae can develop. After the acute phase, healing occurs with deposition of scar tissue, fibrosis, and atrophy of affected tubules (Fig. 39.7).⁶⁷ Acute pyelonephritis rarely causes renal failure.⁶⁸

FIGURE 39.7 Pyelonephritis. (*Right*) Small, shrunken, irregularly scarred kidney of an individual with chronic pyelonephritis. (*Left*) Kidney is of normal size but also shows scarring on the upper pole. (From Damjanov I: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders.)

◆Clinical Manifestations.

The onset of symptoms is usually acute, with fever, chills, and flank or groin pain. Symptoms characteristic of a UTI, including frequency, dysuria, and costovertebral tenderness, may precede systemic signs and symptoms. Older adults may have nonspecific symptoms, such as low-grade fever and malaise.

◆Evaluation and Treatment.

Differentiating symptoms of cystitis from those of pyelonephritis by clinical assessment alone is difficult. The specific diagnosis is established by urine culture, urinalysis, and clinical signs and symptoms. White blood cell casts indicate pyelonephritis, but they are not always present in the urine. Complicated pyelonephritis requires blood cultures and urinary tract imaging.⁶⁹

Uncomplicated acute pyelonephritis responds well to 2 to 3 weeks of microorganism-specific antibiotic therapy. Follow-up urine cultures are obtained at 1 and 4 weeks after treatment if symptoms recur. Antibiotic-resistant microorganisms or reinfection may occur in cases of urinary tract obstruction or reflux. Intravenous pyelography and voiding cystourethrography identify surgically correctable lesions.

Chronic Pyelonephritis

Chronic pyelonephritis is a persistent or recurrent infection of the kidney leading to scarring of the kidney. One or both kidneys may be involved. The specific cause of chronic pyelonephritis may be unknown (idiopathic) or associated with chronic UTIs, vesicoureteral reflux, renal stones, or obstructive uropathy. Recurrent infections from acute pyelonephritis may be associated with chronic pyelonephritis. Causes other than chronic pyelonephritis include drug toxicity from analgesics such as nonsteroidal antiinflammatory drugs, ischemia, irradiation, and immune-complex diseases.⁷⁰

◆Pathophysiology.

Chronic urinary tract obstruction prevents elimination of bacteria and starts a process of progressive inflammation, alterations of the renal pelvis and calyces, destruction of the tubules, atrophy or dilation and diffuse scarring, and, finally, impaired urine-concentrating ability, leading to chronic kidney failure. The lesions of chronic pyelonephritis are sometimes termed *chronic interstitial nephritis* because the inflammation and fibrosis are located in the interstitial spaces between the tubules (see [Fig. 39.7](#)).

◆Clinical Manifestations.

The early symptoms of chronic pyelonephritis are often minimal and commonly include frequency, dysuria, and flank pain and may include hypertension. Progression of disease leads to renal failure, particularly in the presence of other risk factors (i.e., obstructive uropathy or diabetes mellitus). There is an inability to conserve sodium with loss of tubular function, and development of

hyperkalemia and metabolic acidosis. Risk for dehydration must be considered if there is loss of the ability to concentrate the urine.

◆Evaluation and Treatment.

Urinalysis, intravenous pyelography, and ultrasound are used diagnostically. Treatment is related to the underlying cause. Obstruction must be relieved. Antibiotics may be given, with prolonged antibiotic therapy for recurrent infection.

Glomerular Disorders

Acute Glomerulonephritis

Acute glomerulonephritis is an inflammation of the glomerulus caused by *primary glomerular injury*, including immunologic responses, ischemia, free radicals, drugs, toxins, vascular disorders, and infection. *Secondary glomerular injury* is a consequence of systemic diseases, including diabetes mellitus, systemic lupus erythematosus, and, less commonly, congestive heart failure and HIV-related kidney disease. Glomerular disease is a significant cause of chronic kidney disease and end-stage renal failure worldwide.^{71,72}

◆Pathophysiology.

Immune mechanisms are a major cause of injury for primary and secondary causes of glomerulonephritis (Fig. 39.8). The injury damages the glomerular capillary filtration membrane including the endothelium, basement membrane, and epithelium (podocytes). The most common types of immune injury are (1) deposition of circulating antigen-antibody immune complexes into the glomerulus (type III hypersensitivity); (2) reaction of antibodies in situ against planted antigens within the glomerulus (type II hypersensitivity, cytotoxic); (3) action of antibodies directed against the glomerular capillary wall (antiglomerular basement membrane antibodies), the least common and most severe form of immune injury (type II hypersensitivity); and (4) cell-mediated immune injury (type IV hypersensitivity) (Table

39.5). Nonimmune glomerular injury is related to ischemia, metabolic disorders (e.g., diabetes mellitus), toxin exposure, drugs, vascular disorders (e.g., vasculitis), and infection with direct injury to glomerular cells. Different causes of injury may result in more than one type of glomerular lesion; thus lesions are not necessarily disease specific (Table 39.6).

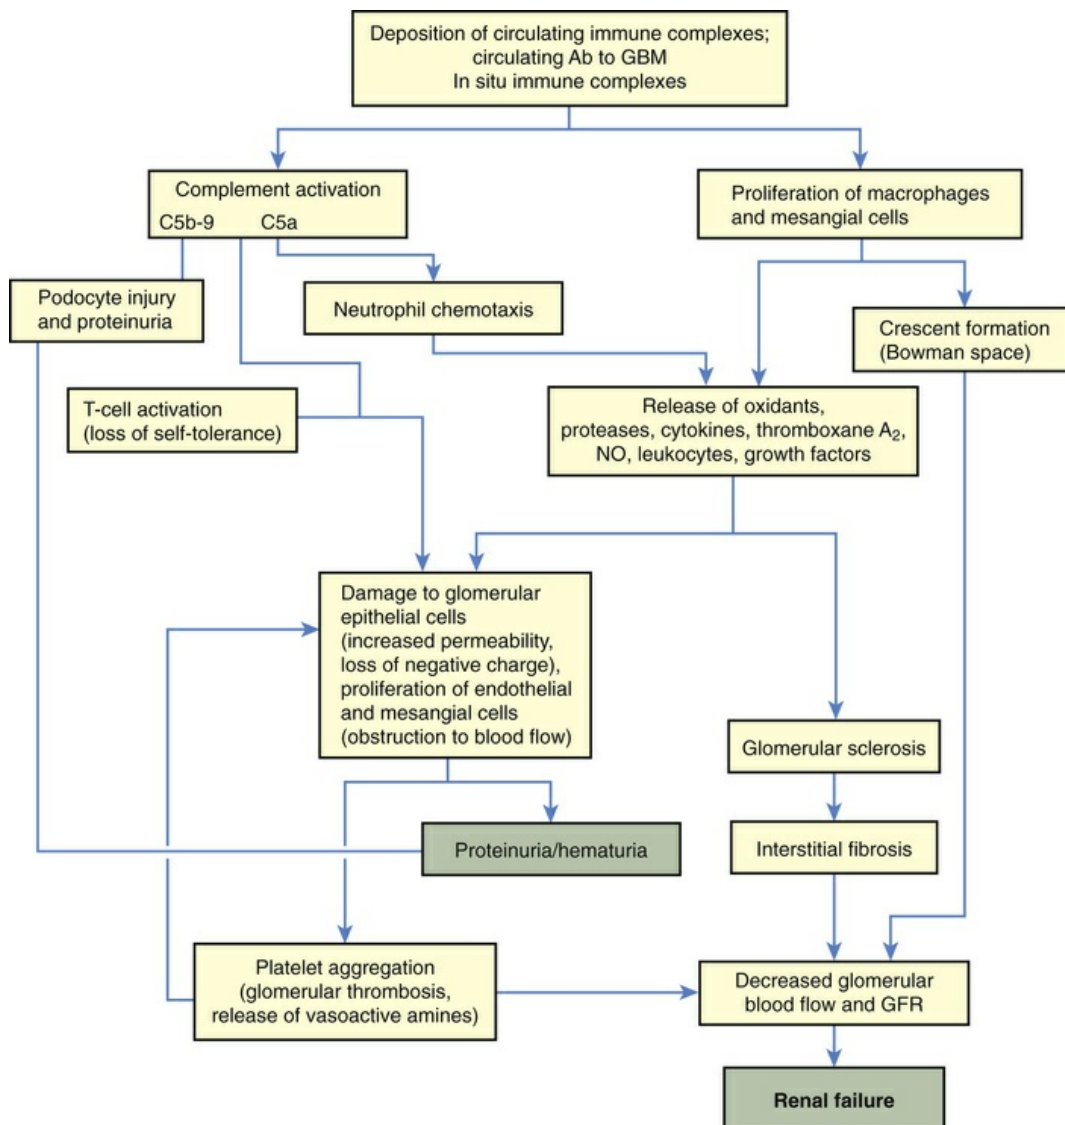

FIGURE 39.8 Mechanisms of Glomerular Injury. *Ab*, Antibody; *GBM*, glomerular basement membrane; *GFR*, glomerular filtration rate; *NO*, nitric oxide.

TABLE 39.5**IMMUNOLOGIC PATHOGENESIS OF GLOMERULONEPHRITIS**

GLOMERULAR INJURY	MECHANISM
Soluble immune-complex glomerulonephritis (90%)	Formation of antibodies stimulated by the presence of endogenous or exogenous antigens results in circulating soluble antigen-antibody complexes, which are deposited in glomerular capillaries, or the in situ formation of immune complexes to planted antigens or to structural components within the glomerulus; glomerular injury occurring with complement deposition and activation and release of immunologic substances that lyse cells and increase membrane permeability; immune deposits with a microscopic appearance that fluoresce in a <i>granular pattern</i> when stained with fluorescein and viewed under ultraviolet light; severity of glomerular injury related to the number of complexes formed; a type III hypersensitivity reaction; immunoglobulin A (IgA) nephropathy and poststreptococcal glomerulonephritis are examples
Antiglomerular basement membrane glomerulonephritis (5%)	Antibodies are formed and act directly against the glomerular basement membrane (type IV collagen); immune response that causes crescent formation and a <i>linear pattern</i> of immunofluorescence; generally associated with rapidly progressive renal failure such as Goodpasture syndrome (type II hypersensitivity reaction)
Alternative complement pathway	An immune mechanism associated with circulating autoantibodies and C3 complement and membranoproliferative glomerulonephritis
Cell-mediated immunity	A delayed hypersensitivity response that damages glomerulus; actual cellular mechanism not clearly understood but may involve cytokine secretion, activation of effector cells such as macrophages or by inducing autoantibodies or immune complexes; cytotoxic CD8+ T-cell responses and failure of regulatory T cells may represent two additional types of antirenal hypersensitivity (type IV hypersensitivity); often seen in rapidly progressive glomerulonephritis

TABLE 39.6**CLASSIFICATION OF GLOMERULAR LESIONS**

LESION	DISTRIBUTION WHEN MANY GLOMERULI CONSIDERED
Diffuse	Relatively uniform involvement of most (>50%) or all glomeruli; most common form of

	glomerulonephritis
Focal	Changes in only some glomeruli (>50%), whereas others are normal
LESION	DISTRIBUTION WHEN SINGLE GLOMERULI CONSIDERED
Global	A lesion involving the entire glomerulus
Segmental- local	Changes in one part of the glomerulus with other parts unaffected
LESION	LESION CHARACTERISTICS
Mesangial	Deposits of immunoglobulins in the mesangial matrix; mesangial cell proliferation
Membranous	Thickening of the glomerular capillary wall with immune deposits (i.e., immunoglobulin G [IgG] and complement 3 [C3])
Proliferative	Increase in the number of glomerular cells: endothelial, epithelial, mesangial
Sclerotic	Glomerular scarring from previous glomerular injury
Crescentic	Accumulation of proliferating cells within Bowman space, making the appearance of a crescent
Interstitial fibrosis	Scarring between the glomerulus and the tubules

Immune injury is caused by activation of biochemical mediators of inflammation (i.e., complement and cytokines from leukocytes) and begins after the antigen-antibody complexes have deposited or formed in the glomerular capillary wall or mesangium. Complement can be deposited with the antibodies, and activation can cause cell lysis or serve as a chemotactic stimulus for attraction of neutrophils, monocytes, and T lymphocytes. These phagocytes, along with activated platelets, further the inflammatory reaction by releasing mediators that injure the glomerular filtration membrane, including epithelial cells, glomerular basement membrane, and endothelial cells (podocytes and filtration slits).⁷³ The injury increases glomerular membrane permeability and reduces glomerular membrane surface area. There also may be swelling and proliferation of mesangial cells and expansion of the extracellular matrix in the Bowman space (Fig. 39.9), contributing to crescent formation (deposition of substances in the Bowman space, forming the shape of a crescent moon). The result is decreased glomerular blood flow, hypoxic injury, decreased driving hydrostatic pressure, decreased GFR, and increased serum creatinine levels.⁷⁴

FIGURE 39.9 Diabetic Glomerulopathy. (Used with permission from Reidy K et al: *J Clin Invest* 124[6]:2333-2340, 2014.)

Loss of negative electrical charge across the glomerular filtration membrane and increase in filtration pore size enhance movement of proteins into the urine. Proteins are normally repelled because they also have a negative charge. Red blood cells also escape if pore size is large enough. Proteinuria or hematuria, or both, develops. The severity of glomerular damage and decline in glomerular function is related to the size, number, and location (focal or diffuse) of cells injured; duration of exposure; and type of antigen-antibody complexes.

The mechanisms of acute glomerulonephritis are presented next, along with membranous glomerulonephritis, crescentic or rapidly progressive glomerulonephritis, mesangial proliferative glomerulonephritis, and membranous proliferative glomerulonephritis.⁷⁵ Immunoglobulin A (IgA) nephropathy is the binding of abnormal IgA to mesangial cells in the glomerulus resulting in injury and mesangial proliferation and presented in

Chapter 40. Features of the types of glomerulonephritis are summarized in Table 39.7.

TABLE 39.7

FEATURES OF THE TYPES OF GLOMERULONEPHRITIS

TYPE AND CAUSE	HISTOPATHOPHYSIOLOGY
Associated with Nephritic Syndrome	
<p>Acute postinfectious glomerulonephritis (PIGN) (e.g., group A beta-hemolytic streptococci [more common in children]; staphylococcus [more common in older adults])</p>	<p>Subepithelial deposits of IgG and complement complexes; infiltration of neutrophils and monocytes; proliferation of mesangial and epithelial cells with occlusion of glomerular capillary blood flow and decreased glomerular filtration; usually diffuse lesions</p>
<p>Rapidly progressive or crescentic glomerulonephritis (a clinical syndrome):</p> <p><i>Type I:</i> Formation of IgG antibodies against pulmonary capillary and glomerular basement membrane (Goodpasture syndrome); activation of complement and neutrophils; more common in young men; causes pulmonary hemorrhage and renal failure</p> <p><i>Type II:</i> Mesangial immune complex deposition (PIGN, SLE, IgA nephropathy)</p> <p><i>Type III:</i> Pauci-immune, lack of anti-GBM antibodies or immune complexes; presence of serum antineutrophil cytoplasmic (ANC) antibodies associated with systemic vasculitides (usually idiopathic); nonspecific response to glomerular injury; can occur in any severe glomerular disease</p>	<p>Accumulation of fibrin, macrophages, and epithelial cell proliferation into the Bowman space forms crescents and occludes glomerular capillary blood flow, decreasing glomerular filtration; antiglomerular basement membrane antibodies lead to necrotizing, proliferative glomerulonephritis, and renal failure; diffuse lesions</p>
<p>Mesangial proliferative glomerulonephritis Can be associated with IgA nephropathy or lupus nephritis</p>	<p>Deposits of immune complexes in the mesangium with mesangial cell proliferation; results in decreased glomerular blood flow and glomerular filtration; leads to hematuria/proteinuria and nephrotic syndrome</p>
Associated with Nephrotic Syndrome	
<p>Minimal change nephropathy (lipoid nephrosis)</p>	<p>Glomeruli look normal under light microscopy; electron microscopy reveals uniform diffuse effacement of</p>

<p>Glomerular basement membrane appears normal</p> <p>Most common cause of nephrotic syndrome in children (see Chapter 40)</p> <p>Usually idiopathic</p>	<p>epithelial (podocyte) foot processes; loss of negative charge in basement membrane and increased permeability lead to severe proteinuria and nephrotic syndrome</p>
<p>Focal segmental glomerulosclerosis</p> <p>Usually idiopathic</p> <p>Can be associated with HIV infection, IgA nephropathy</p>	<p>Focal proliferation of endothelial and mesangial cells and glomerulosclerosis from hyaline deposits in segmental parts of the glomerular membrane; there is effacement (thinning or deletion) of epithelial podocytes, with a significant increase in pore size resulting in proteinuria and nephrotic syndrome; can progress to involve entire glomerulus and development of tubulointerstitial fibrosis</p>
<p>Membranous nephropathy (autoimmune response to unknown renal antigen)</p> <p>Usually idiopathic; can be associated with systemic diseases (i.e., hepatitis B virus, hepatitis C virus, systemic lupus erythematosus, solid malignant tumors)</p>	<p>Diffuse thickening of glomerular basement membrane and capillary wall from deposits of antibody, complement, and release of inflammatory cytokines; increased permeability with proteinuria and leading cause of nephrotic syndrome in white adults</p>
<p>Membranoproliferative glomerulonephritis (MPGN)</p> <p>Usually idiopathic; associated with hypocomplementemia</p> <p><i>Type I:</i> Activation of classical complement pathway with nephrotic syndrome (hepatitides B and C, SLE)</p> <p><i>Type II:</i> Activation of alternate complement pathway with hematuria (idiopathic); no circulating immune complexes</p> <p><i>Type III:</i> Activation of alternative complement pathway with nephrotic syndrome; can be familial</p>	<p>Mesangial cell proliferation; thickening of basement membrane; subendothelial deposits of immune complex occlude glomerular capillary blood flow and decrease glomerular filtration; diffuse lesions</p>
<p>IgA Nephropathy (Berger Disease)</p> <p>Usually idiopathic (can be associated with cirrhosis and minimal change disease); elevated IgA plasma levels (also see Henoch-Schönlein purpura nephritis in Chapter 40)</p>	<p>Mesangial proliferation with deposition of IgA; release of inflammatory mediators with cellular proliferation; crescent formation, glomerulosclerosis, interstitial fibrosis, decreased GFR and hematuria; usually focal, some diffuse lesions</p>

GBM, Glomerular basement membrane; **GFR**, glomerular filtration rate; **HIV**, human immunodeficiency virus; **IgA**, immunoglobulin A; **IgG**, immunoglobulin G; **SLE**, systemic lupus erythematosus.

Focal segmental glomerulosclerosis is a scarring lesion that involves some but not all glomeruli (focal) and some but not all of the glomerular capillaries (segmental). The disease is characterized by primary podocyte injury related to gene alterations in podocyte structure (familial form) or a lesion that occurs secondarily in any type of chronic kidney disease (i.e., related to HIV or drugs). There are increases in mesangial matrix, loss of endothelial cells, and obliteration of capillary lumens by sclerosis and podocyte derangement. It is the most common cause of nephrotic syndrome in adults, compared to minimal change disease in children.⁷⁶

Membranous nephropathy, also known as **membranous glomerulonephritis**, is one of the most common causes of acute glomerulonephritis, affects middle-aged and older adults, and is more common in men than women (sex ratio, 2 : 1). Primary membranous nephropathy is caused by subepithelial deposition of circulating antibodies or antibodies formed in situ to antigens located on glomerular podocytes. Assays are available to detect this antigen.⁷⁷ The antigen-antibody complexes activate C5b-C9 fragments of complement (the membrane attack complex) with injury and release of inflammatory mediators by mesangial and epithelial cells, resulting in increased membrane permeability, thickening of the glomerular membrane, and ultimately glomerular sclerosis. Secondary membranous nephropathy is associated with various disorders including infections (e.g., hepatitis B and C), systemic lupus erythematosus, some drugs (i.e., penicillamine), and some cancers. Proteinuria and nephrotic syndrome are the most common manifestations with risk for thromboembolism.⁷⁸ Alkylating agents plus corticosteroids or calcineurin inhibitors are used for treatment.

Rapidly progressive (crescentic) glomerulonephritis (RPGN), also known as *subacute* or *extracapillary glomerulonephritis*, is a rare disease and develops over days to weeks. The disease affects primarily adults in their 50s and 60s and may be idiopathic or associated with a proliferative glomerular disease (diffuse proliferation of extracapillary cells), such as lupus or poststreptococcal glomerulonephritis. Anti-glomerular basement membrane antibodies and anti-neutrophil

cytoplasmic autoantibody (ANCA)-associated vasculitis are associated with glomerular injury and may be associated with pulmonary hemorrhage (Goodpasture syndrome). There is accumulation of T cells and macrophages with extensive proliferation of glomerular epithelial cells into the Bowman space. The accumulation of cells promotes crescent formation (the shape of the Bowman capsule). Heparin-binding epidermal growth factor–like growth factor (HB-EGF) released from glomerular epithelial cells is associated with the proliferation. Typically the glomerular injury is accompanied by a rapid decline in glomerular function, progressing to renal failure in a few weeks or months. Hematuria (nephritic syndrome) is common and may or may not be accompanied by proteinuria, edema, or hypertension (nephrotic syndrome). There are three types of RPGN distinguished by immunofluorescence and electron microscopic study of the renal biopsy. Types of RPGN are summarized in [Table 39.7](#).⁷⁹

RPGN has a relatively poor prognosis if not diagnosed and treated early. Anticoagulants may be of some benefit in reducing the fibrin component of crescent formation. Plasmapheresis is usually combined with corticosteroids and immunosuppression therapy. Dialysis or transplantation is required when failure is irreversible.⁸⁰

Mesangial proliferative glomerulonephritis is usually idiopathic and involves deposits of immune complex in the mesangium with mesangial cell proliferation. It can be associated with IgA nephropathy, lupus nephritis, or early diabetic nephropathy. Mesangial expansion reduces blood flow and alters filtration membrane permeability with development of hematuria, proteinuria, hypertension, and uremia (nephritic syndrome).

Membranoproliferative glomerulonephritis (MPGN) is an idiopathic pattern of glomerular injury that involves proliferation of mesangial cells and formation of crescents related to the deposition of complement (C3 component) and inflammatory injury. This disease is rare and can be associated with autoimmune diseases, infection such as hepatitis B and C, and monoclonal gammopathy. Hypocomplementemia is associated with all types of MPGN and they are differentiated by light microscopy. All three types stain positive

for complement component C3 and are summarized in [Table 39.7](#). Injury to the glomerular capillary wall in all types of MPGN can cause proteinuria, hematuria, nephrotic syndrome, and acute or chronic kidney failure.⁸¹

◆Clinical Manifestations.

The onset of glomerular disease may be sudden or insidious, and significant loss of nephron function can occur before symptoms develop. Acute glomerulonephritis may be silent, mild, moderate, or severe in symptom presentation; there are no specific clinical signs. Severe or progressive glomerular disease causes oliguria (urine output of 30 mL/hour or less), hypertension, and renal failure. Focal lesions tend to produce less severe clinical symptoms. Salt and water are reabsorbed, contributing to fluid volume expansion, edema, weight gain, and hypertension.

Two major symptoms of more severe glomerulonephritis are (1) proteinuria exceeding 3 g/day to 5 g/day with albumin (macroalbuminuria) as the major protein and (2) hematuria with red blood cell casts. Nephrotic syndrome is associated with gross proteinuria and lipid sediments (see the section on [Nephrotic and Nephritic Syndromes](#)). Nephritic syndrome is associated with red blood cells escaping through the glomerular membrane producing a smoky, brown-tinged urine; red blood cell casts; and an accompanying proteinuria. Glomerular bleeding provides prolonged contact with the acidic urine and transforms hemoglobin to methemoglobin, which has a brownish color and no blood clots. In comparison, bleeding from sites lower in the urinary tract produces a pink- or red-colored urine. The urine sediment of chronic glomerular disease has waxy casts, granular casts, and less protein and blood than found in nephrotic or nephritic syndromes.

◆Evaluation and Treatment.

The diagnosis of glomerular disease is confirmed by the progressive development of clinical manifestations and laboratory findings of abnormal urinalysis with proteinuria, red blood cells, white blood

cells, and casts. Reduced GFR during glomerulonephritis is evidenced by elevated plasma urea, cystatin C, and creatinine concentrations, or by reduced renal creatinine clearance (see [Chapter 38](#)). Renal biopsy provides a specific determination of renal injury and type of pathologic condition. Patterns of antigen-antibody complex deposition or formation within the glomerular capillary filtration membrane have been established using light, electron, and immunofluorescent microscopy. Electron microscopy differentiates morphologic changes within the glomerular capillary wall (e.g., subendothelial and mesangial electron-dense deposits, increased mesangial matrix, mesangialization of capillary loops, and foot process fusion). Staining with fluorescein identifies complement and different antibodies (i.e., immunoglobulin G [IgG] or IgA) and their configurations when viewed under ultraviolet light with light microscopy (see [Chapter 40, Fig. 40.5, C](#)).

Management principles for treating glomerulonephritis are related to treating the primary cause; preventing or minimizing immune responses; and correcting accompanying problems, such as edema and hypertension. Specific treatment regimens are necessary for particular types of glomerulonephritis. Antibiotic therapy is essential for the management of underlying infections that may be contributing to ongoing antigen-antibody responses. Corticosteroids decrease antibody synthesis and suppress inflammatory responses. Cytotoxic agents (e.g., cyclophosphamide) may be used to suppress the immune response in corticosteroid-resistant cases. Anticoagulants may be useful for controlling fibrin crescent formation in rapidly progressive glomerulonephritis.

Chronic Glomerulonephritis

Chronic glomerulonephritis encompasses glomerular diseases with a progressive course leading to chronic kidney disease. There may be no history of renal disease before the diagnosis. Proteinuria and hypercholesterolemia have been associated with progressive glomerular and tubular injury.⁸² The proposed mechanism is related to those observed in glomerulosclerosis and interstitial injury, such as

hyperfiltration and inflammatory processes. The primary cause may be difficult to establish because advanced pathologic changes may obscure specific disease characteristics (Fig. 39.10). Renal insufficiency usually begins to develop after 10 to 20 years, followed by nephrotic syndrome and an accelerated progression to end-stage kidney failure. Symptom patterns vary depending on the underlying cause. Corticosteroids usually do not change the course of chronic glomerular disease, and dialysis or kidney transplantation ultimately may be needed. Diabetes mellitus and systemic lupus erythematosus are common secondary causes of chronic glomerular injury.

FIGURE 39.10 Chronic Glomerulonephritis. The kidneys appear small, are uniformly shrunken, and have a finely granular external surface. (From Damjanov I: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders.)

Diabetic nephropathy develops from metabolic (accumulation of advanced glycosylated end products), inflammatory (transforming growth factor-beta and protein kinase C), and macrovascular and microvascular complications related to chronic hyperglycemia (see [Chapter 22](#)). Changes in the glomerulus are characterized by podocyte injury, progressive thickening and fibrosis of the glomerular basement membrane, expansion of the mesangial matrix (diffuse diabetic glomerulosclerosis), and nodular glomerulosclerosis (Kimmelstiel-

Wilson nodules; see Fig. 39.9) with proteinuria and progression to chronic renal failure. Decline in GFR can be independent of proteinuria.⁸³ Diabetic nephropathy is the most common cause of chronic kidney disease and end-stage renal failure for both type 1 and type 2 diabetes, although the incidence is declining.⁸⁴

Lupus nephritis is an inflammatory complication of the chronic autoimmune syndrome systemic lupus erythematosus (see Chapter 9). The renal component of the disease may be caused by the formation of autoantibodies against double-stranded DNA and nucleosomes with glomerular deposition of the immune complexes. Immune complexes also may be formed in situ by binding to planted antigens of circulating autoantibodies. There is complement activation and a cascade of inflammatory events resulting in damage to the glomerular membrane with mesangial expansion (see Chapter 8).^{85,86} Various glomerular lesion patterns are identifiable on biopsy, including membranous, mesangial, membranoproliferative, and diffuse proliferative glomerulonephritis; tubular fibrosis can also be present (see Table 39.6). Symptom presentation is variable depending on lesion involvement and can include proteinuria, microscopic hematuria, edema, and other signs of nephrotic syndrome. Disease progression may be silent or may progress to end-stage kidney failure over a period of years. Treatment includes the use of immunosuppressive agents and efforts to protect the kidney from secondary nonimmune consequences of acute injury.^{87,88}

Nephrotic and Nephritic Syndromes

Nephrotic syndrome is the excretion of 3.5 g or more of protein in the urine per day, is characteristic of glomerular injury, and occurs when filtration of proteins exceeds tubular reabsorption. *Primary causes of nephrotic syndrome* include minimal change disease (lipoid nephrosis), membranous glomerulonephritis, and focal segmental glomerulosclerosis (see Table 39.7). *Secondary forms of nephrotic syndrome* occur in systemic diseases including diabetes mellitus, amyloidosis, systemic lupus erythematosus, and IgA vasculitis (i.e., Henoch-Schönlein purpura) (see Chapter 40). Nephrotic syndrome

also is associated with certain drugs (e.g., nonsteroidal antiinflammatory drugs and penicillamine), infections, malignancies, and vascular disorders. Familial forms of nephrotic syndrome result from genetic defects that affect the function and composition of the glomerular capillary wall (i.e., alterations in basement membrane type IV collagen [Alport syndrome] and podocyte dysfunction).⁸⁹ It often signifies a more serious prognosis when present as a secondary complication. Nephrotic syndrome is more common in children than in adults and is more commonly idiopathic in adults.

Nephritic syndrome is hematuria and red blood cell casts in the urine. Proteinuria is usually less severe than in nephrotic syndrome and is related to infiltration of inflammatory cells in the mesangium driven by antigen deposition with damage to endothelial cells and escape of red blood cells and protein. It occurs with infection-related glomerulonephritis (i.e., hepatitis B and C and acute post-streptococcal glomerulonephritis), rapidly progressive crescentic glomerulonephritis, and lupus nephritis.⁹⁰

◆Pathophysiology.

In nephrotic syndrome, disturbances in the glomerular basement membrane (GBM) and podocyte injury lead to loss of electrical negative charge and increased permeability (see [Chapter 38](#)). Loss of plasma proteins, particularly albumin and some immunoglobulins, occurs across the injured glomerular filtration membrane ([Fig. 39.11](#)). Loss of plasma proteins decreases plasma oncotic pressure, resulting in edema. The predominant cause of nephrotic syndrome is minimal-change nephropathy, which is common in children (see [Chapter 40](#)). Hypoalbuminemia results from urinary loss of albumin combined with a diminished synthesis of replacement albumin by the liver. Albumin is lost in the greatest quantity because of its high plasma concentration and low molecular weight. Decreased dietary intake of protein from anorexia or malnutrition or accompanying liver disease may also contribute to lower levels of plasma albumin. Loss of albumin stimulates lipoprotein synthesis by the liver and hyperlipidemia and can promote progression of glomerular disease.

Loss of immunoglobulins may increase susceptibility to infections. Sodium retention is common. Hypercoagulation results from alterations in coagulation factors, fibrinolysis, and platelet function.^{91,92}

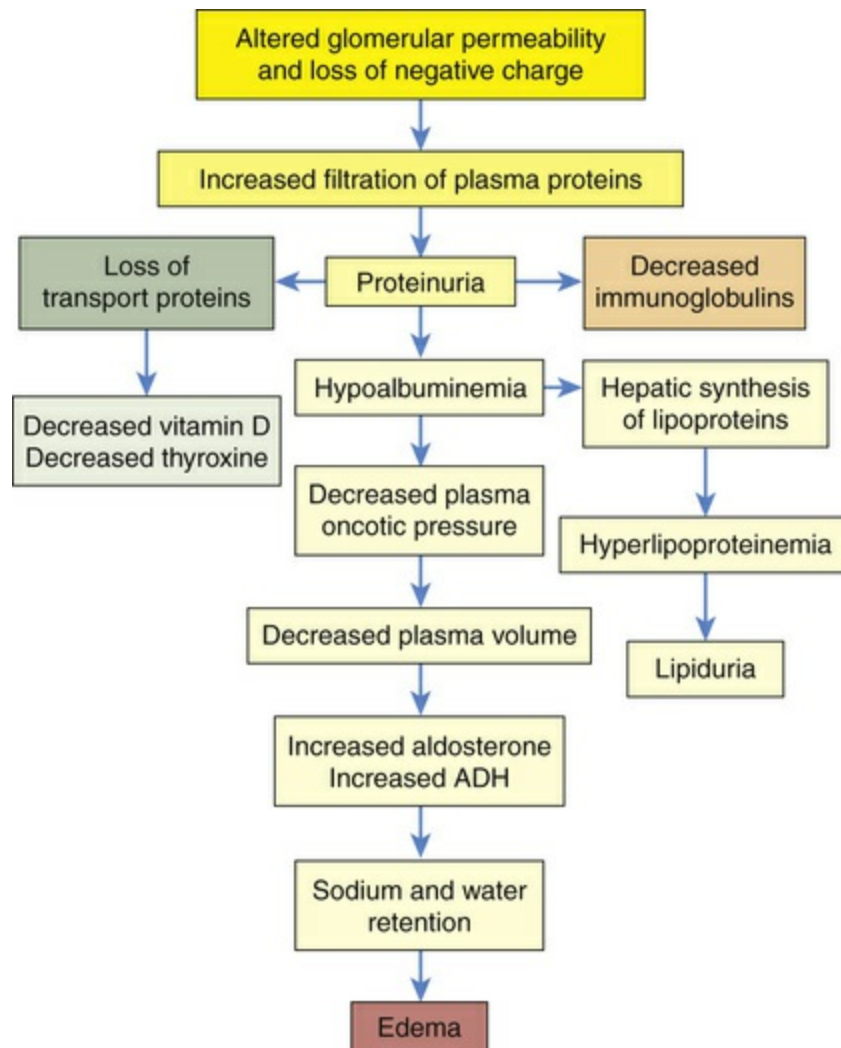

FIGURE 39.11 Pathophysiology of Nephrotic Syndrome.

◀Clinical Manifestations.

Many clinical manifestations of nephrotic and nephritic syndrome are related to loss of serum proteins (Table 39.8) and associated retention of sodium. They include edema, hypertension, hyperlipidemia, lipiduria, vitamin D deficiency, and hypothyroidism. Vitamin D deficiency is related to loss of serum transport proteins and decreased

vitamin D activation by the kidney. Hyperlipidemia can promote atherosclerotic disease. Hypothyroidism can result from urinary loss of thyroid-binding protein and thyroxine, but there may be no symptoms. Hypercoagulability may lead to thromboembolic events.^{93,94}

TABLE 39.8

CLINICAL MANIFESTATIONS OF NEPHROTIC SYNDROME

MANIFESTATIONS	CONTRIBUTING FACTORS	RESULT
Proteinuria	Increased glomerular permeability, decreased proximal tubule reabsorption	Edema, increased susceptibility to infection from loss of immunoglobulins
Hypoalbuminemia	Increased urinary losses of protein	Edema
Edema	Hypoalbuminemia (decreased oncotic pressure, sodium and water retention, increased aldosterone and antidiuretic hormone [ADH] secretion), unresponsiveness to atrial natriuretic peptides	Soft, pitting, generalized edema
Hyperlipidemia	Decreased serum albumin; increased hepatic synthesis of very-low-density lipoproteins; increased cholesterol, phospholipids, triglycerides	Increased atherogenesis
Lipiduria	Sloughing of tubular cells containing fat (oval fat bodies); free fat from hyperlipidemia	Fat droplets that may float in urine
Decreased vitamin D	The globulin to which 1,25-dihydroxy-vitamin D ₃ is attached for transport passes through the glomerulus and is lost in the urine	Decreased absorption of calcium from gut Risk for osteodystrophies
Hypothyroidism	Loss of thyroid-binding globulin and other thyroid hormone transport proteins in the urine	May have no symptoms; may have elevated thyroid-stimulating hormone

◆ **Evaluation and Treatment.**

Nephrotic syndrome is diagnosed when the protein level in a 24-hour urine collection is greater than 3.5 g. Serum albumin level decreases (to less than 3 g/dL), and concentrations of serum cholesterol,

phospholipids, and triglycerides increase. Fat bodies may be present in the urine.

Nephrotic syndrome is commonly treated by consuming a moderate protein-restricted (i.e., 0.8 g/kg body weight/day), low-fat, and salt-restricted diet. Diuretics are used to control hypertension and eliminate fluid. Care must be taken to observe for hypovolemia and hypokalemia or potassium toxicity in the presence of renal insufficiency. Spironolactone may be combined with loop diuretics to suppress aldosterone activity to conserve potassium. Heparinoids are used for prophylactic anticoagulation. Glucocorticoids are used to control immune-mediated disease or may be combined with immunosuppressive drugs. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) lower urine protein excretion and control blood pressure.^{95,96}

The evaluation and treatment of nephritic syndrome are similar to those described for nephrotic syndrome. The course of glomerulonephritis is usually more severe with nephritic syndrome. High-dose corticosteroids and cyclophosphamide represent the standard therapy for rapidly progressive crescentic glomerulonephritis. The addition of plasma exchange (plasmapheresis) also may be helpful.⁷⁹

Acute Kidney Injury

Classification of Kidney Dysfunction

Kidney injury may be acute and rapidly progressive (within hours), and the process may be reversible. Kidney injury also can be chronic, progressing to end-stage kidney failure over a period of months or years. The terms *renal insufficiency*, *renal failure*, *uremia*, and *azotemia* are associated with decreasing renal function but are not specific in relation to cause of kidney disease. Often they are used synonymously, although with some distinctions. Generally, **renal insufficiency** refers to a decline in renal function to about 25% of normal or a GFR of 25 to 30 mL/minute. Levels of serum creatinine

and urea are mildly elevated. The term *acute kidney injury* is preferred to the term **acute renal failure** because it captures the diverse nature of this syndrome, ranging from minimal or subtle changes in renal function to complete renal failure requiring renal replacement therapy. **Renal failure** refers to significant loss of renal function. When less than 10% of renal function remains, this is termed **end-stage kidney disease (ESKD)**. Specific criteria for acute renal dysfunction are discussed in the next section. **Uremia (uremic syndrome)** is a syndrome of renal failure and includes elevated blood urea and creatinine levels accompanied by fatigue, anorexia, nausea, vomiting, pruritus, and neurologic changes. Uremia represents numerous consequences related to renal failure, including retention of toxic wastes, deficiency states, electrolyte disorders, and immune activation promoting a proinflammatory state. **Azotemia** is characterized by increased serum urea levels and frequently increased creatinine levels (normal is 0.7 to 1.4 mg/dL). Renal insufficiency or renal failure causes azotemia. Both azotemia and uremia indicate an accumulation of nitrogenous waste products in the blood, a common characteristic that explains the overlap in definitions of terms.

Acute Kidney Injury

Acute kidney injury (AKI) affects about 5% of hospitalized individuals with a higher percentage in intensive care units and has a mortality of 50% to 80%.⁹⁷ AKI is a sudden decline in kidney function with a decrease in glomerular filtration and urine output with an accumulation of nitrogenous waste products in the blood as demonstrated by an elevation in plasma creatinine and blood urea nitrogen levels. Staging criteria have been developed by the Kidney Disease: Improving Global Outcomes (KDIGO) Working Group to guide the diagnosis of acute renal injury ([Table 39.9](#)).

TABLE 39.9

STAGING OF ACUTE KIDNEY INJURY

STAGE	SERUM CREATININE
-------	------------------

1	1.5–1.9 times baseline OR ≥0.3 mg/dL (≥26.5 μmol/L) increase
2	2.0–2.9 times baseline
3	3.0 times baseline OR Increase in serum creatinine to ≥4.0 mg/dL (≥353.6 μmol/L) OR Initiation of renal replacement therapy OR in individuals <18 years, decrease in eGFR to <35 mL/min per 1.73 m ²

eGFR, Estimated glomerular filtration rate.

◆ Pathophysiology.

AKI commonly results from extracellular volume depletion, decreased renal blood flow, or toxic/inflammatory injury to kidney cells that result in alterations in renal function that may be minimal or severe. Even small changes in renal function may be associated with significant morbidity and mortality. The etiologies of AKI can be described considering three categories of injury: (1) renal hypoperfusion (prerenal AKI); (2) disorders involving the renal parenchymal or interstitial tissue (intrarenal or intrinsic AKI); and (3) disorders associated with acute urinary tract obstruction (postrenal AKI) (Table 39.10). Most types of AKI are reversible if diagnosed and treated early.

TABLE 39.10

CAUSES OF ACUTE KIDNEY INJURY

AREA OF DYSFUNCTION	POSSIBLE CAUSES
Prerenal	Hypovolemia Hemorrhagic blood loss (trauma, gastrointestinal bleeding, complications of childbirth) Loss of plasma volume (burns, peritonitis) Water and electrolyte losses (severe vomiting or diarrhea, intestinal obstruction,

	<ul style="list-style-type: none"> uncontrolled diabetes mellitus, inappropriate use of diuretics) Systemic hypotension or hypoperfusion Septic shock systemic inflammation Cardiac failure or shock Massive pulmonary embolism Stenosis or clamping of renal artery Increased intraabdominal pressure (abdominal compartment syndrome)
Intrarenal	<ul style="list-style-type: none"> Acute tubular necrosis (postischemic or nephrotoxic) Glomerulopathies Acute interstitial necrosis (tumors or toxins) Vascular damage Malignant hypertension, vasculitis Coagulation defects Renal artery/vein occlusion Bilateral acute pyelonephritis
Postrenal	<ul style="list-style-type: none"> Obstructive uropathies (usually bilateral—fibrosis) Ureteral destruction (edema, tumors, stones, clots) Bladder neck obstruction (enlarged prostate) Neurogenic bladder

Prerenal acute kidney injury is the most common cause of AKI and results from inadequate kidney perfusion. Poor perfusion can be caused by hypotension, hypovolemia associated with hemorrhage or fluid loss (e.g., burns), sepsis, inadequate cardiac output (e.g., myocardial infarct), multiple organ dysfunction, renal vasoconstriction (e.g., caused by nonsteroidal antiinflammatory drugs [NSAIDs] or radiocontrast agents), renal artery stenosis, or kidney edema that restricts arterial blood flow. During the early phases of hypoperfusion, protective autoregulatory mechanisms maintain GFR at a relatively constant level through afferent arteriolar dilation and efferent arteriolar vasoconstriction (mediated by angiotensin II). Tubuloglomerular feedback mechanisms also maintain GFR and distal tubular nephron flow (see [Chapter 38](#)). The GFR ultimately declines because of the decrease in filtration pressure. Sepsis/septic shock and cardiogenic shock following cardiac surgery are the most common causes of AKI in the critical care unit.^{98,99} AKI may occur during chronic kidney failure if a sudden stress is imposed on already marginally functioning kidneys, hastening the progression to end-stage kidney disease. Failure to restore blood volume or blood pressure and oxygen delivery can cause cell injury and acute tubular

necrosis and apoptosis or acute interstitial necrosis, a more severe form of AKI.

Intrarenal (intrinsic) acute kidney injury (AKI) can result from ischemic **acute tubular necrosis (ATN)**, nephrotoxic ATN (i.e., exposure to radiocontrast media or antibiotics), acute glomerulonephritis, vascular disease (malignant hypertension, disseminated intravascular coagulation, and renal vasculitis), allograft rejection, or interstitial disease (drug allergy, infection, tumor growth). ATN caused by ischemia is the most common cause of intrarenal AKI. It occurs most often after surgery and severe sepsis (40% to 50% of cases) but also is associated with obstetric complications and severe trauma, including severe burns. A combination of events and predisposing factors leads to the greatest risk for acute renal failure. The terms *acute tubular necrosis* and *acute kidney injury* are sometimes used interchangeably, but the conditions are not the same because acute kidney injury can occur without ATN. ATN is generally described as postischemic or nephrotoxic, or it can be a combination of both. Postischemic ATN involves persistent hypotension, hypoperfusion, and hypoxemia, producing ischemia and reduced levels of ATP and generating toxic oxygen free radicals with loss of antioxidant protection that causes cell swelling, injury, and necrosis. Activation of inflammatory cells (e.g., neutrophils, macrophages, and lymphocytes) and complement and release of inflammatory cytokines contribute to tubular injury. Transport of sodium and other molecules is disrupted with damage primarily to the proximal tubular epithelium and shedding of the brush border with the appearance of tubular granular casts in the urine. Ischemic necrosis tends to be patchy and may be distributed along any part of the nephron tubules. Injury is most severe in the outer medulla (the medulla has the highest oxygen extraction rate of all body tissues, ≈80%) with scattered necrosis in the cortex and loss of cells along the tubular epithelium.¹⁰⁰ Severe disease of the glomeruli (i.e., acute or rapidly progressive glomerulonephritis) or renal microvascular disorders also can cause intrinsic kidney injury. Oliguria is common (urine output less than 30 mL/hour) with intrarenal AKI, but anuria is rare. Creatinine values

in septic renal injury may not reflect renal injury because sepsis decreases production of creatinine without major alterations in body weight, hematocrit level, or amount of extracellular fluid. Creatinine level usually increases with decreased renal blood flow and decreased GFR. However, in sepsis-induced AKI, creatinine values can remain within normal ranges and may be related to alterations in intrarenal microcirculatory blood flow that are different from the kidney ischemia that develops related to systemic hypotension and hypoperfusion of nonseptic AKI. Sepsis-related tubular injury can occur in the absence of hypoperfusion and may be related to inflammation and changes in microcirculation and mitochondrial function.⁹⁹

Nephrotoxic ATN can be produced by radiocontrast media and numerous antibiotics, particularly aminoglycosides (neomycin, gentamicin, tobramycin), because the drugs accumulate in the renal cortex. Other substances, such as carbon tetrachloride, heavy metals (mercury, arsenic), methoxyflurane anesthesia, or bacterial toxins, may promote renal failure. Endogenous substances toxic to renal tubules are excessive myoglobin (oxygen-transporting substance in muscles) and hemoglobin. Dehydration, advanced age, concurrent renal insufficiency, and diabetes mellitus tend to enhance nephrotoxicity. Necrosis and tubular cell apoptosis caused by nephrotoxins are usually uniform and limited to the proximal tubules. The high surface area of the brush border (microvilli) of the proximal tubular cells and the reabsorption properties of epithelial cells make them more vulnerable to toxic injury.

Postrenal acute kidney injury is rare and usually occurs with urinary tract obstruction that affects the kidneys bilaterally (e.g., bilateral ureteral obstruction, bladder outlet obstruction-prostatic hypertrophy, tumors or neurogenic bladder, and urethral obstruction). The obstruction causes an increase in intraluminal pressure upstream from the site of obstruction with a gradual decrease in GFR. A pattern of several hours of anuria with flank pain followed by polyuria is a characteristic finding. This type of AKI can occur after diagnostic catheterization of the ureters, a procedure that

may cause edema with obstruction of the tubular lumen.

Oliguria (less than 400 mL of urine output per day) can occur in AKI, and three mechanisms have been proposed to account for the decrease in urine output. All three mechanisms probably contribute to oliguria in varying combinations and degrees throughout the course of the disease (Fig. 39.12). These mechanisms are as follows:^{100,101}

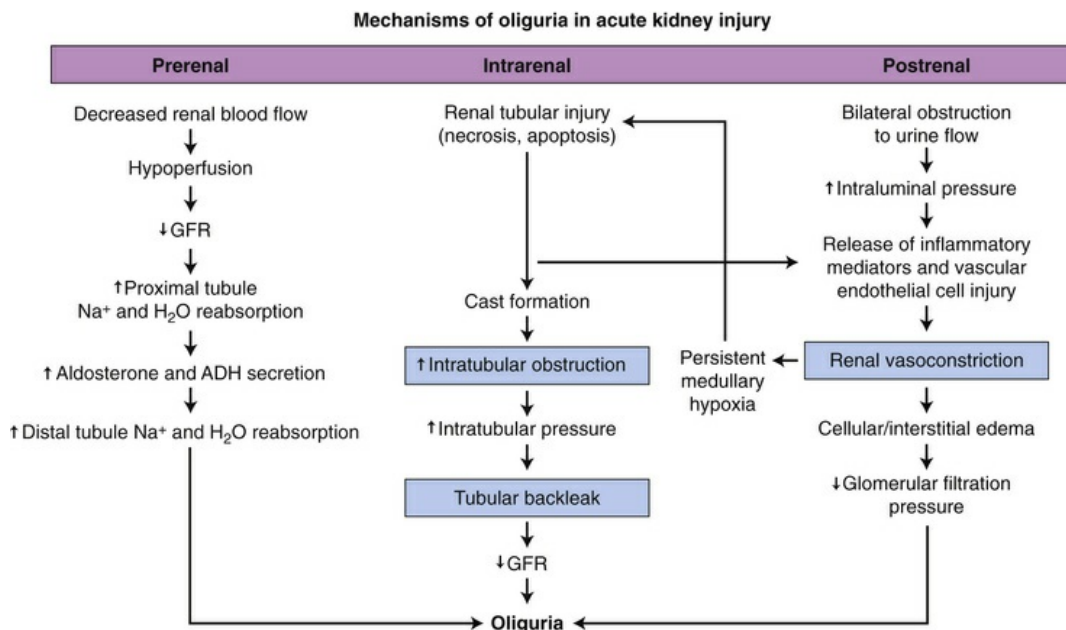

FIGURE 39.12 Acute Kidney Injury and Mechanisms of Oliguria. *ADH*, Antidiuretic hormone; *GFR*, glomerular filtration rate.

1. *Alterations in renal blood flow.* In response to ischemia, blood flow is directed to the highly metabolic renal medulla. With continuing severe ischemia, tubular sodium chloride reabsorption fails and tubuloglomerular feedback at the macula densa activates the renin-angiotensin-aldosterone system (RAAS). There is an increased afferent arteriolar vasoconstriction and decreased GFR. Damaged endothelium and leukocyte activation activate coagulation and further impede microcirculatory blood flow, contributing to ischemia,

reperfusion injury, and decreased GFR. Decreased GFR can be lifesaving; otherwise GFR would not change and death could result from continuing fluid loss during concurrent hypovolemia and hypotension. Autoregulation of blood flow also is impaired, contributing to decreased GFR.

2. *Tubular obstruction.* Necrosis of the tubules causes sloughing of cells, cast formation, and ischemic edema that result in tubular obstruction, which in turn causes a retrograde increase in pressure and reduces the GFR. Renal failure can occur within 24 hours.
3. *Tubular backleak.* Glomerular filtration remains normal, but tubular reabsorption or “leak” of filtrate is accelerated as a result of permeability caused by ischemia and increased tubular pressure from obstruction. Obstruction and backleak probably occur concurrently.

◀Clinical Manifestations.

The clinical progression of acute kidney injury, particularly acute tubular necrosis, occurs in phases: initiation phase, extension phase, maintenance phase, and recovery phase. The *initiation phase* is the phase of reduced perfusion or toxicity in which renal injury is evolving, usually lasting 24 to 36 hours. Prevention of injury is possible during this phase. During the *extension phase*, and with progressive ischemia, there is infiltration of inflammatory cells, mostly neutrophils; release of cytokines; inflammation; and cell injury contributing to tubular obstruction and backleak. The *maintenance* or *oliguric phase* is the period of established renal injury and dysfunction after the initiating event has been resolved and may last from weeks to months. Urine output is lowest during this phase, and serum creatinine, blood urea nitrogen, and serum potassium levels increase; metabolic acidosis develops; and there is salt and water overload. The *recovery phase* is the interval when renal injury is repaired and normal renal function is reestablished. GFR returns toward normal but the regenerating tubules cannot concentrate the filtrate. Diuresis is common during this phase, with a decline in serum creatinine and

urea levels and an increase in creatinine clearance. Polyuria can result in excessive loss of sodium, potassium, and water. Fluid and electrolyte balance requires careful maintenance.

Oliguria begins within 1 day after a hypotensive event and lasts for 1 to 3 weeks, but it may regress in several hours or extend for several weeks, depending on the duration of ischemia or severity of toxic injury and the initiation of treatment. **Anuria** (urine output less than 50 mL/day) is uncommon in ATN, and 10% to 20% of cases have nonoliguric failure. Anuria involves both kidneys and suggests bilateral renal artery occlusion, obstructive uropathy, or acute cortical necrosis. **Nonoliguric renal failure** usually represents less severe injury and is associated with toxin exposure or drug toxicity. The renal tubules have impaired reabsorption and concentration and dilution function. The urine output may be greater than 2 L/day, but the blood urea nitrogen (BUN) and plasma creatinine concentrations increase.

Other early manifestations depend on the underlying cause of renal failure. Individuals who have experienced trauma or surgery or people in a catabolic state may have more rapid elevations in BUN level. They are prone to hyperkalemia and metabolic acidosis. Renal phosphate excretion is decreased, causing hyperphosphatemia. Fluid retention may cause edema. Symptoms of congestive heart failure develop in persons with cardiac disease. Nausea, vomiting, and fatigue accompany uremia and electrolyte imbalances. Wound healing is delayed, and the risk of infection, particularly pneumonia, is greater. Nonoliguric renal failure generally has a better prognosis because of fewer complications and regeneration of the tubular epithelium. Individuals with oliguria may require maintenance dialysis to attenuate symptoms of renal failure.

As renal function improves during the recovery phase, increase in urine volume (diuresis) is progressive. During the early diuretic phase the tubules are still recovering secretory and reabsorptive function. Sodium and potassium are lost in the urine, and the risk for hypokalemia is greater. Volume depletion may ensue, with fluid losses of 3 to 4 L/day. Fluid and electrolyte balance must be carefully

monitored and excessive urinary losses replaced. Return to normal status may take 3 to 12 months. AKI is a risk factor for progression to end-stage kidney disease and other complications, such as cardiovascular events and stroke.^{102,103}

◆ Evaluation and Treatment.

The diagnosis of AKI is related to the cause of the disease. The history can help distinguish the different etiologies of AKI. Prerenal causes are associated with a history of blood volume depletion or other causes of poor kidney perfusion (e.g., shock, heart failure, renal artery thrombi). Intrinsic causes include exposure to nephrotoxins and infection. Postrenal causes are associated with obstructive uropathies (e.g., an enlarged prostate or stones). The diagnostic challenge is to differentiate prerenal acute renal injury from acute tubular necrosis. Urine composition may provide helpful diagnostic clues to changes in tubular function (Table 39.11).

TABLE 39.11

URINE CHARACTERISTICS OF PRERENAL AND INTRINSIC ACUTE KIDNEY INJURY

DIAGNOSTIC INDEX	PRERENAL	ATN
Urine volume	<400 mL	<400 mL
Urine specificity	1.016–1.020	1.010–1.012
Urine osmolality	>500 mOsm	<300 mOsm
Urine sodium	<10 mEq/L	>30 mEq/L
BUN/plasma	>15 : 1	<15 : 1 creatinine
FE _{Na}	<1% (also seen in acute glomerulonephritis)	>1% (also seen in urinary tract obstruction and renal parenchymal disease)
Urine sediment	Usually no cells, some hyaline casts	Brown granular casts, epithelial cells

ATN, Acute tubular necrosis; BUN, blood urea nitrogen; FE_{Na}, fractional excretion of sodium.

The ratios of the BUN to plasma creatinine concentration and fractional excretion of sodium (the ratio of filtered sodium to excreted

sodium) are helpful diagnostic indicators because the tests reflect renal tubular reabsorption ability. In prerenal AKI, tubular function is maintained and salt, water, and urea are reabsorbed. With ATN, reabsorption and urinary concentration abilities are compromised. Other causes of renal failure also may exhibit similar clinical findings. *Cystatin C*, a serum protein constantly produced by nucleated cells, is freely filtered by the glomerulus, and its concentration can serve as a measure of GFR and may be useful for detecting early changes in glomerular filtration rate. Serial measurements of plasma creatinine concentration provide an index of renal function during the recovery phase. However, changes in serum creatinine level occur only if more than 50% of glomerular filtration is lost and are often delayed by more than 24 hours. Such diagnostic delays make the implementation of early therapy very difficult, contributing to disease progression and mortality. Advances are being made in the use of biomarkers that allow assessment of kidney injury and estimates of renal function¹⁰⁴ (see *What's New? Biomarkers and Kidney Injury on Evolve.*)

Prevention of AKI and maintenance of renal perfusion involve maintenance of fluid volume before and after surgery or diagnostic procedures or when nephrotoxic drugs or contrast agents are in use. There is no specific treatment for acute kidney injury, and it requires individualized therapy and monitoring. The primary goal of therapy, once AKI has occurred, is to maintain the individual's life until renal function has recovered. Management principles directly related to physiologic alterations generally include (1) correcting fluid and electrolyte disturbances, (2) managing blood pressure, (3) preventing and treating infections, (4) maintaining nutrition, and (5) remembering that certain drugs or their metabolites are not excreted and can be toxic. Fluid and electrolyte replacement must be carefully calculated with consideration of urine losses, insensible losses (up to 1000 mL/day), and production of endogenous water by oxidation (450 mL/day). Overhydration of individuals dilutes their plasma sodium concentration and can precipitate pulmonary, cerebral, myocardial, and liver edema, and other complications. Metabolic acidosis is treated when serum bicarbonate concentration less than

22 mEq/L.¹⁰⁵

Hyperkalemia can be managed by restricting dietary sources of potassium, using non-potassium-sparing diuretics, or using cation ion exchange resins, which may be administered orally or rectally. These resins exchange potassium for another cation, such as sodium in the bowel, and the potassium is then excreted attached to the resin. With severe hyperkalemia (more than 6.5 mEq/L), dialysis may be required, or potassium can be driven back temporarily into the cells by administering glucose and insulin or by infusing sodium bicarbonate or albuterol. Glucose metabolism causes potassium to move to the intracellular fluid, and insulin infusions therefore can be effective in shifting potassium from the extracellular to intracellular space, along with the transport of glucose, within 30 minutes. (Glucose metabolism is discussed in [Chapter 1](#) and [Chapter 21](#).) Using sodium bicarbonate to cause alkalemia also shifts potassium into cells in exchange for hydrogen ions but requires consideration of hypervolemia.¹⁰⁶ Careful monitoring of the electrocardiogram for peaking T waves is essential for individuals with hyperkalemia. Intravenous infusion of calcium is the most rapid method of treating cardiac effects of hyperkalemia. Calcium decreases the threshold potential and reduces the membrane excitability caused by hyperkalemia (see [Chapter 3](#)). Calcium should be used only in emergencies, however, because hypercalcemia also may cause cardiac arrest.

Azotemia is generally controlled and nutrition maintained with a low-protein, high-carbohydrate diet. Essential amino acid replacement can be given orally or parenterally. Adequate carbohydrate intake slows protein catabolism and helps prevent release of potassium from cellular breakdown. Because sepsis is a common serious and potentially fatal complication of renal failure, observation for signs of infection and early treatment with antibiotics are necessary. Drug dosage levels may require adjustment if they are metabolized or excreted by the kidneys. Recovery may take up to 1 year.

Continuous renal replacement therapy (CRRT [hemodialysis]) (mechanical removal of water, electrolytes, and toxins from the blood) is indicated for uncontrollable hyperkalemia or acidosis or severe

fluid overload. CRRT is particularly promising in critically ill people with multiple organ dysfunction or sepsis. The timing and optimal dose-response relationships for CRRT are individually determined.¹⁰⁷

Chronic Kidney Disease

Chronic kidney disease (CKD) is the progressive loss of renal function associated with systemic diseases such as hypertension, diabetes mellitus (most significant risk factor), hypertension, systemic lupus erythematosus, or intrinsic kidney disease, including acute kidney injury, chronic glomerulonephritis, chronic pyelonephritis, obstructive uropathies, or vascular disorders. The KDIGO guidelines define and stage CKD using estimates of GFR and albuminuria (Table 39.12). *Chronic kidney disease* is the preferred terminology and is referenced to declining GFR. The terms *renal insufficiency* and *chronic renal failure* are still often used to describe declining renal function, but they do not have the specificity of the stages recommended by KDIGO. CKD decreases filtration and tubular functions with consequences manifested throughout all organ systems.

TABLE 39.12

STAGES OF CHRONIC KIDNEY DISEASE

STAGE	SEVERITY*	GFR (mL/min)	ALBUMINURIA (mg/24 hr urine)	PROGRESSION	SYMPTOMS
1	Kidney damage: normal or increased GFR	≥90	A1 <30	None apparent	Usually none Hypertension common
2	Kidney damage: mild ↓ GFR	60–89	Mildly increased	Increasing PTH Early bone disease Increasing plasma creatinine and urea	Subtle hypertension
3	Moderate: ↓ GFR	30–59	A2 30–300	Erythropoietin deficiency,	Mild hypertension

				anemia Increased plasma creatinine and urea	
4	Severe: ↓ GFR	15–29	30–300 A3 >300	Increased triglycerides Metabolic acidosis Hyperkalemia Salt/water retention Increasing plasma creatinine and urea	Moderate hypertension Hyperphosphatemia Anemia
5	End-stage kidney disease; kidney failure	<15	30–300 A3 >300	Uremia	Severe hypertension Hyperphosphatemia Anemia

* Normal glomerular filtration rate in a 70-kg male is about 120 mL/min.

GFR, Glomerular filtration rate; *PTH*, parathyroid hormone.

◆ Pathophysiology.

The kidneys have a remarkable ability to adapt to loss of nephron mass. Symptomatic changes result from increased levels of creatinine, urea, and potassium. Alterations in salt and water balance usually do not become apparent until renal function declines to less than 25% of normal when adaptive renal reserves have been exhausted.

Different theories have been proposed to account for the adaptation to loss of renal function. The *intact nephron hypothesis* proposes that loss of nephron mass with progressive kidney damage causes the surviving nephrons to sustain normal kidney function. These nephrons are capable of a compensatory hypertrophy and expansion or hyperfunction in their rates of filtration, reabsorption, and secretion and can maintain adaptive changes in solute and water regulation in

the presence of overall declining GFR. Although the urine of an individual with chronic kidney failure may contain abnormal amounts of protein and red and white blood cells or casts, the major end products of excretion are similar to those of normally functioning kidneys until the advanced stages of renal failure, when there is a significant reduction of functioning nephrons. With severe or repeated injury, epithelial cells have an impaired proliferative response resulting in interstitial capillary loss and fibroblast proliferation. The progressive process of glomerulosclerosis and tubulointerstitial fibrosis contributes to end-stage kidney disease. The *particular location of kidney damage* also can influence loss of kidney function. For example, tubular interstitial diseases damage primarily the tubular or medullary parts of the nephron, producing problems such as renal tubular acidosis, salt wasting, and difficulty diluting or concentrating the urine. When the damage is primarily vascular or glomerular, proteinuria, hematuria, and nephrotic syndrome are more prominent. A summary of factors involved in the progression of chronic kidney disease is outlined in [Table 39.13](#) and [Fig. 39.13](#).

TABLE 39.13

FACTORS REPRESENTING PROGRESSION OF CHRONIC KIDNEY DISEASE

FACTOR	CHARACTERISTICS
Proteinuria	Glomerular hyperfiltration of protein contributes to tubular intestinal injury by accumulating in the interstitial space and promoting inflammation and progressive fibrosis.
Creatinine and urea clearance	In chronic renal failure, the GFR falls and the plasma creatinine concentration increases by a reciprocal amount; because there is no regulatory adjustment for creatinine, plasma levels continue to rise and serve as an index of changing glomerular function.
	As GFR declines, urea clearance increases. (NOTE: Urea is filtered and reabsorbed and varies with the state of hydration.)
Sodium and water balance	In chronic renal failure, sodium load delivered to nephrons exceeds normal, so excretion must increase; thus less is reabsorbed. Obligatory loss occurs, leading to sodium deficits and volume depletion. As GFR is reduced, ability to concentrate and dilute urine diminishes.
Phosphate and calcium	Changes in acid-base balance affect phosphate and calcium balance. The major disorders associated with chronic renal failure are reduced renal phosphate excretion, decreased renal synthesis of 1,25-(OH) ₂ -vitamin D ₃ , and hypocalcemia.

balance	
	Hypocalcemia leads to secondary hyperparathyroidism, GFR falls, and progressive hyperphosphatemia, hypocalcemia, and dissolution of bone result.
Hematocrit	Lack of erythropoietin and anemia accompany chronic renal failure. Lethargy, dizziness, and low hematocrit are common.
Potassium balance	In chronic renal failure, tubular secretion of potassium increases until oliguria develops. Use of potassium-sparing diuretics also may precipitate elevated serum potassium levels. As disease progresses, total body potassium levels can rise to life-threatening levels and dialysis is required.
Acid-base balance	In early renal insufficiency, acid excretion and bicarbonate reabsorption are increased to maintain normal pH. Metabolic acidosis begins when GFR reaches 30% to 40%. Metabolic acidosis and hyperkalemia may be severe enough to require dialysis when end-stage renal failure develops.
Dyslipidemia	Chronic hyperlipidemia may induce glomerular and tubulointerstitial injury contributing to the progression of chronic kidney disease.

GFR, Glomerular filtration rate.

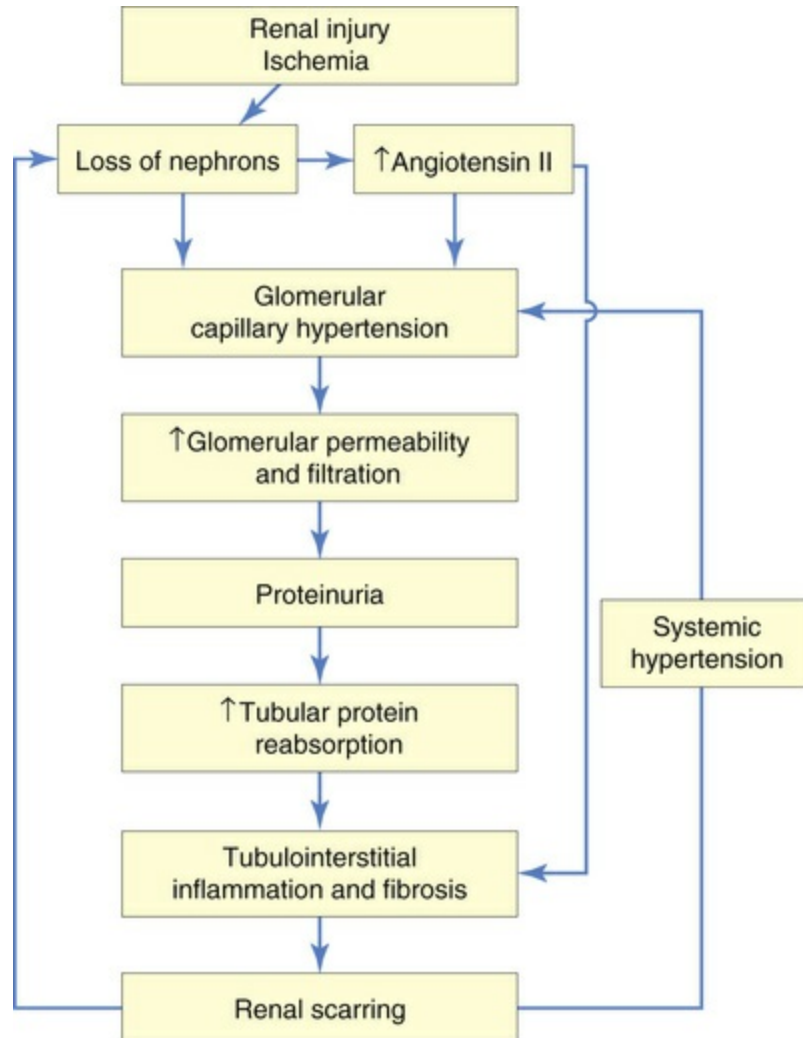

FIGURE 39.13 Mechanisms Related to the Progression of Chronic Kidney Disease.

The factors that contribute to the pathogenesis of CKD are complex and involve the interaction of many cells, cytokines, and structural alterations. Two factors that have consistently been recognized to advance renal disease are proteinuria and angiotensin II activity. Glomerular hyperfiltration and increased glomerular capillary permeability lead to proteinuria. Proteinuria contributes to tubulointerstitial injury by accumulating in the interstitial space and activating complement proteins and other mediators and cells, such as macrophages, that promote inflammation and progressive fibrosis.¹⁰⁸ Angiotensin II activity is elevated with progressive nephron injury. **Angiotensin II** promotes glomerular hypertension and hyperfiltration

caused by efferent arteriolar vasoconstriction and also promotes systemic hypertension. The chronically high intraglomerular pressure increases glomerular capillary permeability, contributing to proteinuria. Angiotensin II also may promote the activity of inflammatory cells and growth factors that participate in tubulointerstitial fibrosis and scarring (see Fig. 39.13).¹⁰⁹

◆Clinical Manifestations.

The clinical manifestations of chronic kidney disease are often described using the terms *azotemia* and *uremia*. Azotemia is manifested by increased levels of serum urea, serum creatinine, and other nitrogenous compounds related to decreasing kidney function. Uremia is a proinflammatory state with many systemic effects known as **uremic syndrome**¹¹⁰ and is associated with the accumulation of urea and other nitrogenous compounds and toxins. Sources of toxins include the accumulation of end products of protein metabolism, alterations in fluid and electrolytes, metabolic acidosis, intestinal absorption of toxins produced by gut bacteria, and results of altered renal hormone synthesis (i.e., anemia, hyperphosphatemia, and hypocalcemia). Generally, the symptoms include hypertension, anorexia, nausea, vomiting, diarrhea or constipation, malnutrition and weight loss, pruritus, edema, anemia, and neurologic, cardiovascular disease, and skeletal changes. The many systemic manifestations associated with uremia are summarized in Table 39.14 and Fig. 39.14.

TABLE 39.14

SYSTEMIC EFFECTS OF CHRONIC KIDNEY DISEASE AND UREMIA

SYSTEM	MANIFESTATIONS	MECHANISMS	TREATMENT
Skeletal	Spontaneous fractures and bone pain Deformities of long bones	Chronic kidney disease—mineral bone disorder: bone inflammation with fibrous degeneration related to hyperparathyroidism; bone resorption	Control of hyperphosphatemia to reduce hyperparathyroidism; administration of calcium and aluminum hydroxide antacids, which bind phosphate

		associated with vitamin D and calcium deficiency	in the gut, together with a phosphate-restricted diet; vitamin D replacement; avoidance of magnesium antacids because of impaired magnesium excretion
Cardiopulmonary	Pulmonary edema, Kussmaul respirations	Fluid overload associated with pulmonary edema and metabolic acidosis leading to Kussmaul respirations	Angiotensin-converting enzyme (ACE) inhibitors; combination of propranolol, hydralazine, and minoxidil for those with high levels of renin; bilateral nephrectomy with dialysis or transplantation
Cardiovascular	Left ventricular hypertrophy, cardiomyopathy, and ischemic heart disease; hypertension, dysrhythmias, accelerated atherosclerosis; pericarditis with fever, chest pain, and pericardial friction rub	Extracellular volume expansion and hypersecretion of renin associated with hypertension; anemia increases cardiac workload; hyperlipidemia promotes atherosclerosis; toxins precipitate into pericardium	Volume reduction with diuretics that are not potassium sparing (to avoid hyperkalemia); lipid-lowering drugs; blood pressure-lowering strategies; dialysis
Neurologic	Encephalopathy (fatigue, loss of attention, difficulty with problem solving); peripheral neuropathy (pain and burning in the legs and feet, loss of vibration sense and deep tendon reflexes); loss of motor coordination, twitching, fasciculations, stupor, and coma with advanced uremia	Progressive accumulation of uremic toxins associated with end-stage renal disease Stroke or intracerebral hemorrhage associated with chronic dialysis	Dialysis or successful kidney transplantation
Endocrine	Restricted growth in children Higher incidence of goiter Osteomalacia	Elevated parathyroid hormone levels Decreased thyroid hormone	Endogenous recombinant human growth hormone; thyroid hormone replacement

			Same as skeletal above
Hematologic	Anemia, usually normochromic normocytic; platelet disorders with prolonged bleeding times	Reduced erythropoietin secretion and reduced red cell production; uremic toxins shorten red blood cell survival and alter platelet function	Dialysis; recombinant human erythropoietin (controversial) and iron supplementation; conjugated estrogens; DDAVP (1-deamino-[8-C-arginine] vasopressin); transfusion
Gastrointestinal	Anorexia, nausea, vomiting; mouth ulcers, stomatitis, urinous breath (uremic factor), hiccups, peptic ulcers, gastrointestinal bleeding, and pancreatitis associated with end-stage renal failure	Retention of metabolic acids and other metabolic waste products	Protein-restricted diet for relief of nausea and vomiting; Na ⁺ -based alkali or alkali-inducing food
Integumentary	Abnormal pigmentation and pruritus	Retention of urochromes, contributing to sallow, yellow color; high plasma calcium levels and neuropathy associated with pruritus	Dialysis with control of serum calcium and phosphate levels
Immunologic	Increased risk of infection that can cause death; increased risk of carcinoma	Suppression of cell-mediated immunity; reduction in number and function of lymphocytes, diminished phagocytosis	Routine dialysis
Reproductive	Sexual dysfunction: menorrhagia, amenorrhea, infertility, and decreased libido in women; decreased testosterone levels, infertility, and decreased libido in men	Dysfunction of ovaries and testes; presence of neuropathies	No specific treatment

FIGURE 39.14 Common Signs and Symptoms of Kidney Dysfunction (See Text for Reference Site). (From Goldman L, Schafer AI: *Goldman-Cecil medicine*, ed 25, Philadelphia, 2016, Saunders; redrawn from Forbes CD, Jackson WF: *Color atlas and text of clinical medicine*, ed 3, London, 2003, Mosby.)

Creatinine, Urea Clearance, and Cystatin C

Creatinine is constantly released from muscle and excreted primarily by glomerular filtration. As the GFR declines in CKD, the serum creatinine (SCr) level increases by a reciprocal amount to maintain a constant rate of excretion (Fig. 39.15). Because no significant tubular adjustment occurs for creatinine (i.e., tubular secretion), the SCr levels continue to increase as the GFR decreases. Therefore measures of plasma creatinine can serve as an index of changing glomerular function. However, SCr as an estimate of GFR is limited when there is reduced muscle mass or fluid overload. Equations including cystatin C or combined with SCr provide a better index (see *What's New?*

Biomarkers and Kidney Injury on Evolve). The clearance of *urea* follows a pattern similar to that of creatinine, but urea is filtered as well as reabsorbed and varies with the state of hydration; it is not a good index of GFR. However, as the GFR decreases, plasma urea concentration also increases.

FIGURE 39.15 Plasma Creatinine (P_{cr}) and Glomerular Filtration Rate (GFR).

Fluid and Electrolyte Balance

Fluid and electrolyte and acid-base balances are significantly disturbed with chronic kidney disease. A summary of electrolyte and acid-base balance alterations is presented in [Table 39.15](#).

TABLE 39.15

ELECTROLYTE AND ACID-BASE ALTERATIONS OF CHRONIC KIDNEY DISEASE

FACTOR	CHARACTERISTICS

Sodium and water balance	In chronic renal failure, sodium load delivered to nephrons exceeds normal, so excretion must increase; thus less is reabsorbed. Obligatory loss occurs, leading to sodium deficits and volume depletion. As GFR is reduced, ability to concentrate and dilute urine diminishes.
Phosphate and calcium balance	Changes in acid-base balance affect phosphate and calcium balance. The major disorders associated with chronic renal failure are reduced renal phosphate excretion, decreased renal synthesis of 1,25-(OH) ₂ -vitamin D ₃ (calcitriol), and hypocalcemia. Hypocalcemia leads to secondary hyperparathyroidism, GFR falls, and progressive hyperphosphatemia, hypocalcemia, and dissolution of bone result.
Potassium balance	In chronic renal failure, tubular secretion of potassium increases until oliguria develops. Use of potassium-sparing diuretics also may precipitate elevated serum potassium levels. As disease progresses, total body potassium levels can rise to life-threatening levels and dialysis is required.
Acid-base balance	In early renal insufficiency, acid excretion and bicarbonate reabsorption are increased to maintain normal pH.
	Metabolic acidosis begins to develop when GFR decreases to 30% to 40% of normal. When end-stage renal failure develops, the metabolic acidosis may be severe enough to require dialysis.

GFR, Glomerular filtration rate.

Levels of *sodium* must be regulated within narrow limits because sodium is the major extracellular solute. In CKD, sodium and water balance is maintained very close to normal until the development of stage 5 ESKD. This occurs because of the increased fractional excretion of sodium, particularly in the distal nephron, in relation to decreasing GFR. Hormones including aldosterone, prostaglandins, and natriuretic peptides also modulate sodium excretion, and their levels are elevated with progressive renal failure. Individual variation in the underlying pathology of CKD must be considered in the management of sodium intake or restriction. Sodium wasting may be present with tubulointerstitial causes of CKD, and there may also be extrarenal losses of sodium from vomiting, diarrhea, or fever. Sodium retention is more likely in ESKD, particularly in the presence of nephrotic syndrome or heart failure. Sodium retention contributes to hypertension, edema, heart failure, and mortality. Interdialytic water intake can cause volume overload and dilutional hyponatremia during dialysis. Management of salt and water balance requires individual assessment, and both hyponatremia and hypernatremia require management.^{111,112}

The regulation of *water balance* and osmolality is normally achieved by urinary concentration mediated by antidiuretic hormone (ADH). As GFR is reduced, ability to concentrate and dilute the urine diminishes. In earlier stages of renal failure, this may be caused by osmotic diuresis produced by increased fractional excretion of solutes by the remaining nephrons or by a decreased tubular response to ADH. Individual nephrons can maintain water balance until severe renal failure occurs and GFR declines to 15% to 20% of normal with extensive loss of nephron and tubular function. At this stage the urinary concentration becomes fixed and approaches that of the plasma at 285 mOsm/L with a specific gravity of about 1.010.

Urinary excretion of *potassium* is related primarily to distal tubular secretion mediated by aldosterone and sodium-potassium adenosine triphosphatase (see [Chapter 3](#)). In renal failure there is increased tubular secretion that provides effective regulation until the onset of oliguria. With hyperkalemia, larger amounts of potassium can be eliminated through the bowel.¹¹³

Although nonoliguric patients can maintain potassium excretion with normal dietary intake, they are more prone to develop hyperkalemia with increased loading (i.e., use of salt substitutes). Use of potassium-sparing diuretics, such as spironolactone (Aldactone), volume depletion, acute infection, severe acidosis, or marked hyperglycemia also may precipitate elevated levels of serum potassium. With progression of disease to end-stage renal failure (ESRF), total body potassium can increase to life-threatening levels and must be controlled by dietary restriction, loop diuretics, cation exchange resins, and dialysis. Hyperkalemia also can be a side effect of ACE inhibitors or receptor blockers often used to prevent diabetic nephropathy. The new drug patiromer sorbitex calcium is FDA approved (exchanges calcium for potassium in the colon). Sodium zirconium cyclosilicate (traps potassium in the colon) is currently investigational. Both are effective in managing hyperkalemia.¹¹⁴ Severe acute hyperkalemia is treated with intravenous 10% calcium gluconate or 10% calcium chloride, intravenous dextrose and insulin, and nebulized or intravenous salbutamol (sympathetic β_2 agonist,

promotes Na⁺-K⁺-ATPase pump and intracellular movement of potassium). Renal replacement therapy may be required (support of renal function using hemodialysis or peritoneal dialysis).¹¹⁵

The intake of a normal diet produces 50 to 100 mEq of hydrogen per day. These ions are secreted from the renal tubules and excreted in the urine combined with phosphate and ammonia buffers (buffering is described in [Chapter 3](#)). *Metabolic acidosis* ([Chapter 3](#)) develops when GFR decreases to less than 20% to 25% of normal. The causes of acidosis are primarily related to decreased hydrogen ion elimination and decreased bicarbonate reabsorption. With ESRF, metabolic acidosis may be severe enough to require alkali therapy and dialysis. Bicarbonate levels should be maintained at about 22 mEq/L.¹¹⁶

Calcium, Phosphate, and Bone

Bone and skeletal changes develop with alterations in **calcium** and **phosphate metabolism** ([Table 39.16](#)). These changes begin when the GFR decreases to 25% or less. *Hypocalcemia* is accelerated by impaired renal synthesis of 1,25-dihydroxy-vitamin D₃ (calcitriol) with decreased intestinal absorption of calcium. Renal phosphate excretion also decreases, and the increased serum phosphate binds calcium, further contributing to hypocalcemia. Acidosis also contributes to a negative calcium balance. Decreased serum calcium level stimulates parathyroid hormone secretion with mobilization of calcium from bone and may cause calcium levels to approach normal. The combined effect of *secondary hyperparathyroidism* and *vitamin D deficiency* can result in renal osteodystrophies (i.e., *osteomalacia* and *osteitis fibrosa* with increased risk for fractures)¹¹⁷ (see [Chapter 45](#)) and vascular calcification, including coronary artery calcification.¹¹⁸ Fractional excretion of magnesium increases as CKD progresses and also may contribute to cardiovascular complications.¹¹⁹

TABLE 39.16

CALCIUM AND PHOSPHATE METABOLISM IN CHRONIC KIDNEY DISEASE

--

KIDNEY	PLASMA	BONE
Decreased renal production of vitamin D ₃	Decreased calcium absorption from gut	Decreased calcium deposition
	Decreased ionized calcium	
	Increased PTH secretion (secondary hyperparathyroidism)	
Decreased phosphate excretion	Elevated phosphate	Release of calcium and phosphate
	Formation of CaHPO ₄	Osteitis fibrosa, osteomalacia, calcium deposits in soft tissue and vascular calcification (occurs when kidney fails to respond to PTH secretion because of loss of renal mass and calcium and phosphate continues to be absorbed from bone)

CaHPO₄, Calcium hydrogen phosphate; PTH, parathyroid hormone.

Protein, Carbohydrate, and Fat Metabolism

Protein, carbohydrate, and fat metabolism are altered in CKD. *Proteinuria* and a catabolic state contribute to a negative nitrogen balance. Levels of serum proteins diminish, including albumin, complement, and transferrin, and there is loss of muscle mass. Proteinuria may independently cause renal damage by promoting tubular inflammation and fibrosis.¹⁰⁸ The amount of proteinuria is also related to the extent of renal injury and predicts disease progression. Monitoring of proteinuria using the albumin-to-creatinine ratio can assist in staging chronic kidney disease.¹²⁰

Hyperinsulinemia and glucose intolerance related to insulin resistance are common and may be related to alterations in adipokines that interfere with insulin action and oxidative stress that contributes to renal tubular and vascular injury in both nondiabetic and diabetic CKD.¹²¹ Hyperparathyroidism also decreases insulin sensitivity and impairs glucose tolerance. High levels of adiponectin have been

associated with increased mortality in progressive CKD.¹²²

Dyslipidemia is common among individuals with CKD. There is a high ratio of low-density lipoprotein (LDL) to high-density lipoprotein (HDL), high levels of triglycerides, and accumulation of LDL particles with accelerated atherosclerosis and vascular calcification. Uremia causes a deficiency in lipoprotein lipase and decreased hepatic triglyceride lipase. Decreased lipolytic activity results in a reduction in HDL level. CKD also impairs the metabolism and protective effects of HDL. Apolipoprotein B concentration also is elevated, thereby accelerating atherogenesis.^{123,124}

Cardiovascular System

Cardiovascular disease (see [Chapter 33](#)) is a major cause of morbidity and mortality in CKD. Proinflammatory mediators, oxidative stress, altered vitamin D metabolism, and metabolic derangements are significant contributors. Declining erythropoietin production causes anemia, which reduces oxygen delivery to the myocardium. Elevated renin level stimulates the secretion of aldosterone, increasing sodium and water reabsorption. *Hypertension* is the result of excess sodium and fluid volume. *Dyslipidemia* occurs early in CKD. Arterial wall thickness increases with decreased elastic fibers and increased extracellular matrix. Atheromatous plaque and arterial calcification contribute to loss of vessel elasticity and obstruction and are accelerated by the oxidative stress of CKD. Macrovascular disease is responsible for increased risk for ischemic heart disease, left ventricular hypertrophy, congestive heart failure, stroke, and peripheral vascular disease in individuals with uremia.¹²⁵ Endothelial cell dysfunction and calcium deposits lead to a loss of vessel elasticity and vascular calcification.¹²⁶ The resulting vascular disease increases the risk for *ischemic heart disease, left ventricular hypertrophy, congestive heart failure, stroke, and peripheral vascular disease* in individuals with uremia. *Pericarditis* can develop from inflammation caused by the presence of uremic toxins. Accumulation of fluid in the pericardial space can compromise ventricular filling and cardiac output.

Pulmonary System

Pulmonary edema results from fluid overload and congestive heart failure. *Dyspnea* is common in ESKD. Metabolic acidosis can cause Kussmaul respirations.

Hematologic System

Hematologic alterations include *normochromic normocytic anemia*, *impaired platelet function*, and *hypercoagulability*. Inadequate production of erythropoietin decreases red blood cell production and is the most significant factor in contributing to anemia. Chronic inflammation, iron deficiency, and decreased half-life of erythrocytes are also contributing factors. Anemia contributes to decreased tissue oxygenation and to progression of kidney disease. Low levels of hemoglobin and symptoms of anemia, such as lethargy, weakness, and dizziness, are common findings. Treatment of anemia includes erythropoiesis stimulating agents (i.e., recombinant human erythropoietin) and intravenous iron. The safety and cost benefit of new drug classes to stimulate erythropoiesis are under investigation.¹²⁷

Disorders of hemostasis in CKD are primarily related to defective platelet aggregation, impaired adhesion of platelets to the vascular endothelium, and alterations in coagulation factors and the fibrinolytic pathway. The consequence is either (1) an increased bleeding tendency (more common with later stages of CKD) manifested by bruising, epistaxis and other mucosal bleeding, gastrointestinal bleeding, and cerebrovascular hemorrhage or (2) excessive formation of thrombi (i.e., deep vein thrombosis, pulmonary embolism and cardiovascular events), which is more common in earlier stages of CKD.¹²⁸

Immune System

Immune system dysregulation with immune suppression, deficient response to vaccination, intestinal barrier dysfunction and dysbiosis, and increased risk for infection develop with CKD. Chemotaxis,

phagocytosis, antibody production, and cell-mediated immune responses are suppressed.¹²⁹

Malnutrition, metabolic acidosis, hyperglycemia, or effects of hemodialysis may amplify immunosuppression.

Neurologic System

Neurologic symptoms are common and progressive with CKD and are related to dysfunction of lower motor and sensory neurons associated with uremic toxicity, chronic hyperkalemic depolarization, and anemia. Neuromuscular irritation can cause hiccups, muscle cramps, and muscle twitching. In advanced stages of renal failure, symptoms may progress to seizures and coma. Peripheral neuropathies also develop with impaired sensations, decreased tendon reflexes, muscle weakness, and muscle atrophy, most commonly in the lower extremities. Symptoms may include headache, drowsiness, pain, sleep disorders, impaired concentration, memory loss, and impaired judgment (uremic encephalopathy). Diabetic neuropathy can occur concurrently. Renal replacement therapy or kidney transplant improves symptoms.¹³⁰

Gastrointestinal System

Gastrointestinal complications are common in individuals with CKD. Uremic gastroenteritis can cause bleeding ulcer and significant blood loss. Nonspecific symptoms include anorexia, nausea, vomiting, and constipation or diarrhea. Uremic fetor is a form of bad breath caused by the breakdown of urea by salivary enzymes. Malnutrition is common.

Endocrine and Reproductive Systems

Endocrine and reproductive alterations develop with progression of CKD. Males and females have a decrease in the levels of circulating sex steroid hormones. Males often experience a reduction in testosterone levels and may be impotent. Oligospermia and germinal

cell dysplasia can result in infertility. Females have reduced estrogen levels, amenorrhea, and difficulty with conception and maintaining a pregnancy to term. A decrease in libido occurs in both genders.¹³¹ Renal replacement therapy and kidney transplantation improve sexual dysfunction. There are no guidelines related to sex hormone replacement therapy and end-stage kidney disease.¹³²

Insulin resistance is common in uremia. Low-grade systemic inflammation, oxidative stress, vitamin D deficiency, and anemia may be contributing factors with increased risk for cardiovascular disease. As CKD progresses, the ability of the kidney to clear adiponectin and leptin and degrade insulin is reduced, and the half-life of insulin is prolonged. Individuals with diabetes mellitus and CKD need to carefully manage their insulin dosages. Low-protein diets and renal replacement therapy improve insulin sensitivity.¹³³

CKD also causes alterations in thyroid hormone metabolism and low thyroid hormone levels and is known as *nonthyroidal illness syndrome (euthyroid sick syndrome)* and increases risk for cardiovascular disease. Low-grade inflammation and oxidative stress may be contributing factors. Uremia also reduces conversion of triiodothyronine (T₃) to tetraiodothyronine (T₄-thyroxine).¹³⁴

Integumentary System

Skin changes are associated with other complications that develop with CKD. Anemia can cause pallor and bleeding into the skin and results in hematomas and ecchymosis. Retained urochromes manifest as a sallow skin color. Hyperparathyroidism and uremic skin residues, related to calcium and phosphorus levels and alterations in opioid receptors, are associated with irritation and pruritus with scratching, excoriation, increased risk for infection, impaired sleep, and depression.¹³⁵

◆ Evaluation and Treatment.

Early screening and evaluation of CKD are based on risk factors, history, presenting signs and symptoms, and diagnostic testing. Prediction equations incorporating serum creatinine or cystatin C, or

both, are used for estimating GFR. Markers of kidney damage include urine protein, particularly albumin, and examination of urine sediment. New biomarkers for predicting progression of CKD are being evaluated (see *What's New? Biomarkers and Kidney Injury on Evolve*). Renal biopsy confirms the diagnosis.

Management involves dietary control, including management of protein intake, vitamin D supplementation, sodium and fluid maintenance, potassium restriction, adequate caloric intake, management of dyslipidemias, erythropoietin-stimulating agents (ESAs), and adjuvant iron therapy as needed^{127,136} (see [Nutrition & Disease: End-Stage Kidney Disease \[ESKD\] and Protein-Energy Wasting](#)). Hyperphosphatemia is managed with a low phosphorus diet, phosphate binders, vitamin D replacement, calcimimetics, and parathyroidectomy while maintaining normal serum calcium levels. ESKD related to diabetic nephropathy can be significantly reduced with control of hyperglycemia, hypertension, hyperlipidemia, and albuminuria. ACE inhibitors or receptor blockers are often used to control systemic hypertension, decrease albuminuria, and provide renoprotection in the presence of diabetes mellitus and mild chronic kidney injury. They are under investigation for advanced CKD.¹³⁷

Statins and fibrates are used to control hyperlipidemia (i.e., elevated low density lipoprotein cholesterol [LDL-C]).¹³⁸ Sodium glucose cotransporter 2 (SGLT2) inhibitors are being evaluated for nephroprotective actions and renal gluconeogenesis inhibition.¹³⁹ ESKD is treated with dialysis, supportive therapy, and renal transplantation.¹⁴⁰

Nutrition & Disease

End-Stage Kidney Disease (ESKD) and Protein-Energy Wasting

The malnutrition-inflammation complex syndrome or protein-energy wasting (decreased body storage of protein and energy) is a common condition associated with renal failure and loss of appetite

and leads to accelerated atherosclerosis, cardiovascular disease, and increased mortality for individuals with ESKD. Elevated levels of leptin, ghrelin, adiponectin, and inflammatory cytokines, including interleukin-6, tumor necrosis factor-alpha, and interferon, suppress appetite and cause muscle proteolysis and decreased protein assimilation. Acidosis also acts synergistically with inflammatory cytokines and insulin resistance to promote mitochondrial dysfunction and protein catabolism. Reduced renal function, oxidative stress, decreased levels of antioxidants, infection and other comorbidities, exposure to dialysis tubing and membranes during hemodialysis, and back-filtration of contaminants during hemodialysis contribute to inflammation. Proteins and amino acids may be lost in the dialysate. The provision of supplemental formulations, including adequate calories and protein that includes amino acids, in the form of oral, enteral interdialytic, or enteral or parenteral intradialytic feeding helps a person to meet metabolic requirements. Dietary supplements of antioxidants, such as vitamins A and C, selenium, and carotenoids, are required. Low-protein, low-phosphorus, and low-sodium diets assist with reducing proteinuria, preventing hyperphosphatemia and secondary hyperparathyroidism, and lowering blood pressure, but diets must be individualized. Protein intake of plant origin may improve lipid profiles, provide fiber, and reduce phosphorus intake. Adequate nutritional support promotes renal recovery and may prevent consequences of muscle weakness and immune dysfunction.

Summary Review

Urinary Tract Obstruction

1. Obstruction can occur anywhere in the urinary tract, and may be anatomic or functional, including kidney stones, tumors, an enlarged prostate gland, or strictures of the ureter or urethra. The most serious complications are hydronephrosis, hydroureter, ureterohydronephrosis, and infection caused by the accumulation of urine behind the obstruction.
2. Tubulointerstitial fibrosis and dysregulated apoptosis can result in progression to chronic kidney disease in untreated obstructive uropathy.
3. Compensatory hypertrophy and hyperfunction of the opposite kidney compensate for loss of function of the kidney with obstructive disease.
4. Relief of obstruction is usually followed by postobstructive diuresis and may cause fluid and electrolyte imbalance.
5. Kidney stones are caused by supersaturation of the urine with precipitation of stone-forming substances, changes in urine pH, or urinary tract infection. Most stones are unilateral.
6. The most common kidney stone is formed from calcium oxalate and most often causes obstruction by lodging in the ureter.
7. Obstructions of the bladder are a consequence of neurogenic or anatomic alteration of the bladder or both.
8. A neurogenic bladder is caused by a neural lesion that interrupts innervation of the bladder.
9. Upper motor neuron lesions above the pontine micturition center result in detrusor hyperreflexia and uninhibited or reflex bladder.
10. Upper motor neuron lesions between C2 and S1 result in overactive or hyperreflexive bladder function and detrusor sphincter dyssynergia (lack of coordinated neuromuscular contraction).
11. Lower motor neuron lesions below S1 result in detrusor areflexia with underactive, hypotonic, or atonic bladder function.
12. OAB syndrome is an uncontrollable or premature contraction

- of the bladder that results in urgency with or without incontinence, frequency, and nocturia.
13. Anatomic obstructions to urine flow include prostatic enlargement, urethral stricture, and pelvic organ prolapse in women.
 14. Partial obstruction of the bladder can result in overactive bladder contractions with urgency. There is deposition of collagen in the bladder wall over time, resulting in decreased bladder wall compliance and ineffective detrusor muscle contraction.
 15. Renal cell carcinoma is the most common renal neoplasm. The larger neoplasms tend to metastasize to the lung, liver, and bone.
 16. Bladder tumors are commonly composed of transitional cells with a papillary appearance and a high rate of recurrence.

Urinary Tract Infection

1. UTIs are commonly caused by the retrograde movement of bacteria into the urethra and bladder. UTIs are uncomplicated when the urinary system is normal or complicated when there is a defect or abnormality.
2. Host defenses that protect against urinary tract infection include high osmolality and acidic pH of urine, mucus, uromodulin and other antimicrobial proteins that activate the immune response, sphincters that prevent reflux, and urine flow that washes out bacteria.
3. Virulent uropathogens have pili or fimbriae, or both, that promote binding to the uroepithelium and retrograde movement in the urinary tract. Formation of biofilms enhances colonization and resists host defenses and antimicrobial therapy.
4. Cystitis is an inflammation of the bladder commonly caused by bacteria and may be acute or chronic. Manifestations of frequency, urgency, and dysuria are caused by inflammation.

5. Interstitial cystitis/painful bladder syndrome may be an autoimmune injury with increased permeability of the glycosaminoglycan layer of the bladder mucosa.
6. Pyelonephritis is an acute or chronic inflammation of the renal pelvis often related to ascending infection and obstructive uropathies and may cause abscess formation and scarring with acute or chronic kidney injury.

Glomerular Disorders

1. Glomerular disorders are a group of related diseases of the glomerulus that can be primary and caused by immune injury, infection, ischemia, toxins or drugs, or vascular disorders or, secondarily, caused by systemic diseases.
2. Acute glomerulonephritis commonly results from inflammatory damage to the glomerulus as a consequence of immune reactions including deposition of circulating immune complexes, antibodies reacting in situ to planted antigens, antibodies directed against the glomerular basement membrane, and complement activation.
3. The urine sediment may contain large amounts of protein (nephrotic sediment) or have red and white blood cells and protein (nephritic sediment).
4. Acute postinfectious glomerulonephritis is commonly associated with immune complex deposition in the glomerulus or in situ formation.
5. Lupus nephritis is caused by the formation of autoantibodies against double-stranded DNA (dsDNA) and nucleosomes in the glomerulus, causing inflammation and injury.
6. IgA nephropathy is the binding of abnormal IgA to mesangial cells in the glomerulus resulting in injury and mesangial proliferation.
7. Focal segmental glomerulosclerosis is a scarring lesion that involves some but not all glomeruli (focal) and some but not all of the glomerular capillaries (segmental).

7. Membranous nephropathy is complement-mediated glomerular injury with increased glomerular permeability and glomerulosclerosis.
8. RPGN is associated with injury that results in the proliferation of glomerular capillary endothelial cells and a rapid loss of renal function.
9. Mesangial proliferative glomerulonephritis is usually idiopathic and involves deposits of immune complex in the mesangium with mesangial cell proliferation.
10. Membranoproliferative glomerulonephritis involves mesangial cell proliferation, complement deposition, and crescent formation.
11. Chronic glomerulonephritis is related to a variety of diseases that cause deterioration of the glomerulus and a progressive loss of renal function over a period of months to years, including diabetic nephropathy and lupus nephritis.
12. Diabetic nephropathy develops from metabolic, inflammatory, and microvascular complications associated with chronic hyperglycemia.
13. Lupus nephritis is caused by the formation of autoantibodies against dsDNA and nucleosomes in the glomerulus, causing inflammation and injury.
14. Nephrotic syndrome is the excretion of at least 3.5 g of protein (primarily albumin) in the urine per day primarily because of glomerular injury with increased capillary permeability and loss of membrane negative charge. The principal signs are hypoproteinemia, hyperlipidemia, and edema. The liver cannot produce enough protein to adequately compensate for urinary loss.
15. Nephritic syndrome is hematuria and red blood cell casts in the urine and less severe proteinuria.

Acute Kidney Injury

1. AKI is the sudden decline in kidney function with decreased

glomerular filtration and an increase in serum creatinine, cystatin C, and BUN levels.

2. AKI is considered in three categories as prerenal, intrarenal, or postrenal and is usually accompanied by oliguria with elevated plasma BUN and plasma creatinine levels.
3. Prerenal acute renal failure is caused by decreased renal perfusion with a decreased GFR, ischemia, and tubular necrosis.
4. Intrarenal acute renal failure is associated with several systemic diseases or to drug toxicity but is commonly related to ATN.
5. Postrenal acute renal failure is associated with diseases that obstruct the flow of urine from the kidneys.
6. Oliguria is a urine output of less than 400 mL per day and can be caused by alterations in renal blood flow, tubular obstruction, or tubular fluid backleak, or by a combination of these events.

Chronic Kidney Disease

1. Chronic kidney disease is a progressive loss of renal function. Plasma creatinine levels gradually become elevated as GFR declines, sodium is lost in the urine, potassium is retained, acidosis develops, activation of vitamin D declines, calcium and phosphate metabolism are altered, and erythropoietin production is diminished.
2. Symptomatic changes usually do not become evident until renal function declines to less than 25%.
3. Glomerular hypertension, hyperfiltration, and tubulointerstitial inflammation and fibrosis contribute to the progression of chronic kidney disease. Proteinuria and angiotensin II promote the pathologic changes of chronic renal injury.
4. Uremic syndrome is a proinflammatory state with the accumulation of urea and other nitrogenous compounds as

well as toxins and alterations in fluid, electrolyte, and acid-base balance that result from chronic kidney failure.

5. All organ systems are affected and contribute to disease symptoms.

Congenital Abnormalities, 1280

Glomerular Disorders, 1282

Kidney Injury, 1286

Bladder Disorders, 1287

Urinary Incontinence, 1289

Renal and urinary disorders occur in children as well as adults. In childhood, however, the kidney and genitourinary structures are continuing to develop, so renal dysfunction may be associated with mechanisms and manifestations that are different from those in adults. In addition, some renal and urinary disorders are congenital

and involve structural anomalies of the kidney and urinary drainage system.

Structure and Function of the Urinary System in Children

Development of the Urinary System

The embryonic urinary system develops as three sets of sequentially replaced organs: the pronephros, mesonephros, and metanephros. The **pronephros** is a nonfunctional structure that arises at the level of the cervical and upper thoracic regions during the third fetal week and connects the primitive wolffian duct to the cloaca as the foundation for male sexual development (Fig. 40.1). The development of the **mesonephros** and **metanephros** is described in Fig. 40.1. The Wilms tumor 1 (*WT1*) gene plays an important role at all stages of kidney development and maintenance of kidney function.¹

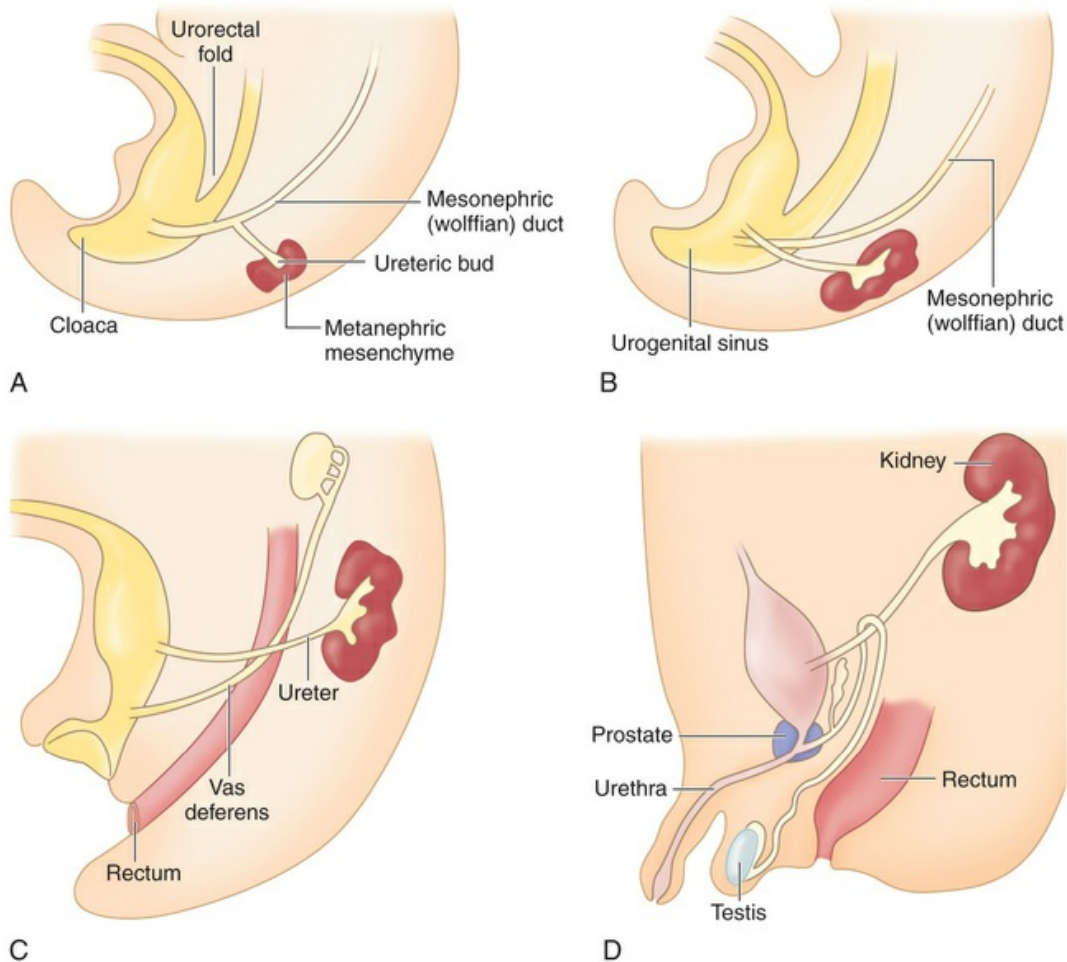

FIGURE 40.1 Embryonic Development of the Kidneys. The mesonephros begins development more caudally about the fourth fetal week and begins excretory function in the sixth week. Most of the mesonephros degenerates and disappears by the end of the embryonic period. The metanephros, the permanent kidney, arises distal to the bifurcation of the aorta and develops from two different sources: (1) the *ureteric bud* (metanephric duct) forms as an outgrowth of the mesonephric (wolffian) duct and grows dorsocranially and starts subdividing to become the collecting system for the kidneys by forming the ureter, renal pelvis, and calyces; by the fifth fetal month it will have progressively branched into the collecting ducts; and (2) the *metanephrogenic mesenchyme* sits atop the terminal branches of the collecting ducts and develops into primitive glomeruli and uriniferous tubules (A). Genetic information from the metanephrogenic mesenchyme guides the development of the ureteric bud. Establishing the connection between the uriniferous tubules and the collecting ducts is a vital part of kidney development; errors in this stage can result in polycystic kidneys. As the embryo grows, the definitive kidneys migrate from the caudal position to the lumbar region and the ureters connect with the bladder (B–D). In the 8-week male embryo, the wolffian duct begins to give rise to the epididymis, the seminal vesicles, and the caudal part of the vas deferens (C). The external genitalia develop between 8 and 16 weeks, and testicular descent begins in month 7 of gestation (D). (From Goldman L, Schafer AI: *Goldman's Cecil medicine*, ed 24, Philadelphia, 2012, Saunders.)

After glomeruli and tubules form, the tissues organize and progressively differentiate over approximately 30 days. Initial glomerular development is staggered, so there are glomeruli in various stages. In fact, a few of the first glomeruli that are formed degenerate and disappear during the later stages of fetal development. Progressive development continues into the ninth fetal month, when all metanephrogenic tissue then disappears.

As the embryo develops and the vertebral column straightens, the kidneys appear to ascend to the sacral area at about 6 weeks, to the third lumbar area by the third month, and to the first lumbar area at term. The kidneys rotate 90 degrees as they ascend so that renal tissue is lateral and the collecting system is medial.

While the kidneys mature, the *cloaca* becomes the urogenital sinus. It then differentiates into the vesicourethral canal, which forms the bladder and the upper urethra, and the urogenital sinus, which forms the main part of the urethra.

At birth the kidneys occupy a large portion of the posterior abdominal wall, and the ureters are proportionately shorter than those of an adult. All the nephrons are present at birth, and their number does not increase as the kidney grows and matures. The kidney reaches adult size by adolescence and, because of maturation of the tubular system, increases in weight fivefold from the time of birth.

Urine formation and excretion begin by the third month of gestation, contributing to the amniotic fluid. In infancy the bladder lies close to the abdominal wall, making urinary bladder aspiration for diagnostic purposes a relatively simple procedure. The bladder descends into the pelvis with growth, changing from a cylindrical organ to the adult pyramidal shape. Although small amounts of urine are found in the bladder at birth, the newborn may not void for 12 to 24 hours.

Immediately at birth the renal blood flow and glomerular filtration rate (GFR) increase because of a decrease in vascular resistance and the need to perform excretory functions no longer performed by the placenta. Renal vascular resistance remains higher in newborns and infants, however, which may be attributed to increased levels of

circulating renin. The resistance progressively declines during the first year of development, with an increasing fraction of the cardiac output going to the kidney. The GFR continues to increase, achieving adult levels by 2 years of age.

Fluid and Electrolyte Balance in Children

Because the kidney develops from the center toward the periphery, renal distribution of blood flow during the newborn period is primarily to the renal medulla. The result is a preferential flow to the medullary nephrons, which have comparatively short loops at this stage of development. The combination of higher blood flow and shorter loops produces a more dilute urine up to 6 months of age—approximately 400 to 600 mOsm (compared with 800 to 1200 mOsm in adults) (see [Chapter 3](#)). The immature kidney is also less responsive to the actions of antidiuretic hormone (vasopressin)² (see [Fig. 3.6](#)). The dilute urine is accentuated by a low rate of urea excretion, which is necessary to establish the concentration gradient in the medulla. Urea excretion is low primarily because infants are in a high anabolic state and use their protein for growth.

Because of a high hydrogen ion concentration, limited ability to regulate the internal environment, and lowered osmotic pressure, the infant's renal system has a narrow chemical safety margin. The immaturity and smaller surface area of the tubules also may diminish the water reabsorption response to antidiuretic hormone (ADH). An immature tubular transport capacity means that the ability to excrete a potassium load, reabsorb bicarbonate, or buffer hydrogen with ammonia does not become efficient until approximately 2 years of age. Consequently, any disturbance such as diarrhea, infection, fasting for diagnostic tests, or improper feeding can rapidly lead to severe acidosis and fluid imbalance because the infant can rapidly develop over- or underhydration or edema (see [Chapter 3](#)).³

At birth infants have a natriuretic response to atrial natriuretic peptide and a normal contraction in extracellular fluid (ECF) volume with an accompanying loss of body weight. After birth the proportion of total body water to body weight does not change markedly.

Considerable change occurs, however, in the location of that body water as the child matures (see [Chapter 3](#)). Compared to an adult, the percentage of extracellular fluid volume of the newborn infant is nearly double. Decrease in extracellular fluid volume occurs in two different periods of rapid growth—infancy and adolescence.

An infant has not only a greater content of extracellular fluid but also a greater rate of fluid exchange. The adult consumes and excretes approximately 2000 mL of water daily, representing 5% of the total body fluid or 14% of the extracellular fluid. In contrast, the infant's daily exchange of 600 to 700 mL represents 290% of the total or nearly 50% of the extracellular volume, making control of dehydration and overhydration more difficult.

The composition of body fluids differs slightly with age. The total electrolyte concentration in extracellular fluids is greater in the newborn than in the adult. The concentrations of sodium, chloride, phosphates, and organic acids are also greater. The concentration of bicarbonate ions is lower in the infant than in the older child, with a mild acidosis evidenced by a lowered pH. These variations, combined with a lowered plasma protein level, cause a reduced oncotic pressure of the vascular compartment and favor accumulation of fluid in the tissue spaces and an increased GFR. In the healthy child these differences remain for a few weeks or months. The premature infant and the normal newborn infant are usually in a state of well-compensated acidosis and potential edema.

Alterations in Renal and Bladder Function in Children

Congenital Abnormalities

Congenital abnormalities of the kidney and urinary tract occur in about 1% of newborns.⁴ Structural abnormalities range from minor, nonpathologic, or easily correctable anomalies to those that are incompatible with life. For example, the kidneys may fail to ascend from the pelvis to the abdomen, causing ectopic kidneys—which

usually function normally. The kidneys also may fuse in the midline as they ascend, causing a single U-shaped **horseshoe kidney**, with an incidence rate of about 1 in 600 births.⁵ Approximately one-third of individuals with horseshoe kidneys are asymptomatic. The most common associated problems are hydronephrosis, infection, stone formation, and tumors.⁶ Collectively, structural anomalies of the renal system account for approximately 45% of cases of renal failure in children in developed countries. Many are linked to gene defects.⁷

Some anomalies are obvious at birth, whereas others remain silent or become apparent in childhood. The following structural anomalies can be associated with urinary tract malformations:^{6,8}

- Low-set, malformed ears, sensorineural deafness
- Chromosomal disorders, especially trisomy 13 (Patau syndrome) and trisomy 18
- Absent abdominal muscles (prune-belly syndrome)
- Vertebral and extremity anomalies
- Imperforate anus
- Renal (nephroblastoma) and extrarenal tumors
- Ocular abnormalities (coloboma of the iris, congenital cataracts)
- Hepatic cysts or cirrhosis

Hypospadias

Hypospadias is a congenital condition in which the urethral meatus is located on the ventral side or undersurface of the penis. The meatus can be located anywhere on the glans (proximal hypospadias), the penile shaft, the base of the penis, the penoscrotal junction, or the perineum (distal hypospadias) (Fig. 40.2). Partial absence of the foreskin, inguinal hernia, and cryptorchidism (undescended testes; see

Chapter 26) are associated with the anomaly. This is the most common anomaly of the penis. The incidence varies geographically ranging from 1.86 to 5 per 10,000 infant boys.⁹ The etiology is multifactorial and related to disruptions in male hormones, including testosterone biosynthesis defects, steroid 5 α -reductase type 2 mutations, genes associated with penile and urethral development, hormones administered for in vitro fertilization, advanced maternal age, and other environmental factors.¹⁰ Chordee or penile torsion may accompany hypospadias. In *chordee* a shortage of skin on the ventral surface causes the penis to bend or to “bow” ventrally (Fig. 40.3). *Penile torsion* is a rotation, usually in a counterclockwise direction, of the penile shaft.¹¹

FIGURE 40.2 Hypospadias. (Courtesy H. Gil Rushton, MD, Children's National Medical Center, Washington, DC; from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 10, St Louis, 2015, Mosby.)

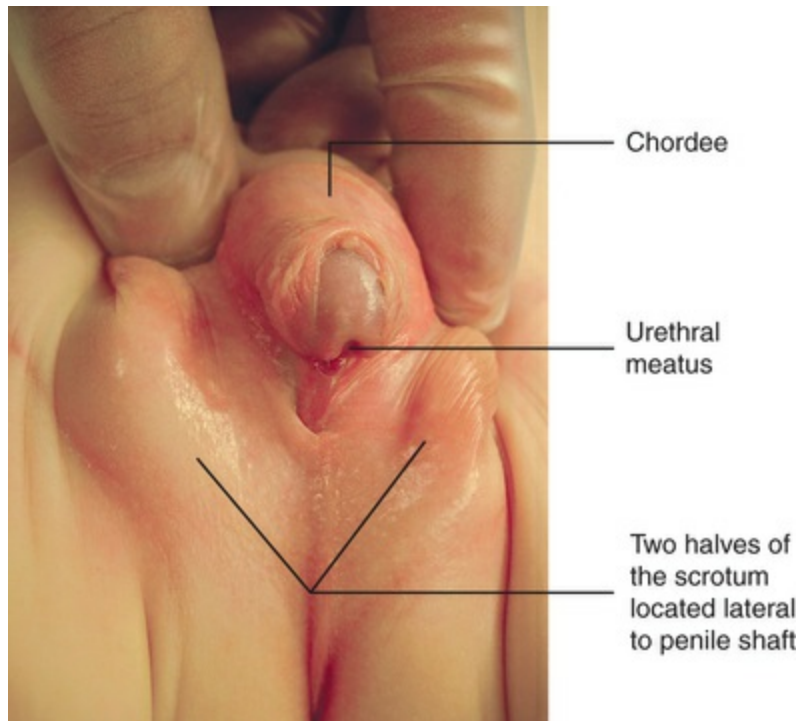

FIGURE 40.3 Perineal Hypospadias with Chordee and Partial Penoscrotal Transposition. (From Kliegman RM et al, editors: *Nelson textbook of pediatrics*, ed 19, Philadelphia, 2011, Saunders.)

The goals for corrective surgery on the child with hypospadias are (1) a straight penis when erect to facilitate sexual intercourse as an adult, (2) a uniform urethra of adequate caliber to prevent spraying during urinations, (3) a cosmetic appearance satisfactory to the individual, and (4) repair completed in as few procedures as possible. Improvements in microsurgical techniques have enhanced outcomes and decreased complications and the need for follow-up surgery. Surgery is usually performed between 6 and 12 months of age.¹²

Epispadias

Epispadias and exstrophy of the bladder are the same congenital defect but expressed to a different degree. The dorsal urethra is not fused in epispadias and has failed to form into a tube. In boys the urethral opening may be small and situated behind the glans (anterior epispadias), or a fissure may extend the entire length of the penis and into the bladder neck (posterior epispadias). In females a cleft along the ventral urethra usually extends to the bladder neck. The incidence

of epispadias is about 9.25 per 100,000 in-hospital live births¹³; it is seen predominantly in males. Continence is determined in part by the location of the defect, with urinary incontinence rates of up to 75% in children with distal epispadias.¹⁴ Treatment is surgical reconstruction.

Exstrophy of the Bladder

Exstrophy of the bladder is a rare extensive congenital anomaly of herniation of the bladder through the abdominal wall with failure of the abdominal muscles, pelvic ring, and pelvic floor musculature to fuse in the midline (Fig. 40.4). The posterior portion of the bladder mucosa is exposed and appears bright red. The prevalence of exstrophy of the bladder is about 1.7 in 100,000 live births.¹³

FIGURE 40.4 Exstrophy of Bladder. (Courtesy H. Gil Rushton, MD, Children's National Medical Center, Washington, DC; from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 10, St Louis, 2015, Mosby.)

Exstrophy of the bladder is caused by intrauterine failure of the abdominal wall and the mesoderm of the anterior bladder to fuse. The clitoris in girls is divided into two halves with the urethra between them. The penis in boys is epispadias. Urine seeps onto the abdominal wall from the ureters, causing a constant odor of urine and excoriation of the surrounding skin. Because the exposed bladder mucosa

becomes hyperemic and edematous, it bleeds easily and is painful. It should be covered with Silastic or a plastic dressing (e.g., kitchen plastic wrap) for protection from irritation while permitting urine drainage. The unrepaired exstrophic bladder is cosmetically unacceptable and prone to cancerous changes as soon as 1 year after birth. The rectus muscles below the umbilicus are separated, and the pubic rami (bony projections of the pubic bone) are not joined. In addition, the posterior aspect of the pelvis is externally rotated, which retroverts the acetabula and causes external rotation of the feet. This causes a waddling gait when the child first learns to walk. Most children learn to compensate, but surgical intervention may be required. Ideally the bladder and pubic defect should be closed before the infant is 72 hours old. Surgical reconstruction is usually performed within the first year, either as a complete primary repair or as staged procedures. Staged procedures may include bladder augmentation and bladder neck and epispadias repair.¹⁵ Objectives of management include preservation of renal function, attainment of urinary control, prevention of infection, and improvement of sexual function and quality of life.

Cloacal exstrophy is the most rare and severe form of bladder exstrophy. The intestines, genitourinary tract, and spine may be involved, and reconstruction with restored urine and fecal control is difficult.

Ureteropelvic Junction Obstruction

Ureteropelvic junction (UPJ) obstruction is a blockage of the tapered point where the renal pelvis transitions into the ureter. Most cases are caused by intrinsic factors, such as a stricture or an aperistaltic ureteral segment, whereas extrinsic factors, such as crossing vessels, are rarely seen.¹⁶ It is the most common cause of hydronephrosis in neonates.¹⁷ Diagnosis is made by ultrasound. Open or endoscopic surgery to relieve the obstruction occurs if there is decline of renal drainage or function.¹⁸ **Secondary ureteropelvic junction obstruction** is caused by kinking or extrinsic compression by an aberrant lower pole vessel.¹⁹ Children with UPJ obstruction have an increased risk of

vesicoureteral reflux.²⁰ UPJ obstruction can be associated with ureteral duplication, including complete ureteral duplication (abnormal growth of two ureters and ureteral orifices draining a single kidney) and incomplete duplication (bifurcation of the ureter terminates into one ureteral orifice and serves a single kidney). Obstruction of the distant ureter (**ureterovesical junction obstruction**) causes dilation of the entire ureter, renal pelvis, and calyceal system (megaureter). **Megaureter** can occur when a short acontractile segment of the ureter develops just above the ureterovesical junction or from ureteral reflux.²¹ A **ureterocele** (cystic dilation of the intravesical ureter) impedes drainage from the associated kidney.

Bladder Outlet Obstruction

Congenital causes of bladder outlet obstruction are rare and include urethral valves, urethral polyps, and urethral atresia. A **urethral valve** is a thin membrane that occludes the urethral lumen and obstructs urinary outflow in males. It is the most common cause of congenital lower urinary tract obstruction and renal failure. Most valves occur in the posterior urethra (PUV), although a few arise from the embryologically distinct anterior urethra.²² **Urethral polyps** arising from the prostatic urethra are rare. Symptoms of polyps may include hematuria; voiding issues, such as urinary retention or straining to void; and dilation of the upper tracts.²³ **Urethral atresia** is absence of the urethra and is rare. Congenital urethral valves or polyps can be diagnosed with prenatal ultrasound and treated with prenatal bladder shunting or with resection during the first days of life. Severe obstruction may impair renal embryogenesis and lead to renal failure.²⁴

Hypoplastic or Dysplastic Kidneys

During embryologic development, the ureteric duct grows into the metanephric tissue, triggering the formation of the kidneys. If this growth does not occur, the kidney is absent—a condition called **renal aplasia**. A **hypoplastic kidney** is small with a decreased number of

nephrons. These conditions may be unilateral or bilateral; the occurrence may be incidental or familial. Bilateral hypoplastic kidneys are a common cause of chronic renal failure in children. Segmental hypoplasia (the Ask-Upmark kidney) may be congenital or secondary to vesicoureteral reflux. Systemic hypertension is a common presentation.

Renal dysplasia usually results from abnormal differentiation of the renal tissues; for example, primitive glomeruli and tubules, cysts, and nonrenal tissue (such as cartilage) are found in the dysplastic kidney. Dysplasia may be secondary to antenatal obstruction of the urinary tract from ureteroceles, posterior urethral valves, or prune-belly syndrome.

Renal Agenesis

Renal agenesis (the absence of one or both kidneys) may be unilateral or bilateral and may occur randomly or be hereditary. It may be an isolated entity or associated with anomalies in other organs. *Unilateral renal agenesis* occurs in approximately 1 of 1000 live births in the United States. Males are more often affected, and it is usually the left kidney that is absent. The single kidney is often completely normal, so that the child can expect a normal, healthy life. The normal solitary kidney grows because of compensatory hypertrophy before and after birth. By the time the child is several years older, the volume of this kidney may approach twice the normal size. In some instances the single kidney is abnormally formed and associated with abnormalities of its collecting system.²⁵ Because the child has a decreased number of nephrons, there is a risk of “hyperfiltration injury,” increasing the chance of developing proteinuria, hypertension, and chronic kidney disease.²⁶ Extrarenal congenital abnormalities of the urogenital, skeletal, cardiac, and other systems may coexist.²⁷ *Bilateral renal agenesis* (also called **Potter syndrome**) is a rare disorder incompatible with extrauterine life.²⁸ Approximately 75% of affected infants are male. Bilateral renal agenesis results from either an abnormal development of the normal progression from pronephros to mesonephros to metanephros or an isolated bilateral failure of

development of the ureteral buds. The term *Potter syndrome* refers to the association with a specific group of facial anomalies (wide-set eyes, parrot-beak nose, low-set ears, and receding chin). Oligohydramnios (low amount of amniotic fluid) leads to underdeveloped lungs. Affected infants rarely live more than 24 hours because of pulmonary insufficiency. Approximately 40% of affected infants are stillborn. Renal agenesis can be detected prenatally by ultrasound.

Polycystic Kidneys

Autosomal dominant polycystic kidney disease (ADPKD) is an inherited disorder that occurs in about 1 in 1000 live births in the United States. Mutations of two genes, *PKD-1* (chromosome 16) and *PKD-2* (chromosome 4), account for the disease most often presenting in late childhood or adulthood. The gene products (polycystins) regulate growth and differentiation of the tubular epithelium.²⁹ Defects in the formation of epithelial cells and their cilium result in cyst formation and obstruction accompanied by destruction of renal parenchyma, interstitial fibrosis, and loss of functional nephrons. Cysts may occur in other organs including the liver, seminal vesicles, and pancreas. Hypertension, heart valve defects, and cerebral and aortic aneurysms may develop.³⁰ Urinary tract infection, hematuria, and flank pain may occur. Diagnosis is usually confirmed by ultrasound. Individuals may live for decades before developing symptoms of renal disease, and not all progress to end-stage disease.³¹ Tolvaptan (a competitive vasopressin receptor 2 antagonist) may slow progression of the condition.³² **Autosomal recessive PKD (ARPKD)** with cystic changes in the kidney and liver is often first suspected on a prenatal ultrasound. Gene mutations in *PKHD1* result in reduced or absent function of fibrocystin which is required for tubulogenesis.³³ Renal replacement therapy is usually required during childhood or adolescence.³⁴

Glomerular Disorders

The most common glomerular disorders in children are glomerulonephritis, nephrotic syndrome, and hemolytic uremic syndrome. Most glomerular diseases are acquired and immunologically mediated. The disease can be acute or chronic. The likelihood of developing renal failure depends on the specific condition. The most common glomerular disorders in children are presented next.

Glomerulonephritis

Acute glomerulonephritis includes a number of renal disorders in which inflammation of the glomeruli are secondary to an immune mechanism (Table 40.1). (The types of glomerulonephritis and their histologic characteristics can be reviewed in Chapter 39 and Table 39.7.) The symptoms usually include the sudden onset of hematuria with red blood cell casts and proteinuria, and can be accompanied by renal salt and water retention, edema, hypertension, and in severe cases azotemia (i.e., decreased glomerular filtration rate). Glomerulonephritis is the causative factor for 15% to 29% of end-stage renal disease in children.³⁵

TABLE 40.1

PRIMARY GLOMERULONEPHRITIS IN CHILDREN

CLASSIFICATION	FINDINGS
Cause	Poststreptococcal infection Related to other bacterial or viral infection Unknown
Immunologic mechanism	Antigen-antibody complex deposition Planted antigens with immune complex formed in situ Formation of antiglomerular basement membrane antibodies (rare) No immunologic cause established
Histopathology	No lesion Diffuse, focal, or segmented Membranous, proliferative, or combination of types Lobular, exudative, necrotizing, and other types Chronic with glomerular proliferation
Clinical manifestations of disease	Acute glomerulonephritis

Acute Poststreptococcal Glomerulonephritis.

Acute poststreptococcal glomerulonephritis (PSGN) is one of the most common immune complex–mediated renal diseases in children ages 5 to 15 years, and it is representative of acute glomerulonephritis. It most commonly occurs after a throat (pharyngitis) or skin (impetigo) infection with nephritogenic strains of group A beta-hemolytic streptococci, although other bacteria (e.g., *Staphylococcus*) and viruses also may be responsible. Occurrences have been observed after bacterial endocarditis, which may be associated with streptococcal or staphylococcal microorganisms, or after viral diseases, such as varicella and hepatitides B and C. Glomerulonephritis develops with the deposition of antigen-antibody complexes (immunoglobulin G [IgG] and C₃ complement) (see [Chapter 8](#)) in the glomerulus, or the antigen may be trapped within the glomerulus and immune complexes formed in situ.³⁶ The exact mechanism of immune complex formation is unknown. The immune complexes initiate inflammation and glomerular injury. Immunofluorescence microscopy shows lumpy deposits of IgG and C₃ on the glomerular basement membrane ([Fig. 40.5](#)). The thickened glomerular membrane contributes to decreased GFR. Activated complement, inflammatory cytokines, oxidants, proteases, and growth factors attack epithelial cells, alter membrane permeability, and cause hematuria and proteinuria. Hypertension occurs primarily because of fluid retention.

FIGURE 40.5 Glomerulonephritis. A, Normal glomerulus; note single-contoured walls, patent capillaries, inconspicuous mesangium, and degree of cellularity. (Periodic acid–methenamine silver stain.) B, Acute postinfectious glomerulonephritis. There is considerable increase in cellularity, mainly because of accumulation of numerous polymorphonuclear leukocytes in capillary lumina. Note numerous subepithelial hump-shaped fuchsinophilic deposits in many capillary walls. Protein precipitates (hyalinization) are in the arteriole. (Masson trichrome stain.) C, Postinfectious glomerulonephritis. Irregular mesangial and capillary wall immunostaining for C₃. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Symptoms usually begin 1 to 2 weeks after an upper respiratory tract infection (more common during cold weather) and up to 6 weeks after skin infections, such as impetigo (more common during warm weather). The onset of symptoms in the child is abrupt, varying with disease severity. The urine is usually smoky brown or cola colored because of the presence of red blood cells. The child may complain of flank or midabdominal pain, irritability, general malaise, and fever. Acute hypertension may cause headache, vomiting, somnolence, and other central nervous system (CNS) manifestations, including seizures. Cardiovascular symptoms are related to circulatory overload and are compounded by hypertension. These include dyspnea, tachypnea, and an enlarged, tender liver. The most severely affected children develop acute renal failure with oliguria. The disease is

usually mild and runs its course in 1 month, but urine abnormalities may be found up to 1 year after the onset. As many as half the children affected are asymptomatic. Fewer than 5% of children become oliguric or develop rapidly progressive glomerulonephritis, or progress to chronic glomerulonephritis. Prolonged proteinuria and abnormal GFR indicate an unfavorable prognosis. More than 95% recover completely. Fewer than 1% of children develop end-stage renal disease.³⁷

Immunoglobulin A Nephropathy.

Immunoglobulin A (IgA) nephropathy is the most common form of glomerulonephritis in children and young adults worldwide and occurs more often in males. The cause is unknown. It is characterized by deposition primarily of IgA and complement proteins in the mesangium of the glomerulus. Abnormal glycosylated IgA-1 (galactose-deficient IgA-1) is produced by the bone marrow. Glycan-specific IgA antibodies are formed against abnormal IgA-1, can activate complement, and bind to glomerular mesangial cells, stimulating them to proliferate, secrete extracellular matrix proteins, and release inflammatory cytokines and chemokines (interleukin-6, tumor necrosis factor-alpha, and transforming growth factor-beta 1) that cause injury. The immune response contributes to diffuse mesangioproliferative glomerular injury and glomerulosclerosis, which is usually reversible.³⁸ Children with this disease have recurrent gross hematuria concurrent with a respiratory tract infection (i.e., tonsillitis) or gastroenteritis. Most continue to have microscopic hematuria between the attacks of gross hematuria and have mild proteinuria. Treatment is supportive. Proteinuria, edema, and hypertension are more severe symptoms and must be treated to prevent future loss of kidney function. Some children recover completely, whereas 20% to 40% will eventually require dialysis and transplantation.³⁹ IgA nephropathy may recur following transplantation.

Henoch-Schönlein Purpura Nephritis.

Henoch-Schönlein purpura (HSP) nephritis (anaphylactoid purpura) is an immune-mediated IgA vasculitis that affects glomerular blood vessels, causing inflammation and damage to the vessel wall. The disease also involves small vessels in the skin and gut. Classic symptoms of HSP include palpable purpura, arthritis, and abdominal pain. About 21% of children develop renal disease characterized by gross or microscopic hematuria with mild or no proteinuria,⁴⁰ usually within 4 weeks of disease onset. Kidney biopsy demonstrates IgA deposition in the mesangium.⁴¹ The development of interstitial fibrosis and crescent formation from subepithelial immune deposits along the glomeruli increases the risk of chronic renal failure.⁴² Most children recover with supportive care, although some progress to kidney failure. Severe symptoms require corticosteroids, other immunosuppressant drugs, or angiotensin-converting enzyme (ACE) inhibitors.⁴³

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is an acute disorder characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal impairment. It is the most common community-acquired cause of acute renal failure in young children. The disease occurs most frequently in infants and children younger than 4 years of age. The prognosis has improved dramatically in recent years, with more than 90% of children surviving and most regaining normal renal function.

◆Pathophysiology.

HUS has been associated with both bacterial and viral agents, as well as endotoxins, especially those from *Escherichia coli* 0157:H7 and recently *Escherichia coli* 0104:H4.⁴⁴ Potential sources of exposure include animals, unpasteurized beverages, and contaminated meat and vegetables. The disease also occurs with cancer and use of chemotherapeutic agents.⁴⁵ In HUS, verotoxin (Shiga toxin) from *E. coli* is absorbed from the intestines into the blood, binds to polymorphonuclear leukocytes, and is transported to the kidney,

causing a cascade of effects, including lysis of glomerular capillary endothelial cells, separation of endothelial cells from the basement membrane, activation and aggregation of platelets, and activation of the coagulation cascade. The glomerular arterioles become swollen and occluded with platelets and fibrin clots. There is decreased glomerular filtration, and the damaged glomerular membrane results in hematuria and proteinuria. Oliguria with renal failure occurs in up to 50% of children. Narrowed vessels damage passing erythrocytes. These damaged red blood cells, identified as burr cells, helmet cells, and fragmented red blood cells, are removed by the spleen, causing acute hemolytic anemia. Fibrinolysis, the process of dissolution of a clot, acts on precipitated fibrin, causing the fibrin split products to appear in serum and urine. The platelet clustering within damaged vessels, combined with the damage and removal of platelets, produces thrombocytopenia. Fibrin-rich thrombi can be found throughout the microcirculation. Other tissues, including the brain, liver, heart, and intestines, are often involved.⁴⁶

◆Clinical Manifestations.

Typical HUS is preceded by a prodromal gastrointestinal (GI) illness with diarrhea (usually caused by Shiga toxin-producing *E. coli*) and is known as *D+* HUS. Atypical HUS (aHUS) is not associated with diarrhea and is known as *D-* HUS. Dysregulation of the alternative complement pathway is often noted.⁴⁷ Familial aHUS is rare and defined as the diagnosis of aHUS in at least two members of the same family at least 6 months apart.⁴⁸ The onset of *D+* HUS occurs about 1 to 2 weeks after a GI illness with a symptom-free 1- to 5-day period. There is sudden onset of pallor, bruising or purpura, irritability, and oliguria. Slight fever, anorexia, vomiting, diarrhea (with the stool characteristically watery and blood stained—hemorrhagic diarrhea), abdominal pain, mild jaundice, and circulatory overload are accompanying symptoms. Seizures and lethargy indicate CNS involvement. Renal failure is apparent within 2 days to 2 weeks of onset. The renal failure causes metabolic acidosis, uremia, hyperkalemia, and often hypertension.

◆ Evaluation and Treatment.

Clinical evaluation includes history of preexisting illness, presenting symptoms, and urine and blood analysis. Antibiotics are not used in the initial treatment because they increase Shiga toxin release and increase the risk of HUS. Management consists of maintaining nutrition and hydration and controlling hypertension, hyperkalemia, and seizures. When renal failure occurs, dialysis is indicated. Blood transfusions with packed red blood cells are needed to maintain reasonable hemoglobin levels. Eculizumab, a C5 inhibitor, has been demonstrated to be efficacious in the treatment of aHUS.⁴⁹ Most children recover; however, some will develop hypertension, proteinuria, or renal insufficiency or failure. Death usually occurs from complications related to CNS, infectious, or myocardial causes.⁵⁰ Preventing Shiga toxin-producing bacterial infection (i.e., *E. coli*) prevents D+ HUS.

Nephrotic Syndrome

Nephrotic syndrome is a term used to describe a symptom complex characterized by proteinuria, hypoalbuminemia, hyperlipidemia, and edema. The syndrome is more common in children than adults. When no identifiable cause is found, the condition is termed **primary (idiopathic) nephrotic syndrome**. If it results from a systemic disease or other causes (e.g., drugs, toxins, diabetes mellitus, lupus nephritis) it is called **secondary nephrotic syndrome**. Primary nephrotic syndrome is usually described by histopathologic results (i.e., minimal change nephropathy [MCN], focal segmental glomerulosclerosis [FSGS], membranous nephropathy [MN], or membranoproliferative glomerulonephritis [MPGN]) (see [Table 39.7](#)). Secondary nephrotic syndrome has the same patterns of histopathology but is associated with an underlying cause.

Approximately 95% of cases of nephrotic syndrome in children occur in the absence of systemic or preexisting renal disease. Primary nephrotic syndrome is found predominantly in preschool children, with a peak incidence of onset between 2 and 3 years of age. Onset is rare after 8 years of age. Boys are affected more often than girls. No

prevalent racial or geographic distributions are evident. The incidence is approximately 2 to 3 per 100,000 children per year.⁵¹

◆Pathophysiology.

The cause of nephrotic syndrome in children is usually idiopathic and includes MCN (85%), FSGS (10%), and mesangial proliferative nephropathy (MPN) (5%)⁵² (see [Chapter 39, Table 39.7](#)). Secondary nephrotic syndrome may develop during the course of several different renal or systemic diseases. The pathophysiology (see [Fig. 39.11](#)) and common clinical manifestations of nephrotic syndrome in adults are described in [Chapter 39](#) (see [Table 39.8](#)) and are similar in children. The most common causes of nephrotic syndrome in children are presented here.

Minimal change nephropathy (MCN), also known as *lipoid nephrosis*, is the most common cause of nephrotic syndrome in children ages 2 to 6 years. A systemic immune mechanism is a likely cause of the disease, but the true etiology is unknown. The mechanism of increased glomerular permeability is unknown but is related, in part, to release of permeability factors from abnormal circulating T cells that injure the glomerular epithelial cells.⁵³ The glomeruli appear normal by light microscopy, and immunoglobulin deposition is usually absent. The only change is *fusion of epithelial cell podocyte foot processes*.⁵⁴ Loss of the electrical negative charge and increased permeability within the glomerular capillary wall lead to albuminuria. Hyperlipidemia leads to lipiduria and primarily results from increased hepatic lipid synthesis and decreased plasma lipid catabolism.

Focal segmental glomerulosclerosis (FSGS) is present in approximately 10% of children with nephrotic syndrome and is more common in blacks. The frequency of FSGS is increasing in children and adults.⁵⁵ The primary injury is effacement (thinning or deletion) of epithelial podocytes, with a significant increase in pore size leading to impairment of size selectivity and proteinuria. Progressive disease results in proliferation of endothelial and mesangial cells with occlusion and sclerosis of glomerular capillaries. The more severe the

proteinuria, the more likely it is that end-stage renal disease will occur. FSGS is usually steroid resistant.⁵⁶

Edema is the classic symptom of nephrotic syndrome. Factors theorized to contribute to edema formation include hypoalbuminemia (decreased plasma oncotic pressure) and sodium retention.⁵⁷ The movement of fluid from the vascular to the interstitial space can decrease blood volume, increase the activity of aldosterone and antidiuretic hormone (vasopressin), and decrease atrial natriuretic peptide concentration, all of which promote fluid retention.⁵⁸

Hyperlipidemia occurs in inverse proportion to the decrease in plasma proteins, particularly albumin. There are high concentrations of triglycerides, low-density lipoprotein (LDL), and very-low-density lipoprotein (VLDL) cholesterol. High-density lipoprotein (HDL) cholesterol concentration is decreased. Hypoalbuminemia leads to a deficiency in the carrier protein for the transport of fatty acids, and they remain elevated in the serum. There is hepatic compensation for hypoalbuminemia with increased synthesis of lipoproteins to maintain plasma oncotic pressure. Hypoalbuminemia also leads to an increased hepatic stimulus for synthesis of LDL and VLDL cholesterol by the liver. Serum lipids may remain elevated from 1 to 3 months after remission of proteinuria.

Hypercoagulation with risk for arterial or venous thrombosis results from abnormalities in the coagulation pathways during nephrotic syndrome. Although rare, thrombosis can occur in the brain or lung. Family history and predisposing risk factors should be evaluated. Anticoagulants may be required.⁵⁹

Congenital nephrotic syndrome—Finnish type is usually caused by an autosomal recessive mutation of the *NPHS1* gene that encodes an immunoglobulin-like protein, nephrin, at the podocyte slit membrane. Lack of nephrin causes heavy proteinuria. The disease usually manifests before 3 months of life. Treatment consists of intravenous albumin infusions, nutritional supplement, and bilateral nephrectomy followed by dialysis and kidney transplantation.⁶⁰

◆Clinical Manifestations.

Onset of nephrotic syndrome is often insidious, with periorbital edema as the first sign. Periorbital edema is most noticeable in the morning but subsides during the day as fluid shifts to the abdomen and lower extremities (Fig. 40.6). Parents may notice diminished, frothy, or foamy urine output. When edema becomes pronounced, ascites, respiratory difficulty from pleural effusion, and labial or scrotal swelling may develop.

FIGURE 40.6 Nephrotic Syndrome. A, Facial edema. B, Gross edema of scrotum and legs with abdominal distention from ascites. (From Lissauer T, Clayden G: *Illustrated textbook of paediatrics*, ed 4, London, 2012, Mosby.)

Edema of the intestinal mucosa may cause diarrhea, anorexia, and poor absorption. Edema often masks the malnutrition caused by malabsorption and protein loss. Because of protein deficiency, changes in the quality of hair indicate a malnourished state. Pallor, with shiny skin and prominent veins, may be present. Blood pressure is usually normal. The child has an increased susceptibility to infection, especially pneumonia, peritonitis, cellulitis, and septicemia. Irritability, fatigue, and lethargy are common. Infants born with congenital nephrotic syndrome have large fontanelles and separated cranial sutures.

◆ Evaluation and Treatment.

The diagnosis of nephrotic syndrome is evident from the clinical presentation and findings of proteinuria, hyperlipidemia, and edema. Diagnostic tests, including kidney biopsy, may be required to determine whether the cause is an intrinsic renal disease or a consequence of systemic disease. The goals of treatment are to reduce the excretion of protein and to maintain protein-free urine. Prevention or treatment of infection, control of edema, establishment of a balanced nutritional state, and restoration of normal metabolic processes also are important in managing the disorder and avoiding adverse aspects of treatment. Basic management of nephrotic syndrome includes administering glucocorticosteroids (prednisone); adhering to a low-sodium, well-balanced diet; performing good skin care; and, if edema becomes problematic, administering diuretics (furosemide, metolazone).⁶¹ ACE inhibitors inhibit formation of angiotensin II and aldosterone, resulting in decreased blood pressure and decreased renal sodium reabsorption. Nephrotic syndrome is often described by the response to steroid therapy (Table 40.2). **Steroid-sensitive nephrotic syndrome** results in remission with steroid therapy alone. **Steroid-resistant nephrotic syndrome** is the term for children who fail to respond to prednisone within 8 weeks. They may be treated with noncorticosteroid immunosuppressive agents (i.e., cyclophosphamide) or a combination of corticosteroids and noncorticosteroid immunosuppressives to prolong remission.⁶² Intravenous rituximab, a monoclonal antibody, has been shown to induce and prolong remissions in some children with steroid-dependent or -resistant nephrotic syndrome.⁶³ Children with minimal change disease tend to have a very favorable prognosis, whereas those with steroid-resistant nephrotic syndrome may develop end-stage kidney disease.⁶⁴

TABLE 40.2

CORTICOSTEROID RESPONSE IN CHILDREN WITH NEPHROTIC SYNDROME

RESPONSE TO	OUTCOMES
-------------	----------

CORTICOSTEROID	
Steroid sensitive	May have just one or recurrent episodes.
Steroid dependent or frequently relapsing	May require low-dose prednisone or treatment with other immunosuppressive agents to prevent recurrence
Steroid resistant	Treatment with immunosuppressive and nonimmunosuppressive medications; risk for development of end-stage kidney disease

Data from Hodson EM, et al: *Cochrane Database Syst Rev* 10:CD003594, 2016; Larkins N, et al: *Arch Dis Child* 101(4):404-408, 2016.

Kidney Injury

Kidney injury is rare in children. The pathophysiology (see Fig. 39.12) and management are similar to those for kidney injury in adults. A modification of the RIFLE criteria (*R*, risk; *I*, injury; *F*, failure; *L*, loss; and *E*, end-stage kidney disease [ESKD]) that was proposed to standardize the definition of acute kidney injury in adults has been used in critically ill children (pRIFLE criteria)⁶⁵ (Table 40.3).

TABLE 40.3

PEDIATRIC-MODIFIED RIFLE (pRIFLE) CRITERIA

RISK CATEGORY	ESTIMATED CCL-GFR CRITERIA	URINE OUTPUT CRITERIA
Risk	eCCL decrease by 25%	<0.5 mL/kg/hr for 8 hr
Injury	eCCL decrease by 50%	<0.5 mL/kg/hr for 16 hr
Failure	eCCL decrease by 75% or eCCL <35 mL/min/1.73 m ²	<0.3 mL/kg/hr for 24 hr or anuric for 12 hr
Loss (of kidney function)	Persistent failure >4 weeks	
End-stage	End-stage renal disease (persistent failure >3 months)	

eCCL, Estimated creatinine clearance; GFR, glomerular filtration rate; pRIFLE, pediatric risk, injury, failure, loss, and end-stage renal disease.

Data from Akcan-Arikan A et al: *Kidney Int* 71(10):1028-1035, 2007.

The most common causes of *prerenal acute kidney injury* are dehydration, hemorrhage, and sepsis. Glomerulonephritis, hemolytic

uremic syndrome, and hypersensitivity reactions to drugs or infectious agents are the most common causes of *intrinsic acute kidney injury*. Obstructive uropathies, such as posterior urethral valves and obstruction of the ureteropelvic junction, are associated with *postrenal acute kidney injury*.

End-stage renal disease in children is commonly associated with congenital renal structural abnormalities. In older children the most common cause is a glomerulonephropathy.^{66,67} Renal replacement modalities available for children with end-stage renal disease include peritoneal and hemodialysis and kidney transplant. The use of growth hormone before and after transplant has contributed to normal growth and development.⁶⁸

Nephroblastoma (Wilms tumor) is an embryonal tumor of the kidney arising from epigenetic and genetic changes that lead to abnormal proliferation of renal stem cells (metanephric blastema). The incidence of Wilms tumor remains constant in the United States, with approximately 500 children diagnosed each year. Most children are between 1 and 5 years of age when they are diagnosed. The peak incidence occurs between 2 and 3 years of age. Wilms tumor is slightly more common in females and in black than in white children and is less common in Asian children.⁶⁹

Microscopically, Wilms tumor is composed of three cellular components: stromal, epithelial, and blastemic. This occurs because blastemic cells, which are primitive and undifferentiated, may have partially developed into epithelial or stromal tissue. With each of these three cellular components, varying stages of differentiation may be evident within the tumor.

◆Pathogenesis.

Wilms tumor has sporadic and inherited origins. The sporadic form occurs in children with no known genetic predisposition. Inherited cases, which are relatively rare (1% to 2% of cases), are transmitted in an autosomal dominant fashion. A “two-hit” hypothesis for the development of Wilms tumor has been proposed wherein children who inherit a mutation in one allele of a tumor-suppression gene

require just one more somatic mutation for a tumor to form⁷⁰ (see Fig. 20.16). This hypothesis may not apply to all Wilms tumors, however, because a number of genetic abnormalities have been identified in Wilms tumor. Wilms tumor-suppressor genes *WT1* and *WT2* are located on chromosome 11. Chromosomal abnormalities, including gains, losses, and rearrangements, are often present in Wilms tumors. Gains in chromosomes 1q, 2, 7q, 8, 12, and 13 and losses in chromosomes 1p, 7p, 16q, and 22q are among the most common findings, although multiple other chromosomal abnormalities also have been identified.⁷¹ *WTX* is a tumor-suppressor gene located on the X chromosome. Approximately 10% of children who have Wilms tumor also have deletions or mutations of other genes and, therefore, have a number of congenital anomalies. These anomalies include aniridia (lack of an iris in the eye), hemihypertrophy (an asymmetry of the body), and genitourinary malformations (i.e., horseshoe kidneys, hypospadias, ureteral duplication, polycystic kidneys, or uterine abnormalities).⁶⁹ Children with congenital anomalies as well as Wilms tumor are more likely to have the inherited bilateral form of the disease.

◆Clinical Manifestations.

Most Wilms tumors (90%) present as an enlarging asymptomatic upper abdominal mass in a healthy, thriving child. Many tumors are discovered by the child's parent, who feels or notices an abdominal swelling, usually while dressing or bathing the child. Other presenting complaints include vague abdominal pain, hematuria, and fever. Hypertension may be present, likely because of excessive renin secretion by the tumor.⁷²

◆Evaluation and Treatment.

On physical examination, the tumor feels firm, nontender, and smooth, and generally is a solitary mass of varying size confined to one side of the abdomen. Diagnostic imaging demonstrates a solid intrarenal mass.

Diagnosis is based on surgical biopsy. Additional laboratory and

radiologic studies are used to evaluate the presence or absence of metastasis. The most common sites of metastasis are regional lymph nodes and the lungs and less commonly liver, brain, and bone.

Staging systems for Wilms tumor have been developed and serve as guides to treatment. The most widely accepted system in the United States was developed by the National Wilms Tumor Study Group (Table 40.4). The system is based on surgical findings and the extent of disease at diagnosis.⁷³ Children are further classified as either high or low risk according to favorable or unfavorable histologic presentation (anaplasia).

TABLE 40.4

STAGING OF WILMS TUMOR (NEPHROBLASTOMA)

STAGE* (% OF TUMORS)	TUMOR CHARACTERISTICS
Stage I (40% to 45%)	Tumor limited to the kidney, completely resected
Stage II (20%)	Tumor ascending beyond the kidney or into vessels of renal sinus, but appearing to be totally resected
Stage III (20% to 25%)	Residual nonhematogenous tumor confined to the abdomen, positive lymph nodes in renal hila
Stage IV (10%)	Hematogenous metastases (e.g., lung, liver, bone, brain)
Stage V (5%)	Bilateral disease either at diagnosis or later, but need to stage each kidney

* NOTE: Staging system of the Third National Wilms Tumor Study Group (NWTS-3).

Data from American Cancer Society: *Wilms tumor*. Available at <https://www.cancer.org/cancer/wilms-tumor/detection-diagnosis-staging/staging.html>.

Primary treatment is usually (1) surgical exploration and resection followed by treatment based on histology, or (2) chemotherapy followed by surgical resection, which limits tumor spillage during surgery.⁷⁴ In bilateral disease, surgical intervention may include heminephrectomy of the less involved kidney and nephrectomy of the other. Radiation therapy may be used for children with higher stages of disease and metastases. Survival at 4 years is greater than 90% for localized disease and more than 85% for advanced disease with

favorable histology (Table 40.5).⁷⁵ Congestive heart failure, renal failure, hypertension, and secondary malignancies occur more frequently in long-term survivors than in the general population.⁷⁶

TABLE 40.5

NATIONAL WILMS TUMOR STUDY 4-YEAR SURVIVAL RATES

TUMOR STAGE	FAVORABLE HISTOLOGY	UNFAVORABLE HISTOLOGY (ANAPLASTIC WILMS TUMOR)
I	99%	83%
II	98%	81%
III	94%	72%
IV	86%	38%
V	87%	55%

Bladder Disorders

Urinary Tract Infections

Urinary tract infection (UTI) is the colonization of a pathogen anywhere along the urinary tract (urethra, bladder, ureter, kidney) and occurs commonly in children. During the neonatal period, uncircumcised males and infants with congenital renal abnormalities are at increased risk.⁷⁷ Girls have a greater incidence after 1 year of age with an increasing incidence at adolescence. Sexually active female adolescents are at increased risk to have a UTI. Similar to adult women, susceptibility is increased when genetically controlled blood group antigens (P1 and Lewis blood group nonsecretor) are present on surface uroepithelial cells and act as receptors for bacterial attachment.⁷⁸ UTIs in females occur as a result of perineal bacteria, especially *E. coli*, ascending the urethra, which lies close to the anus.

The pathophysiology of UTIs in children is similar to that of adults (see [Chapter 39](#)). Although nephrolithiasis can be associated with UTI in adults, nephrolithiasis in children is rare, but is increasing in incidence (see [What's New? Kidney Stones in Children](#)). UTIs in children are often clinically categorized as first or recurrent infection. Individual susceptibility, bacterial virulence, anatomy (presence of reflux, obstruction, stasis, stones, or structural anomalies of the urinary tract), and genetics⁷⁹ affect the severity of the disease. The recurrence rate is approximately 20% to 30%.⁸⁰

What's New?

Kidney Stones in Children

Nephrolithiasis in children is rare, although the incidence of calcium stones among children is increasing, particularly in adolescents. There are limited data available regarding the pathogenesis of kidney stones in children, but the mechanisms appear different compared to those in adults. Epidemiologic data indicate that nephrolithiasis is more common in boys during preadolescence and in girls during pubertal years. Proposed risk factors include diets high in salt, protein, or fructose, or low in water or calcium; and use of certain antiseizure, diuretic, vitamin, or antibiotic medications. Kidney stones also can be associated with urinary tract malformations (reflux disease and megaureter). Calcium stones are the most common stone type (72% to 88%). Children who form stones often have supersaturation of urinary calcium, oxalate, or phosphate. The most common symptom presentations are pain and gross hematuria. Prevention and treatment are individualized, and any metabolic cause needs to be evaluated. Adequate fluid intake is the mainstay of treatment. Medications such as stone inhibitors (e.g., potassium citrate) or thiazide diuretics may be helpful for some children. Surgical methods include extracorporeal shock wave lithotripsy, ureteroscopy, and percutaneous nephrolithotomy.

Cystitis, or infection of the bladder, results in mucosal inflammation and congestion. This causes detrusor muscle hyperactivity and a resulting decrease in the bladder capacity. It also can lead to transient reflux of urine up the ureters, sending bacteria all the way to the kidney, causing acute or chronic pyelonephritis and renal abscesses or scarring.

Symptoms of UTI in children are nonspecific, and differentiating whether an infection is in the bladder or kidneys is difficult based on symptoms alone. Infants usually develop fever, vomiting, diarrhea, or jaundice. Some children may present only with fever of undetermined origin, and others may present with urinary tract symptoms of frequency; urgency; enuresis or incontinence in a previously dry child; abdominal, flank, or back pain; foul-smelling urine; and sometimes hematuria. **Acute pyelonephritis** usually causes chills, fever, and flank or abdominal pain along with enlarged kidney(s) caused by edema. **Chronic pyelonephritis** may be asymptomatic.

Diagnosis of UTIs is by urine culture of a pathogen before antimicrobial treatment. An accompanying urinalysis can show pyuria, nitrites, and hematuria. The presence of casts in the urine can indicate pyelonephritis. Ultrasound, voiding cystourethrography (VCUG) or radionuclide cystography, or computed tomography (CT) scan may be necessary to rule out obstructions, abscesses, or reflux, particularly in young children who do not respond to antimicrobial therapy.

With treatment, UTI symptoms are usually relieved in 1 to 2 days, and the urine becomes sterile. A 2- to 4-day course of oral antibiotics is effective for an uncomplicated UTI.⁸¹ Longer treatment may be required if the child has recurrent UTIs, has a complicated UTI including congenital abnormalities of the urinary tract, or is immunosuppressed. Imaging of children after a first UTI is controversial.⁸² The age of the child and seriousness of the infection

should be considered when making imaging decisions. Repeat urine cultures are not needed if a child has responded to treatment.⁸³ Management of constipation, promotion of adequate fluid intake, and elimination of dysfunctional voiding patterns are the cornerstones of minimizing the risk of recurrence.⁸⁴ Prophylactic antibiotics may be helpful for some children. Educating families about signs and symptoms of UTI allows for early identification and treatment. Surgical correction of vesicoureteral reflux or obstruction may be necessary.

Vesicoureteral Reflux

Vesicoureteral reflux (VUR) is the retrograde flow of bladder urine into the kidney and/or ureters. Reflux allows infected urine from the bladder to reach the kidneys. Reflux perpetuates infection by preventing complete emptying of the bladder as refluxed urine drains back into the bladder at the end of each void. In addition, reflux allows the maximal intravesical pressure to be transmitted to the renal calyces and pyramids. The combination of reflux and infection is an important cause of pyelonephritis, especially in children younger than 5 years.

Vesicoureteral reflux occurs more often in girls by a ratio of 10 : 1 and is less common in blacks. Its incidence is unknown because in the absence of urinary tract infections, VUR is often undiagnosed. Siblings of those affected have about a 27% to 51% chance of having reflux, and children with parents who had reflux have an almost 70% chance of reflux.⁸⁵ The shortness of the submucosal segment of the ureter during infancy and childhood renders the antireflux mechanism relatively inefficient and delicate. Thus reflux is seen commonly in association with infections during early childhood but rarely in older children and adults. (Among adults with UTIs, the incidence of reflux is approximately 5%.) Reflux may be unilateral or bilateral, and it can be classified or graded ([Fig. 40.7](#)) for comparative purposes:

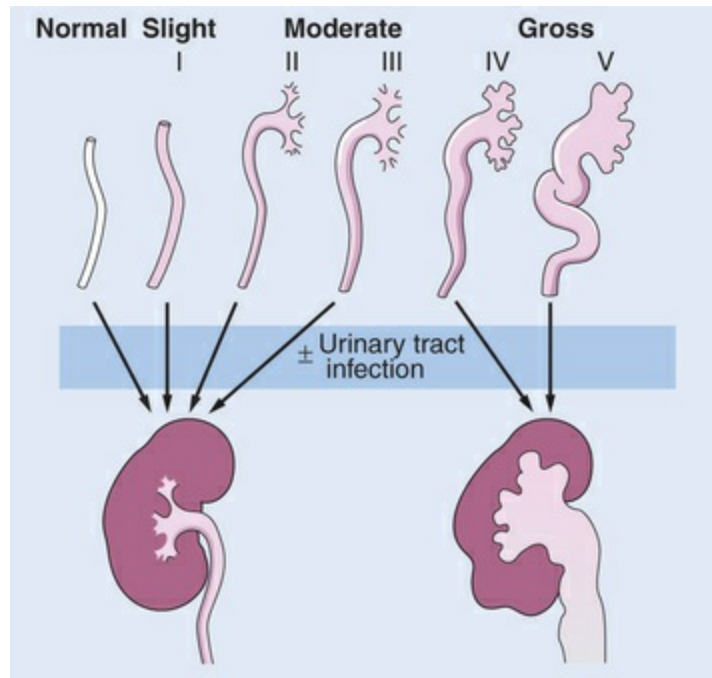

FIGURE 40.7 Grades of Reflux. (From Feehally J, Floege J, Johnson RJ: *Comprehensive clinical nephrology*, ed 3, Philadelphia, 2008, Mosby.)

Grade I—Reflux into a nondilated distal ureter

Grade II—Reflux into the upper collecting system without dilation

Grade III—Reflux into dilated ureter or blunting of calyceal fornices

Grade IV—Reflux into a grossly dilated ureter

Grade V—Massive reflux with ureteral dilation and tortuosity and effacement of the calyceal details; occurs almost exclusively in male infants⁸⁶

◆Pathophysiology.

Primary reflux results from a congenitally abnormal or ectopic insertion of the ureter into the bladder (Fig. 40.8). Occasionally the condition is hereditary. Secondary reflux may be transient or persistent. It develops in association with infection, malformations of the ureterovesical (UV) junction, increased intravesical pressures, voiding disorders, or surgery on the UV junction. Urinary tract infection associated with VUR may lead to permanent renal scarring,

particularly when there is pyelonephritis. The actual cause of renal cell damage and scarring is unknown, but contributing factors include inflammatory cytokines activated by bacterial virulence factors.⁸⁷

FIGURE 40.8 Normal and Abnormal Configuration of the Ureteral Orifices. *Left to right: Progressive lateral displacement of the ureteral orifices and shortening of the intramural tunnels in the bladder. Top row: Endoscopic appearance. Bottom row: Sagittal view through the intramural ureter. (From Kliegman RM et al, editors: Nelson textbook of pediatrics, ed 19, Philadelphia, 2011, Saunders.)*

◆Clinical Manifestations.

Children with reflux may be asymptomatic or may experience recurrent UTIs or unexplained fever, poor growth and development, irritability, and feeding problems. The family history may reveal VUR or urinary tract infections.

◆Evaluation and Treatment.

Prompt treatment of UTIs in children with reflux is important to minimize the risk of renal scar development. Some infants with reflux already have renal scarring at birth.⁸⁸ In addition to the history of recurrent UTIs and other symptoms, imaging may be required for diagnosis and assessment of structural change, scarring, urinary tract function, and risk for future infection and renal damage. Identification and resolution of bowel and/or bladder dysfunction is imperative to

decrease the risk of urinary tract infections and improve the rate of VUR resolution.⁸⁹ Spontaneous remission of grades I, II, and III reflux occurs in 50% to 80% of children. Approximately 20% of grades IV and V will resolve.⁹⁰ The use of prophylactic antibiotics for these children is controversial, with concerns regarding efficacy and the development of antibiotic resistance.⁹¹ Recurrent infection or high-grade reflux are possible indications for surgical intervention or endoscopic injection of biomaterials into the bladder wall below the ureteral orifice. Surgical repair of reflux has been shown to decrease the incidence of pyelonephritis but does not decrease the risk of the development or progression of renal damage.⁹² The value of screening asymptomatic siblings of children with vesicoureteral reflux is debatable. One current recommendation is to perform a renal ultrasound and consider a VCUG only in children with scarring or otherwise abnormal-appearing kidneys.⁹³

Urinary Incontinence

Urinary incontinence refers to the involuntary passage of urine by a child who is beyond the age when voluntary bladder control should have been acquired. Bladder control is accomplished by most children before the age of 5 years, although this is largely influenced by cultural beliefs and parental toilet training practices. Nighttime wetting is called **enuresis**. **Functional incontinence** is urinary incontinence in which no structural or neurologic abnormality can be identified. The underlying mechanism may include disorders of both the storage and voiding phases of the bladder cycle. A child may have daytime incontinence or enuresis, or both.

The incidence of incontinence is difficult to determine because it is not a problem that parents readily share with others and because definitions vary according to cultural norms and family practices. The incidence of enuresis in children older than 5 years ranges from 15% to 20%. Boys are more enuretic than girls by a ratio of 2 : 1. Fewer than 2% of adults experience enuresis. Daytime incontinence occurs in up to 9% of early school-age children.⁹⁴

◆Pathophysiology.

Multiple factors are likely responsible for incontinence. All or part of each one might be operating in a given child. A reasonable approach is to eliminate organic, behavioral, or physiologic causes before exploring the psychologic ones. Organic causes of incontinence account for 2% to 10% of cases. The causes include urinary tract infections; neurologic disturbances; congenital defects of the meatus, urethra, or bladder neck; allergies; constipation;⁹⁵ obesity;⁹⁶ or alteration in renal tubular ion and water transport related to prostaglandin secretion. Disorders that increase the normal output of urine, such as diabetes mellitus and diabetes insipidus, or disorders that impair the concentrating ability of the kidney must be considered in the evaluation of enuresis. Enuresis in children may be associated with a maturational lag. Studies have demonstrated that some children with enuresis have smaller functional bladder capacities than nonenuretic children.⁹⁷ Children who do not have the normal nocturnal elevation of vasopressin produce a higher volume of urine with a lower osmolality than controls.⁹⁸ A number of children experience bladder overactivity with elevated intravesical pressure and spikelike detrusor contractions during bladder filling. Incontinence often spontaneously disappears in children as they get older.

Genetic factors contribute to some types of incontinence. Multiple gene loci associated with enuresis have been identified. Bed-wetting occurs with high frequency among parents, siblings, and other near relatives of symptomatic children. These observations are further supported by a high concordance rate in enuretic monozygotic twins.⁹⁹

Multiple studies have examined the role of sleep architecture in enuresis. Findings have ranged from elevated arousal thresholds¹⁰⁰ to increased light sleep with frequent cortical arousal without complete awakening.¹⁰¹ Enuresis may be associated with obstructive sleep apnea. Inspiratory effort against a closed airway increases intrathoracic negative pressure, causing cardiac distention and release of atrial natriuretic hormone and decreased levels of vasopressin and

renin-angiotensin-aldosterone complex.¹⁰² A variety of psychosocial factors also have been postulated as explanations of enuresis. Enuresis has been associated with attention-deficit/hyperactivity disorders, anxiety disorders, depression, and oppositional defiant disorders.^{103,104}

◆Clinical Manifestations.

Primary incontinence refers to a condition in which the child has never been continent. **Secondary incontinence** occurs when a child who has experienced a period of dryness of at least 6 months after toilet training becomes incontinent again. Secondary enuresis may be diurnal, nocturnal, or a combination of both. Types of incontinence are defined in [Table 40.6](#).

TABLE 40.6

TYPES OF PEDIATRIC INCONTINENCE

TYPES OF INCONTINENCE	DEFINITION
Daytime voiding frequency	Decreased: three or fewer voids/day
	Increased: eight or more voids/day
Dysfunctional voiding	Habitual contraction of the urethral sphincter during voiding; intermittent urine flow, dribbling, hesitancy
Enuresis	Intermittent incontinence of urine while sleeping
Incontinence, intermittent	Leakage of urine in discrete episodes during the day and/or night
Incontinence, stress	Leakage of small amounts of urine with exertion or raised intraabdominal pressure
Urgency	Sudden, unexpected, immediate need to void
Overactive bladder	Child has urgency with or without frequency or incontinence
Underactive bladder	Decreased voiding frequency with use of raised intraabdominal pressure to void

Data from Nevés T et al: *J Urol* 176(1):312-324, 2006.

◆Evaluation and Treatment.

Evaluation of incontinence includes use of questionnaires, drinking

and voiding charts, physical examination, and urinalysis. Underlying pathology, including kidney disease, vesicoureteral reflux, urinary tract infection, or neurogenic bladder, is excluded. Radiologic and urodynamic evaluation may be required.

Therapeutic management of day or night urinary incontinence begins with education. If the child and family understand the probable etiology of the child's condition, they are better able to choose and participate in therapies that are most likely to succeed. Treatment of daytime incontinence includes behavioral therapy, including timed voiding; fluid management; treatment of constipation, urinary tract infections, and other coexisting conditions if present; and medication (anticholinergic, alpha-blocker).¹⁰⁵ Enuresis treatment may also include enuresis alarms or other medications (desmopressin acetate tablets).¹⁰⁶

Summary Review

Structure and Function of the Urinary System in Children

1. The Wilms tumor 1 gene and *WNT* signaling are important for kidney development, growth, and differentiation.
2. The kidney develops from three sets of structures: the pronephros (nonfunctional by the end of the embryonic period), mesonephros (nonfunctional), and metanephros (the functional kidney).
3. All nephrons are present at full-term birth. The number does not increase with maturation, but they do increase in weight and function.
4. Urine formation begins by the third gestational month and contributes to the amniotic fluid.
5. Infants have a narrow chemical safety margin because of high hydrogen ion concentration, limited ability to regulate the internal environment, and lowered osmotic pressure.

6. Any disturbance, such as diarrhea, infection, fasting, or feeding alterations, can lead rapidly to severe acidosis and fluid imbalance in infants.
7. The composition of body fluids differs with age, thus making children more vulnerable to pathophysiologic changes.
8. Because the kidney develops from the medulla to the cortex, blood flow to the medullary nephrons is limited in infancy, and infants thus have limited urine-concentrating capacity.

Alterations in Renal and Bladder Function in Children

1. Congenital renal disorders affect about 1% of newborns. These disorders range in severity from minor, easily correctable anomalies to those incompatible with life.
2. Horseshoe kidney is a single U-shaped kidney that develops from fusion of the kidneys as they descend from the midline. The kidney may be asymptomatic or associated with hydronephrosis, stone formation, or infection.
3. Hypospadias is a congenital condition in which the urethral meatus is located on the undersurface of the penis; epispadias is a congenital condition in which the urethral opening is located on the dorsal surface of the penis.
4. Exstrophy of the bladder is a congenital malformation in which the pubic bones are separated, the lower portion of the abdominal wall and anterior wall of the bladder are missing, and the back wall of the bladder is everted through the opening.
5. Ureteropelvic junction obstruction is blockage where the renal pelvis joins the ureter and is often caused by smooth muscle or urothelial malformation or scarring that leads to hydronephrosis.
6. Bladder outlet obstruction is usually caused by urethral valves or polyps.
7. A dysplastic kidney is the result of abnormal differentiation of

renal tissues. The hypoplastic kidney is a very small but otherwise normal kidney.

8. Renal agenesis is the failure of a kidney to grow or develop. The condition may be unilateral or bilateral and may occur as an isolated entity or in association with other disorders.
9. Polycystic kidney disease is an autosomal dominant or recessive disorder in which the renal tubule or epithelium proliferates; excessive fluid transport causes cyst formation and obstruction.
10. Glomerulonephritis is an inflammation of the glomeruli secondary to immune mechanisms characterized by hematuria, edema, and hypertension. Poststreptococcal glomerulonephritis may occur after infection, especially of the upper respiratory tract.
11. IgA nephropathy results from deposition of IgA immunoglobulins and other immune products in the mesangium of the glomerular capillaries. It is the most common type of childhood glomerulonephritis.
12. Henoch-Schönlein nephritis is an IgA nephropathy that affects glomerular blood vessels.
13. Hemolytic uremic syndrome is an acute disorder characterized by hemolytic anemia, acute renal failure, and thrombocytopenia and can be associated with *E. coli* verotoxin.
14. *Nephrotic syndrome* is a term used to describe a symptom complex characterized by proteinuria, hypoalbuminemia, hyperlipidemia, and edema. Metabolic, biochemical, or physiochemical disturbance in the glomerular basement membrane leads to increased permeability to protein. The most common form is minimal change nephropathy.
15. Acute or chronic renal injury is rare in children, and the most common cause is prerenal acute renal failure related to dehydration, sepsis, or hemorrhage.
16. Wilms tumor is an embryonal tumor of the kidney that usually presents between birth and 5 years of age as an inherited (1% to 2%) or sporadic form. The tumor can be successfully treated

by surgery, with a combination of drugs, and sometimes with radiation therapy.

17. Urinary tract infections can result from general sepsis in the newborn but are usually caused by bacteria ascending the urethra in older children. The bladder alone is infected in cystitis. The infection ascends to the kidney or kidneys in pyelonephritis. Urinary tract anomalies may need surgical correction to prevent frequent recurrent infections.
18. Vesicoureteral reflux, which refers to the retrograde flow of bladder urine into the kidney and/or ureters, provides mechanisms for bladder and kidney infections in children. It can be unilateral or bilateral.
19. Urinary incontinence refers to the involuntary passage of urine beyond the age when normal continence should have occurred. This may occur during the day (incontinence) or night (enuresis). These disorders can have a variety of organic and psychologic causes.

AGING and the Gastrointestinal System, 1315

The digestive system consists of the gastrointestinal tract and accessory organs of digestion: the liver, gallbladder, and exocrine pancreas. The digestive system breaks down ingested food, prepares it for uptake by the body's cells, provides body water, and eliminates wastes. Food breakdown begins in the mouth with chewing and continues in the stomach, where food is churned and mixed with acid, mucus, and enzymes. From the stomach, the fluid and partially digested food pass into the small intestine, where bile and enzymes secreted by the liver, enzymes from the exocrine pancreas, and small intestinal epithelium break it down into absorbable components of proteins, carbohydrates, and fats. These nutrients pass through the small intestinal epithelium into underlying blood vessels and lymphatics that carry them to the liver via the hepatic portal circulation for further processing and storage.

Ingested substances and secretions that are not absorbed in the small intestine pass into the large intestine, where fluid continues to be absorbed. Solid wastes pass into the rectum and are eliminated from the body through the anus.

Except for chewing, swallowing, and defecation of solid wastes, the activities of the digestive system are controlled by hormones and the autonomic nervous system. As ingested substances move through the gastrointestinal tract, they trigger the release of hormones that stimulate or inhibit (1) the muscular contractions (gastrointestinal motility) that mix and propel food from the esophagus to the anus, and (2) the timely secretion of substances that aid in digestion. The autonomic innervation, sympathetic and parasympathetic, is controlled by centers in the brain and by local stimuli that are mediated by neural plexuses of the enteric nervous system within the gastrointestinal walls.

The Gastrointestinal Tract

The **gastrointestinal tract (alimentary canal)** consists of the mouth, esophagus, stomach, small intestine, large intestine, rectum, and anus (Fig. 41.1). It carries out the following digestive processes:

FIGURE 41.1 Structures of the Digestive System. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Elsevier.)

1. Ingestion of food
2. Propulsion of food and wastes from the mouth to the anus
3. Secretion of mucus, water, and enzymes
4. Mechanical digestion of food particles
5. Chemical digestion of food particles
6. Absorption of digested food
7. Elimination of waste products by defecation
8. Immune and microbial protection against infection

Histologically, the gastrointestinal tract consists of four layers. From the inside out, they are the mucosa, submucosa, muscularis, and serosa or adventitia (esophagus only). These concentric layers vary in thickness, and each layer has sublayers (Fig. 41.2). Neurons forming the **enteric nervous system** are located solely within the gastrointestinal tract and are controlled by local and autonomic nervous system stimuli. The enteric nervous system comprises three nerve plexuses located in different layers of the gastrointestinal walls. The **submucosal plexus (Meissner plexus)** is located in the muscularis mucosae, the **myenteric plexus (Auerbach plexus)** between the inner circular and outer longitudinal muscle layers in the muscularis, and the **subserosal plexus** just beneath the serosa. The enteric (intramural) plexus neurons regulate motility reflexes, blood flow, absorption, secretions, and immune response.

FIGURE 41.2 Wall of the Gastrointestinal (GI) Tract. The wall of the GI tract is made up of four layers with a network of nerves between the layers. Shown here is a generalized diagram of a segment of the GI tract. Note that the serosa is continuous with a fold of serous membrane called a *mesentery*. Note also that digestive glands may empty their products into the lumen of the GI tract by way of ducts. (From Patton KT, Thibodeau GA:

Mouth and Esophagus

The **mouth** is a site for the chewing and mixing of food with saliva. There are 32 permanent teeth in the adult mouth, and they are important for speech and mastication. As food particles become smaller and move around in the mouth, taste buds are continuously stimulated, adding to the satisfaction of eating. The tongue's surface and soft palate contains taste buds that contain taste receptors, that can distinguish salty, sour, bitter, savory (umami—taste of glutamate), and sweet tastes. Tastes and food odors, which stimulate the olfactory nerve, help initiate salivation and the secretion of gastric juice in the stomach. Efforts are in progress to identify the taste of fat and the relationship to food selection and diet.¹

Salivation

The three pairs of **salivary glands** (the submandibular, sublingual, and parotid glands) (Fig. 41.3) secrete about 1 L of saliva per day. **Saliva** consists mostly of water that contains varying amounts of mucus, sodium, bicarbonate, chloride, potassium, and **salivary α -amylase (ptyalin)**, an enzyme that initiates carbohydrate digestion in the mouth and stomach.

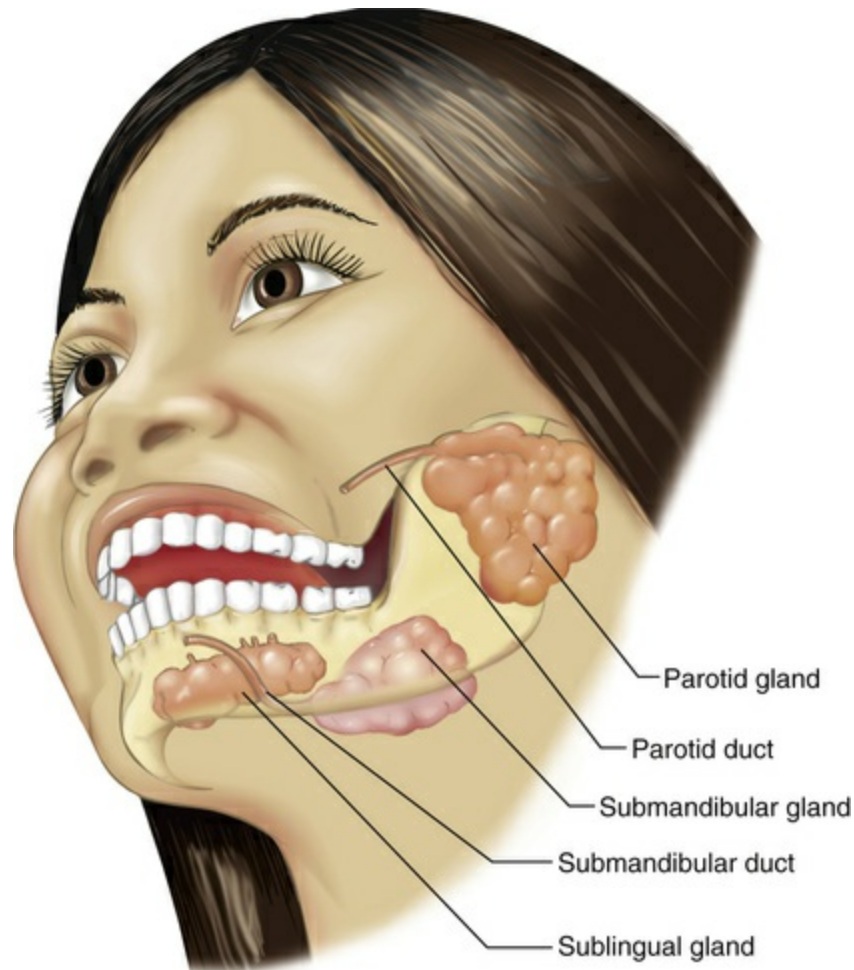

FIGURE 41.3 Salivary Glands. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Elsevier.)

The sympathetic and parasympathetic divisions of the autonomic nervous system control salivation. Cholinergic parasympathetic fibers stimulate the salivary glands, and atropine (an anticholinergic agent) inhibits salivation and makes the mouth dry. β -Adrenergic stimulation from sympathetic fibers also increases salivary secretion. The salivary glands are not regulated by hormones, although hormones are found in saliva (e.g., cortisol, testosterone, and estradiol).²

The composition of saliva depends on the rate of secretion. Aldosterone can decrease the rate of secretion by increasing an exchange of sodium for potassium. Sodium and water are conserved and potassium is excreted. The bicarbonate concentration of saliva sustains a pH of about 7.4, which neutralizes bacterial acids and

prevents tooth decay. Saliva also contains mucin, immunoglobulin A (IgA), and other microbial substances that help prevent infection. Mucin provides lubrication. Exogenous fluoride (e.g., fluoride in drinking water) is absorbed and then secreted in the saliva, providing additional protection against tooth decay.

Swallowing

The **esophagus** is a hollow muscular tube approximately 25 cm long that conducts substances from the oropharynx to the stomach (see [Fig. 41.1](#)). Swallowed food is moved to the stomach by peristalsis, the coordinated sequential contraction and relaxation of outer longitudinal and inner circular layers of muscles. The pharynx and upper third of the esophagus contain striated muscle that is directly innervated by skeletal motor neurons that control swallowing. The middle third contains a mix of striated and smooth muscle, and the lower third is smooth muscle that is innervated by preganglionic cholinergic fibers from the vagus nerve. Peristalsis is stimulated when afferent fibers distributed along the length of the esophagus sense changes in wall tension caused by stretching as food passes. The greater the tension, the greater the intensity of esophageal contraction. Occasionally, intense contractions cause pain similar to “heartburn” or angina.

Each end of the esophagus is opened and closed by a sphincter. The **upper esophageal sphincter (cricopharyngeal muscle)** prevents entry of air into the esophagus during respiration. The **lower esophageal sphincter (cardiac sphincter)** prevents regurgitation from the stomach. The lower esophageal sphincter is located near the esophageal hiatus—the opening in the diaphragm where the esophagus ends at the stomach.

Swallowing is a complex event mediated by the trigeminal nucleus, nucleus tractus solitarius, and reticular formation of the brainstem and also involves other brain regions, including the insula/claustum and cerebellum.

Swallowing occurs in two phases: the oropharyngeal (voluntary) phase and the esophageal (involuntary) phase. During the **oral** and

pharyngeal phases of swallowing, food is segmented into a bolus by the tongue and forced posteriorly toward the pharynx as the tongue pushes upward against the hard palate. The superior constrictor muscle of the pharynx contracts, preventing movement of food into the nasopharynx. At the same time, respiration is inhibited and the epiglottis folds downward to prevent the bolus from entering the larynx and trachea. The movements of the tongue and pharyngeal constrictors propel the food into the esophagus in a series of coordinated events, taking less than 1 or 2 seconds.

During the **esophageal phase of swallowing**, the bolus is transported to the stomach by the coordinated sequential contraction and relaxation of outer longitudinal and inner circular layers of smooth muscle. The wave of relaxation reduces resistance and allows food to pass, after which the wave of contraction pushes food farther along. The terminal 1- to 2-cm portion of the musculature forms the lower esophageal sphincter, which relaxes just before the arrival of a peristaltic wave. The sphincter muscles return to their resting tone after the bolus of food passes into the stomach. The esophageal phase of swallowing takes 5 to 10 seconds, with the bolus moving 2 to 6 cm/second. Throughout swallowing, the sphincters and esophagus work in concert with the peristaltic wave that moves food from the mouth to the stomach.

Peristalsis that immediately follows the oropharyngeal phase of swallowing is called **primary peristalsis**. If a bolus of food becomes stuck in the esophageal lumen, the distention of the esophageal wall stimulates **secondary peristalsis**, a wave of contraction and relaxation that is independent of voluntary swallowing. This is in response to stretch receptors that are stimulated by increased wall tension, causing an increase in impulses from the swallowing center of the brain.

The lower esophageal sphincter is normally constricted and serves as a barrier between the stomach and esophagus. The muscle tone of the lower sphincter changes with neural and hormonal stimulation and relaxes with swallowing. Cholinergic vagal stimulation and the digestive hormone gastrin increase sphincter tone. Nonadrenergic,

noncholinergic vagal impulses relax the lower esophageal sphincter, as do the hormones progesterone, secretin, and glucagon.

Stomach

The **stomach** is a hollow muscular organ that stores food during eating, secretes digestive juices, mixes food with these juices, and propels partially digested food, called **chyme**, into the duodenum of the small intestine. The anatomy of the stomach is presented in [Fig. 41.4](#). Its major anatomic boundaries are the lower esophageal sphincter, where food passes through the **cardiac orifice** at the gastroesophageal junction into the stomach, and the **pyloric sphincter**, which relaxes as food is propelled into the duodenum. Functional areas of the stomach are the **fundus** (upper portion), **body** (middle portion), and **antrum** (lower portion).

FIGURE 41.4 Stomach. A portion of the anterior wall has been cut away to reveal the muscle layers of the stomach wall. Note that the mucosa lining the stomach forms folds called *rugae*. The *dashed lines* distinguish the fundus, body, and antrum of the stomach. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Elsevier.)

The stomach has three layers of smooth muscle: an outer, longitudinal layer; a middle, circular layer; and an inner, oblique layer (the most prominent) (see [Fig. 41.4](#)). These layers become progressively thicker in the body and antrum, where food is mixed,

churned, and pushed into the duodenum. The circular layer is most prominent and the oblique layer is the least complete; the longitudinal layer is absent on the anterior and posterior surfaces. The glandular epithelium is discussed in the section on [Gastric Secretion](#).

The stomach's blood supply comes from a branch of the celiac artery and is so abundant that nearly all arterial vessels must be occluded before ischemic changes occur in the stomach wall. A series of small veins (short gastric, left and right gastric, and left and right gastro-omental) drain blood from the stomach toward the hepatic portal vein.³

Sympathetic and parasympathetic divisions of the autonomic nervous system innervate the stomach. Some of the autonomic nerves are extrinsic; that is, they originate in the central nervous system and are controlled by nerve centers in the brain. Extrinsic sympathetic fibers reach the stomach through the celiac plexus (solar plexus), whereas extrinsic parasympathetic fibers enter through the gastric branch of the vagus nerve. The myenteric (Auerbach) and submucosal (Meissner) plexuses are intrinsic and part of the enteric (intramural) nervous system. They originate within the stomach and respond to local stimuli.

Few substances are absorbed in the stomach. The stomach mucosa is impermeable to water, but the stomach can absorb alcohol and aspirin and other nonsteroidal antiinflammatory agents.

Gastric Motility

In its resting state the stomach is small and contains about 50 mL of fluid. There is minimal wall tension, and the muscle layers in the fundus contract very little. Swallowing causes the fundus to relax (receptive relaxation) to receive a bolus of food from the esophagus. Relaxation is coordinated by efferent, nonadrenergic, noncholinergic vagal fibers and is facilitated by gastrin and cholecystokinin, two polypeptide hormones secreted by the gastrointestinal mucosa. (The actions of digestive hormones and neurotransmitters are summarized in [Table 41.1](#).) Food is stored in vertical or oblique layers as it arrives in the fundus, whereas fluids flow relatively quickly down to the

antrum.

TABLE 41.1
SELECTED HORMONES* AND NEUROTRANSMITTERS OF THE DIGESTIVE SYSTEM

SOURCE	HORMONE/ NEUROTRANSMITTER	STIMULUS FOR SECRETION	ACTION
Mucosa of stomach	Gastrin	Presence of partially digested proteins in stomach	Stimulates gastric glands to secrete hydrochloric acid, pepsinogen, and histamine; growth of gastric mucosa
	Histamine	Gastrin	Stimulates acid secretion
	Somatostatin	Acid in stomach	Inhibits acid, pepsinogen, and histamine secretion and release of gastrin
	Acetylcholine	Vagus and local nerves in stomach	Stimulates release of pepsinogen and acid secretion
	Gastrin-releasing peptide (bombesin)	Vagus and local nerves in stomach	Stimulates gastrin and release of pepsinogen and acid secretion
	Ghrelin	High during fasting	Stimulates growth hormone secretion and hypothalamus to increase appetite
Mucosa of small intestine	Motilin	Presence of acid and fat in duodenum	Increases gastrointestinal motility
	Secretin	Presence of chyme (acid, partially digested proteins, fats) in duodenum	Stimulates pancreas to secrete alkaline pancreatic juice and liver to secrete bile; decreases gastrointestinal motility; inhibits gastrin and gastric acid secretion
	Serotonin (5-hydroxytryptamine)	Intestinal distention; vagal stimulation; presence of acids, amino acids, or hypertonic fluids; released from enterochromaffin cells throughout intestine	Stimulates intestinal secretion, motility and sensation (i.e., pain and nausea), vasodilation; activates gut immune responses
	Cholecystokinin	Presence of chyme (acid, partially digested proteins, fats) in duodenum	Stimulates gallbladder to eject bile and pancreas to secrete alkaline fluid; decreases gastric motility; constricts pyloric sphincter; inhibits gastrin
	Enteroglucagon	Intraluminal fats and carbohydrates	Weakly inhibits gastric and pancreatic secretion and enhances insulin release, lipolysis, ketogenesis, and glycogenolysis
	Gastric inhibitory peptide	Fat and glucose in small intestine	Inhibits gastric secretion and emptying; stimulates insulin release
	Peptide YY	Intraluminal fat and bile acids	Inhibits postprandial gastric acid and pancreatic secretion and delays gastric and small bowel emptying
	Pancreatic polypeptide Vasoactive intestinal peptide	Protein, fat, and glucose in small intestine Intestinal mucosa and muscle	Decreases pancreatic HCO ₃ ⁻ and enzyme secretion Relaxes intestinal smooth muscle

* **NOTE:** The digestive hormones are not secreted into the gastrointestinal lumen but instead into the bloodstream, where they travel to target tissues. There are more than 30 peptide hormone genes expressed in the gastrointestinal tract and more than 100 hormonally active peptides.

The green type indicates a neurotransmitter.

Modified from Johnson LR: *Gastrointestinal physiology*, ed 8, St Louis, 2014, Mosby. Data from Feldman M et al: *Sleisenger and Fordtran's gastrointestinal and liver disease*, ed 10, Philadelphia, 2015, Saunders.

Gastric (stomach) motility increases with the initiation of peristaltic waves, which sweep over the body of the stomach toward the antrum.

The rate of peristaltic contractions is approximately three per minute and is influenced by neural and hormonal activity. **Gastrin**, **motilin** (small intestine hormones), and the vagus nerve increase the rate of contraction by lowering the threshold potential of muscle fibers. (The neural and biochemical mechanisms of muscle contraction are described in [Chapter 44](#).) Sympathetic activity and **secretin** (another small intestine hormone) are inhibitory and raise the threshold potential. The rate of peristalsis is mediated by pacemaker interstitial cells of Cajal that initiate a wave of depolarization (basic electrical rhythm), which moves from the upper part of the stomach to the pylorus.

Gastric mixing and subsequent emptying of gastric contents (chyme) from the stomach take several hours (3 to 6 hours depending on the composition and volume of food intake). Mixing occurs as food is propelled toward the antrum. As food approaches the pylorus, the velocity of the peristaltic wave increases, forcing the contents back toward the body of the stomach. This **retropulsion** effectively mixes food with digestive juices, and the oscillating motion breaks down large food particles. With each peristaltic wave a small portion of the chyme passes through the pylorus and into the duodenum. The pyloric sphincter is about 1.5 cm long and is always open about 2.0 mm. It opens wider during antral contraction. Normally there is no regurgitation from the duodenum into the antrum.

The rate of **gastric emptying** (movement of gastric contents into the duodenum) depends on the volume, osmotic pressure, and chemical composition of the gastric contents. Larger volumes of food increase gastric pressure, peristalsis, and rate of emptying. Solids, fats, and nonisotonic solutions (i.e., hypertonic or hypotonic gastric tube feedings) delay gastric emptying. (Osmotic pressure and tonicity are described in [Chapters 1](#) and [3](#).) Products of fat digestion, which are formed in the duodenum by the action of bile from the liver and enzymes from the pancreas, stimulate the secretion of cholecystikinin. This hormone inhibits food intake, reduces gastric motility, and decreases gastric emptying so that fats are not emptied into the duodenum at a rate that exceeds the rate of bile and enzyme secretion.

Osmoreceptors in the wall of the duodenum are sensitive to the osmotic pressure of duodenal contents. The arrival of hypertonic or hypotonic gastric contents activates the osmoreceptors, which delays gastric emptying to facilitate formation of an isosmotic duodenal environment. The rate at which acid enters the duodenum also influences gastric emptying. Secretions from the pancreas, liver, and duodenal mucosa neutralize gastric hydrochloric acid in the duodenum. The rate of emptying is adjusted to the duodenum's ability to neutralize the incoming acidity. Peristaltic activity in the stomach is also affected by blood glucose levels. Low blood glucose levels stimulate the vagus nerve and gastric smooth muscles, increasing the rate of contraction and gastric emptying. Hyperglycemia delays gastric emptying.⁴

Gastric Secretion

The stomach produces large volumes of gastric secretions when stimulated by eating. Specialized cells located throughout the gastric mucosa produce mucus, acid, pepsinogen, enzymes, hormones, intrinsic factor, and gastroferrin. Intrinsic factor is necessary for the intestinal absorption of vitamin B₁₂, and gastroferrin facilitates small intestinal absorption of iron. The hormones are secreted into the blood and travel to target tissues in the bloodstream. The other gastric secretions are released directly into the stomach lumen under neural and hormonal regulation. Mucus covering the entire mucosa, intercellular tight junctions, bicarbonate secretion, and submucosal acid sensors form a protective barrier against acid and proteolytic enzymes, which otherwise would damage the gastric lining.⁵

In the fundus and body of the stomach the **gastric glands** of the mucosa are the primary secretory units (Fig. 41.5). Several of these glands (three to seven) empty into a common duct known as the **gastric pit**. The **parietal cells (oxyntic cells)** within the glands secrete hydrochloric acid, intrinsic factor, and gastroferrin. The **chief cells** within the glands secrete **pepsinogen**, an enzyme precursor that is readily converted to **pepsin** (a proteolytic enzyme) in the gastric fluid, and acidic lipase. The pyloric gland mucosa in the antrum synthesizes

and releases the hormone gastrin from **G cells**. **Enterochromaffin-like cells** secrete **histamine**, and **D cells** secrete **somatostatin**.

FIGURE 41.5 Gastric Pits and Gastric Glands. Gastric pits are depressions in the epithelial lining of the stomach. At the bottom of each pit is one or more tubular gastric glands. Chief cells produce the enzymes of gastric juice, and parietal cells produce stomach acid. (From Patton KT et al: *Essentials of anatomy & physiology*, St Louis, 2012, Mosby.)

The composition of gastric fluid depends on volume and flow rate (Fig. 41.6). Potassium level remains relatively constant, but its concentration is greater in gastric secretions than in plasma. The rate of secretion varies with the time of day: lower in the morning and higher in the afternoon and evening. Loss of gastric secretions through vomiting, drainage, or suction may decrease body stores of sodium,

potassium, hydrogen, and chloride.

FIGURE 41.6 Relationship Between Secretory Rate and Electrolyte Composition of the Gastric Secretions. Sodium (Na^+) concentration is lower in the gastric secretions than in the plasma, whereas hydrogen (H^+), potassium (K^+), and chloride (Cl^-) concentrations are higher. Gastric secretions are close to isotonic. Secretory rate increases during the cephalic and gastric phases of digestion.

Acid.

The major functions of **gastric hydrochloric acid** are to dissolve food fibers, act as a bactericide against swallowed microorganisms, and convert pepsinogen to pepsin. Gastric acid entering the duodenum facilitates the absorption of ferric iron. The production of acid by the parietal cells requires the transport of hydrogen and chloride from the parietal cells to the stomach lumen. Acid is formed in the parietal cells, primarily through the hydrolysis of water (Fig. 41.7). At a high rate of gastric secretion, bicarbonate moves into the plasma, producing an “alkaline tide” in the venous blood, which also may result in a more alkaline urine.

FIGURE 41.7 Hydrochloric Acid Secretion by Parietal Cell.

Acid secretion is stimulated by the vagus nerve, which releases acetylcholine and stimulates the secretion of gastrin; gastrin then stimulates the release of histamine from enterochromaffin-like cells in the gastric mucosa. Histamine stimulates acid secretion by activating histamine receptors (H₂ receptors) on acid-secreting parietal cells. Caffeine, calcium, and ghrelin also stimulate acid secretion. Somatostatin, secretin, cholecystokinin, glucagon-like peptide-1, atrial natriuretic peptide, and prostaglandins inhibit acid secretion.⁶

Pepsin and Gastric Lipase.

Acetylcholine, through vagal stimulation during the cephalic and gastric phases, is the strongest stimulation for pepsin secretion. The precursor pepsinogen is quickly converted to pepsin at a pH of 2. Acid also stimulates a local cholinergic reflex and stimulates chief cells to secrete pepsin. Gastrin and secretin are weaker pepsinogen secretagogues. **Pepsin** is a proteolytic enzyme that breaks down protein-forming polypeptides in the stomach. Once chyme has entered the duodenum, the alkaline environment of the duodenum inactivates pepsin. **Gastric lipase** is an acid lipase and does not require bile for activation like alkaline pancreatic and intestinal lipases and is active in an acid environment. It accounts for about 30% of fat digestion in adults and up to 50% percent of fat digestion in infants. It cleaves only one monoglyceride from triglyceride so is less efficient than alkaline lipase.

Mucus.

The gastric mucosa is protected from the digestive actions of acid and pepsin by intercellular tight junctions, a coating of mucus called the **mucosal barrier**, and a rich gastric mucosal blood flow.⁵ The quality and quantity of mucus and the tight junctions between epithelial cells make gastric mucosa relatively impermeable to acid. Prostaglandins and nitric oxide protect the mucosal barrier by stimulating the secretion of mucus and bicarbonate and by inhibiting the secretion of acid.

Intrinsic factor (IF), a mucoprotein produced by parietal cells, combines with vitamin B₁₂ in the stomach. It is required for the absorption of vitamin B₁₂ by the ileum. Atrophic gastritis and failure to absorb vitamin B₁₂ result in pernicious anemia (see [Chapter 29](#)).

Phases of Gastric Secretion.

The secretion of gastric juice is influenced by numerous stimuli that together facilitate the process of digestion. The **phases of gastric secretion** are the cephalic phase, gastric phase, and intestinal phase ([Fig. 41.8](#)).

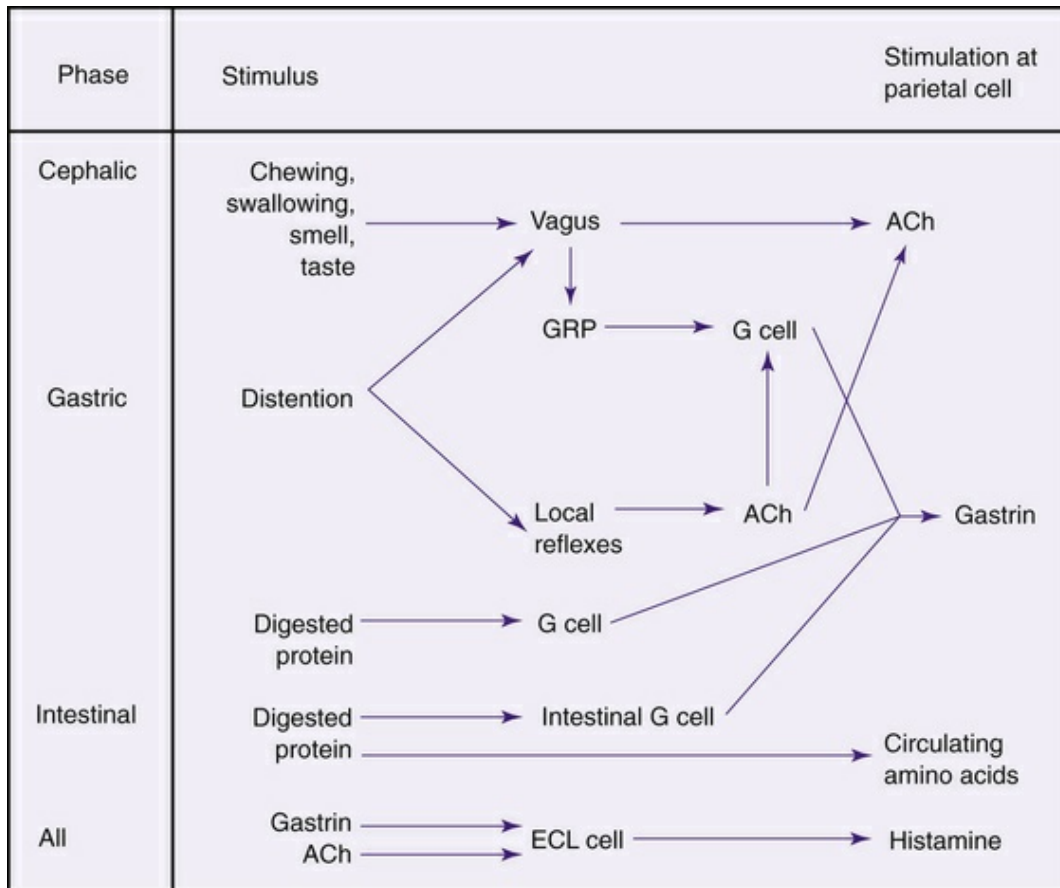

FIGURE 41.8 Mechanisms for Stimulating Acid Secretion. *ACh*, Acetylcholine; *ECL*, enterochromaffin-like cell; *GRP*, gastrin-releasing peptide. (From Johnson LR: *Gastrointestinal physiology*, ed 8, Philadelphia, 2014, Mosby.)

Cephalic Phase.

The anticipatory and sensory experiences of smelling, seeing, tasting, chewing, and swallowing food contribute to the **cephalic phase of secretion**. The cephalic phase of gastric secretion is mediated by the vagus nerve through the myenteric plexus. Insulin secretion by the endocrine pancreas, stimulated by hyperglycemia, also is a strong stimulus for gastric secretion and is mediated by the vagus nerve through sensors located in the hypothalamus. Maintenance of steady serum glucose levels suppresses the gastric response to insulin.

Gastric Phase.

The **gastric phase of secretion** begins with the arrival of food in the

stomach. Two major stimuli have a secretory effect: (1) distention of the stomach, and (2) the presence of digested protein. The vagus and enteric nerve plexuses are stimulated by distention and contribute to gastric secretion through a local reflex. Both neural reflexes are mediated by ACh and can be blocked by atropine. As digestion proceeds, products of protein break down, stimulating the release of more gastrin from G cells.

Intestinal Phase.

The movement of chyme from the stomach into the duodenum initiates the **intestinal phase of secretion**. This phase represents a deceleration of the gastric secretory response; however, the presence of digested protein and amino acids in the duodenum continues to stimulate some gastric secretion.

Concurrently, in response to low duodenal pH and the presence of lipids, inhibitory vagal and enteric reflexes decrease gastric motility when chyme enters the duodenum. The release of secretin and cholecystokinin stimulates pancreatic secretions and inhibits gastric secretions.

Small Intestine

The **small intestine** is coiled within the peritoneal cavity and is about 5 to 6 m long. Functionally, it is divided into three segments: the duodenum, jejunum, and ileum (Fig. 41.9). The **duodenum** begins at the pylorus and ends where it joins the **jejunum** at a suspensory ligament called the *Treitz ligament*. The end of the jejunum and beginning of the **ileum** are not distinguished by an anatomic marker. These structures are not grossly different, but the jejunum has a slightly larger lumen. The **ileocecal valve (sphincter)** controls the flow of digested material from the ileum into the cecum of the large intestine and prevents reflux into the small intestine.

FIGURE 41.9 Small Intestine.

The duodenum lies behind the peritoneum, or retroperitoneally, and has an essential role in mixing food with digestive juices from the liver and pancreas. The ileum and jejunum are suspended from the posterior abdominal wall by a component of the peritoneum called the **mesentery**. The mesentery facilitates intestinal motility and supports blood vessels, nerves, and lymphatics.

The **peritoneum** is the serous membrane surrounding the organs of the abdomen and lining the abdominopelvic cavity. It is analogous to the pericardium and pleura that surround the heart and lungs, respectively. The *visceral peritoneum* lies on the surface of the organs, and the *parietal peritoneum* lines the wall of the body cavity. The space between these two layers is called the **peritoneal cavity**. This cavity normally contains just enough fluid to lubricate the two layers and prevent friction during organ movement.

The arterial supply to the duodenum arises primarily from the gastroduodenal artery, a small branch of the celiac artery. The jejunum and ileum are supplied by branches of the superior mesenteric artery. Blood flow increases significantly during digestion. The superior mesenteric vein drains blood from the entire small

intestine and empties into the hepatic portal circulation. The regional lymphatics drain into the thoracic duct which empties into the subclavian vein.

Enteric nerves from both divisions of the autonomic nervous system innervate the small intestine. Secretion, motility, and intestinal reflexes (e.g., relaxation of the lower esophageal sphincter) are mediated parasympathetically by the vagus nerve. Sympathetic activity inhibits motility and produces vasoconstriction. Intrinsic reflexive activity is mediated by the myenteric plexus (Auerbach plexus) and the submucosal plexus (Meissner plexus) of the enteric nervous system.

The smooth muscles of the small intestine are arranged in two layers: a longitudinal, outer layer; and a thicker, inner circular layer (see [Fig. 41.9](#)). Circular folds of the small intestine mucosa slow the passage of food, thereby providing more time for digestion and absorption. The folds are most numerous and prominent in the jejunum and proximal ileum.

Absorption occurs through **villi** (*sing.*, **villus**), which cover the circular folds and are the functional units of the intestine (see [Fig. 41.9](#)). A villus is composed of absorptive columnar epithelial cells (enterocytes) and mucus-secreting goblet cells of the mucosa. Each villus secretes some of the enzymes necessary for digestion and absorbs nutrients. Near the surface, columnar cells closely adhere to each other at sites called *tight junctions*. Water and electrolytes are absorbed through these intercellular spaces. The surface of each columnar epithelial cell on the villus contains tiny projections called **microvilli** (see [Fig. 41.9](#)). Together the microvilli create a mucosal surface known as the **brush border**. The villi and microvilli greatly increase the surface area available for absorption. Coating the brush border is an “unstirred” layer of water that is important for the absorption of water-soluble substances, including emulsified micelles of fat. The **lamina propria** (a connective tissue layer of the mucous membrane) lies beneath the epithelial cells of the villi and contains lymphocytes and plasma cells, which produce immunoglobulins; and macrophages (see [The Gastrointestinal Tract and Immunity](#) section).

Central arterioles ascend within each villus and branch into a capillary array that extends around the base of the columnar cells and cascades down to the venules that lead to the hepatic portal circulation. The opposing ascending and descending blood flow provides a countercurrent exchange system for absorbed substances and blood gases. A central **lacteal**, or lymphatic capillary, is also contained within each villus and is important for the absorption and transport of fat molecules. Contents of the lacteals flow to regional nodes and channels that eventually drain into the thoracic duct⁷ (see Fig. 41.9).

Between the bases of the villi are the **crypts of Lieberkühn** (intestinal glands), which extend to the submucosal layer. Undifferentiated cells arise from stem cells at the base of the crypt and move toward the tip of the villus, maturing to become columnar epithelial secretory cells (water, electrolytes, and enzymes) and goblet cells (mucus). After completing their migration to the tip of the villus, they function for a few days and then are shed into the intestinal lumen and digested. Discarded epithelial cells are an important source of endogenous protein. The entire epithelial population is replaced about every 4 to 7 days. Many factors can influence this process of cellular proliferation. Starvation, vitamin B₁₂ deficiency, and cytotoxic drugs or irradiation suppresses cell division and shorten the villi. The decreased absorption that results can cause diarrhea and malnutrition. Nutrient intake and intestinal resection stimulate cell production.

Intestinal Digestion and Absorption

The process of intestinal digestion is initiated in the stomach by the actions of gastric hydrochloric acid and pepsin, which break down food fibers and proteins. The chyme that passes into the duodenum is a liquid that contains small particles of undigested food. Digestion continues in the proximal portion of the small intestine by the action of pancreatic enzymes, intestinal brush-border enzymes, and bile salts. Carbohydrates are broken down to monosaccharides and disaccharides in the proximal small intestine, proteins are degraded further to amino acids and peptides, and fats are emulsified and

reduced to fatty acids ([Box 41.1](#)) and monoglycerides ([Fig. 41.10](#)). These nutrients, along with water, vitamins, and electrolytes, are absorbed across the intestinal mucosa and into the blood by active transport, diffusion, or facilitated diffusion. Products of carbohydrate and protein breakdown move into villus capillaries and then to the liver through the hepatic portal vein. Digested fats move into the lacteals and eventually reach the liver through the systemic circulation. Intestinal motility exposes nutrients to a large mucosal surface area by mixing chyme and moving it through the lumen. Different segments of the gastrointestinal tract absorb different nutrients. Digestion and absorption of all major nutrients occur in the small intestine. Sites of absorption are shown in [Fig. 41.11](#).

FIGURE 41.11 Sites of Absorption of Major Nutrients.

Water and Electrolyte Transport by the Small Intestine.

The epithelial cell membranes of the small intestine are formed of lipids and therefore are hydrophobic, or tend to repel water. (The properties of cell membranes are described in [Chapter 1](#).) Therefore water and electrolytes are transported in both directions (toward the capillary blood or toward the intestinal lumen) through the tight

junctions and intercellular spaces rather than across cell membranes. Water diffuses passively across hydrostatic pressure and osmotic gradients established by the active transport of sodium and other substances. Approximately 85% to 90% of the water that enters the gastrointestinal tract each day is absorbed in the small intestine. The remaining water and electrolytes are absorbed at a constant rate in the large intestine. Sodium passes through the tight junctions and is actively transported across cell membranes. Sodium and glucose share a common active transport carrier (sodium-glucose ligand transporter1 [SGLT1]) so that sodium absorption is enhanced by glucose transport (Fig. 41.12). Potassium moves passively across the tight junctions with changes in the electrochemical gradient. Chloride is actively secreted throughout the large and small intestines.

FIGURE 41.12 Monosaccharides and Sodium Transport. Schematic showing monosaccharides and sodium (Na^+) transport through the small intestinal epithelium. Glucose, galactose, and sodium are transported into the epithelial cell by sodium-glucose ligand transporter 1 (SGLT1). See text for details regarding other glucose transporters.

Carbohydrates.

Only monosaccharides (ribose, galactose, glucose, fructose) are absorbed by the intestinal mucosa; the complex carbohydrates (polysaccharides and oligosaccharides) must be hydrolyzed to their simplest form (see Fig. 41.10). The major disaccharides are sucrose (glucose-fructose), maltose (glucose-glucose), and lactose (glucose-galactose). Salivary and pancreatic amylases break down starches to oligosaccharides by splitting α -1,4-glucosidic linkages of long-chain molecules. Approximately half of starch hydrolysis occurs in the stomach and about half in the duodenum. In the small intestine, disaccharides are hydrolyzed by brush-border enzymes (sucrase, maltase, and lactase) to their respective monosaccharides.

The sugars are absorbed primarily in the duodenum and upper jejunum by facilitated diffusion mediated by glucose transporter proteins.⁸ The monosaccharides pass through the unstirred layer by diffusion. At the cell membrane, glucose and galactose are actively transported with a sodium carrier (SGLT1) and fructose absorption is facilitated by glucose transporter 5 (GLUT5) and GLUT7. Transport of all three monosaccharides from the cytosol to the bloodstream is facilitated by GLUT2 (see Fig. 41.12). Insulin facilitates glucose transport into fat and muscle cells via glucose transporter 4 (GLUT4).

Insulin is not required for the intestinal absorption of glucose. Cellulose is a glucose polysaccharide found in plants. Humans lack enzymes to digest cellulose, and the undigested fiber contributes to stool volume and stimulates large intestine motility.

Proteins.

Adults require 44 to 56 g of protein per day. Approximately 20 to 30 g of protein is derived endogenously from shed epithelial cells and small amounts of plasma proteins. Most ingested protein is absorbed; only 5% to 10% is eliminated in the stool.

The site of digestion of protein depends on the source of the protein. For example, casein from bovine milk precipitates in the stomach and is digested by gastric pepsin and acid, whereas the soluble proteins whey and soy pass rapidly through the stomach and are digested by

pancreatic enzymes. Major protein hydrolysis is accomplished in the small intestine by the pancreatic enzymes trypsin, chymotrypsin, and carboxypeptidase (see [Fig. 41.10](#)). **Trypsin** and **chymotrypsin** (endopeptidase) hydrolyze the interior bonds of the large molecules, and **carboxypeptidases** cleave the end amino acids (exopeptidase). Hydrolysis of proteins is also carried out by the brush-border enzymes and enzymes in the epithelial cytosol (intracellular fluid). The brush-border enzymes hydrolyze the large oligopeptides (proteins composed of three to six amino acids) into smaller peptides, which can cross cell membranes. Enzymes in the cytosol then break them down to amino acids. Amino acids are actively transported from the cytosol into the bloodstream by a sodium-dependent carrier in the basolateral membrane. There also are free amino acids that can be absorbed directly from the intestinal lumen using a membrane transport protein. Like the sugars, proteins are absorbed primarily in the proximal area of the small intestine.

Fats.

Approximately 90 to 100 g of fat is consumed daily by the average American. **Fat** is an important source of calories and is a primary structural component of cell membranes and organelles. Sources of dietary fat are reviewed in [Box 41.2](#). Although triglycerides are the major dietary lipids, cholesterol, phospholipids, and fat-soluble vitamins also have nutritional importance. The digestion and absorption of fat occur in four phases: (1) emulsification and lipolysis, (2) micelle formation, (3) fat absorption, and (4) resynthesis of triglycerides and phospholipids.

Box 41.2

Dietary Fat

Saturated Fatty Acid (Palmitic Acid [C₁₆H₃₂O₂])

Each carbon atom in the chain is linked by single bonds to adjacent

carbon and hydrogen atoms; atoms are solid at room temperature and found in animal fat and tropical oils (coconut and palm oils); they increase low-density lipoprotein (LDL) cholesterol (“bad” cholesterol) blood levels and increase the risk of coronary artery disease.

Unsaturated Fatty Acid

Unsaturated fatty acids are soft or liquid at room temperature; omega-6 fatty acids are found in plants and vegetables (olive, canola, and peanut oils), and omega-3 fatty acids are found in fish and shellfish (eicosapentaenoic acid and docosahexaenoic acid).

1. Monounsaturated fatty acids (e.g., oleic acid [$C_{18}H_{34}O_2$):
Contain one double bond in the carbon chain and are found in plants and animals; may be beneficial in reducing blood cholesterol, glucose levels, and systolic blood pressure; do not lower high-density lipoprotein (HDL) cholesterol (“good” cholesterol) level; low HDL levels have been associated with coronary heart disease.
2. Polyunsaturated fatty acids (e.g., linoleic acid [$C_{18}H_{32}O_2$):
Contain two or more double bonds in the carbon chain and are found in plants and fish oils; omega-6 fatty acids lower total and LDL cholesterol blood levels; high levels of polyunsaturated fatty acids may lower LDL level; omega-3 fatty acids lower blood triglyceride levels, reduce platelet aggregation and blood-clotting tendency, are necessary for growth and development, and may prevent coronary artery disease, hypertension, cancer, and inflammatory and immune disorders.

The mechanical action of the stomach and small intestine disperses the triglyceride droplets into small particles. **Emulsification** is the process by which emulsifying agents (fatty acids, monoglycerides,

lecithin, cholesterol, protein, bile salts) in the small intestinal lumen cover the small fat particles and prevent them from re-forming into fat droplets. Emulsified fat is then ready for **lipolysis** (lipid hydrolysis) by lingual and gastric lipase (acid lipases), pancreatic lipase, phospholipase, and hydrolase (alkaline lipases). **Lipase** breaks down triglycerides to diglycerides, monoglycerides, free fatty acids, and glycerol (see [Fig. 41.10](#)). The action of alkaline lipases requires the presence of **colipase**, a pancreatic coenzyme that allows lipase to penetrate the triglyceride molecule. **Phospholipase** cleaves fatty acids from phospholipids, and **cholesterol esterase** breaks cholesterol esters into fatty acids and glycerol.

The products of lipid hydrolysis must be made water soluble if they are to be absorbed efficiently from the intestinal lumen. This is accomplished by the formation of water-soluble molecules known as **micelles** ([Fig. 41.13](#)). Micelles are formed of bile salts, the products of fat hydrolysis, fat-soluble vitamins, and cholesterol. The fats form the core of the micelle, and the polar bile salts form an outer shell, with the hydrophobic (“water-repelling”) side facing the interior and the hydrophilic (“water-loving”) side facing the aqueous (water-like) content of the intestinal lumen. Because the unstirred layer of the brush border is aqueous, the micelles readily diffuse through it. The micelles maintain the fat molecules in the dissolved or solubilized form, which allows them to move more rapidly from the micelle toward the absorbing surface of the intestinal epithelium. The fat products of the micelle then readily diffuse through the epithelial cell membrane, while the bile salts remain in the lumen and proceed to the ileum, where they are absorbed into the circulation and returned to the liver via the enterohepatic circulation (see [Figs. 41.14](#) and [41.21](#)). Almost all of the bile salts are recycled in this way.

FIGURE 41.13 Structure of Bile Acid and Micelle. **A**, A bile salt molecule in solution. The molecule is amphipathic in that it has a hydrophilic face and a hydrophobic face. The amphipathic structure is key in the ability of the bile salts to emulsify lipids and form micelles. **B**, A model of the structure of a bile salt–lipid mixed micelle, an emulsified fat. (From Levy MN, Koepfen BM, Stanton BA: *Principles of physiology*, ed 4, St Louis, 2006, Mosby.)

FIGURE 41.14 Lipid Absorption in the Small Intestine. Micelles of bile salts and products of lipid digestion diffuse through the unstirred layer and among the microvilli. As digestive products are absorbed from free solution by epithelial cells of the villi, more digestive products dissociate from the micelles. (From Levy MN, Koeppen BM, Stanton BA: *Principles of physiology*, ed 4, St Louis, 2006, Mosby.)

When the fat products reach the inside of the epithelial cell, they are resynthesized into triglycerides and phospholipids. The triglycerides are covered with phospholipids, lipoproteins, and cholesterol to become particles called **chylomicrons**. The chylomicrons travel to the basolateral membrane of the columnar epithelial cells, where they are extruded into the intercellular spaces of the villus. From here they enter the lacteals and lymphatic channels and, eventually, the systemic circulation.

Minerals and Vitamins.

The recommended intake of calcium ranges from 1000 to 1500 mg/day. Between 500 and 600 mg is secreted or shed into the lumen with desquamated epithelial cells. Not all of this calcium is absorbed. Daily absorption of **calcium** is approximately 600 mg. This amount increases with increased intake. When its concentration in the lumen is greater than 5 mmol/L, calcium is absorbed by passive diffusion. At concentrations less than 5 mmol/L, calcium is transported actively across cell membranes, bound to a carrier protein. The carrier formation requires the presence of the active form of

vitamin D₃ (1,25-dihydroxy-vitamin D). The calcium-protein complex moves into the epithelial cell, where the calcium binds to proteins or other substances. Then these complexes move through the basolateral membrane to the interstitial fluid by diffusion or active transport. Calcium is absorbed throughout the small intestine, but primarily in the ileum. Increased serum calcium concentration inhibits parathyroid hormone, which in turn decreases the formation of vitamin D₃ by the kidney, thus regulating calcium absorption.

Increased demand for calcium results in increased uptake, as evidenced by the fact that calcium is absorbed more rapidly in children and pregnant or lactating women. Bile salts enhance calcium absorption indirectly by facilitating the absorption of vitamin D, which is fat soluble.

The recommended intake of **magnesium** for adults is 300 to 350 mg/day. Approximately 50% of it is absorbed by active transport or passive diffusion in the jejunum and ileum. **Phosphate** is also absorbed in the small intestine by passive diffusion and active transport.

The levels of **iron** in the body are regulated primarily by intestinal absorption and secretion. The average intake ranges from 15 to 30 mg/day. Of this amount, menstruating women absorb 1 to 1.5 mg and men absorb 0.15 to 1 mg. Generally the amount of iron absorbed is equal to the amount required. Iron is absorbed more rapidly if a deficiency exists. A primary source of iron is heme from animal protein with a smaller amount of heme from recycling of senescent red blood cells. This iron is rapidly absorbed by the epithelial cells primarily in the proximal duodenum. Inorganic iron (e.g., iron in fruits, cereals, eggs, vegetables) is also readily absorbed. The presence of gastric acid and vitamin C in the duodenum reduces ferric iron to ferrous iron, which is the form more easily absorbed. Calcium phosphate and phosphoproteins (milk and antacids) in the intestinal lumen bind iron and reduce absorption. Tea also binds iron and inhibits absorption by forming iron tannate complexes.

Iron is bound to *intestinal transferrin* in the lumen and is absorbed and bound to the protein *ferritin* and to amino acid chelates in the

cytosol of the enterocytes. Transport of iron across the basolateral membrane is determined by the amount of iron in the circulation. It is transported in the blood by *plasma transferrin*, a glycoprotein, and is carried to body tissues. When there is less need for iron, it remains in the enterocyte as ferritin and is carried into the lumen when the cell is sloughed from the end of the villus. Following hemorrhage, the intestinal cells require 3 days to increase their rate of iron absorption. This is because the need for iron is perceived by the precursor stem cells in the crypts of Lieberkühn, and they take 3 days to mature and migrate to the tips of the villi, where they absorb more iron. **Hepcidin** is a protein synthesized by the liver that inhibits apical uptake of iron by enterocytes and modulates iron trafficking.⁹

The absorption of **vitamins** is summarized in [Table 41.2](#). Most of the water-soluble vitamins are absorbed passively or by sodium-dependent active transport. Most vitamin B₁₂ (cobalamin) is bound to intrinsic factor (making it resistant to digestion) and absorbed in the terminal ileum, although a small amount of the vitamin is absorbed in its free (unbound) form.

TABLE 41.2

INTESTINAL ABSORPTION OF VITAMINS

VITAMIN	MECHANISMS OF ABSORPTION	SITE OF ABSORPTION
Fat-Soluble Vitamins	Micelle formation with bile salts; lipid diffusion	Ileum
A (retinal)		
D ₃ (1,25-dihydroxy-vitamin D)		
E (α-tocopherol)		
K		
Water-Soluble Vitamins		
B ₁ (thiamine)	Active transport (sodium dependent)	Duodenum and jejunum
B ₂ (riboflavin)	Unknown	Duodenum and jejunum
Niacin (nicotinic acid)	Passive diffusion	Jejunum

C (ascorbic acid)	Passive diffusion; active transport (sodium dependent)	Ileum
Folic acid	Active transport (sodium dependent)	Jejunum
B ₁₂ (cobalamin)	Active transport (intrinsic factor dependent)	Terminal ileum
B ₆ (pyridoxine, pyridoxamine, pyridoxal phosphate)	Passive diffusion	Jejunum
Pantothenic acid	Passive diffusion	Duodenum and jejunum
Biotin	Unknown	Unknown

Intestinal Motility

The movements of the small intestine facilitate digestion and absorption. Chyme leaving the stomach and entering the duodenum stimulates intestinal movements that help blend secretions from the liver, gallbladder, pancreas, and intestinal glands. A churning motion brings the luminal content into contact with the absorbing cells of the villi. Propulsive movements then advance the chyme toward the large intestine.

Intestinal motility is regulated by the enteric nervous system, vagal stimulation, and hormones (see [Table 41.1](#)). Two movements promote motility:

1. **Haustral segmentation.** Localized rhythmic contractions of circular smooth muscles divide and mix the chyme, enabling the chyme to have contact with digestive enzymes and the absorbent mucosal surface, and then propel it toward the large intestine.
2. **Peristalsis.** Waves of contraction along short segments of longitudinal smooth muscle allow time for digestion and absorption. The intestinal villi move with contractions of the muscularis mucosae, a thin layer of muscle separating the mucosa and submucosa, with absorption promoted by the swaying of the villi in the luminal contents.

Segmentation consists of localized rhythmic contractions of the circular smooth muscles and occurs more frequently than peristalsis. The contraction waves occur at different rates in different parts of the small intestine in segments of 1 to 4 cm. Frequency is greatest (12/minute) in the upper small intestine and least (8/minute) in the distal part of the ileum. Segmentation divides and mixes the chyme, bringing it into contact with the absorbent mucosal surface. It also helps to propel the chyme toward the large intestine. The frequency of the segmentation is regulated intrinsically by the frequency of the basic electrical rhythm, which arises in the myenteric plexus of longitudinal smooth muscle and is controlled by the interstitial cells of Cajal, the pacemaker cells of the gastrointestinal tract.¹⁰ Although the basic rate of contraction is controlled intrinsically, the force of contraction can be enhanced extrinsically by vagal stimulation.

Intestinal peristalsis involves short segments (about 10 cm) of longitudinal smooth muscle and propels chyme through the intestine. The intestinal villi move with contractions of the muscularis mucosae, a thin layer of muscle separating the mucosa and submucosa, with absorption promoted by the swaying of the villi in the luminal contents. The wave of contraction moves slowly (1 to 2 cm/second) to allow time for digestion and absorption.

Neural reflexes along the length of the small intestine facilitate motility, digestion, and absorption. Through reflex action, receptors in one part of the intestine transmit signals that influence the function of another part. The **ileogastric reflex** inhibits gastric motility when the ileum becomes distended. This prevents the continued movement of chyme into an already distended intestine. The **intestinointestinal reflex** inhibits intestinal motility when one part of the intestine is overdistended or its mucosa is irritated. Both of these reflexes require extrinsic innervation. The **gastroileal reflex**, which is activated by an increase in gastric motility and secretion, stimulates an increase in ileal motility and relaxation of the ileocecal sphincter. This empties the ileum and prepares it to receive more chyme. The gastroileal reflex is probably regulated by the hormones gastrin and cholecystokinin or through the autonomic nerves.

During prolonged fasting or between meals, particularly overnight, slow waves sweep along the entire length of the intestinal tract from the stomach to the terminal ileum. This is known as the *interdigestive myoelectric complex*, and it appears to propel residual gastric and intestinal contents, including bacteria, into the colon.

The intestinal villi move with contractions of the muscularis mucosae, a very thin layer of muscle that separates the mucosa and submucosa. Absorption is promoted by the swaying of villi in the luminal contents. Contractile activity also helps to empty the central lacteals, which contain products of fat digestion.

The **ileocecal valve (sphincter)** marks the junction between the terminal ileum and the large intestine. This valve is intrinsically regulated and is normally closed. The arrival of peristaltic waves from the last few centimeters of the ileum causes the ileocecal valve to open, allowing a small amount of chyme to pass through. Distention of the upper large intestine causes the sphincter to constrict, preventing further distention or retrograde flow of intestinal contents.

Large Intestine

The **large intestine** is approximately 1.5 m long and consists of the cecum, appendix, colon, rectum, and anal canal (Fig. 41.15). The **cecum** is a pouch that receives chyme from the ileum. Attached to the cecum is the **vermiform appendix**, an appendage having little or no physiologic function. From the cecum, chyme enters the **colon**, a four-part length of intestine that loops upward, traverses the abdominal cavity, and descends to the anal canal. The four parts of the colon are the **ascending colon**, **transverse colon**, **descending colon**, and **sigmoid colon**. Two sphincters control the flow of intestinal contents through the cecum and colon: the ileocecal valve, which admits chyme from the ileum to the cecum, and the **rectosigmoid (O'Beirne) sphincter**, which controls the movement of wastes from the sigmoid colon into the rectum. A thick (2.5 to 3 cm) portion of smooth muscle surrounds the anal canal, forming the **internal anal sphincter**. Overlapping it distally is the striated skeletal muscle of the **external anal sphincter**.

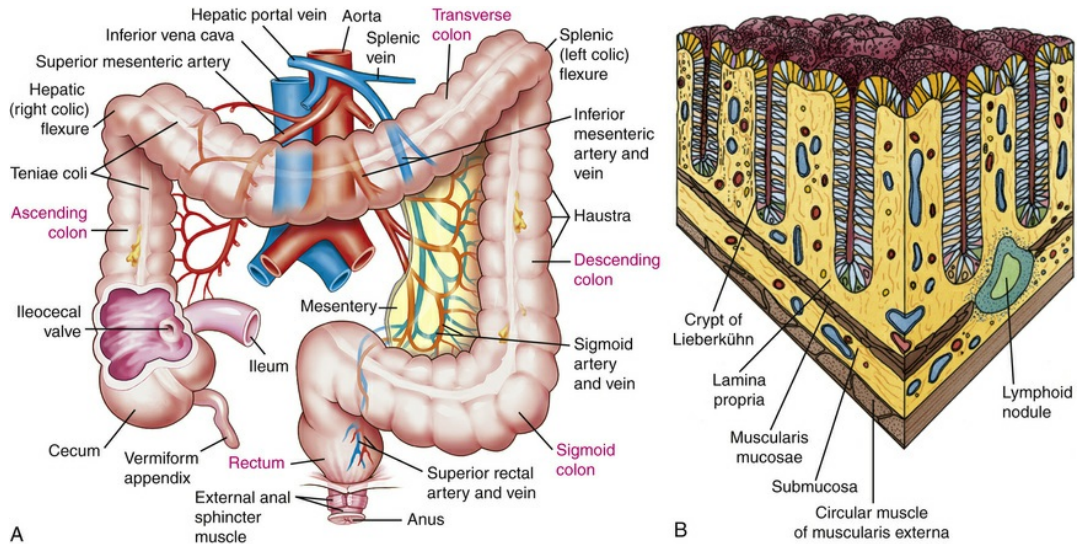

FIGURE 41.15 Large Intestine. A, Structure of the large intestine. B, Microscopic cross section illustrating cellular structures of the large intestine. The wall of the large intestine is lined with columnar epithelium, in contrast to the villi characteristic of the small intestine. The longitudinal layer of muscularis is reduced to become the teniae coli. (A modified from Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis 2018, Mosby; B from Gartner LP, Hiatt JL: *Color textbook of histology*, ed 3, Philadelphia, 2007, Saunders.)

In the cecum and colon the longitudinal muscle layer consists of three longitudinal bands called **teniae coli** (see Fig. 41.15). They are shorter than the colon, giving the colon its “gathered” appearance. The circular muscles of the colon separate the gathers into outpouchings called **haustra** (*sing.*, **haustum**). The haustra become more or less prominent with the contractions and relaxations of the circular muscles. The mucosal surface of the colon has rugae (folds), particularly between the haustra, and Lieberkühn crypts but no villi. Columnar epithelial cells and mucus-secreting goblet cells form the mucosa throughout the large intestine. The columnar epithelium absorbs fluid and electrolytes, and the mucus-secreting cells lubricate the mucosa.

The enteric nervous system regulates motor and secretory activity independently of the extrinsic nervous system. Extrinsic parasympathetic innervation occurs through the vagus nerve and extends from the cecum up to the first part of the transverse colon. Vagal stimulation increases rhythmic contraction of the proximal colon. Extrinsic parasympathetic fibers reach the distal colon through

the sacral parasympathetic splanchnic nerves. The internal anal sphincter is usually contracted, and its reflex response is to relax when the rectum is distended. The myenteric plexus provides the major innervation of the internal anal sphincter, but responds to sympathetic stimulation to maintain contraction and parasympathetic stimulation that facilitates relaxation when the rectum is full. Sympathetic innervation of this sphincter arises from the celiac and superior mesenteric ganglia and the sphincter nerve. The external anal sphincter is innervated by the pudendal nerve arising from sacral levels of the spinal cord. Sympathetic activity in the entire large intestine modulates intestinal reflexes, conveys somatic sensations of fullness and pain, participates in the defecation reflex, and constricts blood vessels. The blood supply of the large intestine and rectum is derived primarily from branches of the superior and inferior mesenteric artery.

The primary type of colonic movement is segmental. The circular muscles contract and relax at different sites, shuttling the intestinal contents back and forth between the contracting and relaxing haustra. The movements massage the intestinal contents, called the **fecal mass** at that point, and facilitate the absorption of water. Propulsive movement occurs with the proximal-to-distal contraction of several haustral units. **Peristaltic movements** also occur and promote the emptying of the colon. The **gastrocolic reflex** initiates propulsion in the entire colon, usually during or immediately after eating, when chyme enters from the ileum. The gastrocolic reflex causes the fecal mass to pass rapidly into the sigmoid colon and rectum, stimulating defecation. Gastrin may participate in stimulating this reflex. Epinephrine inhibits contractile activity as do exogenous opioids.

Approximately 500 to 700 mL of chyme flows from the ileum to the cecum per day. Most of the water is absorbed in the colon by diffusion and active transport. Aldosterone increases colon membrane permeability to sodium, thereby increasing both the diffusion of sodium into the cell and the active transport of sodium across the basolateral membrane to the interstitial fluid. (See [Chapters 3, 21, and 38](#) for a discussion of aldosterone secretion.) This increases the cell-to-

lumen diffusion gradient for potassium. Potassium moves outward, and chloride is absorbed with sodium as the complementary anion. Chloride also enters the cell in exchange for bicarbonate. The colon does not absorb monosaccharides and amino acids, but does absorb some short-chain free fatty acids produced by bacterial fermentation.

Absorption and epithelial transport occur in the cecum, ascending colon, transverse colon, and descending colon. By the time the fecal mass enters the sigmoid colon, the mass consists entirely of wastes and is called the **feces**, composed of food residue, unabsorbed gastrointestinal secretions, shed epithelial cells, and bacteria. The movement of feces into the sigmoid colon and rectum stimulates the **defecation reflex (rectosphincteric reflex)**. The rectal wall stretches and the tonically constricted internal anal sphincter relaxes, creating the urge to defecate. The defecation reflex can be overridden voluntarily by contraction of the external anal sphincter and muscles of the pelvic floor. The rectal wall gradually relaxes, reducing tension, and the urge to defecate passes. Retrograde contraction of the rectum may displace the feces out of the rectal vault until a more convenient time for evacuation. Pain or fear of pain associated with defecation (e.g., rectal fissures or hemorrhoids) can inhibit the defecation reflex. The defecation reflex is regulated by parasympathetic cholinergic fibers. Voluntary inhibition or facilitation of defecation is mediated from cortical projections onto the medulla and down to sacral segments of the cord.

Squatting and sitting facilitate defecation because these positions straighten the angle between the rectum and anal canal and increase the efficiency of straining (increasing intraabdominal pressure). Intraabdominal pressure is increased by initiating the **Valsalva maneuver**—inhaling and forcing the diaphragm and chest muscles against the closed glottis to increase both intrathoracic and intraabdominal pressure which is transmitted to the rectum.

The Gastrointestinal Tract and Immunity

The gastrointestinal tract plays a major role in immune defenses by killing many microorganisms.¹¹ The mucosa of the intestine covers a

large surface area, and mucosal secretions produce antibodies, particularly immunoglobulin A (IgA), and enzymes that provide defenses against pathogenic microorganisms. Small intestinal **Paneth cells**, located near the base of the crypts of Leiberkühn, produce defensins and other antimicrobial peptides and lysozymes important to mucosal immunity. Small intestinal **Peyer patches** (lymph nodules containing collections of lymphocytes, plasma cells, and macrophages) are most numerous in the ileum and produce antimicrobial peptides and IgA as a component of the gut-associated lymph tissue in the small intestine (see Fig. 40.15, B). Peyer patches are important for antigen processing and immune defense (see Fig. 8.3). Intestinal macrophages phagocytize pathogenic bacteria without releasing harmful inflammatory cytokines.¹²

Intestinal Microbiome

The bacterial flora vary greatly in their diversity and number throughout the normal gastrointestinal tract, with an increasing number of bacteria from the stomach to the distal colon. The intestinal tract is sterile at birth but becomes colonized with *Escherichia coli*, *Clostridium welchii*, and *Streptococcus* within a few hours. Within 3 to 4 weeks after birth, the normal flora are established and become stable by 2 years of age. There are hundreds of bacterial species, but the most common bacteria are from the genera *Bacteroides*, *Bifidobacterium*, *Eubacterium*, *Fusobacterium*, *Clostridium*, and *Lactobacillus*, and their diversity and number vary along the length of the intestine. Genetics, diet, environmental pollution, personal hygiene, vaccination, infection, antibiotics and other drugs, and radiation exposure affect the normal composition of bacterial flora. The number and diversity of bacteria change with aging and are influenced by diet, chronic disease, medications, and residential communities.¹³ The intestinal bacteria do not have major digestive or absorptive functions but do play a role in metabolism of bile salts, estrogens, androgens, lipids, carbohydrates, various nitrogenous substances, and drugs. They produce antimicrobial peptides, hormones, neurotransmitters, antiinflammatory metabolites, vitamin K₂, and B vitamins; destroy

toxins; prevent pathogen colonization; and alert the immune system to protect against infection. They are important to overall health, and when altered (dysbiosis) or translocated, they cause disease.¹⁴ The normal flora do not have the virulence factors associated with pathogenic microorganisms, thus permitting immune tolerances.¹⁵ The gastrointestinal microbiota also have regulatory influences on systemic innate and adaptive immune responses and inflammation, including expansion and activity of T-cell populations and systemic antiinflammatory signaling.^{16,17}

Bacteria in the stomach are relatively sparse because of the secretion of hydrochloric acid that kills ingested pathogens or inhibits bacterial growth (with the exception of *Helicobacter pylori*). Bile acid secretion, intestinal motility, and antibody production suppress bacterial growth in the duodenum, and in the duodenum and jejunum there is a low concentration of aerobes (10^1 to 10^4 /mL), primarily streptococci, lactobacilli, staphylococci, enterobacteria, and *Bacteroides*. Anaerobes are found distal to the ileocecal valve. They constitute about 95% of the fecal flora in the colon and contribute one-third of the solid bulk of feces.

Splanchnic Blood Flow

The splanchnic blood flow provides blood to the esophagus, stomach, small and large intestines, liver, gallbladder, pancreas, and spleen (Fig. 41.16). Blood flow is regulated by cardiac output and blood volume, the autonomic nervous system, hormones, and local autoregulatory blood flow mechanisms. The splanchnic circulation serves as an important reservoir of blood volume to maintain circulation to the heart and lungs when needed. The superior and inferior mesenteric arteries provide the blood supply to the large intestine (see Figs. 41.15 and 41.16).

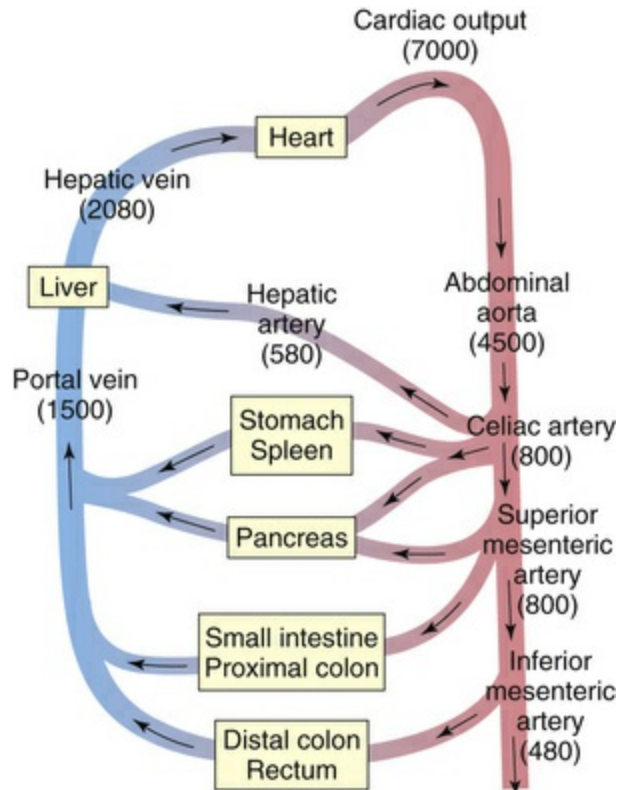

FIGURE 41.16 Major Blood Vessels and Organs Supplied with Blood in the Splanchnic Circulation. Numbers in parentheses reflect approximate blood flow values (mL/min) for each major vessel in an 80-kg normal, resting, adult human subject. Arrows indicate the direction of blood flow. (Modified from Johnson LR: *Gastrointestinal pathophysiology*, St Louis, 2001, Mosby.)

Accessory Organs of Digestion

The liver, gallbladder, and exocrine pancreas all secrete substances necessary for the digestion of chyme. These secretions are delivered to the duodenum through the sphincter of Oddi at the major duodenal papilla (of Vater) (Fig. 41.17). The liver produces bile, which contains salts necessary for fat emulsification and absorption. Between meals bile is stored in the gallbladder. The exocrine pancreas produces enzymes needed for the complete digestion of carbohydrates, proteins, and fats. The exocrine pancreas also produces an alkaline fluid that neutralizes chyme, creating a duodenal pH that supports enzymatic action. The liver receives nutrients absorbed by the small intestine and metabolizes or synthesizes these nutrients into forms

that can be absorbed by the body's cells. It then releases the nutrients into the bloodstream or stores them for later use.

FIGURE 41.17 Locations of the Liver, Gallbladder, and Exocrine Pancreas, Which Are the Accessory Organs of Digestion.

Liver

The **liver**, which weighs 1200 to 1600 g, is the largest solid organ in the body. It is located under the right diaphragm and is divided into right and left lobes. The larger, right lobe is divided further into the caudate and quadrate lobes (Fig. 41.18). The *falciform ligament* separates the right and left lobes and attaches the liver to the anterior abdominal wall. A fibrous cord called the *round ligament (ligamentum teres)* extends along the free edge of the falciform ligament. The round ligament is the remnant of the umbilical vein and extends from the umbilicus to the inferior surface of the liver. The *coronary ligament*

branches from the falciform ligament and extends over the superior surface of the right and left lobes, binding the liver to the inferior surface of the diaphragm. The liver is covered by a fibroelastic capsule called the *Glisson capsule* which contains blood vessels, lymphatics, and nerves. When the liver is diseased or swollen, distention of the capsule causes pain because it is innervated by sensory neurons of the lower intercostal nerves.

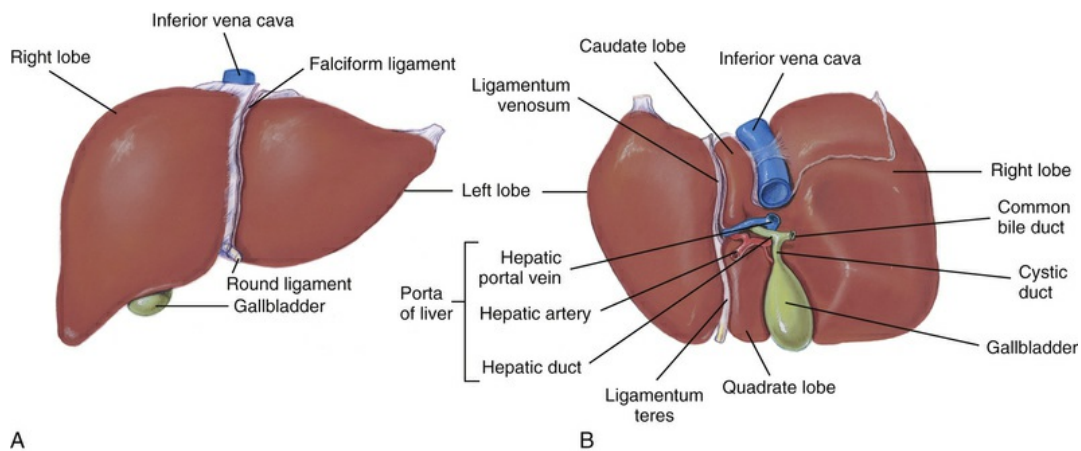

FIGURE 41.18 Gross Structure of the Liver. **A, Anterior surface. B, Visceral surface.** (From Applegate E: *The anatomy and physiology learning system*, ed 4, St Louis, 2011, Saunders.)

The metabolic functions of the liver require a large amount of blood. The liver receives blood from both arterial and venous sources. The **hepatic artery** is formed by the confluence of superior mesenteric and splenic veins and receives blood from the inferior mesenteric, gastric, and cystic veins. It provides oxygenated blood to the liver at the rate of 400 to 500 mL/minute (about 25% of the cardiac output). The **hepatic portal vein**, which receives deoxygenated blood from the inferior and superior mesenteric veins and the splenic vein, delivers about 1000 to 1200 mL/minute of blood to the liver. The hepatic portal vein, which carries 70% of the blood to the liver, is rich in nutrients that have been absorbed from the intestinal tract (Fig. 41.19).

FIGURE 41.19 Hepatic Portal Circulation. In this unusual circulatory route, a vein is located between two capillary beds. The hepatic portal vein collects blood from capillaries in visceral structures located in the abdomen and empties into the liver for distribution to the hepatic capillaries. Hepatic veins return blood to the inferior vena cava. (Organs are not drawn to scale.) (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Elsevier.)

Within the liver lobes are multiple, smaller anatomic units called **liver lobules** (Fig. 41.20). The lobules are formed of cords or plates of **hepatocytes**, which are the functional cells of the liver. These cells are capable of regeneration; therefore damaged or resected liver tissue can regrow. Hepatocytes secrete electrolytes, lipids, lecithin, bile acids, and cholesterol into the canaliculi. Plasma proteins are also synthesized and released into the bloodstream. **Lipocytes** are star-shaped cells that store lipids, including vitamin A. Small capillaries, or **sinusoids**, are located between the plates of hepatocytes. They receive a mixture of venous and arterial blood from branches of the hepatic artery and hepatic portal vein. Blood from the sinusoids drains into a central vein in the middle of each liver lobule. Venous blood from all the lobules then flows into the **hepatic vein**, which empties into the

inferior vena cava. The sinusoids of the liver lobules are lined with highly permeable endothelium. Their permeability enhances the transport of nutrients from the sinusoids into the hepatocytes, where they are metabolized.¹⁸

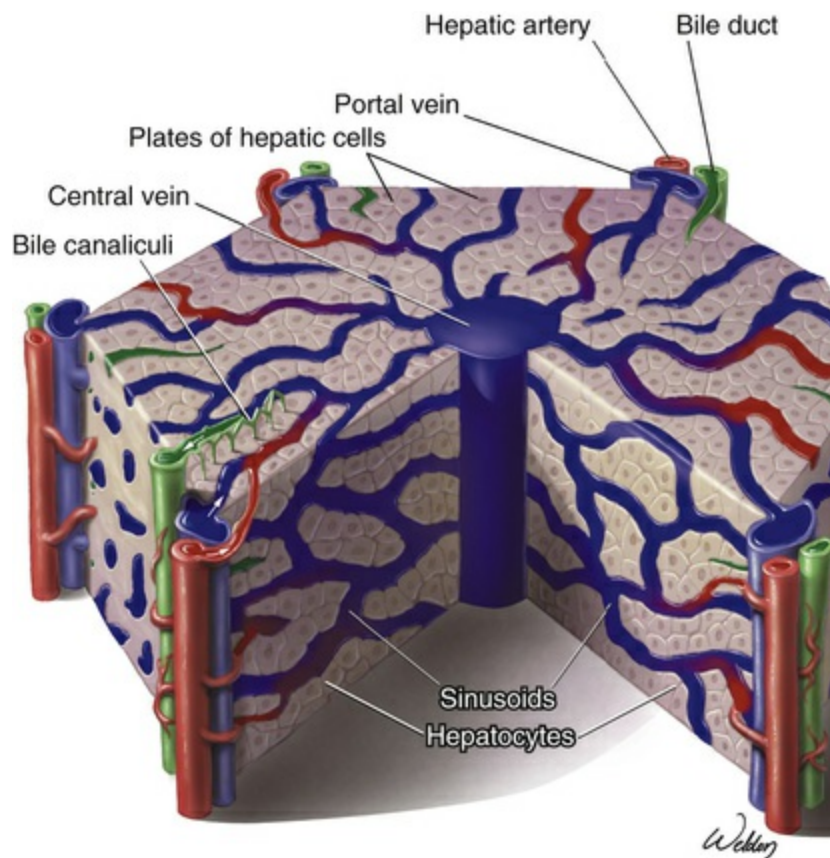

FIGURE 41.20 Diagrammatic Representation of a Liver Lobule. A central vein is located in the center of the lobule, with plates of hepatocytes disposed radially. Branches of the portal vein and hepatic artery are located on the periphery of the lobule, and blood from both vessels perfuses the sinusoids. Peripherally located bile ducts drain the bile canaliculi that run between the hepatocytes. (From Polin RA, et al: *Fetal and neonatal physiology*, ed 4, St Louis, 2011, Saunders.)

Immune functions of the liver are carried out by various cells. Sinusoidal endothelial cells detect microbial infection through pattern recognition receptor activation and as antigen-presenting cells.¹⁹ The sinusoids are lined with phagocytic **Kupffer cells** (macrophages), part of the mononuclear phagocyte system (see [Chapters 7](#) and [28](#)) and are the largest population of tissue macrophages in the body. They are

found in the spaces between sinusoidal endothelial cells, are bactericidal, and are central to innate immunity. Kupffer cells also are important for healing of liver injury and for bilirubin production and lipid metabolism. **Stellate cells** are perisinusoidal cells and contain retinoids (vitamin A), are contractile in liver injury, regulate sinusoidal blood flow, can proliferate into myofibroblasts, participate in liver fibrosis, remove foreign substances from the blood, and trap bacteria. **Natural killer cells (pit cells)** also are found in the sinusoidal lumen; they produce interferon- γ and are important in tumor defense. Between the endothelial lining of the sinusoid and the hepatocyte is the **Disse space**, which drains interstitial fluid into the hepatic lymph system.

Secretion of Bile

The liver assists intestinal digestion by secreting 700 to 1200 mL of bile per day. **Bile** is an alkaline, bitter-tasting yellowish green fluid that contains bile salts (conjugated bile acids), cholesterol, bilirubin (a pigment), electrolytes, and water. It is formed by hepatocytes and secreted into the bile canaliculi, which are small channels adjacent to hepatocytes. **Bile salts** are required for the intestinal emulsification and absorption of fats. The **bile canaliculi** empty into hepatic bile ducts and eventually drain into the **common bile duct** (Fig. 41.21). The union of the common bile duct and pancreatic duct is at the papilla or **ampulla of Vater**, which empties into the duodenum through an opening called the **major duodenal papilla** and is surrounded by the **sphincter of Oddi**. Having facilitated fat emulsification and absorption in the small intestine, most bile salts are actively absorbed in the terminal ileum and returned to the liver through the portal circulation for resecretion. The cycle of hepatic secretion, intestinal absorption, and hepatic resecretion of bile acids is termed the **enterohepatic circulation** (see Fig. 41.21).

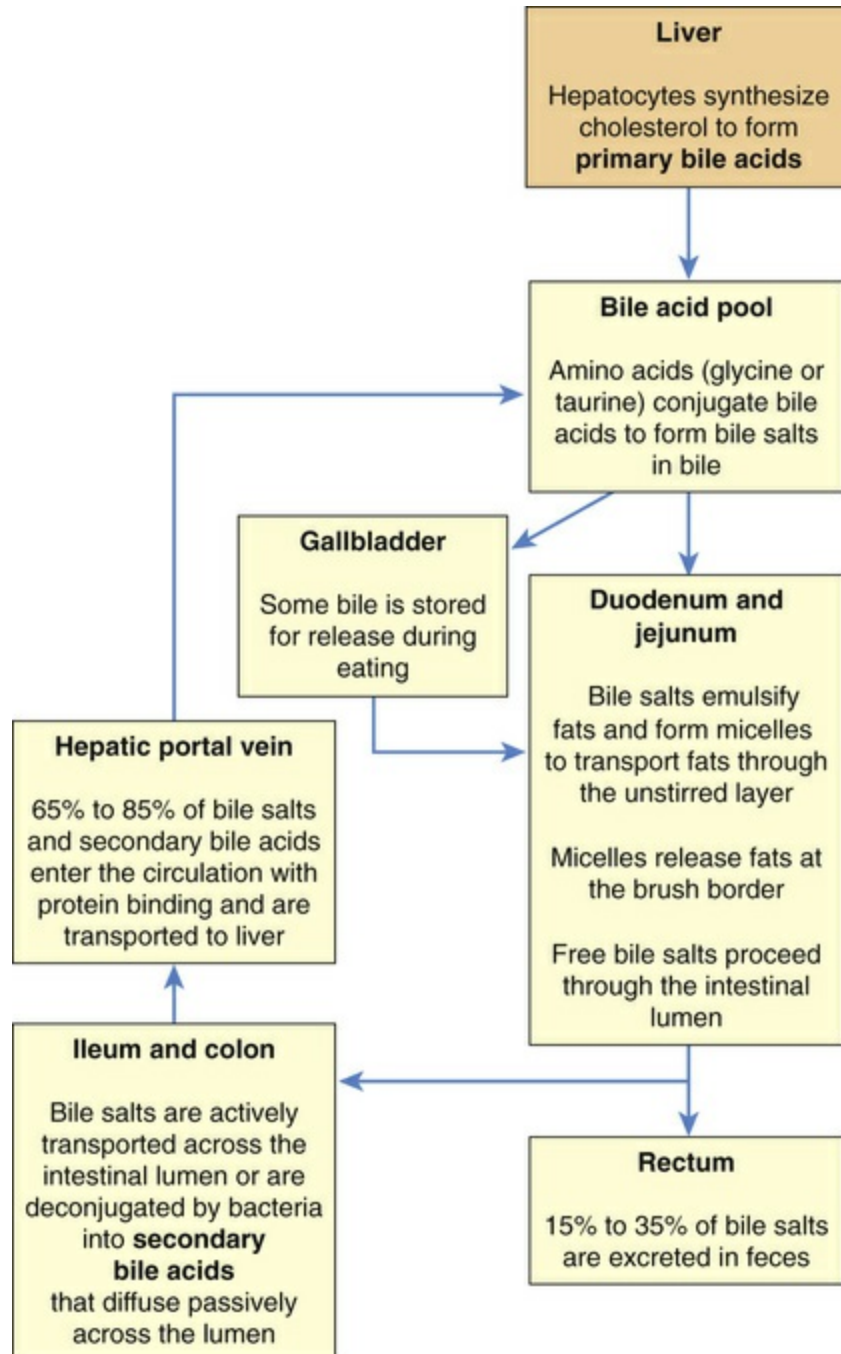

FIGURE 41.21 The Enterohepatic Circulation of Bile Salts.

Bile has two fractional components: the acid-dependent fraction and the acid-independent fraction. Hepatocytes secrete the **bile acid-dependent fraction** of the bile. This fraction consists of bile acids, cholesterol, lecithin (a phospholipid), and bilirubin (a bile pigment). The **bile acid-independent fraction** of the bile, which is secreted by

the hepatocytes and epithelial cells of the bile canaliculi, is a bicarbonate-rich aqueous fluid that gives bile its alkaline pH.

Bile salts are conjugated in the liver from primary and secondary bile acids. The **primary bile acids** are cholic acid and chenodeoxycholic (chenic acid or chenodiol) acid. These acids are synthesized from cholesterol by the hepatocytes. The **secondary bile acids** are deoxycholic acid and lithocholic acid. These acids are formed in the small intestine by the action of intestinal bacteria, after which they are absorbed and flow to the liver (see [Fig. 41.21](#)). Both forms of bile acids are conjugated with amino acids (glycine or taurine) in the liver to form bile salts. Conjugation makes the bile acids more water soluble, thus restricting their diffusion from the duodenum and ileum. The primary and secondary bile acids together form the **bile acid pool**.

Some bile salts are deconjugated by intestinal bacteria to secondary bile acids. These acids diffuse passively into the portal blood from both small and large intestines. An increase in the plasma concentration of bile acids accelerates the uptake and resecretion of bile acids and salts by the hepatocytes. Bile secretion is called **choleresis**. A **choleretic agent** is a substance that stimulates the liver to secrete bile. One strong stimulus is a high concentration of bile salts. Other choleretics include secretin, which increases the rate of bile flow by promoting the secretion of bicarbonate from canaliculi and other intrahepatic bile ducts; cholecystokinin; and vagal stimulation.

Metabolism of Bilirubin

Bilirubin is a byproduct of destruction of aged red blood cells. It gives bile a greenish black color and produces the yellow tinge of jaundice. Aged red blood cells are taken up and destroyed by macrophages of the mononuclear phagocyte system, primarily in the spleen and liver. (In the liver these macrophages are Kupffer cells.) Within these cells, hemoglobin is separated into its component parts—heme and globin ([Fig. 41.22](#)). The globin component is further degraded into its constituent amino acids, which are recycled to form new protein. The

heme moiety is converted to **biliverdin** by the enzymatic (heme oxygenase) cleavage of iron. The iron attaches to transferrin in the plasma and can be stored in the liver or used by the bone marrow to make new red blood cells. The biliverdin is enzymatically converted to bilirubin in the macrophage and then is released into the plasma. In the plasma, bilirubin binds to albumin and is known as **unconjugated bilirubin**, or free bilirubin, which is lipid soluble. Unconjugated bilirubin also has a role as an antioxidant and provides cytoprotection.²⁰

FIGURE 41.22 Bilirubin Metabolism. See text for further explanation.

In the liver, unconjugated bilirubin moves from plasma in the sinusoids into the hepatocyte. Within hepatocytes it joins with glucuronic acid to form **conjugated bilirubin**, which is water soluble. Conjugation transforms bilirubin from a lipid-soluble substance that can cross biologic membranes to a water-soluble substance that can be excreted in the bile. When conjugated bilirubin reaches the distal ileum and colon, it is deconjugated by bacteria and converted to **urobilinogen**. Urobilinogen is then reabsorbed in the intestines and transported to the kidney where it is excreted in the urine as urobilin, giving urine its yellow color. A small amount of urobilin is recirculated back into the liver and eliminated in feces as stercobilin, which contributes to the stool's brown pigmentation.

Vascular and Hematologic Functions

Because of its extensive vascular network, the liver can store a large volume of blood. The amount stored at any one time depends on pressure relationships in the arteries and veins. The liver also can release blood to maintain systemic circulatory volume in the event of hemorrhage.

The liver also has hemostatic functions. It synthesizes most of the clotting factors (see [Chapters 7](#) and [28](#)). Vitamin K₁ (phylloquinone, synthesized by plants and ingested in the diet) and vitamin K₂ (menaquinone, synthesized by intestinal bacteria) are fat-soluble vitamins essential for the synthesis of clotting factors (prothrombin and factors VII, IX, and X). Vitamin K₂ also activates matrix GLA protein (MGP), which inhibits the deposits of calcium in arterial walls.²¹ Because bile salts are needed for absorption of fats, vitamin K absorption depends on adequate bile production in the liver. Impairment of vitamin K absorption diminishes production of clotting factors and increases risk of bleeding.

Metabolism of Nutrients

Fats.

Ingested fat absorbed by lacteals in the intestinal villi enters the liver through the lymphatics, primarily as triglycerides. In the liver the triglycerides can be hydrolyzed to glycerol and free fatty acids and used to produce metabolic energy adenosine triphosphate (ATP), or they can be released into the bloodstream bound to proteins (lipoproteins). The lipoproteins are carried by the blood to adipose cells for storage. The liver also synthesizes phospholipids and cholesterol, which are needed for the hepatic production of bile salts, steroid hormones, components of plasma membranes, and other special molecules.

Proteins.

Protein synthesis requires the presence of all the essential amino acids (obtained only from food), as well as nonessential amino acids. Proteins perform many important functions in the body and are summarized in [Table 41.3](#).

TABLE 41.3

PROTEIN FUNCTIONS IN THE BODY

ROLE	EXAMPLE
Contraction	Actin and myosin enable muscle contraction.
Energy	Proteins can be metabolized for energy.
Fluid balance	Albumin is a major source of plasma oncotic pressure.
Protection	Antibodies, complement, and C-reactive protein protect against infection and foreign substances. α_1 -antitrypsin and α_1 -antichymotrypsin inhibit proteolytic enzymes.
Regulation	Enzymes control chemical reactions; hormones regulate many physiologic processes.
Structure	Collagen fibers provide structural support to many parts of the body; keratin strengthens skin, hair, and nails.
Transport	Hemoglobin transports oxygen and carbon dioxide in the blood; plasma proteins serve as transport molecules; proteins in cell membranes control movement of materials into and out of cells.
Coagulation	Hemostasis is regulated by proteins that balance coagulation and anticoagulation (factors II, VII, IX and X).

Within hepatocytes, amino acids are converted to carbohydrates by the removal of ammonia (NH_3), a process known as **deamination**. The ammonia is converted to urea by the liver and passes into the blood to be excreted by the kidneys. The plasma proteins, including albumins and α - and β - globulins (not gamma globulin, which is formed in lymph nodes and lymphoid tissue), are synthesized by the liver. The liver also synthesizes several nonessential amino acids and serum enzymes that become elevated with liver injury (and other diseases):

- **Aspartate aminotransferase (AST)** (previously called *serum glutamate-oxaloacetate transaminase [SGOT]*): also present in red blood cells and skeletal muscle; AST transfers an α -amino group between aspartate and glutamate.
- **Alanine aminotransferase (ALT)** (previously called *serum glutamate-pyruvate transaminase [SGPT]*): also present in small amounts in the kidneys, heart, skeletal muscle, and pancreas; ALT transfers an amino group from alanine to α -ketoglutarate to form pyruvate and glutamate.
- **Lactate dehydrogenase (LDH)**: catalyzes the conversion of lactate to pyruvate; LDH is widely distributed throughout the body and different isoenzymes are found in different tissues.
- **Alkaline phosphatase**: removes phosphate groups, particularly in an alkaline environment.
- **Gamma-glutamyltransferase**: transfers the gamma-glutamyl moiety of glutathione to an acceptor to form glutamate and is a pro-oxidant.

Reference values for the listed enzymes can be reviewed in [Table 41.6](#), later in this chapter, and are summarized on the inside back book cover.

Carbohydrates.

The liver contributes to the stability of blood glucose levels by releasing glucose during states of hypoglycemia (low blood glucose levels) and taking up glucose during states of hyperglycemia (high blood glucose levels) and storing it as glycogen (glycogenesis) or converting it to fat. When all glycogen stores have been used, the liver can convert amino acids and glycerol to glucose.

Metabolic Detoxification

The liver alters exogenous and endogenous chemicals (e.g., drugs), foreign molecules, and hormones to make them less toxic or less biologically active. This process, called **metabolic detoxification (biotransformation)**, diminishes intestinal or renal tubular reabsorption of potentially toxic substances and facilitates their intestinal and renal excretion. In this way alcohol, barbiturates, amphetamines, steroids, and hormones (including estrogens, aldosterone, antidiuretic hormone, and testosterone) are metabolized or detoxified, preventing excessive accumulation and adverse effects.

Although metabolic detoxification is usually protective, sometimes the end products of metabolic detoxification become toxins or active metabolites. Those of alcohol metabolism, for example, are acetaldehyde and hydrogen, which can damage hepatocytes. Acetaldehyde damages cellular mitochondria, and the excess hydrogen promotes fat accumulation, impairing the liver's ability to function (see [Chapter 2](#)).

Storage of Minerals and Vitamins

The liver stores certain vitamins and minerals, including iron and copper, in times of excessive intake and releases them in times of need. Iron is stored in the liver as ferritin, an iron-protein complex,

and is released as needed for red blood cell production. The liver can store vitamins B₁₂ and D for several months and vitamin A for several years. The liver also stores vitamins E and K. Iron is stored in the liver as ferritin, an iron-protein complex, and is released as needed for red blood cell production.

Gallbladder

The **gallbladder** is a saclike organ that lies on the inferior surface of the liver (see [Figs. 41.18](#) and [41.23](#)). Its primary function is to store and concentrate bile between meals. The wall of the gallbladder is composed of the mucous membrane, muscularis, and serosa. During the interdigestive period, bile flows from the liver through the right or left hepatic duct into the common bile duct and meets resistance at the closed **sphincter of Oddi**, which controls flow into the duodenum and prevents reflux of duodenal contents into the pancreatobiliary system. Bile then flows into the gallbladder through the **cystic duct** where it is concentrated and stored. The mucosa of the gallbladder wall readily absorbs water and electrolytes, leaving a high concentration of bile salts, bile pigments, and cholesterol. The gallbladder holds about 90 mL of bile.

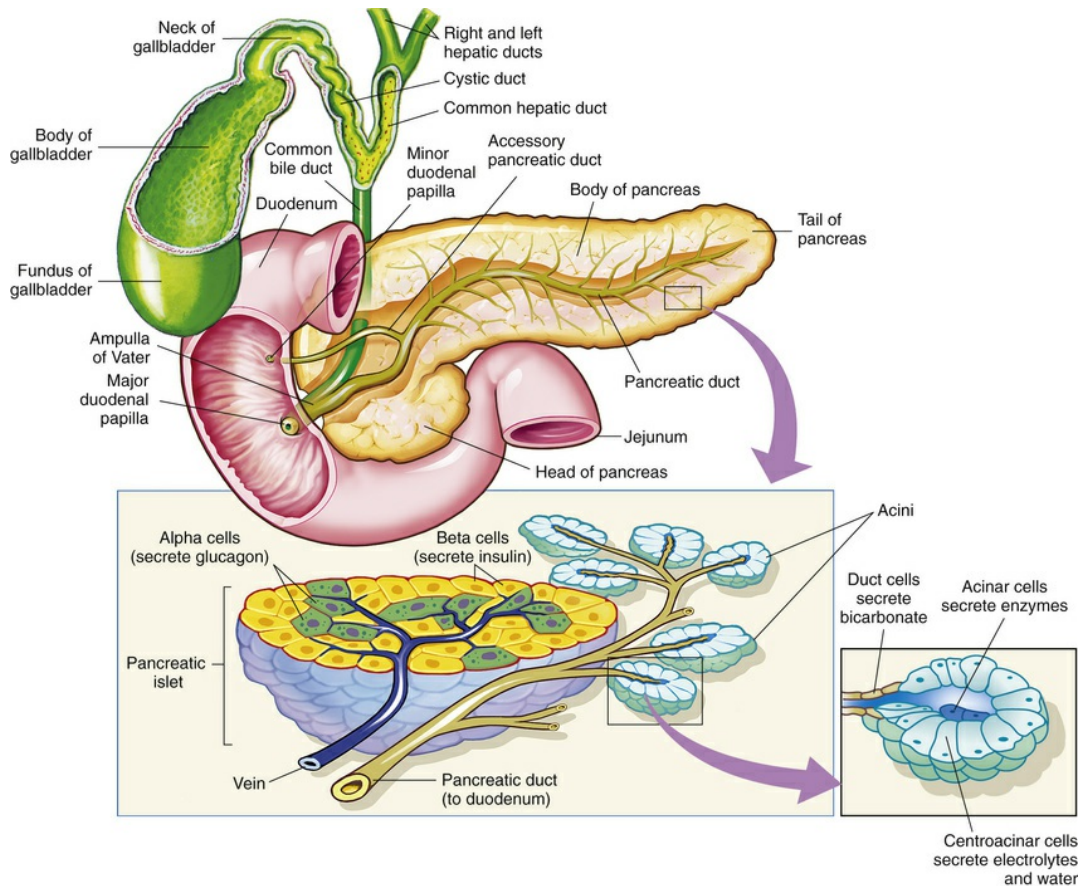

FIGURE 41.23 Associated Structures of the Gallbladder, Pancreas, and Pancreatic Acinar Cells and Duct. (Modified from Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 6, St Louis, 2007, Mosby.)

Within 30 minutes after eating, the gallbladder begins to contract, forcing stored bile through the cystic duct and into the common bile duct. The sphincter of Oddi relaxes, and bile flows into the duodenum through the major duodenal papilla. During the cephalic and gastric phases of digestion (see [the Phases of Gastric Secretion](#) section), gallbladder contraction is mediated by cholinergic branches of the vagus nerve. Hormonal regulation of gallbladder contraction is derived primarily from the release of *cholecystokinin* secreted by the duodenal and jejunal mucosa in the presence of fat. Vasoactive intestinal peptide, pancreatic polypeptide, and sympathetic nerve stimulation relax the gallbladder.

Exocrine Pancreas

The **pancreas** is approximately 20 cm long, with its head tucked into the curve of the duodenum and its tail touching the spleen. The body of the pancreas lies deep in the abdomen, behind the stomach (see [Fig. 41.17](#)). The pancreas is unique in that it has endocrine as well as exocrine functions. The endocrine pancreas secretes insulin, glucagon, somatostatin, and pancreatic polypeptide (see [Chapter 21](#)).

The **exocrine pancreas** is composed of acinar cells that secrete enzymes and networks of ducts that secrete alkaline fluids with important digestive functions. The acinar cells are organized into spherical lobules (acini) around small secretory ducts (see [Fig. 41.23](#)). Secretions drain into a system of ducts that leads to the **pancreatic duct (Wirsung duct)**, which empties into the common bile duct at the ampulla of Vater and then through the duodenal papilla into the duodenum. In some individuals an accessory duct (the duct of Santorini) branches off the pancreatic duct and drains directly into the duodenum at an opening called the *minor duodenal papilla* (see [Fig. 41.23](#)).

Arterial blood is supplied to the pancreas by branches of the celiac and superior mesenteric arteries. Venous blood leaves the head of the pancreas through the tributaries to the hepatic portal vein, with the body and tail being drained through the splenic vein. All hormonal pancreatic secretions also pass through the hepatic portal vein into the liver.

Pancreatic innervation arises from parasympathetic neurons of the vagus nerve, which stimulate enzymatic and hormonal secretion. Sympathetic postganglionic fibers from the celiac and superior mesenteric plexuses innervate the blood vessels and cause vasoconstriction and inhibit pancreatic secretion.

The aqueous secretions of the exocrine pancreas are isotonic and contain potassium, sodium, bicarbonate, magnesium, calcium, and chloride. Sodium and potassium concentrations are about equal to those in the plasma. Pancreatic ductal cells secrete bicarbonate and the concentration in pancreatic juice varies directly with the secretory flow rate. As bicarbonate secretion increases, chloride secretion decreases to maintain a constant anionic concentration. The highly

alkaline pancreatic juice neutralizes the acidic chyme that enters the duodenum from the stomach and provides the alkaline medium needed for the actions of digestive enzymes and the intestinal absorption of fat.

In the pancreas, transport of water and electrolytes through the ductal epithelium involves active and passive mechanisms. The ductal cells actively transport hydrogen into the blood and bicarbonate into the duct lumen. Potassium and chloride are secreted by diffusion according to changes in electrochemical potential gradients. As the secretion flows down the duct, water is osmotically transported into the pancreatic juice until it becomes isosmotic. At low flow rates, bicarbonate is exchanged passively for chloride, but at higher flow rates there is less time for this exchange and bicarbonate concentration increases. Because eating stimulates the flow of pancreatic juice, the juice is most alkaline when it needs to be—during digestion.

The *pancreatic enzymes* hydrolyze proteins (proteases), carbohydrates (amylases), and fats (lipases). The proteolytic (protein-digesting) enzymes (proteases) include trypsin, chymotrypsin, carboxypeptidase, and elastase. These enzymes are secreted in their inactive forms—that is, as trypsinogen, chymotrypsinogen, and procarboxypeptidase—to protect the pancreas from the digestive effects of its own enzymes. For further protection the pancreas produces **trypsin inhibitor**, which prevents the activation of proteolytic enzymes while they are in the pancreas. Once in the duodenum, the inactive forms (proenzymes) are activated by **enterokinase**, an enzyme secreted by the duodenal mucosa. Trypsinogen is the first proenzyme to be activated. Its conversion to trypsin stimulates the conversion of chymotrypsinogen to chymotrypsin and procarboxypeptidase to carboxypeptidase. Each of these enzymes cleaves specific peptide bonds to reduce polypeptides to smaller peptides.

Pancreatic α -amylase is secreted in active form and digests intestinal carbohydrate by cleaving interior α -1,4-glucosidic bonds to yield glucose and maltose at an optimum pH of approximately 6.9. **Pancreatic lipases** hydrolyze triglycerides, cholesterol, and

phospholipids to free fatty acids in the intestine.

Secretion of the aqueous and enzymatic components of pancreatic juice is controlled by hormonal and vagal stimuli. *Secretin* stimulates the acinar and duct cells to secrete the bicarbonate-rich fluid that neutralizes chyme and prepares it for enzymatic digestion. As chyme enters the duodenum, its acidity (pH of 4.5 or less) stimulates the **S cells** of the duodenum to release secretin, which is absorbed by the intestine and delivered to the pancreas in the bloodstream. In the pancreas, secretin causes ductal and acinar cells to release alkaline fluid. Secretin also inhibits the actions of gastrin, thereby decreasing gastric hydrochloric acid secretion and motility. The overall effect is to neutralize the contents of the duodenum.

Enzymatic secretion follows, stimulated by **cholecystokinin**, which activates acetylcholine (ACh) from the vagus nerve and release of ACh from pancreatic stellate cells. Cholecystokinin is released in the duodenum in response to the essential amino acids and fatty acids already present in chyme. Once in the small intestine, activated pancreatic enzymes inhibit the release of more cholecystokinin and ACh. This feedback mechanism inhibits the secretion of more pancreatic enzymes. Pancreatic polypeptide is released after eating and inhibits postprandial pancreatic exocrine secretion. (Table 41.1 summarizes hormonal stimulation of pancreatic secretions.)

Tests of Digestive Function

Gastrointestinal Tract

Although important diagnostic information can be obtained from the patient's medical history and presenting symptoms, numerous disease-specific tests must be performed to evaluate the structure and function of the gastrointestinal tract. A description of selected studies is presented in Tables 41.4 and 41.5. Radiography and imaging techniques—including radionuclide, positron emission tomography (PET), magnetic resonance (MR), computed tomography (CT) scanning, and ultrasound—are procedures for evaluating structure

and function. Plain radiographs using contrast media such as barium- or iodine-containing compounds can be used to outline the gastrointestinal lumen, biliary tree and pancreatic ducts, fistulae, and arteriovenous systems. CT scanning is particularly useful for diagnosis of intestinal lesions and pancreatic or hepatic tumors or cysts. Ultrasonic scanning is a safe, simple, and relatively inexpensive technique used to detect gallstones and intraabdominal masses, particularly abscesses.

TABLE 41.4

SELECTED STUDIES OF GASTROINTESTINAL STRUCTURE

TEST	DESCRIPTION	APPLICATION
Plain roentgenograms	Use of high-energy electromagnetic radiation to evaluate tissue structure by radiopacity or radiolucency	Visualization of the position, size, and structure of abdominal contents
Air or barium contrast roentgenograms	Introduction of radiopaque substances into the upper or lower gastrointestinal tract	Enhanced visualization of the contours, position, and size of the gastrointestinal tract to detect umbilical hernia, ulcers, diverticula, congenital anomalies, polyps, tumors, strictures, obstructions
Endoscopy Esophagoscopy (esophagus) Gastrosocopy (stomach) Duodenoscopy (duodenum) Colonoscopy (large intestine) Sigmoidoscopy (sigmoid colon)	Passage of rigid or flexible (fiberoptic) endoscope into the gastrointestinal tract for visualization or biopsy	Visualization or biopsy of inflamed hernias, polyps, ulcers, strictures, varices, tumors, sites of bleeding, mucosal or neoplastic lesions and for culture of <i>Helicobacter pylori</i> from stomach
Ultrasound	Use of piezoelectric crystal to generate sound waves that are reflected from tissue interfaces to provide an image	Imaging of abdominal organs (gallbladder, liver, pancreas, spleen), masses, stones, abscesses, structural abnormalities
Computed tomography (CT)	Use of a computer to integrate differences in absorption of a large number of x-rays to produce a cross-sectional	Imaging of gallbladder, liver, pancreas, spleen, cysts, hematomas, abscesses, stones, extrahepatic bile ducts, and portal vein

	image; may be done with contrast agents	
Magnetic resonance imaging	Projection of differences in magnetic properties of molecules within different cells and tissues, using the field of a large magnet	Same applications as CT scan; also can detect blood flow and vessel patency

TABLE 41.5

SELECTED TESTS OF GASTROINTESTINAL FUNCTION

TEST	NORMAL FINDINGS	CLINICAL SIGNIFICANCE OF ABNORMAL FINDINGS
Stool studies	Resident microorganisms: clostridia, enterococci, <i>Pseudomonas</i> , a few yeasts	Detection of <i>Salmonella typhi</i> (typhoid fever), <i>Shigella</i> (dysentery), <i>Vibrio cholerae</i> (cholera), <i>Yersinia</i> (enterocolitis), <i>Escherichia coli</i> (gastroenteritis), <i>Staphylococcus aureus</i> (food poisoning), <i>Clostridium botulinum</i> (food poisoning), <i>Clostridium perfringens</i> (food poisoning), <i>Aeromonas</i> (gastroenteritis)
	Fat: 2–6 g/24 hr	Steatorrhea (increased values) can result from intestinal malabsorption or pancreatic insufficiency
	Pus: none	Large amounts of pus are associated with chronic ulcerative colitis, abscesses, and anorectal fistula
	Occult blood: none (orthotolidine or guaiac test)	Positive tests associated with bleeding
	Ova and parasites: none	Detection of <i>Entamoeba histolytica</i> (amebiasis), <i>Giardia lamblia</i> (giardiasis), and worms
D-Xylose absorption	5-hr urinary excretion: 4.5 g/L Peak blood level: >30 mg/dL	Differentiation of pancreatic steatorrhea (normal D-xylose absorption) from intestinal steatorrhea (impaired D-xylose absorption)
Gastric acid stimulation	11–20 mEq/hr after stimulation	Detection of duodenal ulcers, Zollinger-Ellison syndrome (increased values), gastric atrophy, gastric carcinoma (decreased values)
Manometry (use of water-filled catheters connected)	Values vary at different levels	Inadequate swallowing, motility, sphincter function

to pressure transducers passed into the esophagus, stomach, colon, or rectum to evaluate contractility)	of the intestine	
Culture and sensitivity of duodenal contents	No pathogens	Detection of <i>Salmonella typhi</i> (typhoid fever)
Breath tests		
Glucose or D-xylose breath test	Negative for hydrogen or CO ₂	May indicate intestinal bacterial overgrowth
Urea breath test	Negative for isotopically labeled CO ₂	Presence of <i>Helicobacter pylori</i> infection
Lactose breath test	Negative for exhaled hydrogen	Lactose intolerance

Fiberoptic endoscopy, using flexible endoscopes, allows direct visualization of the gastrointestinal tract. A biopsy channel allows tissue sampling, and suction can be applied to remove gastrointestinal secretions or blood. Analysis of stool, gastric secretions, tissue, and plasma provides important clues to infection, malabsorption syndromes, ulcerative lesions, and tumor growth.

Liver

A variety of diagnostic tests can be performed to evaluate liver function (Table 41.6). Imaging techniques similar to those described for the gastrointestinal tract also are useful for evaluating liver structure and function. Elevated plasma levels of liver enzymes are associated with many liver diseases because of the release of cytoplasmic enzymes into the circulation when there is damage to the hepatocyte. Of particular importance are elevations of aminotransferases and lactate dehydrogenase (LDH). Obstruction of bile canaliculi or ducts results in regurgitation of bile back into the hepatic sinusoids and into the circulation, manifesting with elevation of conjugated bilirubin levels. Prothrombin times (a measure of clotting tendency) are often prolonged with both hepatitis and chronic liver disease. In severe disease, other plasma proteins, such as

albumin and globulins, may be diminished as a result of hepatocyte damage. Liver biopsies are often performed to evaluate the extent of liver involvement or degeneration with cirrhosis, hepatitis, or fatty liver disease.

TABLE 41.6

COMMON LIVER FUNCTION TESTS

TEST	NORMAL VALUE	INTERPRETATION
Serum Enzymes		
Alkaline phosphatase	35–150 units/L	Increases with biliary obstruction and cholestatic hepatitis
Gamma-glutamyl transpeptidase	Male 12–38 units/L Female 9–31 units/L	Increases with biliary obstruction and cholestatic hepatitis
Aspartate aminotransferase (previously serum glutamate-oxaloacetate transaminase)	Male 8–40 units/L Female 6–34 units/L	Increases with hepatocellular injury and injury in other tissues (e.g., skeletal and cardiac muscle)
Alanine aminotransferase (previously serum glutamate-pyruvate transaminase)	Male 10–40 units/L Female 9–32 units/L	Increases with hepatocellular injury and necrosis
Lactate dehydrogenase	110–220 units/L	Isoenzyme LD ₅ is elevated with hypoxic and primary liver injury
5'-Nucleotidase	2–11 units/L	Increases with increase in alkaline phosphatase and cholestatic disorders
Bilirubin Metabolism		
Serum bilirubin		
Unconjugated (indirect)	0.1–1.0 mg/dL	Increases with hemolysis (lysis of red blood cells)
Conjugated (direct)	0.1–0.4 mg/dL	Increases with hepatocellular injury or obstruction
TOTAL	<1.0 mg/dL	Increases with biliary obstruction

Urine bilirubin	0	Increases with biliary obstruction
Urine urobilinogen	0–4 mg/24 hr	Increases with hemolysis or shunting of portal blood flow
Serum Proteins		
Albumin	3.5–5.5 g/dL	Reduced with hepatocellular injury
Globulin	2–4 g/dL	Increases with hepatitis
TOTAL	6–7 g/dL	
Albumin/globulin ratio	1.5 : 1 to 2.5 : 1	Ratio reverses with chronic hepatitis or other chronic liver disease
Transferrin	250–300 mcg/dL	Liver damage with decreased values, iron deficiency with increased values
Alpha fetoprotein	6–20 ng/mL	Elevated values in primary hepatocellular carcinoma
Blood-Clotting Functions		
Prothrombin time	10–13 sec or 90%–100% of control	Increases with chronic liver disease (cirrhosis) or vitamin K deficiency
Partial thromboplastin time	22–37 sec	Increases with severe liver disease or heparin therapy
Bromsulphthalein excretion	<6% retention in 45 min	Increased retention with hepatocellular injury

Gallbladder

Evaluation of structural alterations in the gallbladder may be achieved by the use of various imaging techniques. [Table 41.7](#) summarizes these techniques. Obstructive pathology of the bile ducts results in elevated values for both conjugated and total serum bilirubin, increased urine urobilinogen level, clay-colored stools, and development of jaundice. Fat absorption can be impaired and the prothrombin time prolonged if vitamin K is not absorbed. With inflammation of the gallbladder, the white cell count is elevated.

TABLE 41.7

DIAGNOSTIC EVALUATION OF THE GALLBLADDER

TEST	APPLICATION
------	-------------

Plain roentgenogram of the abdomen	Visualization of calcified gallstones
Oral cholecystogram (use of an oral contrast medium such as iopanoic acid, which is excreted with bile and concentrated in the gallbladder for visualization by radiography; may be administered as a double dose)	Visualization of gallstones; evaluation of filling and emptying of gallbladder
Intravenous cholangiography (use of intravenous contrast agents for visualization of gallbladder and bile ducts)	Diagnosis of acute gallbladder inflammation (cholecystitis) or disease of bile ducts
Cholecystography (ultrasound imaging of gallbladder and bile ducts including endoscopic ultrasound)	Preferred method for detecting gallstones; differentiation of hepatic disease from biliary obstruction; diagnosis of chronic cholecystitis
Cholescintigraphy (radioisotope imaging of gallbladder)	Diagnosis of cholecystitis in individuals allergic to iodine-containing contrast agents; diagnosis of cystic duct obstruction
Endoscopic retrograde cholangiography (instillation of contrast medium through cannulation of ampulla of Vater with a duodenoscope)	Differentiation of intrahepatic or extrahepatic obstructive jaundice Diagnosis of gallstones
Computed tomography	Diagnosis of biliary obstruction or malignancy when ultrasound is not successful
Magnetic resonance cholangiography	Diagnosis of complicated cholelithiasis or choledocholithiasis

Exocrine Pancreas

Tests of pancreatic function are summarized in [Table 41.8](#). Evaluation of serum lipase and urinary amylase provides particularly significant measures of pancreatic injury. Inflammation or obstruction of the pancreas results in an early increase in serum amylase levels. Serum lipase level remains elevated after serum amylase has returned to normal levels and provides greater sensitivity with delayed presentation of pancreatitis. Elevation of urine amylase level also occurs later (after 48 hours) when serum amylase may have returned to normal levels. Urinary trypsinogen 2 (available as dipstick) is used to diagnose acute pancreatitis and is comparable to serum amylase and lipase.²² Increased stool fat can reflect pancreatic insufficiency

caused by decreased lipase secretion when biliary function is normal.

TABLE 41.8

SELECTED TESTS OF PANCREATIC FUNCTION

TEST	NORMAL VALUE	CLINICAL SIGNIFICANCE
Serum amylase	25–125 units/mL	Elevated levels with pancreatic inflammation
Serum lipase	20–240 units/mL	Elevated levels with pancreatic inflammation (may be elevated with other conditions; differentiates with amylase isoenzyme study)
Urine amylase	35–260 Somogyi units/hr	Elevated levels with pancreatic inflammation
Secretin test	Volume 1.8 ml/kg/hr Bicarbonate concentration: >80 mEq/L Bicarbonate output: >10 mEq/L/30 sec	Decreased volume with pancreatic disease as secretin stimulates pancreatic secretion
Stool fat	2–5 g/24 hr	Measures fatty acids; decreased pancreatic lipase increases stool fat (malabsorption)
Fecal elastase	>200 µg/g of stool	Decreased in pancreatic insufficiency

Aging and the Gastrointestinal System

Age-related change in gastrointestinal function is variable among individuals and is related to health status and disease treatments, genetics, and environmental factors.²³ Changes can begin to occur before 50 years of age. Tooth enamel and dentin wear down, making the teeth vulnerable to cavities. Teeth are lost, often as a result of periodontal (gum) disease, recession of the gums, osteoporotic bone changes, and more brittle roots that fracture easily. Taste buds decline in number, and the sense of smell diminishes. Together these losses decrease the sense of taste. These oral and sensory changes make eating less pleasurable and reduce appetite in very old adults. Food may not be chewed or lubricated sufficiently, making swallowing

difficult. The esophagus develops decreased motility, and changes in the upper esophageal sphincter, history of stroke, and dementia may affect swallowing and contribute to gastroesophageal reflux.²⁴ Age also diminishes gastric motility, secretion, and blood flow with increased risk for mucosal injury. Acid content of gastric juice is related to gastric atrophy, which results in hypochlorhydria (insufficient hydrochloric acid), delayed gastric emptying, and compromise of the gastric mucosal barrier. Decreased production of intrinsic factor leads to inadequate small intestinal absorption of vitamin B₁₂ and pernicious anemia.²⁵ Aging may be associated with a change in the composition of the intestinal microflora and a decline in pathogen-specific IgA with increased susceptibility to disease.^{13,26} The ileal villi of the small intestine may become broader and shorter, perhaps because of a decrease in cell turnover. Degeneration and density of the enteric nervous system neurons can decrease intestinal absorption, motility, and blood flow, impairing nutrient absorption. Proteins, fats, minerals (including iron and calcium), and vitamins are absorbed more slowly and in lesser amounts, and absorption of carbohydrates is decreased. Intestinal transit time is delayed. Constipation is often described as a condition of old age, but it is probably caused by lifestyle factors (e.g., diet, lack of fluid intake) rather than physiologic decline, although studies demonstrate there can be alterations in both enteric and external intestinal innervation.²⁷

The rate of liver regeneration decreases with advancing age, but the volume of the liver can be maintained.²⁸ Liver blood flow and enzyme activity decrease with age and can influence the efficiency of drug and alcohol metabolism.²⁹ However, liver function test results often remain within relatively normal ranges. Alterations in liver function in older individuals are usually a sign of a pathologic condition. The pancreas undergoes structural changes, such as fibrosis, fatty acid deposits, and atrophy, and there is a decline in β -cell function.³⁰ Pancreatic secretion decreases, but there is usually no observable dysfunction.³¹ Aging does not cause apparent changes in the structure and function of the gallbladder and bile ducts, but the incidence of gallstones increases.³²

Summary Review

The Gastrointestinal Tract

1. The major functions of the gastrointestinal tract are the mechanical and chemical breakdown of food and the absorption of digested nutrients.
2. The gastrointestinal tract is a hollow tube that extends from the mouth to the anus.
3. The walls of the gastrointestinal tract have several layers: mucosa, muscularis mucosa, submucosa, muscularis (circular muscle and longitudinal muscle), and serosa (adventitia in the esophagus).
4. Except for swallowing and defecation, which are controlled voluntarily, the functions of the gastrointestinal tract are controlled by extrinsic autonomic nerves (vagus, parasympathetic splanchnic, and sympathetic nerves) and intrinsic autonomic nerves (enteric nervous system) and intestinal hormones.
5. Digestion begins in the mouth, with chewing and salivation. The digestive component of saliva is α -amylase, which initiates carbohydrate digestion.
6. The esophagus is a muscular tube that transports food from the mouth to the stomach. The muscularis in the upper part of the esophagus is striated muscle, and that in the lower part is smooth muscle.
7. Swallowing is controlled by the swallowing center in the reticular formation of the brain. The two phases of swallowing are the oropharyngeal phase (voluntary swallowing) and the esophageal phase (involuntary swallowing).
8. Food is propelled through the gastrointestinal tract by peristalsis: waves of sequential relaxations and contractions of the muscularis.
9. The lower esophageal sphincter opens to admit swallowed food into the stomach and then closes to prevent regurgitation

of food back into the esophagus.

10. The stomach is a baglike structure that secretes digestive juices, mixes and stores food, and propels partially digested food (chyme) into the duodenum. The smooth muscles of the stomach include the outer longitudinal, middle circular, and internal oblique.
11. The vagus nerve stimulates gastric (stomach) secretion and motility.
12. The hormones gastrin and motilin stimulate gastric emptying; the hormones secretin and cholecystokinin delay gastric emptying.
13. Gastric glands in the fundus and body of the stomach secrete intrinsic factor, which is needed for vitamin B₁₂ absorption, and hydrochloric acid, which dissolves food fibers, kills microorganisms, and activates the enzyme pepsin.
14. Chief cells in the stomach secrete pepsinogen, which is converted to pepsin in the acidic environment created by hydrochloric acid.
15. Acid secretion is stimulated by the vagus nerve, gastrin, and histamine and inhibited by sympathetic stimulation and cholecystokinin. Acetylcholine stimulates pepsin secretion.
16. Mucus is secreted throughout the stomach and protects the stomach wall from acid and digestive enzymes.
17. The three phases of acid secretion by the stomach are the cephalic phase (anticipation and swallowing), the gastric phase (food in the stomach), and the intestinal phase (chyme in the intestine).
18. The small intestine is 5 m long and has three segments: the duodenum, jejunum, and ileum. Digestion and absorption of all major nutrients and most ingested water occur in the small intestine.
19. The peritoneum is a double layer of membranous tissue. The visceral layer covers the abdominal organs, and the parietal layer extends along the abdominal wall.
20. Blood flow to the small intestine is primarily provided by the

superior mesenteric artery.

21. The duodenum receives chyme from the stomach through the pyloric valve. The presence of chyme stimulates the liver and gallbladder to deliver bile and the pancreas to deliver digestive enzymes and alkaline secretions. Bile and enzymes flow through an opening guarded by the sphincter of Oddi.
22. Bile is produced by the liver and is necessary for fat digestion and absorption. Bile's alkalinity helps neutralize chyme, thereby creating a pH that enables the pancreatic enzymes to digest proteins, carbohydrates, and sugars.
23. Enzymes secreted by the small intestine (maltase, sucrase, lactase), pancreatic enzymes (proteases, amylase, and lipase), and bile salts act in the small intestine to digest proteins, carbohydrates, and fats.
24. Digested substances are absorbed across the intestinal wall and then transported to the liver through the hepatic portal vein, where they are metabolized further.
25. The ileocecal valve connects the small and large intestines and prevents reflux into the small intestine.
26. Villi are small finger-like projections that extend from the small intestinal mucosa and increase its absorptive surface area.
27. Carbohydrates, amino acids, and fats are absorbed primarily by the duodenum and jejunum; bile salts and vitamin B₁₂ are absorbed by the ileum. Vitamin B₁₂ absorption requires the presence of intrinsic factor.
28. Bile salts emulsify and hydrolyze fats and incorporate them into water-soluble micelles that transport them through the unstirred layer to the brush border of the intestinal mucosa. The fat content of the micelles readily diffuses through the epithelium into lacteals (lymphatic ducts) in the villi. From there fats flow into the lymphatics and into the systemic circulation, which delivers them to the liver.
29. Minerals and water-soluble vitamins are absorbed by active and passive transport throughout the small intestine.

30. Peristaltic movements created by longitudinal muscles propel the chyme along the intestinal tract, whereas contractions of the circular muscles (segmentation) mix the chyme and promote digestion.
31. The ileogastric reflex inhibits gastric motility when the ileum is distended.
32. The intestinointestinal reflex inhibits intestinal motility when one intestinal segment is overdistended.
33. The gastroileal reflex increases intestinal motility when gastric motility increases.
34. The large intestine consists of the cecum, appendix, colon (ascending, transverse, descending, and sigmoid), rectum, and anal canal.
35. The teniae coli are three bands of longitudinal muscle that extend the length of the colon.
36. Haustra are pouches of colon that are formed with alternating contraction and relaxation of the circular muscles.
37. The mucosa of the large intestine contains mucus-secreting cells and mucosal folds, but no villi.
38. The large intestine massages the fecal mass and absorbs water and electrolytes.
39. Distention of the ileum with chyme causes the gastrocolic reflex, or the mass propulsion of feces to the rectum.
40. Defecation is stimulated when the rectum is distended with feces. The conically contracted internal anal sphincter relaxes and, if the voluntarily regulated external sphincter relaxes, defecation occurs.
41. The largest numbers of intestinal bacteria are in the colon. They are anaerobes consisting of *Bacteroides*, clostridia, coliforms, and lactobacilli.
42. The intestinal tract is sterile at birth and becomes totally colonized within 3 to 4 weeks.
43. Endogenous infections of the gastrointestinal tract occur by excessive proliferation of bacteria, perforation of the intestine, or contamination from neighboring structures.

Accessory Organs of Digestion

1. The liver is the largest organ in the body. It has digestive, metabolic, hematologic, vascular, and immunologic functions.
2. The liver is divided into the right and left lobes and is supported by the falciform, round, and coronary ligaments.
3. Liver lobules consist of plates of hepatocytes, which are the functional cells of the liver.
4. The hepatic artery supplies blood to the liver. The hepatic portal vein, formed by the confluence of superior mesenteric and splenic veins, receives blood from the inferior mesenteric, gastric, and cystic veins.
5. Hepatocytes synthesize 700 to 1200 mL of bile per day and secrete it into the bile canaliculi, which are small channels between the hepatocytes. The bile canaliculi drain bile into the common bile duct and then into the duodenum through an opening called the *major duodenal papilla (sphincter of Oddi)*.
6. Sinusoids are capillaries located between the plates of hepatocytes. Blood from the hepatic portal vein and hepatic artery flows through the sinusoids to a central vein in each lobule and then into the hepatic vein and inferior vena cava.
7. Kupffer cells, which are part of the mononuclear phagocyte system, line the sinusoids and destroy microorganisms in sinusoidal blood.
8. The primary bile acids are synthesized from cholesterol by the hepatocytes. The primary acids are then conjugated to form bile salts. The secondary bile acids are the product of bile salt deconjugation by bacteria in the intestinal lumen.
9. Most bile salts and acids are recycled. The absorption of bile salts and acids from the terminal ileum and their return to the liver are known as the *enterohepatic circulation of bile*.
10. Bilirubin is a pigment liberated by the lysis of aged red blood cells in the liver and spleen. Unconjugated bilirubin is fat soluble and can cross cell membranes. Unconjugated bilirubin is converted to water-soluble, conjugated bilirubin by

hepatocytes and is secreted with bile.

11. Fats are synthesized by the liver from protein and carbohydrates and include glycerol, free fatty acids, phospholipids, and cholesterol. Fat absorbed by intestinal lacteals is primarily triglyceride, which is hydrolyzed to glycerol and free fatty acid.
12. Protein synthesis by the liver requires all essential amino acids. The liver synthesizes albumin, globulin, and several serum enzymes and can convert amino acids to carbohydrates by removal of ammonia.
13. Carbohydrates can be released as glucose, stored as glycogen, or converted to fat.
14. The liver performs many metabolic functions including detoxification of exogenous and endogenous substances.
15. The gallbladder is a saclike organ located in the inferior surface of the liver. The gallbladder stores bile between meals and ejects it when chyme enters the duodenum.
16. Stimulated by cholecystokinin, the gallbladder contracts and forces bile through the cystic duct and into the common bile duct. The sphincter of Oddi relaxes, enabling bile to flow through the major duodenal papilla into the duodenum.
17. The pancreas is a gland located behind the stomach. The endocrine pancreas produces hormones (glucagon and insulin) that facilitate the formation and cellular uptake of glucose. The exocrine pancreas secretes an alkaline solution and the enzymes (trypsin, chymotrypsin, carboxypeptidase, α -amylase, lipase) that digest proteins, carbohydrates, and fats.
18. Secretin stimulates pancreatic secretion of alkaline fluid, and cholecystokinin and ACh stimulate secretion of enzymes. Pancreatic secretions originate in acini and ducts of the pancreas and empty into the duodenum through the common bile duct or an accessory duct that opens directly into the duodenum.

Tests of Digestive Function

1. Numerous diagnostic tests can evaluate structure and function (digestion, secretion, absorption) of the gastrointestinal tract. Radiographs and scans are most commonly used to evaluate structure, in addition to direct observation by endoscopy. Gastric and stool analysis and blood studies provide important information about digestion, absorption, and secretion.
2. Plasma chemistry levels and imaging procedures are commonly used to diagnose alterations in liver function. Of particular importance are the enzymes LDH, AST, and ALT. Plasma bilirubin levels reflect alterations in bilirubin and bile metabolism, and prothrombin times are prolonged in hepatitis and chronic liver disease.
3. Obstructive diseases of the gallbladder are evident by elevated serum bilirubin levels, elevated urine urobilinogen levels, and increased stool fat. The serum leukocyte levels become elevated with inflammation of the gallbladder.
4. The most significant indicators of pancreatic dysfunction are serum amylase and stool fat. Both values are increased with pathology of the pancreas.

Aging and the Gastrointestinal System

1. Advancing age is often associated with the loss or deterioration of teeth, diminished senses of taste and smell, and diminished salivary secretions, all of which may make eating difficult and reduce appetite.
2. Aging reduces gastric motility and secretions, particularly of hydrochloric acid. These changes slow gastric digestion and emptying.
3. Intestinal motility and absorption of carbohydrates, proteins, fats, and minerals decrease with age.
4. Efficiency of drug and alcohol metabolism decreases with age and can be related to decreased liver perfusion and decreased liver enzymes.

Key Terms

Alanine aminotransferase (ALT), 1312
Alkaline phosphatase, 1312
Ampulla of Vater, 1310
Antrum of stomach, 1296
Ascending colon, 1306
Aspartate aminotransferase (AST), 1312
Bile, 1310
Bile acid-dependent fraction, 1310
Bile acid-independent fraction, 1310
Bile acid pool, 1311
Bile canaliculi, 1310
Bile salt, 1310
Bilirubin, 1311
Biliverdin, 1311
Body of stomach, 1296
Brush border, 1301
Calcium, 1304
Carboxypeptidase, 1302
Cardiac orifice, 1296
Cecum, 1306
Cephalic phase of secretion, 1299
Chief cell, 1298
Cholecystokinin, 1314
Choleresis, 1311
Choleretic agent, 1311
Cholesterol esterase, 1303
Chylomicron, 1303
Chyme, 1296
Chymotrypsin, 1302
Colipase, 1303

Disorders of the gastrointestinal tract disrupt one or more of its functions. Structural and neural abnormalities can slow, obstruct, or accelerate the movement of intestinal content at any level of the gastrointestinal tract. Inflammatory and ulcerative conditions of the gastrointestinal wall disrupt secretion, motility, and absorption. Inflammation or obstruction of the liver, pancreas, or gallbladder can alter metabolism and result in local or systemic symptoms, or both. Many clinical manifestations of gastrointestinal tract disorders are nonspecific and can be caused by a variety of impairments. These manifestations are described in the following section.

Disorders of the Gastrointestinal Tract

Clinical Manifestations of Gastrointestinal Dysfunction

Anorexia

Anorexia is lack of a desire to eat despite physiologic stimuli that would normally produce hunger. Anorexia is a nonspecific symptom that is often associated with nausea, abdominal pain, diarrhea, psychologic distress, and aging. Side effects of drugs and disorders of other organ systems, including cancer, heart disease, and renal disease, are often accompanied by anorexia. Anorexia can lead to weight loss, sarcopenia, and functional decline and is often associated with cachexia.¹

Vomiting

Vomiting is the forceful emptying of stomach and intestinal contents through the mouth. The vomiting center, called *area postrema*, lies in the medulla oblongata and includes the reticular formation, tractus solitarius nucleus, and the parabrachial nucleus. Stimulation of the vomiting center occurs directly by irritants or indirectly. Indirect stimulation includes the cerebral cortex and thalamus (anxiety and pain); the vestibular system through the eighth cranial nerve (motion

sickness); several types of intestinal, vagal, or sympathetic input, including the presence of ipecac or copper salts in the duodenum; side effects of many drugs; distention of the stomach or duodenum; or torsion or trauma affecting the ovaries, testes, uterus, bladder, or kidney. Serotonin (5-hydroxytryptamine [5-HT]) stimulates the vomiting center and appears to be released from enterochromaffin cells in the intestinal wall, which activate vagal afferents leading to the chemoreceptor trigger zone (CTZ). Activation of the CTZ, which lies in the area postrema between the medulla and floor of the fourth ventricle, leads to vomiting by triggering receptors for substances such as dopamine (D₂), opioids, acetylcholine, substance P, serotonin (5-hydroxytryptamine type 3), and neurokinin-1. Serotonin and neurokinin-1 antagonists are effective antiemetics and have been used to treat nausea and vomiting associated with postoperative vomiting and cancer chemotherapy. Olanzapine is an antagonist to both serotonin and dopamine. Corticosteroids are usually given in combination with other therapies to prevent chemotherapy-induced nausea. Apomorphine, levodopa, and bromocriptine are dopamine D₂ agonists that cause nausea and vomiting. D₂ antagonists (metoclopramide, domperidone) are effective antiemetics.^{2,3}

Nausea and retching usually precede vomiting, although they are distinct entities. **Nausea** is a subjective experience that is associated with various conditions, including visceral pain, labyrinthine stimulation (i.e., motion), and use of opiate medications. Specific neural pathways have not been identified for nausea. Hypersalivation and tachycardia are common associated symptoms. **Retching** is the muscular event of vomiting without the expulsion of vomitus.

Vomiting begins with deep inspiration. The glottis closes, the intrathoracic pressure falls, and the esophagus becomes distended. Simultaneously, the abdominal muscles contract, creating a pressure gradient from abdomen to thorax. The lower esophageal sphincter and body of the stomach relax, but the duodenum and antrum of the stomach spasm. The reverse peristalsis and pressure gradient force chyme from the stomach and duodenum up into the esophagus. Because the upper esophageal sphincter is closed, chyme does not

enter the mouth. As the abdominal muscles relax, the contents of the esophagus drop back into the stomach. This process may be repeated several times before vomiting occurs. A diffuse sympathetic discharge causes the tachycardia, tachypnea, and sweating that accompany retching and vomiting. The parasympathetic system mediates copious salivation, increased gastric motility, and relaxation of the upper and lower esophageal sphincters.

With vomiting, the duodenum and antrum of the stomach produce retrograde peristalsis while the body of the stomach and the esophagus relax. When the stomach is full of gastric contents, the diaphragm is forced high into the thoracic cavity by strong contractions of the abdominal muscles. The higher intrathoracic pressure forces the upper esophageal sphincter to open, and chyme is expelled from the mouth. Then the stomach relaxes and the upper part of the esophagus contracts, forcing the remaining chyme back into the stomach. The lower esophageal sphincter then closes. The cycle is repeated if there is a volume of chyme remaining in the stomach.

Projectile vomiting is spontaneous vomiting that is not preceded by nausea or retching. It is caused by direct stimulation of the vomiting center by neurologic lesions (e.g., increased intracranial pressure, tumors, or aneurysms involving the brainstem [see [Chapters 17](#) and [20](#)]) or gastric outlet obstruction. The metabolic consequences of vomiting are fluid, electrolyte, and acid-base disturbances, including hyponatremia, hypokalemia, hypochloremia, and metabolic alkalosis (see [Chapter 3](#)).

Constipation

Constipation is difficult or infrequent defecation and is estimated to affect 2% to 28% of the population. Constipation must be individually defined because patterns of bowel evacuation differ greatly among individuals. Normal bowel habits range from two or three evacuations per day to one per week. Constipation is not significant until it causes health risks (e.g., severe abdominal distention or fecal impaction) or impairs quality of life.

◆Pathophysiology.

Constipation can occur as a primary or secondary condition. Primary constipation is generally classified into three categories. *Normal transit (functional) constipation* involves a normal rate of stool passage, but there is difficulty with stool evacuation. *Functional constipation* is most common and is associated with sedentary lifestyle, low-residue diet (the habitual consumption of highly refined foods), or low fluid intake, which decreases the volume and number of stools and can contribute to constipation. Lack of access to toilet facilities, consistent suppression of the urge to empty the bowel, and dehydration are other causes. *Slow-transit constipation* involves impaired colonic motor activity with infrequent bowel movements, straining to defecate, mild abdominal distention, and palpable stool in the sigmoid colon. *Pelvic floor dysfunction* (pelvic floor dyssynergia-anismus), or *outlet dysfunction*, is difficulty expelling stool because of failure of the pelvic floor muscles or anal sphincter to relax with defecation. Examples include pelvic floor dyssynergia, rectal fissures or fistula, strictures, or hemorrhoids.

Secondary constipation can be caused by diet, medications, or neurogenic disorders (e.g., stroke, Parkinson disease, spinal cord injury, multiple sclerosis, Hirschsprung disease) in which neurotransmitters or neural pathways are diseased or degenerated, resulting in delayed colon transit time. Antacids containing calcium carbonate or aluminum hydroxide; anticholinergics; iron; and bismuth tend to inhibit bowel motility. *Opioid-induced constipation* is caused by drugs that activate μ -opioid receptors in the gut. Endocrine or metabolic disorders associated with constipation include hypothyroidism, diabetes mellitus, hypokalemia, and hypercalcemia. Pelvic hiatal hernia (herniation of the bowel through the floor of the pelvis), diverticular disease, irritable bowel syndrome—constipation predominant, and pregnancy also are associated with constipation. Aging can result in constipation caused from changes in neurons in the myenteric plexus and decreased neurotransmitter function with decreased colon motility, use of medications, and comorbid medical conditions.⁴ Many mechanical conditions can slow intestinal transit

time. The abdominal muscles are normally used to create the intraabdominal pressure required to evacuate the rectum. Weakness or pain can interfere with the generation of adequate intraabdominal pressure. With the urge to defecate, the sphincter becomes hypertonic and the stool is not eliminated. Depression often impairs bowel evacuation, partly because depressed individuals tend to be sedentary and lack the motivation to eat a healthy diet. The problem is made worse if antidepressant drugs (e.g., anticholinergics) are used to treat the depression.

◆Clinical Manifestations.

Indicators of constipation include two of the following for at least 3 months: (1) straining with defecation at least 25% of the time, (2) lumpy or hard stools at least 25% of the time, (3) sensation of incomplete emptying at least 25% of the time, (4) manual maneuvers to facilitate stool evacuation for at least 25% of defecations, and (5) fewer than three bowel movements per week.⁵ Changes in bowel evacuation patterns, such as less frequent defecation, smaller stool volume, hard stools, difficulty passing stools (straining), or a feeling of bowel fullness and discomfort or blood in the stools, require investigation. Fecal impaction (hard, dry stool retained in the rectum) is associated with rectal bleeding, abdominal or cramping pain, nausea and vomiting, weight loss, and episodes of diarrhea. Compression of capillary perfusion in the intestinal wall can lead to ischemia and necrosis.⁶ Straining to evacuate stool may cause engorgement of the hemorrhoidal veins and hemorrhoidal disease or thrombosis with rectal pain, bleeding, and itching. Passage of hard stools can cause painful anal fissures.

◆Evaluation and Treatment.

The history, current use of medications, physical examination, and stool diaries provide precise clues regarding the nature of constipation. Sudden-onset constipation can accompany the development of colorectal cancer and requires careful evaluation. The individual's description of frequency, stool consistency, associated

pain, and presence of blood or whether evacuation was stimulated by enemas or cathartics (laxatives) is important. Cramping abdominal pain may be symptomatic of partial bowel obstruction. Palpation discloses colonic distention, masses, and tenderness. Blood may be caused by bleeding hemorrhoids or a neoplastic lesion of the colon.

Digital examinations of the rectum and anorectal manometry are performed to assess sphincter tone and detect anal lesions. Colonoscopy is performed with serious symptoms or for colon cancer screening. Colonic transit studies and imaging techniques can assist in identifying the etiology of constipation.

The treatment for constipation is to manage the underlying cause or disease for each individual. Management usually consists of bowel retraining, in which the individual establishes a satisfactory bowel evacuation routine without becoming preoccupied with bowel movements. Moderate exercise, increased fluid and fiber intake, bulking agents, stool softeners, and laxative agents (bisacodyl and senna) are useful and inexpensive for some individuals. Glycerine suppositories and enemas can be used to establish bowel routine, but they should not be used habitually. Biofeedback training may be effective for dyssynergic defecation.⁷ Drugs used to treat severe constipation include colonic secretagogues lubiprostone, linaclotide and plecanatide, and the 5-HT₄ agonist prucalopride. Peripherally acting μ -opioid receptor antagonists methylnaltrexone, naloxone, naloxegol, and alvimopan (for postoperative ileus) are used to treat opioid-induced constipation.⁸

Diarrhea

Diarrhea is the presence of loose, watery stools. Acute diarrhea is more than three loose stools developing within 24 hours and lasting less than 14 days. Persistent diarrhea lasts longer than 14 to 30 days and chronic diarrhea lasts longer than 30 days.^{9,10} Diarrhea can have high rates of morbidity and mortality in children less than 5 years of age, particularly in developing countries (see [Chapter 43](#)) and in the elderly. Many factors determine stool volume and consistency, including the water content of the colon, diet, the presence of

unabsorbed food, unabsorbable material, and intestinal secretions. Stool volume in the normal adult averages less than 200 g/day. Stool volume in children depends on age and size. An infant may pass up to 100 g/day. The adult intestine processes approximately 9 L of luminal contents per day; 2 L is ingested, and the remaining 7 L consists of intestinal secretions. Of this volume, 99% of the fluid is absorbed—90% (7 to 8 L) in the small intestine and 9% (1 to 2 L) in the colon. Normally, approximately 150 mL of water is excreted daily in the stool.

◆Pathophysiology.

Diarrhea in which the volume of feces is increased is called *large-volume diarrhea*. Large-volume diarrhea generally is caused by excessive amounts of water or secretions, or both, in the intestines. *Small-volume diarrhea*, in which the volume of feces is not increased, usually results from excessive intestinal motility.

The three major mechanisms of diarrhea are osmotic, secretory, and motility. (Specific mechanisms of diarrhea in children are described in [Chapter 43](#).)

In **osmotic diarrhea**, a nonabsorbable substance in the intestine draws water into the lumen by osmosis and increases stool weight and volume, producing large-volume diarrhea. Large oral doses of poorly absorbed ions, such as magnesium, sulfate, and phosphate, can increase intraluminal osmotic pressure. Excessive ingestion of synthetic, nonabsorbable sugars (e.g., sorbitol); introduction of full-strength tube feeding formulas; and dumping syndrome associated with gastric resection draw water into the intestinal lumen. Osmotic diarrhea disappears when ingestion of the osmotic substance stops. Malabsorption related to lactase deficiency, pancreatic enzyme or bile salt deficiency, small intestine bacterial overgrowth, or celiac disease also causes osmotic diarrhea.

Secretory diarrhea is a form of large-volume diarrhea caused by excessive mucosal secretion of chloride- or bicarbonate-rich fluid or inhibition of net sodium absorption. Infectious causes include viruses (e.g., rotavirus), bacterial enterotoxins (e.g., *Escherichia coli*, *Vibrio*

cholerae, Shiga toxin), or exotoxins from overgrowth of *Clostridium difficile* following antibiotic therapy or small bowel bacterial overgrowth. These infections cause secretion of transmitters from enteroendocrine cells (e.g., 5-HT) and activation of afferent neurons that stimulate submucosal secretomotor neurons and altered sodium and chloride transport resulting in decreased water absorption. Neoplasms (such as gastrinoma or thyroid carcinoma) produce hormones that stimulate intestinal secretion causing diarrhea.

Small-volume diarrhea usually is caused by an inflammatory disorder of the intestine, such as ulcerative colitis, Crohn disease, or microscopic colitis. Inflammation of the colon causes smooth muscle contraction, cramping pain, urgency, and frequency. Small-volume diarrhea also can be caused by fecal impaction, a severe form of constipation. This diarrhea consists of secretions (mucus and fluid) produced by the colon to lubricate the impacted feces and move it toward the anal canal. These secretions flow around the impaction and cause low-volume, secretory diarrhea.

Motility diarrhea is caused by resection of the small intestine (short bowel syndrome), surgical bypass of an area of the intestine, fistula formation between loops of intestine, irritable bowel syndrome—diarrhea predominant, diabetic neuropathy, hyperthyroidism, and laxative abuse. Excessive motility decreases transit time, mucosal surface contact, and opportunities for fluid absorption, resulting in diarrhea.

◆Clinical Manifestations.

Diarrhea can be acute or chronic, depending on its cause. Systemic effects of prolonged diarrhea are dehydration, electrolyte imbalance (hyponatremia, hypokalemia), metabolic acidosis, and weight loss. Manifestations of acute bacterial or viral infection include fever, with or without vomiting or cramping pain. Most infectious diarrhea usually lasts less than 2 weeks. The exceptions are *Clostridium difficile*, *Aeromonas*, and *Yersinia enterocolitica*. Fever, cramping pain, and bloody stools accompany chronic diarrhea caused by inflammatory bowel disease or dysentery. Steatorrhea (fat in the stools), bloating,

and diarrhea are common signs of malabsorption syndromes. Anal and perineal skin irritation can occur.

◆Evaluation and Treatment.

A thorough history is taken to document the onset, frequency, and volume of stools. Exposure to contaminated food or water is indicated if the individual has traveled in foreign countries or areas where drinking water might be contaminated. Iatrogenic diarrhea is suggested if the individual has undergone abdominal radiation therapy, intestinal resection, or treatment with selected drugs (e.g., antibiotics, diuretics, antihypertensives, or laxatives). Physical examination helps the clinician to identify underlying systemic disease. Stool culture, polymerase chain reaction, examination of stool specimens for blood, microscopy for protozoal infections, abdominal roentgenograms, endoscopy, and intestinal biopsies provide more specific data.¹¹

Treatment for diarrhea includes restoration of fluid and electrolyte balance, antimotility (e.g., loperamide [an opiate] or Lomotil [atropine]) and/or water-absorbent (e.g., attapulgit and polycarbophil) medications, and treatment of causal factors. Nutritional deficiencies need to be corrected in cases of chronic diarrhea or malabsorption. Natural bran and commercial preparations of psyllium are inexpensive and effective treatments for mild diarrhea. Probiotics can be useful for preventing and treating *Clostridium difficile*-associated diarrhea as an approach to restoring normal microflora in addition to antibiotic therapy.¹² Fecal transplantation can be used for cases that are resistant to conventional therapies, particularly *Clostridium difficile*-associated diarrhea.¹³

Abdominal Pain

Abdominal pain is the presenting symptom of a number of gastrointestinal (GI) diseases and can be acute or chronic. The pathophysiologic mechanisms are *mechanical*, *inflammatory*, or *ischemic*. Abdominal pain may be generalized to the abdomen or localized to a particular abdominal quadrant. The pain can be variably described as

sharp, dull, or colicky. Generally, the abdominal organs are not sensitive to mechanical stimuli, such as cutting, tearing, or crushing. These organs are, however, sensitive to stretching and distention, which activate nerve endings in both hollow and solid structures. The onset of pain is associated with rapid distention; gradual distention causes little pain. Traction on the peritoneum caused by adhesions, distention of the common bile duct, or forceful peristalsis resulting from intestinal obstruction causes pain because of increased tension. Capsules that surround solid organs, such as the liver and gallbladder, contain pain fibers that are stimulated by stretching if these organs swell.

Biochemical mediators of the inflammatory response, such as histamine, bradykinin, and serotonin, stimulate pain nerve endings and produce abdominal pain. The edema and vascular congestion that accompany chemical, bacterial, or viral inflammation also cause painful stretching. Obstruction of blood flow from the distention of bowel obstruction or mesenteric vessel thrombosis produces the pain of ischemia, and increased concentrations of tissue metabolites stimulate pain receptors.

Abdominal pain can be parietal (somatic), visceral, or referred. **Parietal pain** arises from the parietal peritoneum. This pain is more localized and intense than visceral pain, which arises from the organs themselves. Nerve fibers from the parietal peritoneum are predominantly A-delta fibers and travel with somatic peripheral nerves to the spinal cord. The sensation of pain corresponds to skin dermatomes T6 and L1. Parietal pain lateralizes because, at any particular point, the parietal peritoneum is innervated from only one side of the nervous system.

Visceral pain arises from a stimulus (distention, inflammation, ischemia) acting on mechanical and chemical nociceptors of abdominal organs. Chronic low-grade inflammation can cause pain hypersensitivity with involvement of neurokinins, histamine, serotonin, proteases, and voltage-gated ion channels.¹⁴ Pain is usually felt near the midline in the epigastrium, midabdomen, or lower abdomen because sensory afferents enter the spinal cord bilaterally

and lack side specificity. Visceral pain, compared to somatic pain, is poorly localized, dull rather than sharp, and difficult to describe. Visceral pain is diffuse and vague because nerve endings in abdominal organs are predominantly unmyelinated C fibers, sparse, and multisegmented. Pain arising from the stomach, for example, is experienced as a sensation of fullness, cramping, or gnawing in the midepigastic area. **Referred pain** is visceral pain felt at some distance from a diseased or an affected organ. Referred pain is usually well localized and is felt in the skin dermatomes or deeper tissues because visceral afferent neurons and regional somatic neurons converge on second-order neurons at the same level of the spinal cord. Gallbladder pain is, for example, referred to the right shoulder or scapulae.^{15,16}

Gastrointestinal Bleeding

Upper gastrointestinal (GI) bleeding is bleeding in the esophagus, stomach, or duodenum and is characterized by frank, bright red bleeding in emesis or dark, grainy digested blood (“coffee grounds”) in stool. Upper GI bleeding is caused by bleeding esophageal or gastric varices, a Mallory-Weiss tear at the esophageal-gastric junction from severe retching, cancer, arteriovenous malformations, or peptic ulcers and is associated with various drugs (nonsteroidal antiinflammatory drugs [NSAIDs]), aspirin, selective serotonin reuptake inhibitors, and antiplatelet and anticoagulant medications.¹⁷

Lower gastrointestinal (GI) bleeding is bleeding from the jejunum or ileum of the small intestine, colon, or rectum and can be caused by polyps, inflammatory bowel disease, diverticular disease, cancer, mucosal vascular ectasias, or hemorrhoids.¹⁸ **Occult bleeding** is usually caused by slow, chronic blood loss. It is not obvious and results in iron deficiency anemia as iron stores in the bone marrow are slowly depleted.

Physiologic response to gastrointestinal bleeding depends on the amount and rate of the loss (Fig. 42.1). Changes in blood pressure and heart rate are the best indicators of massive blood loss in the gastrointestinal tract. During the early stages of blood volume depletion, the peripheral arteries and arterioles constrict to maintain

blood pressure and shunt blood to vital organs, including the brain. Blood losses of 1000 mL or more over a short time cause a decrease in blood pressure and a corresponding increase in heart rate. With losses of 1000 mL or more, the heart rate is greater than 100 beats/minute and systolic blood pressure is less than 100 mmHg. Signs of large-volume blood loss are postural hypotension (a drop in blood pressure that occurs with a change from the recumbent position to a sitting or upright position), lightheadedness, and loss of vision. Tachycardia develops as a compensatory response to maintain cardiac output and tissue perfusion. If blood loss continues, hypovolemic shock develops. Diminished blood flow to the kidneys causes decreased urine output and may lead to oliguria (low urine output), tubular necrosis, and renal failure. Ultimately, insufficient cerebral and coronary blood flow causes irreversible anoxia and death.

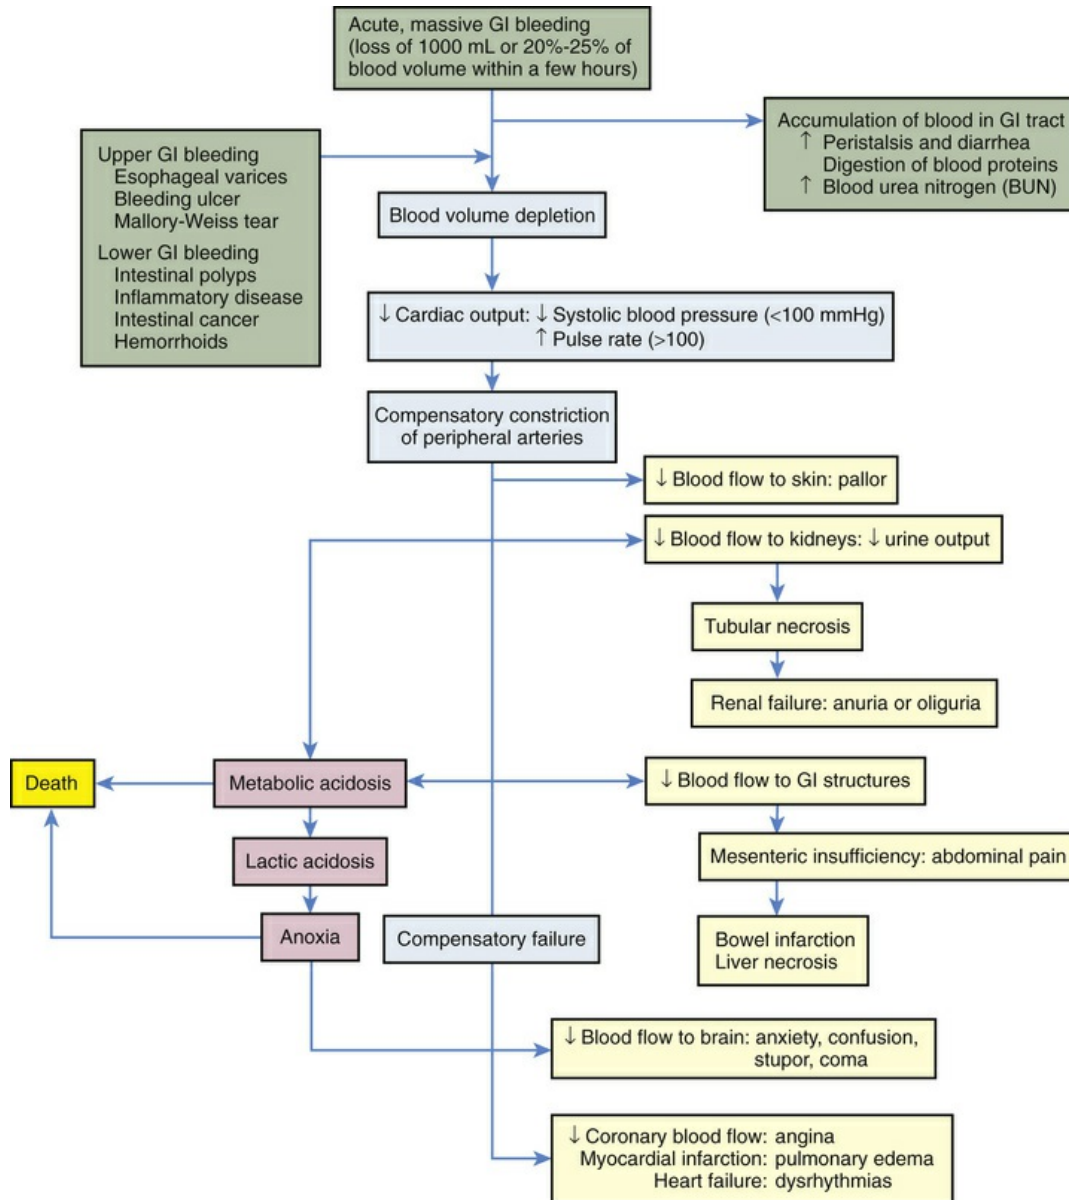

FIGURE 42.1 Pathophysiology of Gastrointestinal (GI) Bleeding.

The presentation of GI bleeding is summarized in [Table 42.1](#). Acute, severe GI bleeding is life threatening depending on the volume and rate of blood loss, associated disease, age, and effectiveness of treatment. The accumulation of blood in the gastrointestinal tract is irritating and increases peristalsis, causing vomiting (**hematemesis**) or diarrhea, or both. If bleeding is from the lower GI tract, the diarrhea is frankly bloody. Bleeding from the upper GI tract also can be rapid enough to produce bright red stools (**hematochezia**), but generally some digestion of the blood components will have occurred,

producing **melena**, black or tarry stools that are sticky and have a characteristic foul odor. The digestion of blood proteins originating from massive upper GI bleeding is reflected by an increase in blood urea nitrogen (BUN) levels (see Fig. 42.1).

TABLE 42.1

PRESENTATIONS OF GASTROINTESTINAL BLEEDING

PRESENTATION DEFINITION	
Acute Bleeding	
Hematemesis	Bloody vomitus; either fresh, bright red blood or dark, grainy, digested blood with “coffee grounds” appearance
Melena	Black, sticky, tarry, foul-smelling stools caused by digestion of blood in the gastrointestinal tract
Hematochezia	Fresh, bright red blood passed from the rectum
Occult Bleeding	Trace amounts of blood in normal-appearing stools or gastric secretions; detectable with a guaiac test

The hematocrit and hemoglobin values are not the best indicators of acute gastrointestinal bleeding because plasma and red cell volume are lost proportionately. As the plasma volume is replaced, the decreasing hematocrit and hemoglobin values begin to reflect the extent of blood loss. The interpretation of these values is modified to account for exogenous replacement of fluids and the hydration status of the tissues. Anemia associated with chronic GI bleeding is caused by iron depletion. Evaluation and treatment involve identifying and treating the source of the bleeding and replacing iron losses. Administration of blood products may be used for massive hemorrhage. Guidelines are available for the diagnosis and management of gastrointestinal bleeding.¹⁹⁻²¹

Disorders of Motility

Dysphagia

◆ Pathophysiology.

Dysphagia is difficulty swallowing or perception of obstruction during swallowing. Dysphagia can be classified as oropharyngeal or substernal/esophageal, depending on the location of the sensation. It can result from mechanical obstruction of the esophagus or a functional disorder that impairs esophageal motility. *Mechanical obstructions* can be intrinsic or extrinsic. Intrinsic obstructions originate in the wall of the esophageal lumen. Tumors, strictures, and diverticular herniations (outpouchings) are all causes of intrinsic mechanical obstruction. Extrinsic mechanical obstructions originate outside the esophageal lumen and narrow the esophagus by pressing inward on the esophageal wall. The most common cause of extrinsic mechanical obstruction is tumor.

Functional dysphagia is caused by neural or muscular disorders that interfere with voluntary swallowing or peristalsis. Disorders that affect the striated muscles of the upper esophagus interfere with the oropharyngeal (voluntary) phase of swallowing. Typical causes of functional dysphagia in the upper esophagus are dermatomyositis (a muscle disease) and neurologic impairments caused by stroke, multiple sclerosis, Parkinson disease, amyotrophic lateral sclerosis, or myasthenia gravis.²²

Achalasia is a rare disorder related to loss of inhibitory neurons in the myenteric plexus with smooth muscle atrophy in the middle and lower portions of the esophagus. The etiology is unknown but may be related to a cell-mediated and antibody-mediated immune response against an unknown antigen in myenteric neurons. There is loss of inhibitory myenteric innervation, loss of esophageal peristalsis, and failure of lower esophageal sphincter (LES) relaxation, thus causing functional obstruction of the lower esophagus. Food accumulates above the obstruction, distends the esophagus, and causes dysphagia. Cough and aspiration can occur. As hydrostatic pressure increases, food is slowly forced past the obstruction into the stomach. Chronic inflammation from esophageal food retention can increase risk for esophageal cancer.

◆Clinical Manifestations.

Clinical manifestations of dysphagia vary according to the location of the obstruction. Distention and spasm of the esophageal muscles during eating or drinking may cause a mild or severe stabbing pain at the level of obstruction. Discomfort occurring 2 to 4 seconds after swallowing is associated with upper esophageal obstruction. Discomfort occurring 10 to 15 seconds after swallowing is more common in obstructions of the lower esophagus. If the cause of obstruction is a growing tumor, dysphagia begins with difficulty swallowing solids and advances to difficulty swallowing semisolids and liquids. Retrosternal pain, regurgitation of undigested food, unpleasant taste, vomiting, and weight loss are common manifestations of all types of dysphagia. Aspiration of esophageal contents can lead to chronic cough and pneumonia.

◆Evaluation and Treatment.

Knowledge of the individual's history and clinical manifestations contributes significantly to a diagnosis of dysphagia. Videofluoroscopy and high-frequency ultrasound are used to visualize the contours of the esophagus and identify structural defects. High-resolution manometry with topography and intraluminal impedance monitoring documents motility disorders and the duration and amplitude of abnormal pressure changes associated with obstruction or loss of neural regulation. A video-modified barium swallow may be used for motility evaluation in oropharyngeal dysphagia. Esophageal endoscopy is performed to examine the esophageal mucosa, obtain biopsy specimens, or perform corrective surgery.²³

The individual is taught to manage symptoms by eating slowly, eating small meals, taking fluid with meals, and sleeping with the head elevated to prevent regurgitation and aspiration. Oral medications may need to be formulated so they can be swallowed. Tube feedings may be required for some individuals, particularly following stroke. Definitive treatments include dilation or surgical myotomy of the lower esophageal sphincter (LES) or botulinum toxin injection if surgery or dilation is not an option.²⁴

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is the reflux of acid and pepsin or bile salts from the stomach to the esophagus that causes **esophagitis**. The prevalence of GERD is estimated at 18% to 27% in North America.²⁵ Risk factors for GERD include obesity, hiatal hernia, and drugs or chemicals that relax the LES (anticholinergics, nitrates, calcium channel blockers, nicotine). GERD may be a trigger for asthma, chronic cough, or sinusitis.²⁶ Gastroesophageal reflux that does not cause symptoms is known as *physiologic reflux*. In *nonerosive reflux disease (NERD)*, individuals have symptoms of reflux disease but no visible or minimal esophageal mucosal injury (functional heartburn).²⁷

◆Pathophysiology.

Abnormalities in lower esophageal sphincter function, esophageal motility, and gastric motility or emptying can cause GERD. The resting tone of the LES tends to be lower than normal from either transient relaxation or weakness of the sphincter in those who develop GERD. Vomiting, coughing, lifting, bending, obesity, or pregnancy increases abdominal pressure, contributing to the development of reflux esophagitis. Hiatal hernia can weaken the LES. Delayed gastric emptying contributes to reflux esophagitis by (1) lengthening the period during which reflux is possible and (2) increasing the acid content of chyme. Disorders that delay emptying include gastroparesis; gastric or duodenal ulcers, which can cause pyloric edema; and strictures that narrow the pylorus.²⁸

The severity of the esophagitis depends on the composition of the gastric contents and esophageal mucosa exposure time. An acid pocket is an area of postprandial unbuffered gastric acid immediately distal to the gastroesophageal junction. It is enlarged in hiatal hernia and can contribute to GERD. If the gastric content is highly acidic or contains bile salts and pancreatic or intestinal enzymes, reflux esophagitis can be severe. In individuals with weak esophageal peristalsis, refluxed chyme remains in the esophagus longer than usual. This increases the amount of time the esophageal mucosa is

exposed to acids, enzymes, and bile. The refluxate causes mucosal injury and inflammation with hyperemia, increased capillary permeability, edema, tissue fragility, erosions, and ulcerations (Fig. 42.2). Fibrosis and thickening may develop. Precancerous lesions (Barrett esophagus, see the [Cancer of Gastrointestinal Tract](#) section) with progression to adenocarcinoma can be a long-term consequence.

FIGURE 42.2 Esophagitis with Esophageal Ulcerations.

◀Clinical Manifestations.

The clinical manifestations of reflux esophagitis are related to mucosal injury from acid regurgitation and the frequency and duration of reflux events. Manifestations include heartburn, chronic cough, asthma attacks ([Chapter 36](#)), laryngitis, sinusitis, and upper abdominal pain within 1 hour of eating. The symptoms worsen if the individual lies down or if intraabdominal pressure increases (e.g., as a result of coughing, vomiting, or straining at stool). Symptoms may be present when no acid is in the esophagus. Edema, fibrosis (strictures),

esophageal spasm, or decreased esophageal motility may result in dysphagia with weight loss. Alcohol or acid-containing foods, such as citrus fruits, can cause discomfort during swallowing.

◆Evaluation and Treatment.

Diagnosis of GERD is based on the history and clinical manifestations. Esophageal endoscopy shows hyperemia, edema, erosion, and strictures. Dysplastic changes (Barrett esophagus) can be identified by tissue biopsy. Impedance/pH monitoring measures the movement of stomach contents upward into the esophagus and the acidity of the refluxate.

Proton pump inhibitors are the agents of choice for controlling symptoms and healing esophagitis. Other therapies include histamine-2 (H₂) receptor antagonists, prokinetics, and antacids. Weight reduction, smoking cessation, elevation of the head of the bed 6 inches, and avoiding tight clothing also help to alleviate symptoms. Laparoscopic fundoplication is the most common surgical intervention when medical treatment fails.²⁹

Eosinophilic esophagitis is a rare, idiopathic inflammatory disease of the esophagus characterized by esophageal infiltration of eosinophils associated with atopic disease, including asthma and food allergies. It occurs in adults and children. Dysphagia, food impaction, vomiting, and weight loss are common symptoms. Endoscopy with biopsy identifies the eosinophilic infiltration and differentiation from GERD. Treatment is symptomatic, including elimination diets and topical corticosteroids. Proton pump inhibitors are effective for many individuals.³⁰

Hiatal Hernia

◆Pathophysiology.

Hiatal hernia is a type of diaphragmatic hernia with protrusion (herniation) of the upper part of the stomach through the diaphragm and into the thorax. There are four types: sliding (type I); paraesophageal (type II); and mixed (type III), which include elements

of types I and II (Fig. 42.3). In type IV the entire stomach and other abdominal organs slide into the thorax.³¹

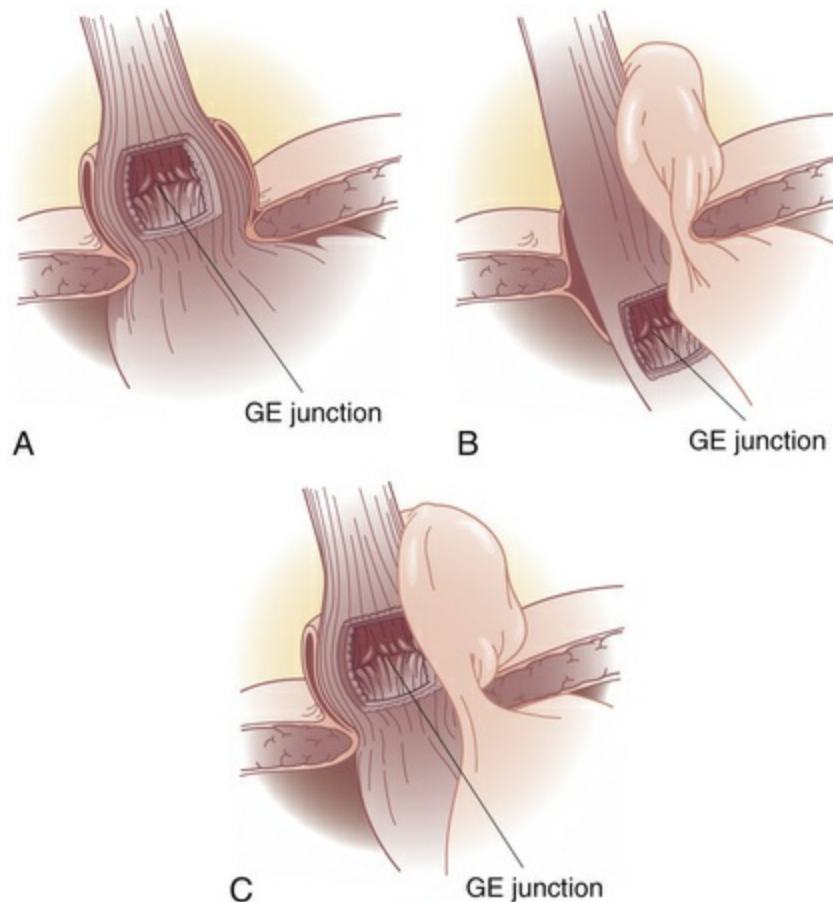

FIGURE 42.3 Three Types of Hiatal Hernia. A, Type I—*sliding hernia*. The visceral peritoneum remains intact and restrains the size of the hernia in sliding hiatal hernia. B, Type II—*paraesophageal or rolling hernia*. The membrane becomes thinner or defective in paraesophageal hernia, allowing a true peritoneal sac to protrude into the posterior mediastinum where negative intrathoracic pressure causes it to enlarge. C, Type III—*mixed hernia*. GE, Gastroesophageal. NOTE: Type IV—complex paraesophageal hernia is not shown. (From Townsend CM et al: *Sabiston textbook of surgery*, ed 19, Philadelphia, 2012, Saunders.)

In type I, **sliding hiatal hernia** (the most common type, 90% to 95%), the proximal portion of the stomach moves into the thoracic cavity through the esophageal hiatus, an opening in the diaphragm for the esophagus and vagus nerves. A congenitally short esophagus, fibrosis or excessive vagal nerve stimulation, or weakening of the diaphragmatic muscles at the gastroesophageal junction contributes to

the hernia. While the individual is in the supine position, the lower esophagus and stomach are pulled into the thorax. Standing causes the organs to “slide” back into the abdomen. Sliding hiatal hernia is exacerbated by factors that increase intraabdominal pressure, such as coughing, bending, wearing tight clothing, ascites, obesity, or pregnancy. This type of hernia is associated with gastroesophageal reflux because the hernia diminishes the resting pressure of the LES. In pregnant women with sliding hiatal hernia, progesterone and estrogen may lower the resting pressure of the LES further.

In type II, **paraesophageal hiatal hernia** (rolling hiatal hernia), herniation of the greater curvature of the stomach is through a secondary opening in the diaphragm (see [Fig. 42.3](#)). A giant paraesophageal hiatal hernia develops when 30% to 60% of the stomach moves into the thorax. As the stomach protrudes through the opening into the thorax, it lies alongside the esophagus. The gastroesophageal junction remains below the diaphragm. With paraesophageal hernia, reflux is uncommon. The position of a portion of the stomach above the diaphragm, however, causes congestion of mucosal blood flow and can lead to gastritis and ulcer formation. A mechanical strangulation of the hernia is a major complication, and surgical correction is required. Strangulation occludes blood vessels and causes vascular engorgement, edema, ischemia, and hemorrhage.

Type III, **mixed hiatal hernia**, is a combination of both types I and II and tends to occur in conjunction with several other diseases, including gastroesophageal reflux, peptic ulcer, cholecystitis (gallbladder inflammation), cholelithiasis (gallstones), chronic pancreatitis, and diverticulosis. Type IV is an aggravated form of type III and includes herniation of other abdominal viscera.

◆Clinical Manifestations.

Hiatal hernias are often asymptomatic. Generally, a wide variety of symptoms develop later in life and are associated with other gastrointestinal disorders, primarily GERD. Manifestations of the various types of hiatal hernia are difficult to distinguish. Symptoms include heartburn, regurgitation, dysphagia, and epigastric pain.

Ischemia from hernia strangulation causes acute, severe chest or epigastric pain, nausea, vomiting, and GI bleeding.

◆Evaluation and Treatment.

Diagnostic procedures include chest x-ray with oral barium, endoscopy, high-resolution manometry, and reflux monitoring. A chest x-ray often will show the protrusion of the stomach into the thorax, indicating paraesophageal hiatal hernia.

Treatment for sliding hiatal hernia is usually conservative. The individual can diminish reflux by eating small, frequent meals and avoiding the recumbent position after eating. Abdominal supports and tight clothing are avoided, and weight control is recommended for obese individuals. Proton pump inhibitors alleviate reflux esophagitis. Histamine 2 receptor agonists and antacids are less effective. Drugs that relax the LES (anticholinergic, nitrates, calcium channel blockers) are contraindicated because they delay gastric emptying. Laparoscopic surgery (i.e., laparoscopic fundoplication) may be performed for paraesophageal hiatal hernia or if medical management fails to control symptoms.³²

Gastroparesis is delayed gastric emptying in the absence of mechanical gastric outlet obstruction. It is most commonly associated with diabetes mellitus, surgical vagotomy, or fundoplication. It can be idiopathic. The pathophysiology is not well understood but involves abnormalities of the autonomic nervous system, smooth muscle cells, enteric neurons, and gastrointestinal hormones. Diabetic gastroparesis represents a form of neuropathy involving the vagus nerve and loss of interstitial cells of Cajal. Symptoms include nausea, vomiting, abdominal pain, postprandial fullness or bloating, and weight loss. Treatment options include dietary management; prokinetic drugs; and, in some cases, gastric electrical stimulation and/or pyloroplasty or surgical venting gastrostomy.³³

Pyloric Obstruction

◆Pathophysiology.

Pyloric obstruction (gastric outlet obstruction) is the narrowing or blocking of the opening between the stomach and the duodenum. This condition can be congenital (i.e., infantile hypertrophic pyloric stenosis, see [Chapter 43](#)) or acquired. Acquired obstruction is caused by peptic ulcer disease or carcinoma near the pylorus. Duodenal ulcers are more likely than gastric ulcers to obstruct the pylorus. Ulceration causes obstruction resulting from inflammation, edema, spasm, fibrosis, or scarring. Tumors cause obstruction by growing into the pylorus.

◆Clinical Manifestations.

Early in the course of pyloric obstruction, the individual experiences vague epigastric fullness, which becomes more distressing after eating and later in the day. Nausea and epigastric pain may occur as the muscles of the stomach contract in attempts to force chyme past the obstruction. These symptoms disappear when the chyme finally moves into the duodenum. As obstruction progresses, anorexia develops, sometimes accompanied by weight loss. Severe obstruction causes gastric distention and atony (lack of muscle tone and gastric motility). Gastric distention stimulates gastric secretion, which increases the feeling of fullness. Rolling or jarring of the abdomen produces a sloshing sound called the *succussion splash*. At this stage, vomiting is a cardinal sign of obstruction. It is usually copious and occurs several hours after eating. The vomitus contains undigested food but no bile. Prolonged vomiting leads to dehydration, which is accompanied by a hypokalemic and hypochloremic metabolic alkalosis caused by the respective loss of gastric potassium and acid. Because food does not enter the intestine, stools are infrequent and small. Prolonged pyloric obstruction causes severe malnutrition and dehydration.

◆Evaluation and Treatment.

Diagnosis is based on clinical manifestations, a history of peptic ulcer disease, and examination of residual gastric contents. Endoscopy is performed if gastric carcinoma is the suggested cause of pyloric

obstruction.

Obstructions resulting from ulceration often resolve with conservative management. A large-bore nasogastric tube is used to aspirate stomach contents and relieve distention. Nasogastric suction is then maintained for 2 to 3 days to decompress the stomach and restore normal motility. Gastric secretions that contribute to inflammation and edema can be suppressed with proton pump inhibitors or histamine-2 (H₂) receptor antagonists. Fluids and electrolytes (saline and potassium) are given intravenously to effect rehydration and correct hypochloremia, alkalosis, and hypokalemia (see [Chapter 3](#)). Severely malnourished individuals may require parenteral hyperalimentation (intravenous nutrition). Surgery or stenting may be required to treat gastric carcinoma or persistent obstruction caused by fibrosis and scarring.³⁴

Intestinal Obstruction and Paralytic Ileus

Intestinal obstruction can be caused by any condition that prevents the normal flow of chyme through the intestinal lumen or failure of normal intestinal motility in the absence of an obstructing lesion (ileus) ([Table 42.2](#)). Obstructions can occur in either the small or the large intestine. The small intestine is more commonly obstructed because of its narrower lumen. Classifications of intestinal obstruction are summarized in [Table 42.3](#). Intestinal obstruction is classified by cause as simple or functional. *Simple obstruction* is mechanical blockage of the lumen by a lesion, but blood flow is preserved. It is the most common type of intestinal obstruction. In a *strangulated obstruction*, blood flow is compromised, leading to intestinal ischemia and, if left untreated, necrosis and perforation. **Paralytic ileus**, or *functional obstruction*, is a failure of motility after intestinal or abdominal surgery, acute pancreatitis, or hypokalemia. Anesthetic agents, local inflammatory reactions, use of opioid analgesia, and hyperactivity of the sympathetic nervous system contribute to postoperative ileus.

TABLE 42.2

COMMON CAUSES OF INTESTINAL OBSTRUCTION

CAUSE	PATHOPHYSIOLOGY
Herniation	Protrusion of the intestine through a weakness in the abdominal muscles or through the inguinal ring
Intussusception	Telescoping of one part of the intestine into another; this usually causes strangulation of the blood supply; more common in the ileocecal area in infants 10 to 15 months of age than in adults
Torsion (volvulus)	Twisting of the intestine on its mesenteric pedicle, with occlusion of the blood supply; often associated with fibrous adhesions in the small intestine; occurs most often in the large intestine in older adults
Diverticulosis	Inflamed saccular herniations (diverticula) of the mucosa and submucosa through the tunica muscularis of the colon; diverticula are interspersed between thick, circular, fibrous bands; most common in obese individuals older than 60 years
Tumor	Tumor growth into the intestinal lumen; adenocarcinoma of the colon and rectum is the most common tumoral obstruction; most common in individuals older than 60 years
Paralytic (adynamic) ileus	Loss of peristaltic motor activity in the intestine; associated with abdominal surgery, peritonitis, hypokalemia, ischemic bowel, spinal trauma, pneumonia, neuropathies, or myopathies; affects small and large intestines
Fibrous adhesions	Peritoneal irritation from surgery or trauma leads to formation of fibrin and adhesions that attach to intestine, omentum, or peritoneum and can cause traction and obstruction; most common in small intestine

TABLE 42.3

CLASSIFICATION OF INTESTINAL OBSTRUCTION

CRITERIA FOR CLASSIFICATION	DEFINITION
Onset	
Acute	Sudden onset; often caused by torsion, intussusception, or herniation
Chronic	Protracted onset; more commonly from tumor growth or progressive formation of strictures
Extent of Obstruction	
Partial	Incomplete obstruction of intestinal lumen
Complete	Complete obstruction of intestinal lumen
Location of Obstructing Lesion (Small Intestine or Colon)	
Intrinsic	Obstruction develops within intestinal lumen; examples: luminal edema or hemorrhage, foreign bodies (gallstones), tumors, intussusception, or intraluminal fibrosis

Extrinsic	Obstruction originates outside the intestine; examples: tumors, torsion, fibrosis, hernia
Effects on Intestinal Wall	
Simple	Luminal obstruction without impairment of blood supply
Strangulated	Luminal obstruction with occlusion of blood supply
Closed loop	Obstruction at each end of a segment of the intestine
Causal Factors	
Mechanical	Blockage of the intestinal lumen by intrinsic or extrinsic lesions; usually treated surgically
Functional (paralytic ileus)	Paralysis of the intestinal musculature as a result of accidental or surgical trauma, peritonitis, electrolyte imbalances, or spasmolytic agents; usually treated medically

Simple obstruction of the small intestine from fibrous adhesions is the most common type of intestinal obstruction. Acute obstructions usually have mechanical causes, such as adhesions or hernias (Fig. 42.4). Chronic or partial obstructions are more often associated with tumors or inflammatory disorders, particularly of the large intestine.³⁵

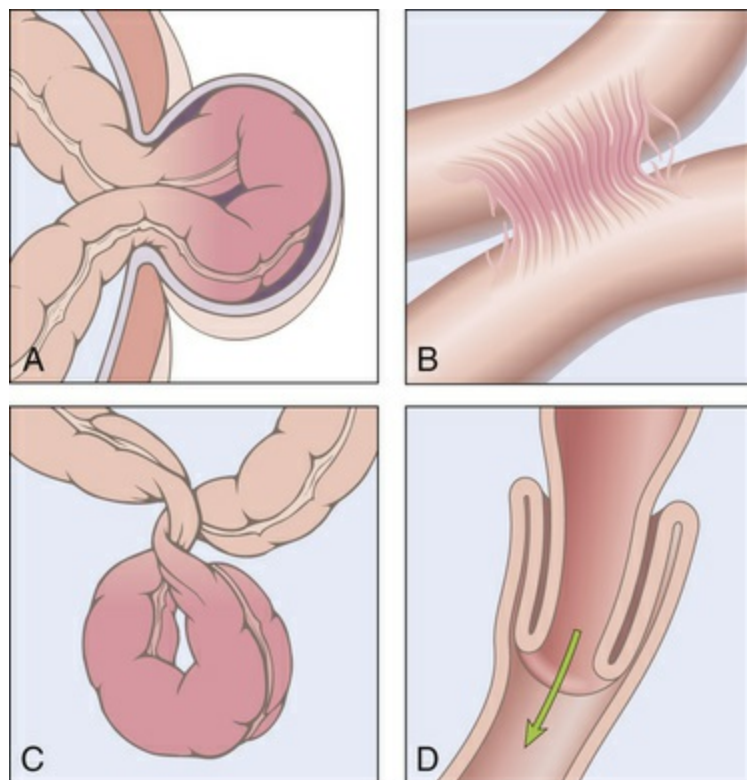

FIGURE 42.4 Intestinal Obstructions. A, Hernia. B, Constriction from

adhesions. C, Volvulus. D, Intussusception. (From Kumar V, Abbas AK, Aster J: *Robbins basic pathology*, ed 9, Philadelphia, 2013, Saunders.)

◆Pathophysiology.

The consequences of intestinal obstruction are related to its onset and location, the length of intestinal tract proximal to the obstruction, and the presence and severity of ischemia. The major pathophysiologic alterations are presented in Fig. 42.5. Postoperative paralytic ileus results from inhibitory neural reflexes associated with inflammatory mediators, and the influence of exogenous (meperidine or morphine) and endogenous opioids (endorphins) that affect the entire GI tract, including the stomach.³⁶ **Small bowel obstruction (SBO)** is caused by postoperative adhesions (66%), tumors, Crohn disease, hernias, and intussusception. SBO leads to distention caused by impaired absorption and increased secretion with the accumulation of fluid and gas inside the lumen proximal to the obstruction. Distention decreases the intestines' ability to absorb water and electrolytes and increases the net secretion of these substances into the lumen. Gas from swallowed air, and to a lesser extent from bacterial overgrowth, contributes to the distention. Distention begins almost immediately, as gases and fluids accumulate proximal to the obstruction. Within 24 hours, up to 8 L of fluid and electrolytes enters the lumen in the form of saliva, gastric juice, bile, pancreatic juice, and intestinal secretions. Distention initially increases peristalsis and then leads to decreased peristalsis and bacterial overgrowth. Copious vomiting or sequestration of fluids in the intestinal lumen prevents fluid reabsorption and produces severe fluid and electrolyte disturbances. Extracellular fluid volume and plasma volume decrease, causing dehydration. Hemoconcentration (decreased plasma volume) causes elevated hematocrit level, hypotension, and tachycardia. Severe dehydration leads to hypovolemic shock.

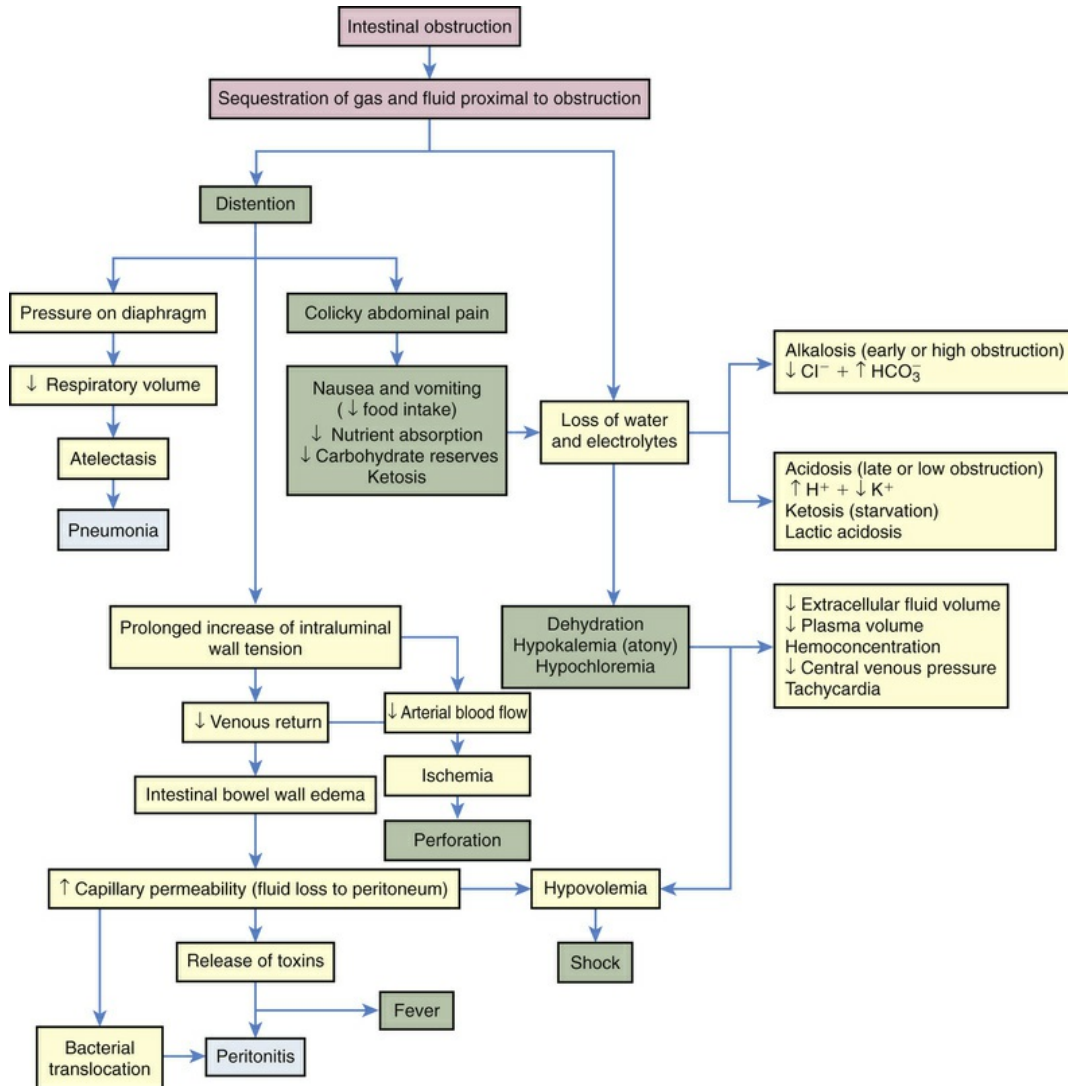

FIGURE 42.5 Pathophysiology of Intestinal Obstruction.

If the obstruction is at the pylorus or high in the small intestine, metabolic alkalosis develops initially as a result of excessive loss of hydrogen ions that normally would be reabsorbed from the gastric juice and vomiting. With prolonged obstruction or obstruction lower in the intestine, metabolic acidosis is more likely to occur because bicarbonate from pancreatic secretions and bile cannot be reabsorbed. Hypokalemia from vomiting and decreased potassium absorption can be extreme, promoting acidosis and atony of the intestinal wall. Metabolic acidosis also may be accentuated by ketosis, the result of declining carbohydrate stores caused by starvation. Lack of circulation permits the buildup of significant amounts of lactic acid, which

worsen the metabolic acidosis. If pressure from the distention is severe enough, it occludes venous drainage and the arterial circulation, causing ischemia, necrosis, perforation, and peritonitis. Fever and leukocytosis are often associated with overgrowth of bacteria, ischemia, and bowel necrosis. Bacterial proliferation and translocation across the mucosa to the mesenteric lymph nodes or systemic circulation cause sepsis. The release of inflammatory mediators and toxins into the circulation causes multiple organ failure (see [Chapter 49](#)).

Large bowel obstruction is less common and often related to carcinoma. Diverticulitis, inflammatory bowel disease, volvulus, and other causes of obstruction are less common. **Acute colonic pseudo-obstruction (Ogilvie syndrome)** is a rare functional, massive dilation of the large bowel that is related to excessive sympathetic motor input or decreased parasympathetic motor input with absence of mechanical obstruction. It occurs primarily in people who are critically ill and immobilized older adults.³⁷

◆Clinical Manifestations.

Signs and symptoms of *small intestine obstruction* include colicky pains caused by intestinal distention followed by nausea and vomiting. Pain intensifies for seconds or minutes as a peristaltic wave of muscle contraction meets the obstruction. Pain may be continuous with severe distention and then diminish in intensity. If ischemia occurs, the pain loses its colicky character, becoming more constant and severe. Sweating and tachycardia occur as a sympathetic nervous system response to hypotension. Fever, severe leukocytosis, abdominal distention, and rebound tenderness develop as ischemia progresses to necrosis, perforation, and peritonitis.

Obstruction at the pylorus causes early, profuse vomiting of clear gastric fluid. Obstruction in the proximal small intestine causes mild distention and vomiting of bile-stained fluid. Obstruction in the distal small intestine causes more pronounced distention because a greater length of intestine is proximal to the obstruction. In this case, vomiting may not occur or may occur later and contain fecal material. Partial

obstruction can cause diarrhea or constipation, but complete obstruction usually causes constipation only. Complete obstruction increases the number of bowel sounds, which may be tinkly and accompanied by peristaltic rushes and crampy, abdominal pain. Signs of hypovolemia and metabolic acidosis may be observed as early as 24 hours after the occurrence of complete obstruction. Distention may be severe enough to push against the diaphragm and decrease lung volume. This can lead to atelectasis and pneumonia, particularly in debilitated individuals.

Large intestine obstruction usually presents with hypogastric pain and abdominal distention. Pain can vary from vague to excruciating, depending on the degree of ischemia and the development of peritonitis. Vomiting occurs late in the obstructive process. Small and large intestinal perforation presents the same with acute, persistent abdominal pain, nausea, vomiting, and fever.³⁸ *Acute colonic pseudo-obstruction* is characterized by abdominal distention, abdominal pain, and nausea and vomiting without any mechanical cause. Bowel sounds are usually present.

◆Evaluation and Treatment.

Evaluation is based on clinical manifestations and imaging studies. Successful management requires early identification of the site and type of obstruction. Replacement of fluid and electrolytes and decompression of the lumen with gastric or intestinal suction are essential forms of therapy. Laparoscopic procedures can release adhesions. Immediate surgical intervention is required for strangulation and complete obstruction or perforation. Colonic stents may be placed for malignant obstruction. Neostigmine, a parasympathomimetic, is used for colonic pseudo-obstruction, and colonoscopic decompression may be required.³⁹ Management of intestinal perforation requires intravenous antibiotics, fluid resuscitation, and surgery related to the underlying cause of perforation.³⁸

Gastritis

Gastritis is an inflammatory disorder of the gastric mucosa. It can be acute or chronic and can affect the corpus, fundus or antrum, or the entire mucosa (pangastritis).

Acute gastritis is caused by injury of the protective mucosal barrier by drugs, chemicals, or *Helicobacter pylori* infection (Fig. 42.6). Mucosal lesions can be superficial or deep erosions with or without hemorrhage. Nonsteroidal antiinflammatory drugs (NSAIDs [e.g., ibuprofen, naproxen, indomethacin, and aspirin]) inhibit the action of cyclooxygenase-1 (COX-1) and cause gastritis because they inhibit prostaglandin synthesis, which normally stimulates the secretion of mucus and suppresses inflammation. With the exception of aspirin, NSAIDs also cause gastric hypermotility, causing mucosal compression and injury. Alcohol, histamine, and metabolic disorders, such as uremia, are contributing factors. *H. pylori*-associated acute gastritis causes inflammation, increased gastric secretion in antral gastritis, decreased gastric secretion in fundal gastritis, pain, nausea, and vomiting (Box 42.1). Shock and hypotension can decrease mucosal blood flow contributing to acute gastritis.

FIGURE 42.6 Acute Erosive Gastritis. Acute erosive gastritis is shown in the opened stomach. The mucosa appears hyperemic, and the foci of superficial ulceration are manifested as scattered, small, red areas termed *erosions*. (From Kumar V et al: *Pathologic basis of disease*, ed 7, Philadelphia, 2006, Saunders.)

Box 42.1

Pathogenesis of *Helicobacter pylori*-Related Disease

H. pylori is a gram-negative spiral bacterium with a flagellum and is a major cause of acute and chronic gastritis, peptic ulcer disease in the duodenum and stomach, gastric adenocarcinoma, and gastric mucosa-associated lymphoid tissue (MALT) in about 20% of infected individuals. *H. pylori* is transmitted through the fecal-oral route and is usually acquired in childhood. Infection is asymptomatic in about 70% of cases. In other cases, inflammation and immune responses promote mucosal ulcerations or prevent healing of injured tissue. Gene-environment interaction and different pathogenic strains of *H. pylori* increase risk for disease. Patterns of gastritis and disease progression vary by site of infection and strain of *H. pylori*. Pathogenic and virulence factors include the following:

1. An ability to colonize and adhere to gastric epithelial cells
2. The possession of flagella, which allows movement through the luminal mucous layer to a site of higher pH
3. A lipopolysaccharide membrane component evades immune protection and promotes inflammation
4. Secretion of urease that produces ammonia and carbon dioxide, resulting in a more alkaline environment
5. Release of vacuolating cytotoxin (*VacA*) that promotes bacterial survival and causes epithelial injury
6. The presence of cytotoxin-associated gene (*CagA*) strains that can escape normal immune responses and cause inflammation with release of inflammatory cytokines and reactive oxygen metabolites that damage mucosal epithelial cells and cause loss of the protective mucosal barrier; they also promote tumor development by degrading *tp53* tumor suppression

7. An ability of adherent strains to suppress acid secretion to improve their survival, particularly *CagA* and *VacA* strains
8. Recruitment and activation of neutrophils, macrophages, and mast cells with release of inflammatory cytokines (tumor necrosis factor-alpha [TNF- α], interleukin-1 [IL-1], IL-6, IL-8, IL-17, histamine) that promote cellular injury
9. Downregulation of antral somatostatin leading to increased gastrin, increased acid, impaired mucosal bicarbonate production, and increased mucosal exposure to acid and pepsin
10. Activation or inhibition of T- and B-cell immune responses that may contribute to mucosal injury
11. Release of cytokines and chemokines that promote gastric epithelial cell death (apoptosis) that can result in atrophy, ulcers or cell proliferation, and dysplasia or malignant growth

Data from Amieva M, Peek RM Jr: *Gastroenterology* 150(1):64-78, 2016; Backert S et al: *Helicobacter* 21 Suppl 1:19-25, 2016; Li H et al: *Helicobacter* 21(6):445-461, 2016; Tohidpour A: *Microb Pathog* 93:44-55, 2016.

The clinical manifestations of acute gastritis can include vague abdominal discomfort, epigastric tenderness, and bleeding. Healing usually occurs spontaneously within a few days. Discontinuing injurious drugs, using antacids, decreasing acid secretion with a histamine H₂-receptor antagonist, or proton pump inhibitor also promote healing.

Chronic gastritis can occur at any age and involves chronic inflammation, mucosal atrophy, and epithelial metaplasia that progresses over years.⁴⁰ Chronic gastritis is usually classified as type A, or immune (fundal), or type B, nonimmune (antral) associated with *H. pylori*. When both types of chronic gastritis occur, it is known as *type AB*, or *pangastritis*, and the antrum is more severely involved. Type C gastritis is associated with reflux of bile and pancreatic secretions into the stomach, causing chemical injury.

Chronic fundal gastritis, or type A, is the most rare and severe form of

gastritis and is associated with loss of T-cell tolerance and development of autoantibodies against parietal cells or intrinsic factor, or both, with gastric H⁺-K⁺-ATPase protein as the causal antigen. The gastric mucosa degenerates extensively in the body and fundus of the stomach, leading to gastric atrophy. Loss of parietal cells leads to achlorhydria and loss of intrinsic factor. Pernicious anemia can develop from decreased vitamin B₁₂ absorption (see [Chapter 29](#)). Because acid secretion is insufficient, the feedback mechanism that normally inhibits gastrin secretion is impaired, causing elevated plasma levels of gastrin. Chronic fundal gastritis occurs in association with other autoimmune diseases (e.g., rheumatoid arthritis, autoimmune thyroid disease, or type 1 diabetes mellitus) and is a risk factor for gastric carcinoma, particularly in individuals who develop pernicious anemia.

Type B chronic nonimmune (antral gastritis) generally involves the antrum only and is more common than fundal gastritis. Infection with *H. pylori* may trigger the immune response through molecular mimicry (a mechanism of autoimmune disease with similarities between foreign and self-antigens sufficient to result in cross-activation of autoreactive T or B cells)⁴¹ or by causing mucosal injury and exposure of gastric H⁺-K⁺-ATPase protein.⁴² Chronic use of alcohol, tobacco, and nonsteroidal antiinflammatory drugs are contributing factors. There are high levels of hydrochloric acid secretion with an increased risk of duodenal ulcers. *H. pylori* can also progress to autoimmune atrophic gastritis and involve the fundus, thus becoming pangastritis.⁴⁰

Signs and symptoms of chronic gastritis often include vague symptoms such as anorexia, fullness, nausea, vomiting, and epigastric pain. Gastric bleeding may be the only clinical manifestation of gastritis. Gastroscopic examination and biopsy may show a long-standing inflammatory process and gastric atrophy in an individual with no history of abdominal distress. Gastric secretion analysis confirms achlorhydria and loss of intrinsic factor. Pernicious anemia can develop because intrinsic factor is less available to facilitate vitamin B₁₂ absorption. There also may be iron deficiency. The

presence of antiparietal cell antibody and elevated plasma ghrelin level are specific for atrophic gastritis. *H. pylori* infection is evidence for *H. pylori* chronic gastritis with infiltration of neutrophils and lymphocytes. Both invasive and noninvasive diagnostic tests are available. Surveillance for gastric carcinoma is recommended with chronic atrophic gastritis and *H. pylori* infection.⁴³

Symptoms can usually be managed with consumption of smaller meals, including a soft, bland diet, and with avoidance of alcohol and NSAIDs. Combination antibiotics are used to eradicate *H. pylori*, and the emergence of antimicrobial resistance is a concern.⁴⁴ Vitamin B₁₂ is administered to correct pernicious anemia (see [Chapter 29](#)).

Alkaline reflux gastritis is a stomach inflammation caused by reflux of bile and alkaline pancreatic secretions that contain proteolytic enzymes and disrupt the mucosal barrier in the remnant stomach. This form of gastritis occurs in 5% to 20% of individuals who have undergone gastrectomy, pyloroplasty, or pancreaticoduodenectomy. Clinical manifestations include nausea, bilious vomiting (vomiting in which the vomitus contains bile), and sustained epigastric pain that worsens after eating and is not relieved by antacids. Endoscopy shows a hemorrhagic and friable gastric mucosa. Antacids do not consistently improve symptoms. Avoidance of aspirin and alcohol may decrease gastric irritation, and a low-fat diet may limit bile secretion. Surgical correction may ultimately be required.⁴⁵

Peptic Ulcer Disease

A **peptic ulcer** is a break, or ulceration, in the protective mucosal lining of the lower esophagus, stomach, or duodenum. The prevalence of peptic ulcer in 2011 in the United States was estimated at 15.5 million people.⁴⁶ Risk factors for peptic ulcer disease include genetic predisposition, *H. pylori* infection of the gastric mucosa (see [Box 42.1](#)), and habitual use of aspirin and NSAIDs. Additional factors include excessive use of alcohol, smoking, acute pancreatitis, chronic obstructive pulmonary disease, obesity, cirrhosis, age greater than 65 years, and socioeconomic status.^{47,48} Psychologic stress contributes to

risk for peptic ulcer disease but the exact mechanism of causation is not known.^{49,50} Peptic ulcers also can be idiopathic or caused by gastrinoma.

Peptic ulcers can be single or multiple, acute or chronic, and superficial or deep. Superficial ulcerations are called *erosions* because they erode the mucosa but do not penetrate the muscularis mucosae (Fig. 42.7). True ulcers extend through the muscularis mucosae and damage blood vessels, causing hemorrhage or perforating the gastrointestinal wall.

FIGURE 42.7 Chronic Peptic Ulcer. Gross photograph of a chronic peptic ulcer located in the lesser curvature, straddling the antrum and corpus of the stomach. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Chronic use of NSAIDs suppresses mucosal prostaglandin synthesis, resulting in decreased bicarbonate secretion and mucin (a component of the gut barrier) production and increased secretion of hydrochloric acid. The interaction of NSAIDs and *H. pylori* can contribute to the pathogenesis of peptic ulcer. Disruption of the mucosa exposes submucosal areas to gastric secretions and autodigestion, causing erosion and ulceration.

Zollinger-Ellison syndrome is a rare syndrome also associated with peptic ulcers caused by a gastrin-secreting neuroendocrine tumor or multiple tumors (gastrinoma) of the pancreas or duodenum. Gastrin

stimulates a proliferation of gastric parietal cells and chronic secretion of gastric acid. The resulting excess acid causes gastric and duodenal ulcers, gastroesophageal reflux with abdominal pain, and diarrhea. Diagnosis includes secretin- or calcium-stimulated measures of gastrin levels, gastric pH levels less than 2, and symptomatic evidence of peptic ulcer disease. Proton pump inhibitors reduce gastric acid secretion, and surgical removal of tumors limits metastasis.⁵¹

Duodenal Ulcers

Duodenal ulcers occur with greater frequency than other types of peptic ulcers and are commonly caused by *H. pylori* infection and NSAID use.⁵² Idiopathic duodenal ulcers are rare and can be associated with altered mucosal defenses, rapid gastric emptying, elevated serum gastrin levels, or acid production stimulated by smoking.⁵³

◆Pathophysiology.

Causative factors, singly or in combination, cause acid and pepsin concentrations in the duodenum to penetrate the mucosal barrier and lead to ulceration (Fig. 42.8). Acid in the duodenum facilitates *H. pylori* infection.

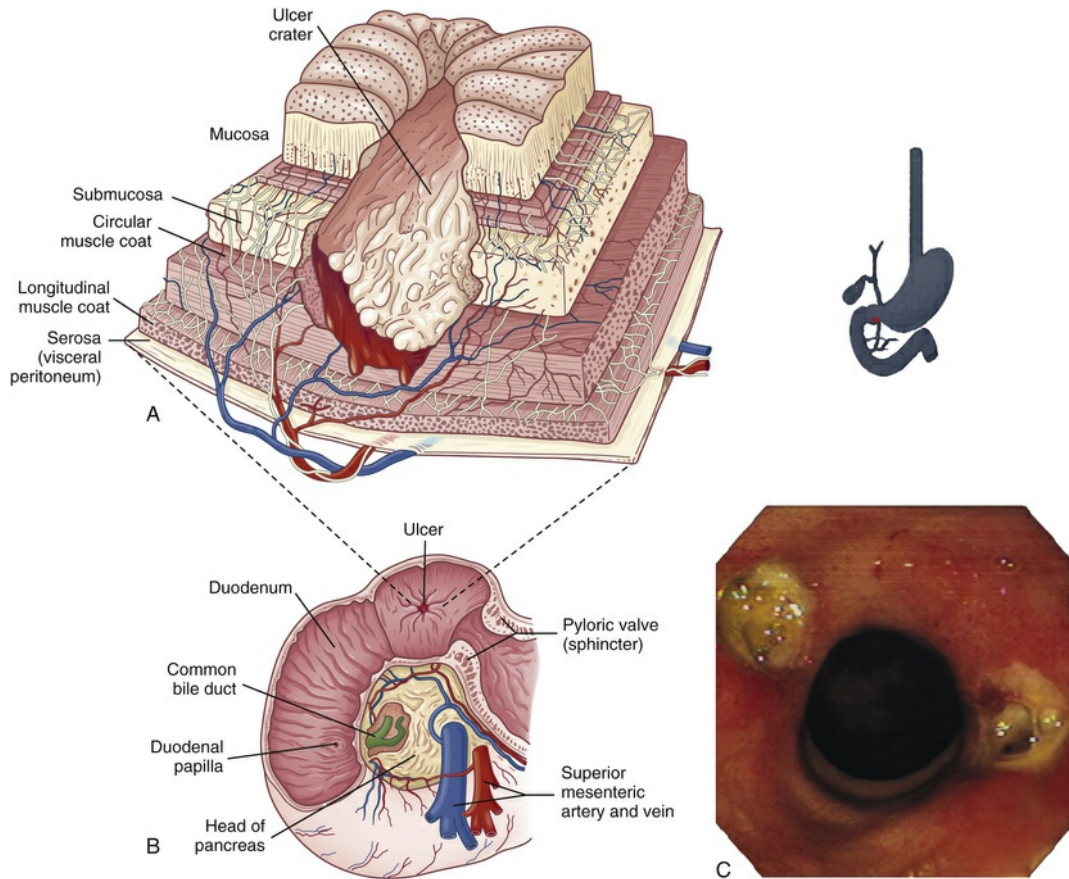

FIGURE 42.8 Duodenal Ulcer. A, A deep ulceration in the duodenal wall extending as a crater through the entire mucosa and into the muscle layers. B, Duodenal ulcer. C, Bilateral (kissing) duodenal ulcers in a person using nonsteroidal antiinflammatory drugs (NSAIDs). (C courtesy David Bjorkman, MD, Department of Gastroenterology, University of Utah School of Medicine, Salt Lake City, UT.)

◆Clinical Manifestations.

The characteristic manifestation of a duodenal ulcer is chronic intermittent pain in the epigastric area. The pain begins 30 minutes to 2 hours after eating, when the stomach is empty. It is not unusual for pain to occur in the middle of the night and disappear by morning. The pain results from sensorineural stimulation by acid or muscle spasm, or both. Pain is relieved rapidly by ingestion of food or antacids, creating a typical “pain-food-relief” pattern. Some individuals with duodenal ulcer have no symptoms, particularly older adults; the first manifestation may be hemorrhage or perforation, particularly with a history of NSAID or anticoagulant use. Healing is

accompanied by relief of pain. Constant, unremitting pain may be caused by complications, such as intestinal obstruction or perforation. Bleeding from duodenal ulcers causes hematemesis or melena. It is not clear why individuals infected with *H. pylori* duodenal ulcers are negatively associated with gastric cancer, but it may be related to heterogeneity of host and *H. pylori* genetic factors.⁵⁴

◆Evaluation and Treatment.

Several diagnostic approaches are used to differentiate duodenal ulcers from gastric ulcers or gastric carcinoma. Endoscopic evaluation allows visualization of lesions and biopsy. Radioimmune assays of gastrin levels are evaluated to identify ulcers associated with gastric carcinomas. *H. pylori* is detected using the urea breath test, *H. pylori*-specific serum immunoglobulin G (IgG) and immunoglobulin A (IgA) antibodies, and measurement of *H. pylori* stool antigen levels. Findings from gastric biopsy detect *H. pylori* infection and confirm eradication after treatment. Polymerase chain reaction testing provides additional virulence and antibiotic sensitivity profiling.⁵⁵

Management of duodenal ulcers is aimed at relieving the causes and effects of hyperacidity and preventing complications. Antacids neutralize gastric contents, elevate pH, inactivate pepsin, relieve pain, and are cytoprotective. Acid secretion can be suppressed with proton pump inhibitors or H₂ receptor blockers. *H. pylori* is eradicated with combinations of antibiotics, although there is increasing drug resistance.⁴⁴ Probiotics may provide an added benefit.⁵⁶

Ulcer-coating agents, such as sucralfate and colloidal bismuth, promote healing. Anticholinergic drugs may be used to inhibit gastric secretion, suppress gastric motility, and delay gastric emptying. Diet therapy includes a diet high in vitamin A, vitamin C, zinc, selenium, and fiber.⁵⁷ Surgical resection may be required for complications including bleeding, perforation, obstruction, or peritonitis. Development of a vaccine against *H. pylori* is progressing slowly.⁵⁸

Gastric Ulcers

Gastric ulcers are ulcers of the stomach and usually occur between

the ages of 55 and 65 years. They are less common than duodenal ulcers (Table 42.4 and Fig. 42.9).

TABLE 42.4

CHARACTERISTICS OF GASTRIC AND DUODENAL ULCERS

CHARACTERISTICS	GASTRIC ULCER	DUODENAL ULCER
Incidence		
Age at onset	50–70 years	20–50 years
Family history	Usually negative	Positive
Sex (prevalence)	Equal in women and men	Equal in women and men
Stress factors	Increased	Average
Ulcerogenic drugs	Normal use	Increased use
Cancer risk	Increased	Not increased
Pathophysiology		
<i>Helicobacter pylori</i> infection	Often present (60%–80%)	Often present (95%–100%)
Abnormal mucus	May be present	May be present
Parietal cell mass	Normal or decreased	Increased
Acid production	Normal or decreased	Increased
Serum gastrin	Increased	Normal
Serum pepsinogen	Normal	Increased
Associated gastritis	More common	Usually not present
Clinical Manifestations		
Pain	Located in upper abdomen	Located in upper abdomen
	Intermittent	Intermittent
	Pain-antacid-relief pattern	Pain-antacid or food-relief pattern
	Food-pain pattern	Nocturnal pain common
Clinical course	Chronic ulcer without pattern of remission and exacerbation	Pattern of remissions and exacerbations for years

FIGURE 42.9 Macroscopic Appearance of Benign Gastric Ulcers. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

◆Pathophysiology.

Gastric ulcers generally develop in the antral region, adjacent to the acid-secreting mucosa of the body (see [Box 42.1](#)). The primary defect is an abnormality that increases the mucosal barrier's permeability to hydrogen ions. Risk factors include *H. pylori* infection, duodenal reflux, and use of NSAIDs. Gastric secretion may be normal or less than normal, and there may be a decreased mass of parietal cells. Chronic autoimmune pangastritis is often associated with development of gastric ulcers and may precipitate ulcer formation by limiting the mucosa's ability to secrete a protective layer of mucus ([Fig. 42.10](#)).⁴¹

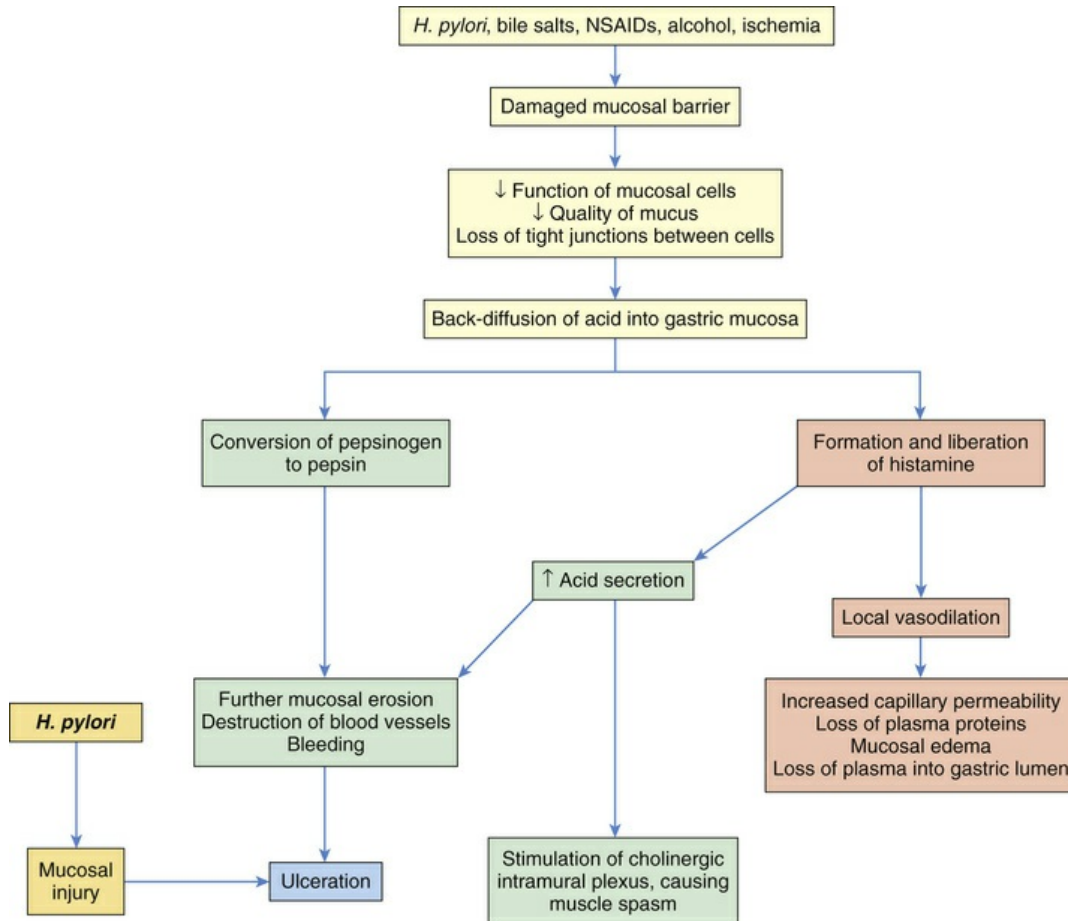

FIGURE 42.10 Pathophysiology of Gastric Ulcer Formation.

Duodenal reflux of bile is associated with gastric ulcer (alkaline reflux gastritis), and may occur after cholecystectomy, pyloroplasty, or gastrojejunostomy. The pyloric sphincter also may fail to respond to stimuli that normally increase resting tone, such as entry of acid, protein, and fat into the duodenum, allowing reflux of bile and pancreatic enzymes to damage the gastric mucosa. The damaged mucosal barrier permits hydrogen ions to diffuse into the mucosa, where they disrupt permeability and cellular structure. A vicious cycle can be established as the damaged mucosa liberates histamine, which stimulates the increase of acid and pepsinogen production, blood flow, and capillary permeability. The disrupted mucosa becomes edematous and loses plasma proteins. Destruction of small vessels causes bleeding.

◆ Clinical Manifestations.

The clinical manifestations of gastric ulcers are similar to those of duodenal ulcers (see [Table 42.4](#)). The pattern of pain, food, and relief is common, but the pain of gastric ulcers also occurs immediately after eating. Gastric ulcers also tend to be chronic rather than alternate between periods of remission and exacerbation and cause more anorexia, vomiting, and weight loss than duodenal ulcers.

◆ **Evaluation and Treatment.**

The evaluation and treatment of gastric ulcers are similar to the evaluation and treatment of duodenal ulcers.

Stress-Related Mucosal Disease

Stress-related mucosal disease (stress ulcer) is an acute form of erosive, inflammatory peptic ulcer that tends to accompany the physiologic stress of severe illness; multisystem organ failure; or major trauma, including severe burns or head injury. Usually, multiple sites of ulceration are distributed within the stomach or duodenum. Stress ulcers may be classified as ischemic ulcers or Cushing ulcers.

Ischemic ulcers develop within hours of an event—such as hemorrhage, multisystem trauma, severe burns, heart failure, or sepsis—that causes ischemia of the stomach and duodenal mucosa. Stress ulcers that develop as a result of burn injury are often called **Curling ulcers**. **Cushing ulcer** is a stress ulcer associated with severe head trauma or brain surgery. Decreased mucosal blood flow and hypersecretion of acid caused by overstimulation of the vagal nuclei damage the mucosal barrier, initiating the processes (see [Fig. 42.10](#)).

The primary clinical manifestation of stress-related mucosal disease is bleeding that occurs more readily with the presence of coagulopathy or mechanical ventilation. Other symptoms may not be present. The bleeding may be slight or, if a small vessel is perforated, amount to hundreds of milliliters. Prophylactic treatment regimens are used to prevent this disease.⁵⁹ Stress ulcers seldom become chronic.

Surgical Treatment of Ulcer

Advances in the medical treatment of peptic ulcer disease with proton pump inhibitors and eradication of *H. pylori*, as well as laparoscopic and endoscopic repair techniques, have significantly reduced the number of cases requiring open surgery. The indications for ulcer surgery are recurrent or uncontrolled bleeding and complicated perforation of the stomach or duodenum. The primary objectives of surgical treatment are to reduce stimuli for acid secretion, decrease the number of acid-secreting cells in the stomach, and correct complications of ulcer disease.

Acute complications of gastrectomy or anastomosis, such as poor wound healing, abscess formation, or suture failure, are relatively uncommon except in the debilitated person. Chronic complications, however, occur more often and are likely to develop if a large portion of the stomach has been removed. These complications and their pathophysiologic mechanisms are described in the next section.

Postgastrectomy Syndromes

Postgastrectomy syndromes are a group of signs and symptoms that occur after gastric resection for the treatment of peptic ulcer, gastric carcinoma, or bariatric surgery for extreme obesity. They are caused by anatomic and functional changes in the stomach and upper small intestine.

Dumping syndrome is the rapid emptying of hypertonic chyme from the surgically created, residual stomach (the stomach component remaining after surgical resection following gastric or bariatric surgery) into the small intestine 10 to 20 minutes after eating (early dumping syndrome). It occurs with varying severity in 5% to 10% of individuals who have undergone partial gastrectomy, bariatric surgical procedures, or pyloroplasty.⁶⁰ It is not as common in individuals who have undergone a Billroth II anastomosis (gastrojejunostomy) accompanied by vagotomy. Factors that promote *early dumping syndrome* include (1) loss of gastric capacity, (2) loss of emptying control when the pylorus is removed, and (3) loss of

feedback control by the duodenum when it is removed. Rapid gastric emptying and creation of a nonphysiologic, high osmotic gradient within the small intestine cause a sudden shift of fluid from the vascular compartment to the intestinal lumen. Plasma volume decreases, causing vasomotor responses, such as increased pulse rate, hypotension, weakness, pallor, sweating, and dizziness. Rapid distention of the intestine produces a feeling of epigastric fullness, cramping pain, nausea, and vomiting. *Diarrhea* can accompany dumping syndrome or occur as a solitary symptom. Diarrhea can occur as frequent, persistent elimination of liquid stool or as intermittent, precipitous, and unpredictable elimination of a large volume of stool. Both types can be either mild or severe.

A less common form of dumping syndrome, *late dumping syndrome*, occurs 1 to 3 hours after eating. The symptoms include weakness, diaphoresis, and confusion. After a high-carbohydrate meal, individuals who have undergone gastrectomy may develop hypoglycemia, which causes the symptoms. The hypoglycemia is caused by an increase in insulin secretion stimulated by the hyperglycemia that follows eating. Other hormonal responses also may participate in the development of hypoglycemia.

Most cases of dumping syndrome respond well to dietary management. Frequent small meals that are high in protein and low in carbohydrates relieve symptoms. Acarbose slows intestinal digestion of carbohydrates, and somatostatin analogs slow gastric emptying. Other measures include drinking fluids between meals instead of at mealtime and reclining on the left side after eating. Some cases require surgical intervention, including reconstruction of the pylorus or a gastrojejunostomy. Octreotide reduces abdominal and vasomotor symptoms of dumping syndrome by inhibiting insulin and gut hormone release, slowing intestinal transit time, and inhibiting food-induced circulatory changes.⁶¹

Alkaline reflux gastritis is caused by reflux of bile and alkaline pancreatic secretions containing proteolytic enzymes that disrupt the mucosal barrier in the remnant stomach. Symptoms include nausea, bilious vomiting, and sustained epigastric pain that worsens after

eating, is not relieved by antacids, and responds somewhat to avoidance of aspirin and alcohol.⁶² Surgical correction may be required.

Afferent loop obstruction is a rare complication of Billroth II gastrojejunostomy. Symptoms include intermittent severe pain and epigastric fullness after eating as a result of volvulus, hernia, adhesion, or stenosis of the duodenal stump on the proximal side of the gastrojejunostomy; vomiting relieves symptoms; management includes low-fat diet, but decompression or surgery revision is required for complete obstruction.⁶³

Weight loss is commonly caused by inadequate caloric intake because the individual cannot tolerate carbohydrates or a normal-size meal; the stomach is also less able to mix, churn, and break down food. In the case of bariatric surgery for extreme obesity, weight loss is the intended outcome, but nutrient deficiencies, including vitamins and minerals, must be supplemented.⁶⁴

Anemia results from iron malabsorption caused by decreased acid secretion, lack of vitamin B₁₂ or folate, and resection of the duodenum after a Billroth II gastrojejunostomy. Bone and mineral disorders are related to altered calcium absorption and metabolism with increased risk for fractures and deformity, and malabsorption of vitamins and nutrients, such as vitamin D.

Malabsorption Syndromes

Malabsorption syndromes interfere with nutrient absorption in the small intestine. Historically malabsorption disorders have been classified as maldigestion or malabsorption. **Maldigestion** is failure of the chemical processes of digestion that take place in the intestinal lumen or at the brush border of the intestinal mucosa of the small intestine. **Malabsorption** is the failure of the intestinal mucosa to absorb (transport) the digested nutrients. The two syndromes are often interrelated or occur together, making classification difficult. Generally, however, maldigestion is caused by deficiencies of enzymes, such as pancreatic lipase or intestinal lactase, which are necessary for digestion; inadequate secretion of bile salts; and

inadequate reabsorption of bile in the ileum. Malabsorption is the result of mucosal disruption caused by gastric or intestinal resection, vascular disorders, or intestinal disease.

Pancreatic Exocrine Insufficiency

The pancreatic enzymes (lipase, amylase, trypsin, and chymotrypsin) are required for the digestion of proteins, carbohydrates, and fats. **Pancreatic insufficiency** is the deficient production of these enzymes by the pancreas. Causes of pancreatic insufficiency include chronic pancreatitis, pancreatic carcinoma, pancreatic resection, and cystic fibrosis. Significant damage to or loss of pancreatic tissue must occur before enzyme levels decrease sufficiently to cause maldigestion. Although pancreatic insufficiency causes poor digestion of all nutrients, fat maldigestion is the chief problem. Salivary amylase and enzymes secreted by the intestinal brush border assist in carbohydrate and protein digestion, but these enzymes do not digest fats. Absence of pancreatic bicarbonate in the duodenum and jejunum causes an acidic pH that worsens maldigestion by preventing activation of pancreatic enzymes that are present. A large amount of fat in the stool (steatorrhea) and weight loss are the most common signs of pancreatic insufficiency. Several pancreatic function tests are available.⁶⁵ Lipase supplementation, which may be in combination with antacids or antisecretory therapy, is usually successful.⁶⁶

Lactase Deficiency (Lactose Intolerance)

Deficiency of disaccharidase at the villus brush border of the small intestine is caused by a genetic defect in which a single enzyme, usually lactase, is lacking. **Lactase deficiency** inhibits the breakdown of lactose (milk sugar) into monosaccharides and therefore prevents lactose digestion and absorption across the intestinal wall. Lactase deficiency is most common in blacks, Latinos, and Native Americans and usually does not develop until adulthood. Congenital lactase deficiency causes watery diarrhea in breast milk or lactose-containing formulas in infants. Lactase expression is lost before adulthood in

adult-type lactose intolerance. Secondary (acquired) lactase deficiency can be caused by several diseases of the intestine, including celiac disease (see [Chapter 43](#)), enteritis, and bacterial overgrowth.⁶⁷

The undigested lactose remains in the intestine, where bacterial fermentation causes formation of gases. Undigested lactose also increases the osmotic gradient in the intestine, causing irritation and osmotic diarrhea. Clinical manifestations of lactose consumption with lactase deficiency are bloating, crampy pain, diarrhea, and flatulence. The disorder is diagnosed by tests for lactose malabsorption and lactose tolerance. Avoiding milk products and adhering to a lactose-free diet relieve symptoms. Lactase enzyme replacement is an option. Maintaining an adequate calcium intake with restricted intake of milk products decreases risk of osteoporosis.⁶⁸

Bile Salt Deficiency

Conjugated bile acids (bile salts) are necessary for the digestion and absorption of fats in the small intestine. Bile salts are conjugated in the bile that is synthesized from cholesterol and secreted from the liver. When bile enters the duodenum, the bile salts aggregate with fatty acids and monoglycerides to form micelles. Micelle formation makes fat molecules more soluble and allows them to pass through the unstirred layer at the brush border of the small intestinal villi (see [Chapter 41](#)). A minimum concentration of bile salts, termed the *critical micelle concentration*, is required to allow micelles to form. Therefore conditions that decrease the production or secretion of bile result in decreased micelle formation and fat malabsorption. These conditions include advanced liver disease, which decreases production of bile salts; obstruction of the common bile duct, which decreases flow of bile into the duodenum; intestinal stasis (lack of motility), which permits overgrowth of intestinal bacteria that deconjugate bile salts; and diseases or resection of the ileum, which prevent the reabsorption and recycling of bile salts (enterohepatic circulation).

Clinical manifestations of bile salt deficiency are related to poor intestinal absorption of fat and fat-soluble vitamins (A, D, E, and K). Increased fat in the stools (steatorrhea) leads to diarrhea and

decreased plasma proteins. The losses of fat-soluble vitamins and their effects include the following:

1. Vitamin A deficiency results in night blindness.
2. Vitamin D deficiency results in decreased calcium absorption with bone demineralization (osteoporosis), bone pain, and fractures.
3. Vitamin K deficiency prolongs prothrombin time, leading to spontaneous development of purpura (bruising) and petechiae.
4. Vitamin E deficiency has uncertain effects but may cause testicular atrophy and neurologic defects in children.

The most effective treatment for fat-soluble vitamin deficiency is to increase the amount of medium-chain triglycerides in the diet, for example, by using coconut oil for cooking. Vitamins A, D, and K are given parenterally. Cholestyramine is used to treat steatorrhea related to ileal disease and failure of bile reabsorption.⁶⁹

Inflammatory Bowel Disease

Ulcerative colitis and Crohn disease are chronic, relapsing idiopathic inflammatory bowel diseases (IBDs). The prevalence of IBD is about 3 million people in the United States.⁷⁰ The disease is more prevalent among white populations and Ashkenazi Jews. Risk factors and theories of causation include susceptibility genes, environmental factors, alterations in epithelial cell barrier functions, an altered immune response to intestinal microflora, and varying phenotypes.⁷¹ Unknown environmental factors or infections are thought to alter the barrier function of the mucosal epithelium, promote loss of immune tolerance to normal intestinal antigens, and increase uptake of luminal antigens. There is possible loss of discrimination of potentially harmful pathogens from commensal microorganisms in the intestinal mucosa.⁷² The loss of tolerance activates dendritic cells, triggering their transport to mesenteric lymph nodes, where they promote differentiation of naïve T cells to T helper1 (Th1), Th2, and Th17 cells,

or T-regulatory cells. Production of proinflammatory cytokines and chemokines, including tumor necrosis factor, interleukins, toxic oxygen free radicals, and interferon-gamma (IFN- γ), damages the intestinal epithelium.⁷³ The risk of colon cancer increases significantly after 30 to 35 years of inflammatory bowel disease, particularly in untreated disease.⁷⁴ Future research is directed at an integration of these factors to refine understanding of disease cause and trajectory, particularly interactions between genetics, the microflora, mucosa, and immune responses.^{75,76}

Ulcerative Colitis

Ulcerative colitis (UC) is a chronic inflammatory disease that causes ulceration of the colonic mucosa, most commonly in the rectum and sigmoid colon (Fig. 42.11). The lesions appear in susceptible individuals between 20 and 40 years of age. UC is less common in people who smoke, but smoking may not improve the natural history of ulcerative colitis.⁷⁷

FIGURE 42.11 Distribution Patterns of Crohn Disease and Ulcerative Colitis. Comparison of distribution patterns of Crohn disease and ulcerative colitis as well as different conformations of ulcers and wall thickenings. (From Kumar V et al: *Robbins basic pathology*, ed 8, St Louis, 2008, Mosby.)

◆Pathophysiology.

The primary lesion of UC begins with inflammation at the base of the crypt of Lieberkühn. The disease involves the rectum (proctitis) and may extend proximally to the entire colon (pancolitis). The lesions are limited to the mucosa, are not transmural, and do not involve skip lesions. The inflammation involves infiltration and release of inflammatory cytokines from Th2-associated cytokines (i.e., IL-4 and IL-13) that activate neutrophils, lymphocytes, plasma cells, macrophages, eosinophils, and mast cells. Activated macrophages also contribute cytokines that cause fever and the acute phase response. The inflammation damages the epithelial mucosal barrier with leak of fluids into the gut.⁷⁸

With milder inflammation, the mucosa is hyperemic and edematous and may appear dark red and velvety (Fig. 42.12). In more severe inflammation, the mucosa becomes hemorrhagic, and small erosions form and coalesce into ulcers. Abscess formation occurs in the crypts. Necrosis and ragged ulceration of the mucosa ensue with formation of granulation tissue. Edema and thickening of the muscularis mucosae may narrow the lumen of the involved colon. In chronic disease, inflammatory polyps (pseudopolyps) develop in the colon from rapidly regenerating epithelium.

FIGURE 42.12 Acute Ulcerative Colitis. A gross specimen of subtotal ulcerative colitis showing diffuse continuous disease starting from the distal rectum and continuing up to the midportion of the ascending colon. (From Odze RD, Goldblum JR, editors: *Surgical pathology of the GI tract, liver, biliary tract, and pancreas*, ed 2, Philadelphia, 2009, Saunders.)

◀Clinical Manifestations.

The course of UC consists of intermittent periods of remission and exacerbation. Clinical manifestations vary with the severity and extent of disease. Loss of the absorptive mucosal surface and decreased colonic transit time can cause large volumes of watery diarrhea. Mucosal destruction causes bleeding, cramping pain, and an urge to defecate. Frequent bloody diarrhea with passage of purulent mucus is common. Mild UC involves less mucosa and may be limited to proctitis, so that frequency of bowel movements, bleeding, and pain are minimal. Severe forms may involve the entire colon (pancolitis) and are characterized by fever, elevated pulse rate, frequent diarrhea (more than six movements per day), urgency, obviously bloody stools, continuous crampy pain, dehydration, weight loss, and anemia.⁷⁹ Complications include anal fissures, hemorrhoids, and perirectal abscess. Severe hemorrhage is rare, but chronic blood loss may precipitate hypotension and shock. Edema, strictures, or fibrosis can obstruct the colon. Perforation is an unusual but possible

complication. The risk of colon cancer increases significantly after many years of ulcerative colitis.⁸⁰ Extraintestinal manifestations include cutaneous lesions (erythema nodosum and pyoderma gangrenosum), migratory polyarthritis and sacroiliitis, osteopenia and osteoporosis, mouth ulcers, episcleritis or anterior uveitis of the eye, and primary sclerosing cholangitis in the liver. Gallstones are common. Chronic inflammation causes alterations in coagulation and can cause life-threatening microthrombi, deep vein thrombosis, and other thromboembolic events.⁸¹

◆Evaluation and Treatment.

Diagnosis of ulcerative colitis is based on the medical history, clinical manifestations, imaging procedures, and biopsy findings. Endoscopic evaluation shows an inflamed and hemorrhagic mucosa. Radiologic assessment may show loss of haustra, ulceration, and irregular mucosa. The laboratory data include low hemoglobin values, hypoalbuminemia, and low serum potassium levels. There are no specific serologic markers. Infectious causes are ruled out by stool culture. The symptoms of ulcerative colitis can be very similar to those of Crohn disease, making differential diagnosis challenging.⁸² Chromoendoscopy is recommended over random biopsies in detecting dysplasia and colorectal cancer for those with long-standing disease.⁸³

Treatment is individualized and depends on the severity of symptoms and the extent of mucosal involvement. Mild disease is treated with 5-aminosalicylic acid (mesalazine) or sulfasalazine followed by corticosteroids to suppress the inflammatory response and alleviate cramping pain. Azathioprine and immunomodulatory agents (cyclosporine and tumor necrosis factor [TNF] blocking agents) tacrolimus or vedolizumab are used for recurrent or serious disease.^{84,85} Severe, unremitting disease can require hospital admission and administration of intravenous fluids. Extreme malnutrition may require intravenous hyperalimentation. Surgical approaches for severe UC include total proctocolectomy, with end ileostomy or ileorectal anastomosis, or ileal pouch anal anastomosis (IPAA), the

preferred procedure.⁸⁶ *Pouchitis* is a complication of restorative proctocolectomy with ileal pouch anal anastomosis performed as surgical treatment for both UC and Crohn disease. Antibiotic treatment is usually successful.⁸⁷ New endoscopic imaging techniques are emerging to detect dysplasia and colorectal cancer with long-standing disease.⁸⁸

Crohn Disease

Crohn disease (CD) (granulomatous colitis, ileocolitis, or regional enteritis) is an idiopathic inflammatory disorder that is distinguished from UC in that it affects any part of the gastrointestinal tract from the mouth to the anus and involves “skip lesions” with inflamed areas mixed with uninflamed areas, noncaseating granulomas, fistulas, and deep penetrating ulcers. The distal small intestine and proximal large colon are most commonly affected by the disease. In a small percentage of cases, CD is difficult to differentiate from ulcerative colitis (Table 42.5). Risk factors include family history, cigarette smoking, Jewish ethnicity, urban residency, age less than 40 years, a slight predominance in women, and an altered gut microbiome.⁸⁹ The *CARD15/NOD2* (nucleotide-binding-oligomerization-domain-containing protein 2) gene mutations have the strongest association with CD (35% to 45% of cases), although many other genes have been identified. The *CARD15/NOD2* genes code for a protein (a toll-like receptor; see Chapter 10) involved in the recognition of gram-negative and gram-positive bacterial wall fragments by intestinal epithelial cells. Their mutation may promote dysbiosis and reduced levels of defensins.⁹⁰ Th1-mediated inflammation with activation of TNF- α , IFN- γ , IL-12, and Th17-associated cytokines causes mucosal injury. Recruited leukocytes release proinflammatory substances, including prostaglandins, leukotrienes, proteases, reactive oxygen species, and nitric oxide, which cause further injury and inflammation.⁷³

TABLE 42.5

FEATURES OF ULCERATIVE COLITIS AND CROHN DISEASE

FEATURE	ULCERATIVE COLITIS	CROHN DISEASE
Risk Factors		
Age at onset	Any age; 10–40 years most common	Any age; 10–30 years most common
Family history	Less common	More common
Sex (prevalence)	Equal in women and men	About equal in women and men
Cancer risk	Increased	Increased
Pathophysiology		
Location of lesions	Colon and rectum, no “skip” lesions	All of GI tract: mouth to anus, “skip” lesions common
Inflammation and ulceration	Mucosal layer involved	Entire intestinal wall involved
Granulomas	Rare	Common
Friable mucosa	Common	Less common
Fistulae and abscesses	Rare	Common
Strictures and possible obstruction	Rare	Common
Clinical Manifestations		
Abdominal pain	Occasional	Common
Diarrhea	Common	Common
Bloody stools	Common	Less common
Abdominal mass	Rare	Common
Small intestinal malabsorption	Rare	Common
Steatorrhea	Rare	Common
Potential for malignancy	Common	Common
Antineutrophil cytoplasmic antibodies	Common	Rare
Anti- <i>Saccharomyces cerevisiae</i> antibodies	Rare	Common
Clinical Course	Remissions and exacerbations	Remissions and exacerbations

GI, Gastrointestinal.

◆ Pathophysiology.

The inflammatory lesions begin in the intestinal submucosa and

spread with discontinuous transmural involvement (“skip lesions”). The ascending colon and the transverse colon are the most common sites of the disease; however, both the large and small intestines may be involved, particularly the ileum. One side of the intestinal wall may be affected and not the other. Progression of the disease involves neutrophil infiltration of the crypts, resulting in abscess formation and crypt destruction. The ulcerations of CD produce longitudinal and transverse fissures that extend inflammation into lymphoid tissue. The typical lesion is a granuloma with cobblestone projections of inflamed tissue surrounded by areas of ulceration (Fig. 42.13). (Granulomas are described in Chapter 7.) Fistulae may form in the perianal area between loops of intestine or extend into the bladder, rectum, or vagina. Strictures may develop, promoting obstruction. Smoking increases the risk of relapse.⁹¹

FIGURE 42.13 Crohn Disease. A, The mucosa in Crohn disease demonstrates a cobblestone pattern as a result of fissured ulcers (*U*) with intervening areas of edematous mucosa (*M*). B, Compared with normal small bowel wall (*N*), the Crohn segment (*C*) shows wall thickening that has caused a stenosis. (From Kumar V et al: *Pathologic basis of disease*, ed 7, Philadelphia, 2006, Saunders.)

◆Clinical Manifestations.

Individuals with CD may have no specific symptoms other than an “irritable bowel” for several years. Symptoms vary according to the location of the disease but are similar to those for UC. Diarrhea is one of the most common symptoms and, occasionally, rectal bleeding if the colon is involved. Other manifestations are related to the location and extent of intestinal involvement. Inflammation of the ileum, for example, causes tenderness in the lower right side of the abdomen, and the individual may be anemic as a result of malabsorption of

vitamin B₁₂. There also may be deficiencies in folic acid, vitamin D absorption, and calcium leading to bone disease. Proteins may be lost, leading to hypoalbuminemia. Weight loss is common. Anal manifestations occur in about 30% of cases, including anal fissure, perianal abscess, and fistula. Individuals with CD of long duration also are at risk for intestinal adenocarcinoma. Extraintestinal manifestations include arthropathies, skin, oral, and ocular lesions and may be the presenting symptoms.⁹²

◆ Evaluation and Treatment.

The diagnosis and treatment of CD are similar to the diagnosis and treatment of ulcerative colitis. Imaging of the small intestine is used in the diagnosis of CD, including either a small bowel series or a capsule endoscopy (camera pill). There are no specific biomarkers or definitive treatments. Treatment includes corticosteroids, 5-aminosalicylates, and immunomodulatory agents (thiopurines and TNF- α -blocking agents). New biologic agents are under development.⁹³ Smoking cessation is a component of therapy. Surgery is generally performed to manage complications such as strictures, fistulae, abscesses, and perforation, or to relieve obstruction. When treatment involves surgical resection of small intestinal segments, complications related to **short bowel syndrome** can occur, including malabsorption, diarrhea, and nutritional deficiencies. Symptoms are related to the extent and location of resection. Cancer screening should be performed for long-standing disease.

Microscopic Colitis

Microscopic colitis is a relatively common cause of chronic, watery diarrhea. Risk factors include age 50 years or older, female sex, weight loss, absence of abdominal pain, use of proton pump inhibitors or nonsteroidal antiinflammatory drugs, celiac disease, and smoking. Although the mucosa appears normal, there are two histologic forms: lymphocytic and collagenous. Lymphocytic colitis shows more than 20 intraepithelial lymphocytes per 100 epithelial cells. Collagenous colitis is characterized by a thickened (10 to 20 μ m) subepithelial

collagen band, alteration of the vascular mucosal pattern, and mucosal nodularity. The cause is unknown.⁹⁴

The symptoms of frequent, chronic, daily watery diarrhea are the same for both types and can be accompanied by abdominal pain and weight loss. Diagnosis is made by endoscopic biopsy. Antidiarrheal agents and budesonide (a local antiinflammatory steroid) are the best documented treatments. The disease is negatively associated with colorectal cancer.⁹⁵

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) currently is considered a disorder of brain-gut interaction characterized by abdominal pain with altered bowel habits. The prevalence in North America is about 12% and is probably underestimated.⁹⁶ It is more common in women, with a higher prevalence in youth and middle age. Individuals with IBS are more likely to have anxiety and depression and reduced quality of life.⁹⁷

◆Pathophysiology.

There are no specific structural or biochemical alterations that have been currently identified as a cause of IBS, but there is increasing evidence to explain a multisystem interaction as a cause of the varying symptom presentations. They are summarized as follows:

1. *Visceral hypersensitivity or hyperalgesia*, particularly with distention of the rectum but also other areas of the gut. This occurs in about 30% to 40% of those with IBS. The cause is unknown; it may originate in the peripheral, enteric, or central nervous system. The mechanism may be related to pain and a dysregulation of the bidirectional “brain-gut axis” (alterations in gut or central nervous system processing of gut nociceptive information). Factors include genetic related changes in the function of serotonin-secreting cells of gut-brain pain modulation, alterations in gut microbiota metabolite production with activation of the gut immune system,

increased visceral sensitivity, permeability, and altered motility and secretion.⁹⁸

2. *Abnormal gastrointestinal permeability, motility, secretion, and sensitivity* are associated with IBS. Individuals with diarrhea-type IBS have more rapid colonic transit times and increased intestinal permeability. Those with bloating and constipation have delayed transit times and decreased intestinal permeability. The mechanisms may be related to dysregulation of the brain-gut axis or alterations in the function of gut neuroendocrine cells or dorsal root ganglion neurons. Enteroendocrine cells, mast cell proliferation, and activation with release of intrinsic and peripheral neuromediators, enzymes, and inflammatory mediators contribute to the symptoms of IBS. Sex hormones also may be a contributing factor.⁹⁹⁻¹⁰¹
3. *Postinflammatory IBS* has been associated with intestinal infection (bacterial enteritis) and low-grade inflammation. Alterations in gut microbiota, immune activation in gut tissues, and changes in intestinal permeability with bidirectional neurohormonal communication between the gut and the brain have been proposed.¹⁰²
4. *Alteration in gut microbiota (dysbiosis)* influences the sensory, motor, and immune systems of the gut and interacts with higher brain centers and may contribute to symptoms of IBS.¹⁰³ Small intestine overgrowth of normal gut bacteria may be associated with IBS symptoms in some cases.¹⁰⁴
5. *Food allergy or food intolerance* is associated with IBS in some cases. Food antigens may activate the mucosal immune system, alter intestinal flora, or mediate hypersensitivity reactions and IBS symptoms. Allergic conditions, including rhinitis and asthma, have been associated with IBS.¹⁰⁵
6. *Psychosocial factors (epigenetic factors)*, including early life trauma or abuse or chronic emotional stress, lead to alterations in neuroendocrine, neuroimmune, and autonomic nervous systems and gut microbiota; release of inflammatory

mediators; and pain modulatory responses contributing to the symptoms of IBS.^{106,107}

◀Clinical Manifestations.

IBS symptoms may be mild or debilitating. Clinical manifestations are characterized by lower abdominal pain and bloating. IBS can be subtyped as presented in [Box 42.2](#) Individuals also may describe fecal urgency and incomplete evacuation. Symptoms are usually relieved with defecation and usually do not interfere with sleep.

Box 42.2

Diagnostic Criteria* for Irritable Bowel Syndrome

Rome IV Criteria

Recurrent abdominal pain, on average, at least 1 day per week in the last 3 months, associated with two or more of the following criteria:

1. Related to defecation
2. Associated with a change in frequency of stool
3. Associated with a change in form (appearance) of stool

IBS subtypes include:

- IBS with predominant constipation (IBS-C)
- IBS with predominant diarrhea (IBS-D)
- IBS with mixed bowel habits (IBS-M)
- IBS unclassified (IBS-U)

IBS, Irritable bowel syndrome.

*Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

Adapted from Drossman DA: *Gastroenterology* 150(6):1262-1297, 2016; Lacey BE et al: *Gastroenterology* 150(6):1393-1407, 2016.

◆ Evaluation and Treatment.

The diagnosis of IBS is based on personal history of signs and symptoms, physical examination, and the exclusion of structural or biochemical causes of other diseases with symptoms similar to IBS (celiac disease, lactose intolerance, and inflammatory bowel disease). In the absence of “alarm symptoms,” such as fever, weight loss, gastrointestinal bleeding, anemia, or abdominal mass, only limited diagnostic tests are needed (complete blood count and inflammatory markers [C-reactive protein or fecal calprotectin]). The individual may be evaluated for food allergies, lactose intolerance, parasites or bacterial growth, and thyroid disease. A colonoscopy may be completed if clinically indicated. The Rome IV criteria provide guidelines for diagnosing IBS and includes IBS subtypes (Box 42.2).¹⁰⁸

There is no cure for IBS, and treatment is individualized based on predominant symptoms. Treatment may include laxatives, soluble dietary fiber, restriction of gluten and fermentable oligosaccharides, disaccharides, monosaccharides, polyols (FODMAPs), antidiarrheals, antispasmodics, pro-secretory drugs, visceral analgesics, low-dose antidepressants, serotonin agonists or antagonists (90% to 95% of the body's total serotonin is produced by intestinal enteroendocrine cells), and antibiotics. Alternative therapies including prebiotics (stimulate growth of healthy gut bacteria), probiotics, selected herbal treatments (e.g., peppermint oil), hypnosis, and psychotherapy are treatment options. Research continues to advance the understanding of the pathophysiology and specificity of treatment of this complex syndrome.¹⁰⁹

Diverticular Disease of the Colon

Diverticula are herniations or saclike outpouchings of mucosa

through the muscle layers of the colon wall. **Diverticulosis** is asymptomatic diverticular disease. **Diverticulitis** represents inflammation. The cause of diverticular disease is unknown. Approximately 300,000 hospital admissions per year are related to diverticular disease.¹¹⁰ Predisposing factors include older age, genetic predisposition, obesity, smoking, diet, lack of physical activity, and medication use, such as aspirin and nonsteroidal antiinflammatory drugs. Lack of dietary fiber may or may not contribute to diverticular disease.¹¹¹ Altered intestinal microbiota, visceral hypersensitivity, and abnormal colonic motility also may be contributing factors.¹¹²

◆Pathophysiology.

Diverticula can occur anywhere in the gastrointestinal tract, with the most common sites in the left colon (prevalent in Western countries) and the right colon (prevalent in Asian countries). They rarely occur in the small intestine¹¹³ and are associated with increased intracolonic pressure, abnormal neuromuscular function, and alterations in intestinal motility. The diverticula form at weak points in the colon wall, where arteries penetrate the tunica muscularis to nourish the mucosal layer. The colonic mucosa herniates through the smooth muscle layers (Fig. 42.14). A common associated finding is thickening of the circular and longitudinal (teniae coli) muscles surrounding the diverticula. Increased collagen and elastin deposition, not muscle hypertrophy, is associated with wall thickening and contributes to increased intraluminal pressure and herniation. Habitual consumption of a low-residue diet reduces fecal bulk, thus reducing the diameter of the colon. According to Laplace's law (see Chapter 32), wall pressure increases as the diameter of a cylindrical structure decreases. Therefore pressure within the narrow lumen can increase enough to cause local ischemia and rupture the diverticula. However, the exact cause of diverticula is uncertain.

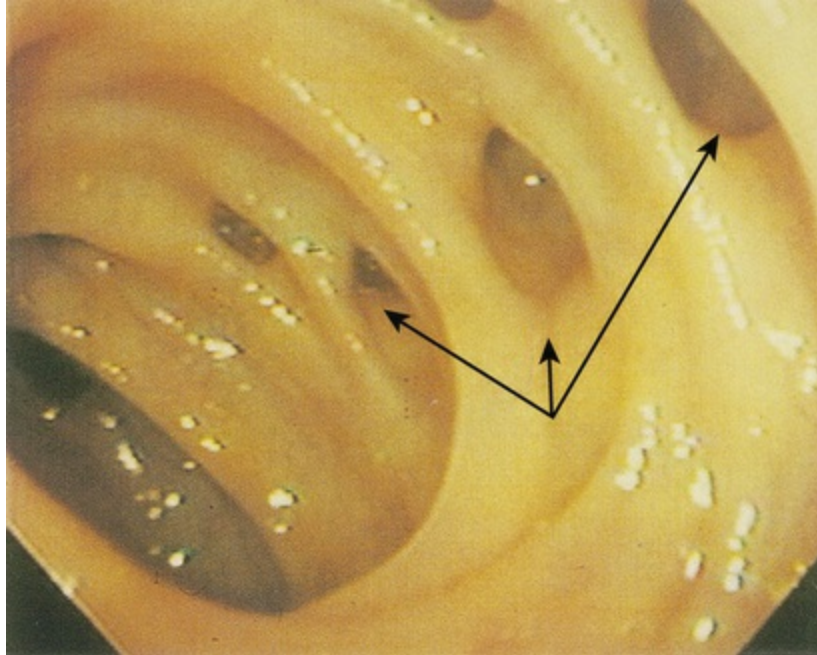

FIGURE 42.14 Diverticular Disease. In diverticular disease, the outpouches (*arrows*) of mucosa seen in the sigmoid colon appear as slitlike openings from the mucosal surface of the opened bowel. (From Townsend CM et al: *Sabiston textbook of surgery*, ed 19, Philadelphia 2012, Saunders.)

◆Clinical Manifestations.

Symptoms of uncomplicated diverticular disease are usually vague or absent. Cramping pain of the lower abdomen can accompany constriction of the thickened colonic wall. Diarrhea, constipation, distention, or flatulence may occur. If the diverticula become inflamed or abscesses form, the individual develops fever, leukocytosis (increased white blood cell count), and tenderness of the lower left quadrant.

◆Evaluation and Treatment.

Diverticula are often discovered during diagnostic procedures performed for other problems. Ultrasound, sigmoidoscopy, or colonoscopy permits direct observation of the lesions. Abdominal computed tomography (CT) is used for complicated cases.

An increase of dietary fiber intake increases stool weight, lowers colonic pressures, improves transit times, and often relieves

symptoms, although data are lacking (see *Nutrition & Disease: Diverticular Disease and Diet*). Uncomplicated diverticular disease is treated with bowel rest and analgesia. Antibiotics (i.e., rifaximin) and surgical resection are used to treat severe disease.¹¹⁴ Radiographic, endoscopic, and laparoscopic procedures are implemented for more severe complications, including hemorrhage, bowel stenosis, obstruction, abscesses, fistulae, bowel perforation, and peritonitis.^{115,116}

Nutrition & Disease

Diverticular Disease and Diet

Daily consumption of fiber-enriched foods is being re-evaluated for the prevention of diverticula. A high-fiber diet increases fecal bulk, decreases transit time, lowers intracolonic pressures, and eases stool elimination. The recommendation for fiber has been 20 to 35 g/day. Some examples of high-fiber choices are whole wheat bread and other grain products, baked potato with skin, fresh fruit with skins, raw vegetables, beans, peas, legumes, wheat bran, and brown rice. Side effects may include flatulence, intestinal rumbling, cramps, and diarrhea and the possibility that frequent bowel movements promote a greater prevalence of diverticular disease. A gradual increase in dietary fiber over 1 or 2 months helps to avoid these problems. Other potential problems with an excessively high-fiber diet (greater than 40 to 45 g) might include a decrease in nutrient absorption because of the increased volume of intestinal contents, which in turn decreases the ability of the digestive enzymes to come into contact with the food. An increase of water intake (eight 8-ounce glasses) is important so intestinal blockage will not occur. For small children and older adults, a high-fiber diet increases the volume of food needed to meet energy requirements, and that increase may be difficult to obtain. Although some physicians recommend restricting nuts, seeds, and foods containing seeds such as berries, kiwi, and tomatoes that might lodge in the pouches, there is no evidence that this happens. If the diverticula become

inflamed, a low-fiber, low-residue (no milk products), or elemental diet, or in complicated cases total parenteral nutrition (TPN), is required to prevent continued irritation of the inflamed tissue. Controlled clinical trials are needed to evaluate the effectiveness of high-fiber diets in preventing diverticular disease. The efficacy of probiotics in modifying gut microbiota and relieving symptoms of diverticular disease also requires more investigation.

Appendicitis

Appendicitis is an inflammation of the vermiform appendix, which is a projection from the apex of the cecum. It is the most common surgical emergency of the abdomen, usually occurs between 10 years and 19 years of age (although it may develop at any age), and has an incidence in the United States of 7 to 10 per 10,000 persons.¹¹⁷ Disease occurrence is higher in individuals with a family history of appendicitis.¹¹⁸

◆Pathophysiology.

The exact cause of appendicitis is controversial. Obstruction of the lumen with stool, tumors, or foreign bodies with consequent increased intraluminal pressure, ischemia, bacterial infection, and inflammation is the most common theory. The obstructed lumen does not allow drainage of the appendix, and as mucosal secretion continues, intraluminal pressure increases. The resultant increased pressure decreases mucosal blood flow, and the appendix becomes hypoxic. The mucosa ulcerates, promoting bacterial or other microbial invasion with further inflammation and edema. Inflammation may involve the distal or entire appendix. Gangrene develops from thrombosis of the luminal blood vessels, followed by perforation.¹¹⁹ The appendix may harbor bacteria that contribute to the development of appendicitis.¹²⁰

◆Clinical Manifestations.

Epigastric or periumbilical pain is the typical symptom of an inflamed appendix. The pain may be vague at first, increasing in intensity over 3 to 4 hours. It may subside and then recur with a shift of location to the right lower quadrant with rebound tenderness. Right lower quadrant pain is associated with extension of the inflammation to the surrounding tissues. Nausea, vomiting, and anorexia follow the onset of pain, and fever is common. Diarrhea occurs in some individuals, particularly children; others have a sensation of constipation. Perforation, peritonitis, and abscess formation are the most serious complications of appendicitis.

◆Evaluation and Treatment.

In addition to clinical manifestations, the clinician can usually locate the painful site with one finger. Rebound tenderness is usually referred to the right lower quadrant. There are no specific biomarkers. The white blood cell count ranges from 10,000 to 16,000 cells/mm³ with elevations in the levels of neutrophils and C-reactive protein. Abdominal ultrasound, CT scans, and MRI (particularly for pregnant women and children) assist with diagnostic accuracy and help rule out nonappendiceal disease. Clinical decision rules and risk scores can assist with diagnosis.¹²¹ Antibiotics and appendectomy are the treatment for uncomplicated or perforated appendicitis. There is controversy regarding antibiotics first, then surgery.¹²² Laparoscopic surgery provides quick recovery for uncomplicated appendicitis and provides an opportunity to discover malignancy. Nonoperative management is an option for some individuals.¹²³ Recovery is more complicated in cases of perforation or abscess formation and in individuals of older age.

Mesenteric Vascular Insufficiency

Mesenteric vascular insufficiency is rare with an incidence of about 2 to 3 cases per 100,000 persons. Mesenteric vascular insufficiency includes arterial, venous, occlusive, or nonocclusive etiologies. Three branches of the abdominal aorta supply the stomach and intestines:

the celiac artery and the superior and inferior mesenteric arteries (see Fig. 42.15). The inferior mesenteric vein drains into the splenic vein. The superior mesenteric vein combines with the splenic vein to form the hepatic portal vein. **Mesenteric venous thrombosis** is the least common of the causes of mesenteric vascular insufficiency. Hypercoagulability, endothelial injury, malignancies, right-sided heart failure, and deep venous thrombosis are risk factors. Mesenteric venous thrombosis presents with nonspecific abdominal pain and is treated with anticoagulants.¹²⁴

Acute mesenteric ischemia is more common in the elderly and results in a significant reduction in mucosal blood flow to the large and small intestines.¹²⁵ Preexisting morbidities include dissecting aortic aneurysms and arterial thrombi. Embolic obstruction is associated with atrial fibrillation, mitral valve disease, heart valve prostheses, or myocardial infarction. The superior mesenteric artery has a more direct line of flow from the aorta; therefore emboli enter it more readily than they enter the inferior branch, causing ischemia and necrosis of the small intestine. Ischemia and necrosis alter membrane permeability. Initially there is increased motility, nausea and vomiting, urgent bowel evacuation, and severe abdominal pain. Ischemia leads to decreased motility and distention. The damaged intestinal mucosa cannot produce enough mucus to protect itself from digestive enzymes. Mucosal alteration causes fluid to move from the blood vessels into the bowel wall and peritoneum. Fluid loss causes hypovolemia and further decreases in intestinal blood flow. As intestinal infarction progresses, shock, fever, bloody diarrhea, and leukocytosis develop. Bacteria invade the necrotic intestinal wall, causing gangrene and peritonitis.¹²⁶

Chronic mesenteric ischemia is rare. It can develop secondary to atherosclerotic stenosis or occlusion (most common); secondary to congestive heart failure, acute myocardial infarction, dysrhythmias, hemorrhage, thrombus formation, or aortic aneurysm; or secondary to any condition that decreases arterial blood flow. Chronic occlusion is often accompanied by formation of collateral circulation. The collateral vessels may be able to nourish the resting intestine, but after

eating, when the intestine requires more blood, the arterial supply may be insufficient. Ischemia develops, causing a cramping abdominal pain, called *abdominal angina*, a cardinal symptom. Some individuals suffer significant weight loss because they stop eating to control the pain. Progressive vascular obstruction eventually causes continuous abdominal pain and necrosis of the intestinal tissue and can precipitate acute mesenteric insufficiency.¹²⁷ Reperfusion injury related to reactive oxygen metabolites and inflammatory mediators contributes to tissue damage following revascularization.¹²⁸

Diagnosis of acute and chronic mesenteric ischemia is based on clinical manifestations, laboratory findings, and imaging studies. A bruit often can be heard over a partially occluded artery. Treatment includes aggressive rehydration and the use of antibiotics, anticoagulation, vasodilators, and inhibitors of reperfusion injury. Surgery, including endovascular techniques, is required to remove necrotic tissue, repair sclerosed vessels, and revascularize affected tissue. Acute occlusion is a surgical emergency, and mortality is high (50% to 90%). Early diagnosis and aggressive treatment result in the best survival rates.^{129,130}

Disorders of the Accessory Organs of Digestion

The accessory organs of digestion (liver, gallbladder, and pancreas) secrete substances necessary for digestion and, in the case of the liver, carry out metabolic functions needed to maintain life. Disorders of these organs include inflammatory disease, obstruction of ducts, and tumors. (Cancers of the digestive system are described at the end of this chapter.)

Common Complications of Liver Disorders

Of all the accessory organ disorders, acute or chronic liver disease leads to the most systemic, life-threatening complications. Complications of chronic liver disorders include portal hypertension, varices, splenomegaly, hepatopulmonary syndrome and portopulmonary syndrome, ascites, hepatic encephalopathy, jaundice, and hepatorenal syndrome.¹³¹

Portal Hypertension

Portal hypertension is abnormally high blood pressure in the portal venous system caused by resistance to portal blood flow. Pressure in this system is normally 3 to 5 mmHg; portal hypertension is the elevation of hepatic venous pressure above 5 mmHg.

◆Pathophysiology.

Portal hypertension is caused by disorders that obstruct or impede blood flow through any component of the hepatic portal system. *Intrahepatic causes* result from vascular remodeling with intrahepatic shunts, thrombosis, inflammation, or fibrosis, as occurs in cirrhosis of the liver, viral hepatitis, or schistosomiasis (a parasitic infection). *Posthepatic causes* occur from hepatic vein thrombosis or cardiac disorders that impair the pumping ability of the right side of the heart

(i.e., right-sided heart failure). This causes blood to back up and increases pressure in the portal system. The most common cause of portal hypertension is fibrosis and obstruction caused by cirrhosis of the liver. Thrombosis or narrowing of the hepatic portal vein is the major *prehepatic* cause. Long-term portal hypertension causes several pathophysiologic problems that are difficult to treat and can be fatal. These problems include varices, splenomegaly, hepatopulmonary syndrome, ascites, and hepatic encephalopathy.

Varices are distended, tortuous, collateral veins. Prolonged elevation of pressure in the hepatic portal vein causes collateral veins to open between the portal vein and systemic veins and their transformation into varices, particularly in the lower esophagus and stomach, but also over the abdominal wall (known as the *caput medusae* [*Medusa head*]), rectum (hemorrhoidal varices), or spleen (Fig. 42.15). Rupture of varices can cause life-threatening hemorrhage.

FIGURE 42.15 Varices Related to Portal Hypertension. Portal vein, its major tributaries, and the most important shunts (collateral veins) between the portal and caval systems. (From Monahan FD et al: *Phipps' medical-surgical nursing: concepts and clinical practice*, ed 8, St Louis, 2007, Mosby.)

Splenomegaly is enlargement of the spleen. Portal hypertension contributes to congestive splenomegaly caused by increased pressure in the splenic vein, which branches from the portal vein. Thrombocytopenia from platelet sequestration is the most common symptom of congestive splenomegaly and can contribute to an increased bleeding tendency.¹³² Splenomegaly also can be predictive of severity of esophageal varices.

Hepatopulmonary syndrome (HPS) (intrapulmonary vasodilation,

intrapulmonary shunting, hypoxia), and **portopulmonary hypertension (PPH)** (pulmonary vasoconstriction and vascular remodeling) are respiratory complications of advanced liver disease and portal hypertension and occur in about 15% to 30% of cases. In HPS there is pulmonary vasodilation, probably because of increased nitric oxide synthesis, increased pulmonary venous congestion, and right-to-left shunting that induces hypoxemia. PPH is associated with vascular remodeling and pulmonary artery vasoconstriction. There are no specific clinical manifestations, although dyspnea, cyanosis, and digital clubbing may occur. Diagnosis is made by arterial blood gas analysis, contrast echocardiography, transthoracic echocardiography, and right heart catheterization. In portopulmonary hypertension, mean pulmonary artery pressure is greater than 25 mmHg at rest. There is no specific treatment for HPS. Treatment of PPH includes targeting the pulmonary arterial vasculature to reduce pulmonary hypertension with various medication options (endothelin receptor antagonists, phosphodiesterase type-5 inhibitors, and prostanoids). Liver transplant is required.¹³³

◆Clinical Manifestations.

The most common clinical manifestation of portal hypertension is vomiting of blood from bleeding **esophageal varices**.¹³⁴ Bleeding is usually from varices that have developed slowly over a period of years. Slow, chronic bleeding from varices causes anemia or melena.

Acute rupture of esophageal varices causes hemorrhage and voluminous vomiting of dark blood. The ruptured varices are usually painless. Rupture is caused by a combination of erosion by gastric acid and elevated venous pressure. Mortality from ruptured esophageal varices ranges from 15% to 20%. Hemorrhoidal varices present as hematochezia and copious rectal bleeding. Recurrent bleeding of esophageal or gastric varices indicates a poor prognosis. Most individuals die within 1 year.

◆Evaluation and Treatment.

Diagnosis of portal hypertension is often made at the time of variceal

bleeding and confirmed by endoscopy and evaluation of portal venous pressure. Liver elastography (shear wave ultrasound or magnetic resonance imaging) provides a noninvasive measure of liver stiffness and extent of fibrosis.¹³⁵ Distended collateral veins may radiate over the abdomen, giving rise to caput medusae (Medusa head) from opening of the paraumbilical veins. The individual usually has a history of hepatitis or alcoholism.

Nonselective beta-blockers (that block both beta₁ [β_1] and beta₂ [β_2] receptors) can be effective in preventing variceal bleeding. Endoscopic vein ligation also is an option. Emergency management of bleeding varices includes fluid resuscitation, red blood cell replacement, prophylactic antibiotics, vasoactive drugs (e.g., octreotide, somatostatin, terlipressin), endoscopic variceal band ligation, compression of the varices with an inflatable tube or balloon, and injection of a sclerosing agent. Surgical construction of a transjugular intrahepatic portosystemic shunt (TIPS) (anastomosis of the portal vein to the inferior vena cava) may decompress the varices, but this treatment can precipitate encephalopathy or liver failure resulting from reduced hepatic blood flow.¹³⁴ There is no definitive treatment for portal hypertension.

Ascites

Ascites is the accumulation of fluid in the peritoneal cavity and is a complication of portal hypertension. Ascites traps body fluid in the peritoneal cavity from which it cannot escape. The effect reduces the amount of fluid available for normal physiologic functions. Cirrhosis is the most common cause of ascites; ascites is the most common complication of cirrhosis. Other diseases associated with ascites include right heart failure, abdominal malignancies, nephrotic syndrome, and malnutrition. Twenty-five percent of individuals who develop ascites caused by cirrhosis die within 1 year. Continued heavy drinking of alcohol is associated with this mortality and is related to cirrhosis.

◀Pathophysiology.

Several factors contribute to the development of ascites, including portal hypertension, decreased synthesis of albumin by the liver, splanchnic arterial vasodilation, and renal sodium and water retention. The *overflow theory* proposes that portal hypertension and reduced serum albumin levels cause capillary hydrostatic pressure to exceed capillary osmotic pressure (see [Chapter 3](#)), pushing water into the peritoneal cavity (transudative effusion). Portal hypertension also increases capillary hydrostatic pressures in the intestinal wall, which causes fluid to “weep” into the peritoneal cavity. Reduced capillary oncotic pressure adds to the fluid shift. The *underfill theory* proposes an increase in hepatic sinusoidal hydrostatic pressure and decreased plasma oncotic pressure with weeping of lymph fluid from the surface of the liver. The resulting decrease in effective circulating plasma volume activates antidiuretic hormone release and the renin-angiotensin-aldosterone system, stimulating the kidney to retain water and sodium leading to intravascular volume overload. The *peripheral arterial vasodilation theory*, or *forward theory*, is a synthesis of the overflow and underfill theories and the most accepted theory. This theory proposes that circulating nitric oxide and carbon monoxide cause splanchnic vasodilation. The decrease in systemic vascular resistance overcomes compensatory cardiac output. Stimulation of baroreceptors activates renal sodium retention through activation of the renin-angiotensin-aldosterone system, increased sympathetic tone, secretion of antidiuretic hormones, and fluid retention. Combined portal hypertension and splanchnic vasodilation causes fluid transudation and lymph formation, producing ascites. Translocation of bacteria and release of endotoxin cause spontaneous peritonitis with an inflammatory response that increases mesenteric capillary permeability and fluid movement into the peritoneal cavity, promoting ascites. [Fig. 42.16](#) summarizes the mechanisms by which cirrhosis of the liver causes ascites.

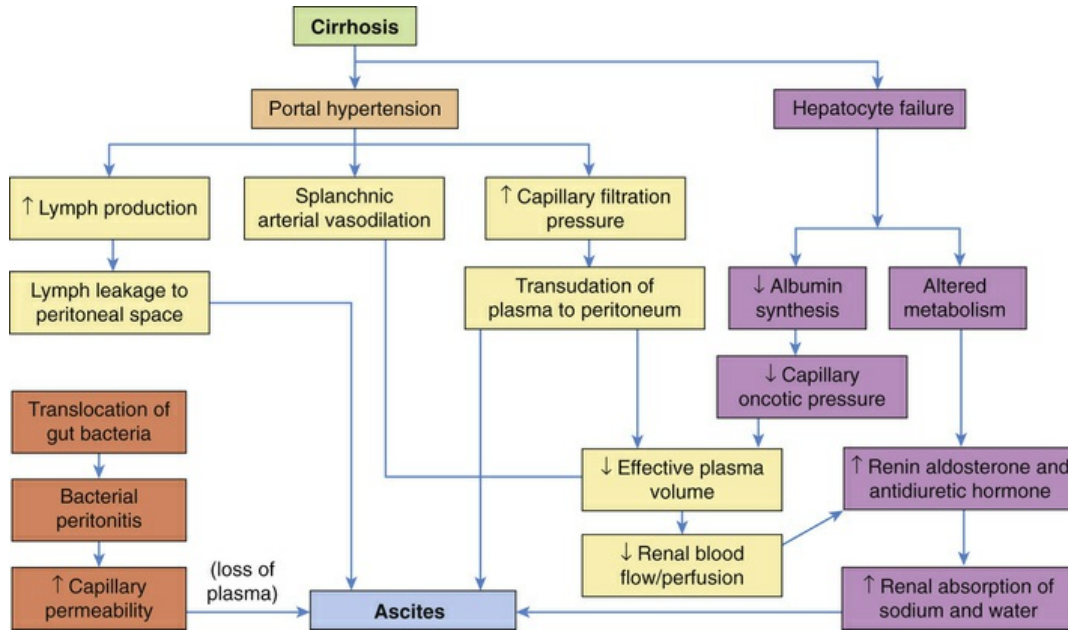

FIGURE 42.16 Mechanisms of Ascites Caused by Cirrhosis.

◀Clinical Manifestations.

The accumulation of ascitic fluid causes abdominal distention, increased abdominal girth, and weight gain (Fig. 42.17). Large volumes of fluid (10 to 20 L) displace the diaphragm and cause dyspnea by decreasing lung capacity. Respiratory rate increases, and the individual assumes a semi-Fowler position to relieve the dyspnea. Some peripheral edema is usually present. Dilutional hyponatremia is a consequence of excess fluid volume. Approximately 10% of individuals with ascites develop bacterial peritonitis, either spontaneously or as a result of paracentesis (needle aspiration of ascitic fluid). Peritonitis causes fever, chills, abdominal pain, decreased bowel sounds, and cloudy ascitic fluid.

FIGURE 42.17 Massive Ascites in an Individual with Cirrhosis. Distended abdomen, dilated upper abdominal veins, and everted umbilicus are classic manifestations. (From Goldman L, Schafer AI: *Goldman's Cecil medicine*, ed 24, Philadelphia, 2012, Saunders.)

◆ Evaluation and Treatment.

Diagnosis of ascites is usually based on clinical manifestations and identification of liver disease. The serum-ascites albumin gradient (SAAG) from ascitic fluid analysis is the most specific diagnostic indicator for portal hypertension–related ascites. Chest and abdominal x-rays, ultrasonography, or CT scans are used to evaluate the cause and extent of the ascites and complications such as peritonitis. The goal of treatment is to relieve discomfort. If the restoration of liver function is possible (e.g., in ascites caused by viral hepatitis), the ascites diminishes spontaneously. In the meantime, dietary salt restriction and potassium-sparing diuretics (i.e., spironolactone, an aldosterone antagonist) can reduce ascites. Strong diuretics, such as furosemide or ethacrynic acid, may be used, and vasopressin receptor-2 antagonists are effective for dilutional hyponatremia. Albumin may be given. Serum electrolyte levels are monitored carefully because the individual is at risk for hyponatremia and hypokalemia.

Palliative measures include paracentesis to remove 1 or 2 L of ascitic fluid and relieve respiratory distress. This procedure can have serious complications, however. The removal of too much fluid too fast relieves pressure on blood vessels, causing arteriolar vasodilation,

which carries the risk of hypotension, shock, or death. Despite repeated paracentesis, ascitic fluid reaccumulates in individuals with irreversible disease, drawing more albumin and electrolytes out of the vascular compartment. Paracentesis is also likely to cause peritonitis. Bacterial peritonitis is treated with antibiotics.¹³⁶ Other procedures include peritoneovenous shunt (peritoneal fluid into veins) and transjugular intrahepatic portosystemic shunt (TIPS) (bypass of blood flow from the portal venous branch to the hepatic venous branch). Individuals with ascites and portal hypertension have a poor prognosis, and liver transplant is the best treatment option.¹³⁷

Hepatic Encephalopathy

Hepatic encephalopathy (portosystemic encephalopathy) is a complex neurologic syndrome characterized by impaired behavioral, cognitive, and motor function. The syndrome has three types and may develop rapidly during acute fulminant hepatitis (type A); after portosystemic bypass or shunting without liver disease (type B); or slowly during the course of cirrhosis, chronic liver disease, or portosystemic bypass (type C, which can be episodic, persistent, or covert).¹³⁸ Risk factors in the presence of advanced liver disease include gastrointestinal bleeding, increased dietary protein, electrolyte imbalance, and hypoxia.

◆Pathophysiology.

Hepatic encephalopathy results from a combination of biochemical alterations that affect neurotransmission.¹³⁹ Liver dysfunction and collateral vessels that shunt blood around the liver to the systemic circulation permit neurotoxins and other harmful substances absorbed from the gastrointestinal tract to accumulate and circulate freely to the brain. Substances include inflammatory cytokines, short-chain fatty acids, serotonin, tryptophan, and false neurotransmitters. The most hazardous substances are end products of intestinal protein digestion, particularly ammonia, which cannot be converted to urea by the diseased liver. The digestion of blood from leaking or ruptured varices adds to the amount of ammonia present in systemic blood, as

does the action of ammonia-forming bacteria in the colon. Ammonia that reaches the brain is metabolized to glutamine, with osmotic disturbances and alterations in cerebral blood flow that interfere with neurotransmitters and cause astrocyte edema (cytotoxic edema) and oxidation. Permeability of the blood-brain barrier also may be increased (vasogenic edema), contributing to astrocytes swelling, brain edema, and intracranial hypertension. Excessive amounts of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter from benzodiazepine-like compounds from the intestinal flora, may contribute to reduced levels of consciousness. Infection, hemorrhage, inflammation, electrolyte imbalance, sedatives, and analgesics also can precipitate stupor and coma in the presence of liver disease

◆Clinical Manifestations.

Subtle changes in personality, memory loss, irritability, lethargy, and sleep disturbances are common initial manifestations of hepatic encephalopathy and can be covert (minimal hepatic encephalopathy). In acute liver failure, symptom onset can be rapid with confusion, disorientation to time and space, flapping tremor of the hands (asterixis), slow speech, bradykinesia, stupor, convulsions, and coma. Coma is usually a sign of severe liver dysfunction and ultimately results in death. Variceal bleeding and ascites may develop concurrently. Symptoms may be episodic, recurrent, or persistent.

◆Evaluation and Treatment.

There is no specific diagnostic test for hepatic encephalopathy. Diagnosis is based on a history of liver disease, clinical manifestations, and psychometric testing. Electroencephalography and blood chemistry tests, including blood ammonia levels, provide supportive data. Tracking levels of serum ammonia assesses treatment effectiveness and liver function.

Correction of fluid and electrolyte imbalances and withdrawal of depressant drugs metabolized by the liver are the first steps in the treatment of hepatic encephalopathy. Cerebral edema can be managed with hypertonic saline, mannitol, or hypothermia. Dietary protein is

maintained to prevent malnutrition, but at levels that reduce blood ammonia levels. Nonabsorbable disaccharides (e.g., lactulose) prevent ammonia absorption in the colon. Neomycin eliminates ammonia-producing intestinal bacteria but can be nephrotoxic. Glutaminase inhibitors reduce gut ammonia. Rifaximin decreases intestinal production of ammonia and is used for lactulose nonresponders. Extracorporeal liver support systems remove toxins from the blood and are an option for managing overt hepatic encephalopathy.¹⁴⁰

Jaundice

Jaundice, or **icterus**, is a yellow or greenish pigmentation of the skin caused by **hyperbilirubinemia** (total plasma bilirubin concentrations greater than 2.5 to 3 mg/dL). Hyperbilirubinemia and jaundice can result from (1) extrahepatic (posthepatic) obstruction to bile flow (gallstones), (2) intrahepatic obstruction (hepatocellular disease such as cirrhosis or hepatitis), or (3) prehepatic excessive production of unconjugated bilirubin (i.e., excessive hemolysis of red blood cells)¹⁴¹ (Fig. 42.18). Jaundice in newborns is caused by impaired bilirubin uptake and conjugation (see [Chapter 43](#)).

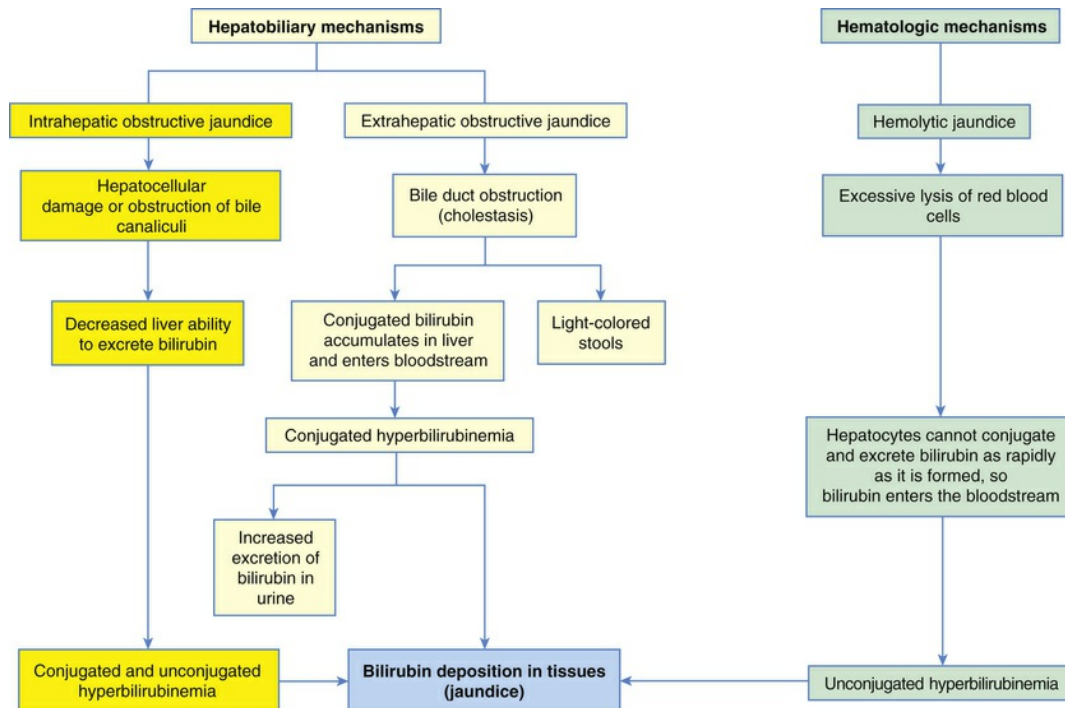

FIGURE 42.18 Mechanisms of Jaundice.

◆ Pathophysiology.

Obstructive jaundice can result from extrahepatic or intrahepatic obstruction.¹⁴² *Extrahepatic obstructive jaundice* develops if the common bile duct is occluded by a gallstone, tumor, or inflammation. Bilirubin conjugated by the hepatocytes cannot flow through the obstructed common bile duct into the duodenum. Therefore it accumulates in the liver and enters the bloodstream, causing hyperbilirubinemia and jaundice. *Intrahepatic obstructive jaundice* involves disturbances in hepatocyte function and obstruction of *bile canaliculi*. The uptake, conjugation, and excretion of bilirubin can be affected with elevated levels of both conjugated and unconjugated bilirubin. Hepatocellular damage increases plasma concentrations of unconjugated bilirubin. The major disorder, however, is obstruction of bile canaliculi, which diminishes flow of conjugated bilirubin into the common bile duct with elevations in the plasma. In mild cases, some of the bile canaliculi open. Consequently, the amount of bilirubin in the intestinal tract may be only slightly decreased.

Excessive hemolysis (destruction) of red blood cells or absorption of

hematoma causes **hemolytic jaundice (prehepatic or nonobstructive jaundice)**. Increased unconjugated bilirubin is formed through metabolism of the heme component of destroyed red blood cells and exceeds the conjugation ability of the liver, causing blood levels of unconjugated bilirubin to rise. Decreased bilirubin uptake or conjugation also causes unconjugated hyperbilirubinemia, as occurs with reaction to some drugs (e.g., rifampin) and in genetic disorders such as Gilbert syndrome. Gilbert syndrome is an inherited autosomal dominant deficiency of glucuronyl transferase enzyme, which is required for the hepatic uptake of unconjugated bilirubin. The causes of jaundice are summarized in [Table 42.6](#).

TABLE 42.6

THREE COMMON TYPES OF JAUNDICE

TYPE	MECHANISM	CAUSES
Hemolytic jaundice (predominantly unconjugated bilirubin)	Excessive destruction of erythrocytes	Membrane defect of erythrocytes Hemolytic anemias
		Immune reaction
		Severe infection
		Toxic substances in the circulation (e.g., snake venom) Transfusion of incompatible blood
Obstructive (cholestatic) jaundice (predominantly conjugated bilirubin)	Obstruction to passage of conjugated bilirubin from liver to intestine	Obstruction of bile duct by gallstones or tumor (extrahepatic obstructive jaundice)
		Obstruction of bile flow through the liver (intrahepatic obstructive jaundice) Drugs
Hepatocellular jaundice (both conjugated and unconjugated bilirubin)	Failure of liver cells (hepatocytes) to conjugate bilirubin and of bilirubin to pass from liver to intestine	Genetic defect of hepatocyte (decreased enzymes), such as occurs in premature infants (see Chapter 43)
		Hepatitis or biliary cirrhosis

◆Clinical Manifestations.

The clinical manifestations of jaundice vary and are related to the underlying pathology. Conjugated bilirubin is water soluble and appears in the urine. Conjugated hyperbilirubinemia may cause the urine to darken several days before the onset of jaundice. The stools may be light colored or clay colored because they lack bile pigments. The stools also lack urobilinogen because bile is not available for conversion to urobilinogen. Extrahepatic biliary obstruction is associated with increased intestinal permeability and bacterial translocation and may contribute to the pathogenesis of sepsis.¹⁴³

Fever, chills, and pain often accompany jaundice resulting from viral or bacterial inflammation of the liver (e.g., viral hepatitis). Manifestations of liver injury from any cause commonly include anorexia, malaise, and fatigue. Yellow discoloration may first occur in the sclera of the eye and then progress to the skin. Skin xanthomas (cholesterol deposits) and pruritus commonly accompany jaundice with an elevation of serum alkaline phosphatase level.

◆Evaluation and Treatment.

Laboratory evaluation establishes whether the elevated level in plasma bilirubin is conjugated or unconjugated or both. The history, physical examination, and laboratory tests identify underlying disorders, such as alcoholism, exposure to hepatitis virus, or gallbladder disease. The treatment for jaundice consists of correcting the cause.

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) is functional renal failure; it develops as a complication usually associated with alcoholic cirrhosis. The renal failure is not caused by primary renal disease or other extrinsic factors, but rather by arterial vasodilation of the splanchnic vasculature, reduced effective blood volume, and renal vasoconstriction in the presence of acute liver disease with advanced liver failure and portal hypertension.

◆Pathophysiology.

There are two types of HRS: type 1 and type 2. Type 1 involves rapid (within 2 weeks) progressive renal failure related to severe reduction in blood volume and decreased cardiac output secondary to massive gastrointestinal or variceal bleeding and hypotension caused by bleeding and splanchnic vasodilation. Type 2 is slower, is more stable, and is accompanied by refractory ascites.¹⁴⁴

The decrease in blood volume and hypotension result in decreased renal perfusion, decreased glomerular filtration, and oliguria (see [Chapter 39](#)). In type 2 HRS, the ability to concentrate and dilute urine is usually maintained. Intrarenal vasoconstriction may result from the selective effects of vasoactive substances that accumulate in the blood because of liver failure. The diseased liver fails to remove excessive angiotensin, vasopressin, prostaglandins, and catecholamines from the blood, which travel to the kidneys and cause vasoconstriction. Vasoconstriction also may be a compensatory response to portal hypotension and vasodilation in the splanchnic circulation. The exact reason for the renal vasoconstriction is unknown but is related to vasoconstrictive mediators and sympathetic nerve stimulation.¹⁴⁴

◆Clinical Manifestations.

The onset of hepatorenal manifestations may be acute or gradual. Type 1 HRS is a rapidly progressive renal failure with serum creatinine >2.5 mg/dL (>221 $\mu\text{mol/L}$) or a decrease of 50% in creatinine clearance (<20 mL/min) in less than 2 weeks. Type 2 HRS is a more gradual renal failure with a serum creatinine of >1.5 mg/dL (>133 $\mu\text{mol/L}$) with diuretic-resistant ascites.¹⁴⁵ Oliguria and complications of advanced liver disease, including jaundice, ascites, and gastrointestinal bleeding, are usually present. Systolic blood pressure is usually less than 100 mmHg. Nonspecific symptoms of hepatorenal syndrome include anorexia, weakness, and fatigue.

◆Evaluation and Treatment.

Diagnosis of HRS is made by excluding all other causes of renal failure. Despite decreased glomerular filtration, serum potassium

levels do not become dangerously elevated until the terminal stages of the hepatorenal syndrome. Serum creatinine values increase rapidly (within 2 weeks) in type 1 HRS and slowly or not at all in type 2 HRS. Urine osmolality is increased, but urine sodium concentrations are below normal (unlike acute tubular necrosis). Urine specific gravity is greater than 1.015. The prognosis for hepatorenal syndrome is usually poor and is related to liver function. Secondary problems, including fluid and electrolyte disorders, bleeding, infections, and encephalopathy, are vigorously treated. Treatments to increase renal perfusion include systemic vasoconstrictors (α -adrenergic agonists and octreotide) and albumin, which are effective in 50% of individuals with type 1 HRS. Vasoconstrictors also may be combined with TIPS as a bridge to liver transplant. Liver transplant reverses symptoms in most individuals, and it may be combined with kidney transplantation.¹⁴⁴

Disorders of the Liver

Acute Liver Failure

Acute liver failure (fulminant liver failure) is a rare clinical syndrome (2000 cases in the United States annually)¹⁴⁶ resulting from severe impairment or necrosis of liver cells without preexisting liver disease or cirrhosis. Acetaminophen overdose is the leading cause of acute liver failure in the United States¹⁴⁷ (Box 42.3). Acute liver failure also can occur with concurrent liver disease (acute on chronic liver failure),¹⁴⁸ including complications of viral hepatitis, particularly hepatitis B virus (HBV) and hepatitis C virus (HCV) infection, and can be compounded by infection with the delta virus, as well as metabolic liver disorders. Edematous hepatocytes and patchy areas of necrosis and inflammatory cell infiltrates disrupt the parenchyma. The death of hepatocytes may be caused by viral or toxic injury or immunologic and inflammatory damage with necrosis or apoptosis.

Box 42.3

Acetaminophen and Acute Liver Failure

Acetaminophen (paracetamol) toxicity from chronic use or intentional overdose is the leading cause of acute liver failure (46%) in the United States and Great Britain (40%-70%). Liver injury may occur with doses of 4 to 10 g/day, and hepatotoxicity with mitochondrial injury and hepatocyte necrosis should be suspected when doses exceed 4 g/day. The onset is sudden and unpredictable with abdominal pain and nausea developing between 12 and 24 hours followed by coagulopathy and encephalopathy within 72 to 96 hours. Elevated serum aminotransferase levels (may be up to 400 × normal) accompanied by hypoprothrombinemia, lactic acidosis, and renal failure support a diagnosis of acute liver failure caused by acetaminophen. Complications of cerebral edema and infection are difficult to diagnose and treat and may lead to multiorgan failure, irreversible brain damage, and death. Early treatment (within 8 hours of overdose) with correct dosing with *N*-acetylcysteine provides a 66% chance of recovery, and there is 70% survival at 1 year after liver transplant.

Data from Jaeschke H: *Dig Dis* 33(4):464-471, 2015; Lee WM: *J Hepatol* 2017 Jul 29 [Epub ahead of print]; Yoon E, et al: *J Clin Transl Hepatol* 4(2):131-142, 2016.

Acute liver failure usually develops 6 to 8 weeks after the initial symptoms of viral hepatitis or a metabolic liver disorder (e.g., Wilson disease), or within 5 days to 8 weeks of acetaminophen overdose. Anorexia, vomiting, abdominal pain, and progressive jaundice are initial signs, followed by ascites and gastrointestinal bleeding. Hepatic encephalopathy is manifested as lethargy and altered motor functions. Coma is related to cerebral edema, ischemia, and brainstem herniation. Liver function tests show elevations in the levels of both conjugated and unconjugated serum bilirubin, serum transaminases, and blood ammonia. Prothrombin time is prolonged. Renal failure and pulmonary distress can occur.¹⁴⁹ Treatment of acute liver failure requires rapid evaluation and critical care. *N*-Acetylcysteine is used for acetaminophen poisoning; antiviral therapy appears to improve

survival in cases of viral hepatitis; and lowering blood ammonia levels may improve prognosis. Liver transplantation is lifesaving. Artificial liver support systems remove toxins and can be a bridge to transplant. Growth factors may promote hepatic regeneration, and stem cell therapy continues to be investigated.¹⁵⁰⁻¹⁵²

Autoimmune Hepatitis

Autoimmune hepatitis is a rare chronic, progressive, autoimmune inflammatory liver disease that affects genetically susceptible individuals, usually women and children. The cause is unknown, but certain infections and drugs are thought to trigger the autoimmune response. Autoreactive T cells trigger secretion of proinflammatory cytotoxic cytokines. Serologically, there are two types: type 1 with positivity for antinuclear and/or anti-smooth muscle antibody, and type 2 with anti-liver kidney microsomal type 1 antibody or anti-liver cytosol type 1 antibody. There is hypergammaglobulinemia and an elevation in aspartate and alanine aminotransferase. Biopsy confirms the diagnosis and shows lymphocytic infiltration with interface (parenchymal-connective tissue interface) hepatitis. There may be no symptoms or jaundice, fatigue, loss of appetite, amenorrhea, or acute liver failure. Most individuals respond to immunosuppressive drug therapy (e.g., corticosteroids or in combination with azathioprine) with remission within 24 months. Relapses are common with treatment withdrawal. About 10% of cases require liver transplant.¹⁵³

Viral Hepatitis

Viral hepatitis is a relatively common systemic disease that affects primarily the liver. Different strains of viruses cause different types of hepatitis. The types and estimated incidence in the United States in 2014 were 2500 cases for hepatitis A virus (HAV), 19,200 cases for hepatitis B virus (HBV), an unknown number for hepatitis D virus (HDV) associated with HBV, 30,500 cases for hepatitis C virus (HCV), and an unknown number for hepatitis E virus (HEV). HVA, HVB, and HVC are the most common in the United States, and hepatitis C cases

tripled from 2010 to 2015 with an estimate of 34,000 cases.^{154,155} Characteristics of the various types of hepatitis are presented in [Table 42.7](#).

TABLE 42.7

CHARACTERISTICS OF VIRAL HEPATITIS

CHARACTERISTIC	HEPATITIS A	HEPATITIS B	HEPATITIS D	HEPATITIS C	HEPATITIS E
Size of virus	27-nm RNA virus	47-nm DNA virus	36-nm RNA virus, defective virus with HBsAg coat	30- to 60-nm RNA virus	32-nm RNA virus
Incubation phase	30 days	60–180 days	30–180 days; dependent on HBV for multiplication	35–72 days	15–60 days
Route of transmission	Fecal-oral, parenteral, sexual	Parenteral, sexual	Parenteral, fecal-oral, sexual	Parenteral	Fecal-oral
Onset	Acute with fever	Insidious	Insidious	Insidious	Acute
Carrier state	Negative	Positive	Positive	Positive	Negative
Severity	Mild	Severe; may be prolonged or chronic	Severe	Mild to severe	Severe in pregnant women
Chronic hepatitis	No	Yes	Yes	Yes	No
Age-group affected	Children and young adults	Any	Any	Any	Children and young adults
Prophylaxis	Hygiene, immune serum globulin, HAV vaccine	Hygiene, HBV vaccine	Hygiene, HBV vaccine	Hygiene, screening blood, interferon-alpha or combined with ribavirin; treatment	Hygiene, safe water and meat

				also related to HCV genotype \pm cirrhosis	
--	--	--	--	--	--

DNA, Deoxyribonucleic acid; *HAV*, hepatitis A virus; *HBsAg*, hepatitis B surface antigen; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *RNA*, ribonucleic acid.

Hepatitis A Virus (HAV).

HAV is in the family Picornaviridae, is a *Hepatovirus*, and causes acute disease. HAV can be recovered from the feces, bile, and sera of infected individuals. The usual mode of transmission is the fecal-oral route (contaminated food or water), but the virus can be spread also by the transfusion of infected blood and men having sex with men.¹⁵⁶ Approximately 45% of adults in urban areas have HAV antibodies in their blood. The disease spreads readily in crowded, unsanitary conditions, usually through contaminated food or water. Person-to-person spread is more likely to occur in institutional care settings where there is contact between clients and caregivers who are not vaccinated.

The incubation period (the time between exposure and onset of symptoms) for HAV is 4 to 6 weeks (Fig. 42.19). Fecal shedding of the virus is greatest for 10 to 14 days before the onset of symptoms and during the first week of symptoms, and up to 3 months after onset of symptoms. The disease is most contagious during this time. Antibodies to HAV (anti-HAV) develop about 4 weeks after infection. The serum immunoglobulin M (IgM) concentration increases initially and is followed by an increase of serum IgG, whose levels remain elevated for several years after infection, creating immunity to the disease (see Chapters 7 and 8 for a description of immune functions). The administration of immunoglobulin before exposure or early in the incubation period can prevent hepatitis A. HAV vaccine and combined HAV and HBV vaccines are available and effective in preventing the disease and confer long-term immunity.¹⁵⁷ Transmission of HAV is prevented by handwashing and use of gloves when disposing fecal matter. Molecular procedures are available for

direct surveillance of HAV in food and water.¹⁵⁸

FIGURE 42.19 Course of Infection with the Hepatitis A Virus (HAV). ALT, Alanine transaminase; IgG, immunoglobulin G; IgM, immunoglobulin M.

Hepatitis B Virus (HBV).

HBV is a parenterally and sexually transmitted hepadnavirus with eight genotypes (A through H) with many subgenotypes. The pathogenic characteristics are unknown. The genotypes vary by geographical region, disease progression, and treatment response.¹⁵⁹ People who are immunosuppressed; receive hemodialysis, multiple blood transfusions, or immunosuppressive drugs; have multiple sex partners; or share needles, syringes, or other drug equipment, as well as infants born to infected mothers, have a greater risk of exposure or less resistance to HBV. Coinfection with HCV, HDV, and HIV is common because these viruses share the same routes of transmission.

Mother-infant transmission of HBV occurs if the mother becomes infected during the third trimester of pregnancy. In women who are seropositive for both hepatitis B surface antigen (HBsAg) and hepatitis B e-antigen (HBeAg), vertical transmission is approximately 90%. Screening for HBV should occur for all pregnant women, and infants born to positive mothers should receive HBV vaccine and HBV

immunoglobulin within 12 hours after birth.¹⁶⁰ Transmission among men having sex with men may be by oral or genital contact with bleeding lesions in the rectal mucosa. HBV is a major cause of chronic hepatitis, cirrhosis, and hepatocellular carcinoma.¹⁶¹

Three types of viral particles are involved in HBV infection. The larger (47 nm) Dane particle probably represents the intact HBV. The Dane particle has a double-layered outer coat and carries HBsAg, which was originally called the *Australia antigen*. HBsAg can be identified in the serum by radioimmunoassay. Hepatitis B core antigen (HBcAg) usually is not detected in the serum. The HBeAg is a derivative of HBcAg and is a marker of HBV replication. The HBV has an incubation period of 6 to 8 weeks. The initial serologic change is a transient increase in IgM levels. Levels of IgG antibodies to HBsAg rise more slowly and remain elevated for years (Fig. 42.20). *Chronic infection* develops in 15% to 30% of those with acute infection. HBV DNA and HBsAg measure viral load and the efficacy of drug treatment. Persistent liver cell injury, chronic low-grade inflammation, and deregulation of cellular growth control genes lead to increased risk for cirrhosis and liver failure and foster oncogenic transformation and hepatocellular carcinoma. Cancer risk is greater with HBV and HCV coinfection.¹⁶²

FIGURE 42.20 Course of Infection with the Hepatitis B Virus (HBV). ALT, Alanine transaminase; *anti-HBe*, antibody to HBeAg; *HBV-DNA*, hepatitis B

virus deoxyribonucleic acid; *IgG*, immunoglobulin G; *IgM*, immunoglobulin M; *HBsAg*, hepatitis B surface antigen; *IgG anti-HBs*, antibody to HBsAg; *HBeAg*, hepatitis B e-antigen; *IgM anti-HBc*, antibody to hepatitis B core antigen.

Antiviral and immunomodulatory treatment for chronic hepatitis B includes monotherapy or combination therapy with nucleoside and nucleotide analogs (targets reverse transcriptase [e.g., entecavir, tenofovir]) and interferon (e.g., peginterferon). Drug resistance and disease recurrence develop because double-stranded HBV DNA is transformed in the nucleus to covalently closed circular DNA (cccDNA), the template necessary for viral RNA synthesis and replication of the virus. cccDNA remains in the hepatocytes after treatment and can be used as a marker of treatment effectiveness; HBV immune control is difficult to induce.^{163,164} Vaccine prevents transmission of hepatitis B, the development of acute or chronic hepatitis B, and reduction of hepatocellular carcinoma, particularly in high-risk populations. Mutant strains can develop with escape from vaccine protection or diagnosis with HBsAg. Hepatitis B immunoglobulin provides postexposure prophylaxis against HBV after contact with blood or body fluids of individuals infected with hepatitis B. HBV vaccine or a combined vaccine for HAV and HBV provides protective immunity. New drugs that target different stages of the HBV life cycle and eradication of cccDNA and HBsAg, as well as vaccines that target different HBV proteins, are under investigation.^{163,165}

Hepatitis C Virus (HCV).

HCV (previously known as *non-A, non-B hepatitis*) is a parenterally transmitted flavivirus with 10 genotypes (A through J). Worldwide, a significant number of HCV cases involve intravenous drug users, who also have a high incidence of HIV infection.¹⁶⁶ HBV infection increases the risk for HCV infection. Approximately 80% of cases develop chronic liver disease.¹⁶⁷ HCV is diagnosed through detection of anti-HCV IgG. Persistent infection with recurring acute symptoms and elevated aminotransferase levels represents the clinical presentation. HCV is often undiagnosed as there may be no symptoms. Direct-

acting antiviral drug therapy is available; it is genotype specific, depends on the presence or absence of cirrhosis, is oral, and is interferon free. Resistance to drug therapy is common, particularly when there is progression to chronic liver disease or selected viral genotypes.¹⁶⁸

Progression of disease to cirrhosis is the most common cause of hepatocellular carcinoma in the United States and of liver transplant worldwide. Extrahepatic manifestations include cryoglobulinemia vasculitis and lymphoproliferative disorders.¹⁶⁹ Viral mutation, genetic diversity between genotypes, and reinfection after treatment have made vaccine development difficult, and there is no vaccine for HCV. The Centers for Disease Control and Prevention have recommended that all persons born from 1945 through 1965 be screened for HCV infection.¹⁷⁰ Individuals with HCV and cirrhosis or liver failure also should be screened for esophageal varices.¹⁷¹

Hepatitis D Virus (HDV).

HDV is a defective, single-stranded RNA virus and occurs as a coinfection with hepatitis B. The delta virus depends on the viral coat of HBsAg molecules on HBV for its replication.¹⁷² Hepatitis D has been shown to suppress replication of HBV. Parenteral drug users have a high incidence of HDV infection. HDV symptoms can be mild or severe with progression to fulminant liver failure. HDV is diagnosed by the presence of antibodies directed against HDAg (anti-HD) and HDV RNA in serum. Treatment for chronic HDV includes pegylated interferon alpha and is effective in about 25% of individuals. New treatments are in clinical development.¹⁷³

Hepatitis E Virus (HEV).

HEV is classified within the *Hepeviridae* family and is most common in Asian and African countries; human genotypes vary by country. It is transmitted by the fecal-oral route, usually by way of contaminated water or uncooked meat. It is also found in developed countries and must be differentiated from drug-induced liver injury. Animal reservoirs of HEV with transmission to humans include domestic

pigs, wild boars, deer, mongoose, and rabbits. It is more prevalent among adults and has the highest mortality in pregnant women and immunosuppressed individuals. Clinically, it can be asymptomatic and resemble HAV or progress to acute liver failure or chronic hepatitis. Extrahepatic manifestations include neurologic symptoms and impaired kidney function. Diagnosis is based on detection of anti-HEV IgM. Ribavirin and pegylated interferon are effective treatments. A vaccine for HEV has been approved in China but not in other countries.¹⁷⁴

◆Pathophysiology.

The pathologic lesions of hepatitis are similar to those caused by other viral infection. Hepatic cell necrosis, scarring, Kupffer cell hyperplasia, and infiltration by mononuclear phagocytes occur with varying severity. Cellular injury is promoted by cell-mediated immune mechanisms (i.e., cytotoxic T cells, T regulatory cells, and natural killer cells).¹⁷⁵ Regeneration of hepatic cells begins within 48 hours of injury. The inflammatory process can damage and obstruct bile canaliculi, leading to cholestasis and obstructive jaundice. In milder cases the liver parenchyma is not damaged. Damage tends to be most severe in cases of hepatitis B and hepatitis C, as these viruses cause liver cell apoptosis. Hepatitis B is also associated with *acute liver failure*, a rare form of the disease that is characterized by massive hepatic necrosis. Mortality is high, but recovery can be complete.

◆Clinical Manifestations.

The clinical manifestations of the various types of viral hepatitis are very similar with nausea, malaise, abdominal pain, and jaundice. The spectrum of manifestations ranges from absence of symptoms to fulminating hepatitis, with rapid onset of liver failure and coma. Acute viral hepatitis causes abnormal liver function test results. The serum aminotransferase values, aspartate transaminase (AST) and alanine transaminase (ALT), are elevated, but their elevation may not be consistent with the extent of cellular damage. The clinical course of hepatitis usually consists of four phases: incubation, prodromal,

icteric, and recovery phases. During the **incubation phase**, the virus is replicating and manifestations vary depending on the virus (see [Table 42.7](#)). There may be no symptoms, but there can be serologic and serum enzyme markers.

Prodromal Phase.

The **prodromal (preicteric) phase** of hepatitis begins about 2 weeks after exposure and ends with the appearance of jaundice. Fatigue, anorexia, malaise, nausea, vomiting, headache, hyperalgia, cough, and low-grade fever are prodromal symptoms that precede the onset of jaundice. About 10% of individuals may develop extrahepatic symptoms including rash, arthralgias, and purpura. HBV and HCV may cause nephritis related to glomerular immune complex deposition.^{176,177} Infection with HCV may have no symptoms. Right upper abdominal pain is common, and a weight loss of 2 to 4 kg is not unusual. The infection is highly transmissible during this phase.

Icteric Phase (Jaundice).

The **icteric phase** begins about 1 to 2 weeks after the prodromal phase and lasts 2 to 6 weeks. Individuals who develop chronic HBV infection do not become jaundiced and may not be diagnosed.¹⁷⁸ Hepatocellular destruction and intrahepatic bile stasis cause jaundice (icterus). The urine may be dark and the stools clay colored before the onset of jaundice from conjugated hyperbilirubinemia. The icteric phase is the actual phase of illness. The liver is enlarged, smooth, and tender, and percussion over the liver causes pain. During the icteric phase, gastrointestinal and respiratory symptoms subside, but fatigue and abdominal pain may persist or become more severe. The stools may be lighter in color as a result of cholestasis. Serum bilirubin levels range from 5 to 10 mg/dL, with conjugated bilirubin fraction increasing. The jaundice may last 2 to 6 weeks or longer. Mild and transient itching often accompanies jaundice. The prothrombin time may be prolonged in individuals with more serious forms of the disease.

Recovery Phase.

The posticteric or **recovery phase** begins with resolution of jaundice, about 6 to 8 weeks after exposure. Although the liver may still be enlarged and tender, symptoms diminish. In most cases, liver function test results return to normal within 2 to 12 weeks after the onset of jaundice.

Chronic hepatitis may begin at this point and is associated with HBV, HCV, and HDV infection. **Chronic active hepatitis** is the persistence of clinical manifestations and liver inflammation after the acute stages. Liver function tests remain abnormal for longer than 6 months, and HBsAg persists. Chronic, active HBV and HCV both predispose individuals to cirrhosis and primary hepatocellular carcinoma.¹⁷⁹ Chronic active hepatitis constitutes a carrier state, and HBV and HCV can be transmitted from mothers to infants.¹⁸⁰

◆Evaluation and Treatment.

Diagnosis and treatment were previously described for the different types of hepatitis viruses. Physical activity may be restricted. A low-fat, high-carbohydrate diet is beneficial if bile flow is obstructed.

There should be no direct contact with blood or body fluids of individuals with hepatitis B or hepatitis C. A combined vaccine for HAV and HBV is available. Hepatitis B immunoglobulin provides passive prophylactic immunity against HBV. Prophylaxis is recommended for healthcare workers, liver transplant recipients, and others who are at risk for contact with infected body fluids.¹⁸¹

Cirrhosis

Cirrhosis is an irreversible inflammatory, fibrotic liver disease and the eighth leading cause of death in the United States. Many disorders can cause cirrhosis and are summarized in [Box 42.4](#). Alcohol abuse and HCV infection are the most common causes, and nonalcoholic steatohepatitis is an increasing cause. The process of cellular injury depends on the cause of cirrhosis; however, not all causes are clearly understood. Structural changes result from injury (alcoholism, viruses, steatosis, chemicals) and fibrosis. Fibrosis is a consequence of Kupffer cell (liver macrophages) activation with release of

inflammatory mediators, reactive oxygen species, and growth factors and activation of fibrogenic hepatic stellate cells.¹⁸² Chaotic fibrosis alters or obstructs biliary channels and blood flow, producing jaundice and portal hypertension. New vascular channels form shunts, and blood from the portal vein bypasses the liver, contributing to portal hypertension, metabolic alterations, and toxin accumulation. The process of regeneration is disrupted by hypoxia, necrosis, atrophy, and (ultimately) liver failure. The formation of fibrous bands and regenerating nodules distorts the architecture of the liver parenchyma and gives the liver a cobbly appearance. The liver may be larger or smaller than normal and is usually firm or hard when palpated. Cirrhosis develops slowly over a period of years. Its severity and rate of progression depend on the cause. The complications of cirrhosis include jaundice, portal hypertension, ascites, hepatic encephalopathy, varices with gastrointestinal bleeding, hepatorenal syndrome, hepatopulmonary syndrome, and portopulmonary syndrome.¹⁸³

Box 42.4

Causes of Cirrhosis

- Hepatitis virus—B and C (common)
- Excessive alcohol intake (common)
- Idiopathic (common)
- Nonalcoholic fatty liver disease (NAFLD), also known as *nonalcoholic steatohepatitis (NASH)*
- Autoimmune disorders
 - Autoimmune hepatitis
 - Primary biliary cirrhosis
 - Primary sclerosing cholangitis
- Hereditary metabolic disorder
 - α_1 -Antitrypsin deficiency
 - Hemochromatosis

Wilson disease
Glycogen or lipid storage diseases
Prolonged exposure to chemicals (e.g., carbon tetrachloride,
cleaning and industrial solvents, copper salts)
Hepatic venous outflow obstruction
Budd-Chiari syndrome
Right-sided heart failure

If alcohol is involved, the rate of cell death and the severity of inflammation depend on the amount of alcohol present.¹⁸⁴ Removal of alcohol slows the progression of liver damage and enhances the process of regeneration.

Alcoholic Liver Disease.

Abuse of any type of alcoholic beverage can cause alcoholic liver disease, and the severity of disease is related to the amount and duration of alcohol consumed and formation of acetaldehyde^{184,185} (see [Chapter 2](#) and [Fig. 2.21](#)). The spectrum of alcoholic liver disease includes steatosis, alcoholic hepatitis, and alcoholic cirrhosis (fibrosis). The incidence of alcoholic cirrhosis is greatest in middle-aged men; however, women develop more severe liver injury than men.¹⁸⁶ In the United States, mortality resulting from cirrhosis is highest among Hispanic white males and females; however, the death rates for all groups are declining.¹⁸⁷ Malnutrition may add to the risk of cirrhosis in alcohol abusers. Many alcoholics are malnourished, and the liver cannot regenerate without adequate nutrition.¹⁸⁸

◆Pathophysiology.

Alcoholic fatty liver (steatosis) is the mildest form of alcoholic liver disease and is reversible with abstinence. It can be caused by chronic ingestion of relatively small amounts of alcohol (more than one alcoholic drink [14 grams of alcohol] per day for women and two alcoholic drinks [28 grams of alcohol] per day for men), may be asymptomatic, and is reversible with cessation of drinking.^{189,190} Fat

deposition (deposition of triglycerides) within the liver is caused primarily by increased lipogenesis and decreased fatty acid oxidation and fat metabolism by hepatocytes. Lipids mobilized from adipose tissue or dietary fat intake may contribute to fat accumulation.

Alcoholic hepatitis (steatohepatitis) is a precursor of cirrhosis characterized by inflammation; degeneration and necrosis of hepatocytes; infiltration of neutrophils, macrophages, and lymphocytes; immunologic alterations; and oxidative stress leading to lipid peroxidation. The injured hepatocytes contain Mallory bodies (hyaline endoplasmic reticulum), indicating the onset of fibrosis. Neutrophils infiltrate and surround degenerating hepatocytes. The mechanism of hepatocyte injury is not clearly understood, but inflammatory mediators, acetaldehyde, reactive oxygen and nitrogen species, and genetic factors are involved. Alcohol also increases gut permeability, and translocation of bacteria-derived lipopolysaccharide contributes to inflammation, oxidative stress, and the severity of alcoholic liver disease. Serum IgA level is often elevated in individuals with alcoholic hepatitis, and liver antigens and antibodies have been identified in persons with progressive alcoholic liver disease. The inflammation and necrosis caused by alcoholic hepatitis stimulate the fibrosis characteristic of the cirrhotic stage of disease. Treatment includes corticosteroids and/or pentoxifylline and alcohol abstinence supported by baclofen.¹⁹¹

Alcoholic cirrhosis is caused by the toxic effects of alcohol metabolism on the liver, immunologic alterations, oxidative stress from lipid peroxidation, and malnutrition. Alcoholic cirrhosis is more severe when associated with HCV. Although alcoholic cirrhosis is the most prevalent of the various types of cirrhosis, the occurrence of cirrhosis among persons with alcoholism is relatively low (approximately 35%). Alcohol is transformed to acetaldehyde. Excessive amounts of acetaldehyde are toxic, induce oxidative stress and lipid peroxidation, and disrupt cytoskeletal and membrane function. Acetaldehyde inhibits export of proteins from the liver, alters metabolism of vitamins and minerals, promotes liver fibrosis, and contributes to malnutrition. Mitochondrial function is impaired,

decreasing oxidation of fatty acid. Enzyme and protein synthesis may be depressed or altered, and hormone and ammonia degradation is diminished. Alcohol also may stimulate the formation of autoantibodies specific to hepatic cells. Alcohol also increases gut permeability, and translocation of bacteria-derived endotoxin from the intestine contributes to progressive injury and inflammation. Cellular damage initiates an inflammatory response. Inflammatory cytokines, including TNF- α and IL-6, IL-8, and IL-18, and activation of complement are associated with alcoholic liver disease. Inflammation and necrosis result in excessive collagen formation. Transforming growth factor-beta (TGF- β) contributes to fibrosis and is produced in part by activated Kupffer cells. TGF- β activates hepatic stellate cells and transforms them to myofibroblasts, which produce excess collagen. Dense bands of fibrosis surround regenerative hepatocellular nodules. Fibrosis and scarring alter the structure of the liver and obstruct biliary and vascular channels, and hepatocytes lose their ability to regenerate.¹⁹²⁻¹⁹⁴ There is increased risk for hepatocellular carcinoma. Examples of liver damage are shown in [Fig. 42.21](#).

FIGURE 42.21 Cirrhosis. A, Micronodular cirrhosis. The nodular appearance develops from regeneration of hepatocytes projecting through fibrous bands of tissue. B, Macronodular cirrhosis. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

◆Clinical Manifestations.

Steatosis causes no specific symptoms or abnormal liver function test results. The liver is usually enlarged, however, and the individual has a history of continuous alcohol intake during the previous weeks or months. The clinical manifestations of alcoholic hepatitis can be mild or severe. Nonspecific symptoms include fatigue, weight loss, and anorexia. Manifestations of acute illness include nausea, anorexia, fever, abdominal pain, and jaundice. Toxic effects of alcohol also can cause gynecomastia, testicular atrophy, reduced libido, azoospermia, and decreased testosterone level in men. Cirrhosis is a multiple-

system disease and causes hepatomegaly, splenomegaly, ascites, gastrointestinal hemorrhage, portal hypertension, hepatic encephalopathy, and esophageal varices. Anemia results from blood loss, malnutrition, and hypersplenism. Hepatorenal syndrome and portopulmonary syndrome are usually late complications. Risk for infection is greater, in part because of innate immune dysfunction. The presence of numerous and severe manifestations increases the risk of death. The clinical features of alcoholic cirrhosis depend on the duration of the disease and the severity of liver damage (Fig. 42.22).

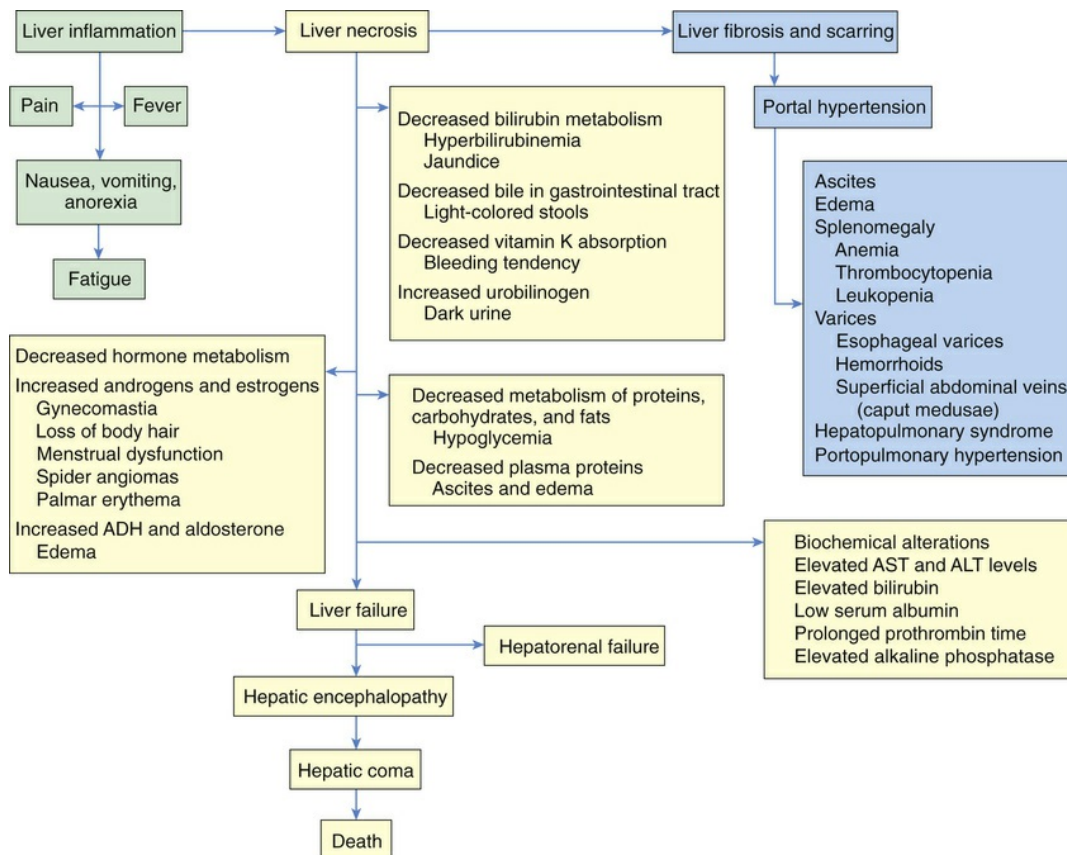

FIGURE 42.22 Clinical Manifestations of Cirrhosis. *ADH*, Antidiuretic hormone; *ALT*, alanine transaminase; *AST*, aspartate transaminase.

◆ Evaluation and Treatment.

The diagnosis of alcoholic hepatitis is based on the individual's history and clinical manifestations. The results of liver function tests are

abnormal, and serologic studies show elevated levels of serum enzymes (i.e., alanine aminotransferase, aspartate aminotransferase, and γ -glutamyltransferase) and bilirubin, and decreased serum albumin levels. Prolonged prothrombin time cannot easily be corrected with vitamin K therapy. Malnutrition is often present. Liver biopsy can confirm the diagnosis of cirrhosis, but biopsy is not necessary if clinical manifestations of cirrhosis are evident.¹⁹⁵

There is no specific treatment for alcoholic liver disease, but many of the complications are treatable. Rest, a nutritious diet, corticosteroids, antioxidants, drugs that slow fibrosis, and management of complications such as ascites, gastrointestinal bleeding, anemia, infection, and encephalopathy slow disease progression.¹⁸³ Cessation of alcohol consumption slows the progression of liver damage, improves clinical symptoms, and prolongs life. Although the liver damage is irreversible, measures that halt the inflammation and destruction of liver cells and fibrosis prolong life. Guidelines are available to guide treatment and predict clinical outcome.¹⁸³ Liver transplant is the treatment for liver failure, and artificial liver support systems are being developed.¹⁹⁶

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis.

Nonalcoholic fatty liver disease (NAFLD) is infiltration of hepatocytes with fat, primarily in the form of triglycerides, but it occurs in the absence of alcohol intake. It is associated with polygenic susceptibility, obesity (including obese children), high levels of cholesterol and triglycerides, metabolic syndrome, type 2 diabetes mellitus, and alterations in the gut microbiome.¹⁹⁷ It is the most common chronic liver disease in the United States. Some individuals with NAFLD will develop **nonalcoholic steatohepatitis (NASH)**, and the most severe forms of NASH progress to cirrhosis, end-stage liver disease, and an increased risk for hepatocellular carcinoma. NASH is difficult to distinguish from alcohol-induced liver disease and requires biopsy. NAFLD is usually asymptomatic and may remain undetected for years. Treatment includes lifestyle modification with

diet and exercise. Pharmacotherapy with insulin sensitizers, vitamin E (antioxidant), and lipid-lowering drugs may be considered. Pioglitazone should be considered for those with NASH, especially those with fibrosis. Bariatric surgery may be an option. Liver transplant is the only option for liver failure.¹⁹⁸

Biliary Cirrhosis.

Biliary cirrhosis differs from alcoholic cirrhosis in that the damage and inflammation leading to cirrhosis begin in bile canaliculi and bile ducts, rather than in the hepatocytes. The two types of biliary cirrhosis are *primary* and *secondary*. Although both involve bile duct pathology, they differ with respect to cause, risk factors, and mechanisms of obstruction and inflammation.

Primary Biliary Cirrhosis.

Primary biliary cirrhosis (PBC) is a chronic, autoimmune, cholestatic liver disease. It is caused by natural-killer T lymphocytes and highly specific antimitochondrial antibody destruction of the small intrahepatic bile ducts. The disease is thought to be caused by superimposed environmental antigens (e.g., infectious agents) in genetically susceptible individuals, but the actual trigger of autoimmunity is unknown.¹⁹⁹ Women are affected more commonly (90%) than men. Symptoms rarely develop before the age of 30 years. Primary biliary cirrhosis often accompanies other autoimmune diseases.²⁰⁰ PBC develops insidiously. Antimitochondrial antibody is the hallmark of the disease, and 30% to 50% of individuals have glycoprotein 210 antinuclear antibodies and anticentromere antibodies.²⁰¹ Pathogenesis includes inflammation, destruction, fibrosis, and obstruction of the intrahepatic bile ducts. Nodular regeneration, cirrhosis, and portal hypertension can develop during later stages of the disease.

Diagnosis is based on two of the following three criteria: (1) biochemical evidence of cholestatic liver disease of at least 6 months' duration, (2) antimitochondrial antibody (AMA) positivity, and (3) histologic features of PBC on liver biopsy. Serologic tests show

elevated levels of alkaline phosphatase, γ -glutamyl transpeptidase and leucine aminopeptidase, hyperbilirubinemia, and hyperlipidemia with or without other clinical manifestations. Most individuals have a circulating IgG antimitochondrial antibody that is not found in other types of liver disease. Biopsy shows cholangitis and excludes other inflammatory liver diseases. Evaluation involves ruling out biliary obstruction caused by gallstones, tumor, or inflammation of the common bile duct (i.e., secondary biliary cirrhosis).

Individuals with primary biliary cirrhosis may be asymptomatic or symptomatic at diagnosis and may have minimal disease or rapid progression to cirrhosis and liver failure. The earliest manifestations are pruritus, fatigue, and abdominal pain. Jaundice and light-colored stools are symptoms of advanced disease. These symptoms are caused by intrahepatic obstruction of bile flow. Steatorrhea and fat-soluble vitamin deficiencies are present in some cases. The malabsorption can lead to osteomalacia and osteoporosis. Cirrhosis, symptoms of portal hypertension, encephalopathy, and ultimately liver failure develop in untreated individuals.

Long-term treatment with ursodeoxycholic acid (UDCA) is highly effective. Bezafibrate may be effective for UDCA nonresponders. The distressing pruritus may be relieved by cholestyramine, which binds bile salts in the intestine. Use of rifampin has shown some success. Intramuscular injections of vitamins D and K alleviate the vitamin deficiency. The other symptoms of cirrhosis are managed as they develop. Liver transplant is the only option for those with progressive disease not responding to medical treatment.²⁰²

Secondary Biliary Cirrhosis.

Secondary biliary cirrhosis develops when there is prolonged partial or complete obstruction of the common bile duct or its branches. The obstruction may be caused by gallstones, tumors, fibrotic strictures, or chronic pancreatitis. Biliary atresia and cystic fibrosis cause secondary biliary cirrhosis in children.

Chronic obstruction to bile flow increases pressure in the hepatic bile duct and results in the accumulation of bile in the centrilobular

spaces. Necrotic areas develop and are followed by proliferation and inflammation of the portal ducts that result in edema and fibrosis. Pools of bile form when the portal ducts rupture into surrounding necrotic areas. Injury is accompanied by regeneration of hepatic cells with the development of finely nodular cirrhosis.

Clinical manifestations are similar to those of primary biliary cirrhosis, with jaundice and pruritus the most distressing symptoms. Right upper quadrant pain is common, and a low-grade fever may be present from bile duct inflammation (cholangitis).

Cholangiography provides the most definitive diagnosis. Laboratory tests usually show elevated conjugated bilirubin and alkaline phosphatase levels. Aminotransferase level increases if there is an accompanying cholangitis. Surgery or endoscopy relieves obstruction, prolongs survival, and diminishes or resolves symptoms. Continued obstruction leads to advanced cirrhosis and liver failure.

Sclerosing Cholangitis.

Primary sclerosing cholangitis (PSC) is a rare, chronic inflammatory fibrotic disease of the hepatic bile ducts that leads to secondary biliary cirrhosis. The disease is immune-mediated, but the exact mechanism is unknown and does not respond to immunosuppressants. PSC is associated with proximal inflammatory bowel disease (75%) and primarily affects genetically susceptible young males. About 30% of cases occur in women. There is no effective sustaining medical or surgical therapy, and liver transplant is required for liver failure.²⁰³ Secondary sclerosing cholangitis is associated with IgG4-related systemic disease, pyrogenic or ischemic cholangitis, eosinophilic cholangitis, or AIDS-related cholangitis.²⁰⁴

Disorders of the Gallbladder

Obstruction and inflammation are the most common disorders of the gallbladder. Obstruction is caused by **gallstones** (cholelithiasis), which are aggregates of substances in the bile. The gallstones may remain in the gallbladder or be ejected, with bile, into the cystic duct. Gallstones that become lodged in the cystic duct obstruct the flow of

bile into and out of the gallbladder and cause inflammation. Gallstone formation is termed *cholelithiasis*. Inflammation of the gallbladder or cystic duct is known as *cholecystitis*.

Cholelithiasis (Gallstones)

Cholelithiasis is a prevalent disorder in developed countries, where the incidence is 15% in white adults and 60% to 70% in Native Americans. Risk factors include obesity; rapid weight loss in obese individuals; middle age; female sex; use of oral contraceptives; Native American ancestry; genetic predisposition; gallbladder, pancreatic, or ileal disease; low high density lipoprotein (HDL) cholesterol level and hypertriglyceridemia; and gene-environmental interactions.²⁰⁵

◆ Pathophysiology.

Gallstones are formed from impaired metabolism of cholesterol, bilirubin, and bile acids. All gallstones contain cholesterol, unconjugated bilirubin, bilirubin calcium salts, fatty acids, calcium carbonates and phosphates, and mucin glycoproteins. Gallstones are of three types depending on chemical composition: *cholesterol* (70% cholesterol and the most common [70% to 80% of gallstones]); *pigmented* (black [hard] and brown [soft] with less than 30% cholesterol); and *mixed*. *Cholesterol gallstones* form in bile that is supersaturated with cholesterol produced by the liver and deficient in bile acids and phospholipids. Supersaturation sets the stage for cholesterol crystal formation, or the formation of “microstones.” More crystals then aggregate on the microstones, which grow to form “macrostones.” This process usually occurs in the gallbladder, which may have decreased motility and biliary stasis. The stones may lie dormant and silent or become lodged in the cystic or common duct, causing pain when the gallbladder contracts and cholecystitis. The stones can accumulate and fill the entire gallbladder (Fig. 42.23). *Pigmented brown gallstones* form from calcium bilirubinate and fatty acid soaps that bind with calcium, usually in common bile duct. They are associated with biliary stasis, bacterial infections, and biliary parasites. They are more common in East Asia. *Black gallstones* are rare

and usually form in the gallbladder. They are associated with chronic liver disease and hemolytic disease and are composed of calcium bilirubinate with mucin glycoproteins.²⁰⁶

FIGURE 42.23 Resected Gallbladder Containing Mixed Gallstones. (From Kissane JM, editor: *Anderson's pathology*, ed 9, St Louis, 1990, Mosby.)

It is not known why the hepatocytes secrete bile that is supersaturated with cholesterol. Proposed mechanisms include (1) an enzymatic defect that increases the hepatocytes' synthesis of cholesterol; (2) diminished secretion of bile acids, which normally promote cholesterol solubility; (3) decreased resorption of bile salts from the ileum, which decrease the bile acid pool; (4) gallbladder smooth muscle hypomotility and stasis; (5) increased secretion of gallbladder mucin and biliary calcium; (6) genetic predisposition; and (7) some combination of these mechanisms. In obese individuals, the mechanism appears to involve cholesterol synthesis, whereas in nonobese individuals, it appears to involve decreased secretion of bile acids.²⁰⁷

◆Clinical Manifestations.

Cholelithiasis is often asymptomatic. Epigastric and right hypochondrium pain and intolerance to fatty foods are the cardinal manifestations of cholelithiasis. Vague symptoms include heartburn, flatulence, epigastric discomfort, pruritus, jaundice, and food intolerances, particularly to fats and cabbage. The pain (*biliary colic*) is most characteristic, occurs 30 minutes to several hours after eating a

fatty meal, and is caused by the lodging of one or more gallstones in the cystic or common duct with obstruction and distention. It can be intermittent or steady and usually is located in the right upper quadrant and radiates to the mid-upper back. Jaundice indicates that the stone is located in the common bile duct. Abdominal tenderness and fever indicate cholecystitis. Complications can include pancreatitis from obstruction of the pancreatic duct.

◆Evaluation and Treatment.

Diagnosis is based on the medical history, physical examination, and imaging evaluation. Imaging techniques include transabdominal ultrasound, endoscopic ultrasound, and magnetic resonance cholangiopancreatography.^{208,209} Oral bile acids (ursodeoxycholic acid or chenodeoxycholic acid) may dissolve cholesterol stones, but the stones may recur when the drug is discontinued. Laparoscopic cholecystectomy is the preferred treatment for gallstones that cause obstruction or inflammation. Use of transluminal endoscopic surgery is advancing rapidly. Endoscopic retrograde cholangiopancreatography and sphincterotomy with stone retrieval are used for the treatment of bile duct stones. Large stones, or intrahepatic stones, may be managed with open surgery or lithotripsy.²¹⁰

Cholecystitis

Cholecystitis can be acute or chronic. Both forms are almost always caused by the lodging of a gallstone in the cystic duct. Obstruction causes the gallbladder to become distended and inflamed. The pain is similar to that caused by gallstones. Pressure against the distended wall of the gallbladder decreases blood flow and can result in ischemia, necrosis, and perforation of the gallbladder. Fever, leukocytosis, rebound tenderness, and abdominal muscle guarding are common findings. Serum bilirubin and alkaline phosphatase levels may be elevated. Nevertheless, the acute abdominal pain of cholecystitis must be differentiated from the pain caused by other disorders, such as pancreatitis, intestinal vascular insufficiency, and

acute pyelonephritis of the right kidney. Cholescintigraphy is the most sensitive imaging for cholecystitis. Ultrasound and magnetic resonance imaging have a substantial margin of error but can demonstrate nonspecific morphologic changes.²¹¹

Treatment includes pain control, replacement of fluid and electrolytes, and fasting. Antibiotics are often prescribed to manage bacterial infection in severe cases. Acute attacks usually require laparoscopic gallbladder resection (cholecystectomy). Obstruction also may lead to reflux of bile into the pancreatic duct, causing acute pancreatitis.^{212,213}

Disorders of the Pancreas

Pancreatitis, or inflammation of the pancreas, is a relatively rare (about 15 cases per 100,000 people in the United States)²¹⁴ and potentially serious disorder. Incidence is about equal in men and women, is more common between 50 and 60 years of age, and is more likely to occur in blacks. Risk factors include obstructive biliary tract disease (particularly cholelithiasis), alcoholism, peptic ulcers, abdominal trauma, hyperlipidemia, smoking, certain drugs, and genetic factors (hereditary pancreatitis, cystic fibrosis). The cause is unknown in 15% to 25% of cases. Pancreatitis can be acute or chronic.

Acute Pancreatitis

Acute pancreatitis is usually a mild disease and resolves spontaneously, but about 20% of those with the disease develop a severe acute pancreatitis requiring hospitalization. Pancreatitis develops because of obstruction to the outflow of pancreatic digestive enzymes caused by bile duct or pancreatic duct obstruction (e.g., gallstones). Acute pancreatitis can also result from direct cellular injury from drugs or viral infection.²¹⁵

◆Pathophysiology.

In obstructive disease, the backup of pancreatic secretions or duodenal contents, or both, triggers activation and release of enzymes (activated

trypsin activates chymotrypsin, lipase, and elastase) within the pancreatic acinar cells. The activated enzymes cause autodigestion (e.g., proteolysis, lipolysis) of pancreatic cells and tissues, resulting in inflammation and release of inflammatory cytokines. The autodigestion causes vascular damage, coagulative necrosis, fat necrosis (see [Chapter 2](#)), and formation of pseudocysts (walled-off collections of pancreatic secretions). Edema within the pancreatic capsule leads to ischemia and can contribute to necrosis. There also may be independent activation of inflammation within acinar cells contributing to the local and systemic responses occurring in acute pancreatitis.²¹⁶ In cases of alcohol abuse, the pancreatic acinar cell metabolizes ethanol with the generation of toxic metabolites that injure pancreatic acinar cells, causing release of activated enzymes. Chronic alcohol use also may cause formation of protein plugs in pancreatic ducts and spasm of the sphincter of Oddi, resulting in obstruction. The obstruction leads to intrapancreatic release of activated enzymes, autodigestion, inflammation, and pancreatitis.²¹⁷

Systemic effects are associated with moderately severe and severe acute pancreatitis.²¹⁸ Proinflammatory cytokines (e.g., interleukin-6, TNF- α , TGF- β , and platelet-activating factor) and vasoactive peptides are released into the bloodstream. There is activation of leukocytes, injury to vessel walls, and coagulation abnormalities with development of vasodilation, hypotension, and shock. Complications can include acute respiratory distress syndrome (ARDS), heart failure, renal failure, coagulopathies, intraabdominal hypertension, and the systemic inflammatory response syndrome (SIRS) ([Chapter 49](#)) ([Figs. 42.24](#) and [42.25](#)). Paralytic ileus and gastrointestinal bleeding can occur. Translocation of intestinal bacteria to the bloodstream causes peritonitis or sepsis. Recurrent inflammation activates pancreatic stellate cells, causing pancreatic fibrosis, strictures, and duct obstruction that lead to chronic pancreatitis.

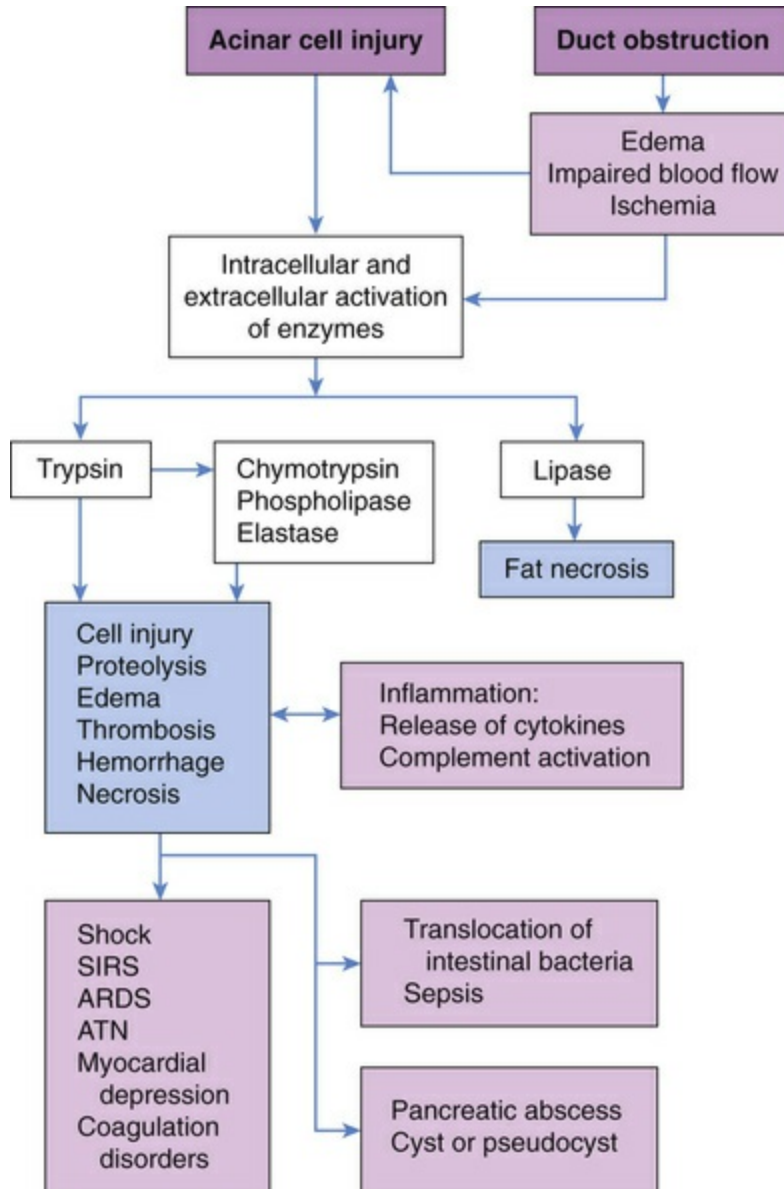

FIGURE 42.24 Pathophysiology of Acute Pancreatitis. *ARDS*, Acute respiratory distress syndrome; *ATN*, acute tubular necrosis; *SIRS*, systemic inflammatory response syndrome.

FIGURE 42.25 Acute Severe Pancreatitis with Hemorrhage. A, Normal pancreas. B, Acute hemorrhagic pancreatitis. The pancreas has hemorrhage, fat necrosis (*white patches*), and a pseudocyst filled with blood (*white arrow*). (A from Klatt EC, editor: *Robbins and Cotran atlas of pathology*, Philadelphia, 2006, Saunders. B from Damjanov I, Linder J, editors: *Pathology: a color atlas*, St Louis, 2000, Mosby.)

◆Clinical Manifestations.

The cardinal manifestation of acute pancreatitis is epigastric or midabdominal constant pain ranging from mild abdominal discomfort to severe, incapacitating pain. The pain may radiate to the back because of the retroperitoneal location of the pancreas. Pain is caused by (1) edema, which distends the pancreatic ducts and capsule; (2) chemical irritation and inflammation of the peritoneum; (3)

irritation or obstruction of the biliary tract; and (4) inflammation of nerves. Fever and leukocytosis accompany the inflammatory response. Nausea and vomiting are caused by paralytic ileus secondary to the pancreatitis or peritonitis. Jaundice can occur from obstruction of the bile duct (e.g., a gallstone) or from pancreatic edema pressing on the duct. Abdominal distention accompanies bowel hypomotility or paralytic ileus and the accumulation of fluids in the peritoneal and retroperitoneal cavities (ascites). Abdominal compartment syndrome is a potential life-threatening complication. Hypovolemia, hypotension, tachycardia, myocardial insufficiency, and shock occur because plasma volume is lost as inflammatory mediators released into the circulation increase vascular permeability and dilate vessels. Tachypnea and hypoxemia develop secondary to ascites, pulmonary edema, atelectasis, or pleural effusions. Hypovolemia can decrease renal blood flow sufficiently to impair renal function and can cause renal failure. Tetany may develop as a result of hypocalcemia when calcium is deposited in areas of fat necrosis or as a decreased response to parathormone. Transient hyperglycemia also can occur if glucagon is released from damaged alpha cells in the pancreatic islets. In severe acute pancreatitis, some individuals develop flank or periumbilical ecchymosis, a sign of poor prognosis. Multiple organ failure or SIRS accounts for most deaths of those with severe acute pancreatitis.

◆Evaluation and Treatment.

Diagnosis is based on clinical findings, identification of associated disorders, laboratory studies, and imaging results (i.e., contrast-enhanced computed tomography, endoscopic ultrasound, or magnetic resonance cholangiopancreatography). Elevated serum amylase concentration is characteristic but is not diagnostic of severity or specificity of disease. Elevated serum lipase level is the primary diagnostic marker for acute pancreatitis. Both enzymes are elevated to at least three times their normal value. An elevated C-reactive protein is suggestive of severe disease.²¹⁹

Acute pancreatitis is difficult to diagnose because several other

disorders can cause similar clinical and laboratory findings (e.g., perforating duodenal ulcer, acute cholecystitis, and kidney stones). Intraabdominal pressure monitoring assesses risk for abdominal compartment syndrome²²⁰ (Box 42.5). Scoring systems are available to predict disease severity.²²¹

Box 42.5

Abdominal Compartment Syndrome

Intraabdominal hypertension (IHA) and abdominal compartment syndrome (ACS) develop when there is abnormally high intraabdominal pressure associated with organ dysfunction. It occurs in 20% to 40% of intensive care unit patients. IHA and ACS are associated with abdominal injury, including trauma, ruptured aortic aneurysm, acute pancreatitis, sepsis, significant thermal injury, liver failure with ascites, massive fluid volume replacement with mechanical ventilation, and pregnancy. Increased intraabdominal pressure increases intrathoracic, intracardiac, and intracranial filling pressures and results in decreased cardiac output, decreased renal perfusion, atelectasis, pulmonary edema, oliguria, compromise of splanchnic and hepatic blood flow, and translocation of bacteria from the gut. The end consequence is multiple organ failure with high mortality.

Normally intraabdominal pressure is slightly greater than atmospheric pressure (5 to 7 mmHg, up to 12 mmHg). Organ dysfunction develops at pressures greater than 20 mmHg that last for more than 6 hours. ACS is difficult to detect from physical diagnosis alone. Automated serial or continuous monitoring of pressure inside the bladder provides a reliable estimate of intraabdominal pressure (greater than 12 mmHg being consistent with IHA and greater than 25 mmHg being consistent with ACS). Gastric monitoring is not always feasible, and inferior vena cava monitoring is more invasive. Treatment is tiered medical management and decompressive laparotomy, which may be performed at the bedside if the individual is too unstable to move.

Paracentesis can be therapeutic in properly selected individuals. Elevating the head of the bed 20 degrees to 30 degrees is helpful for some individuals.

Data from Malbrain ML, Peeters Y, Wise R: *Crit Care* 20:67, 2016; Maluso P, Olson J, Sarani B: *Crit Care Clin* 32(2):213-222, 2016; Rogers WK, Garcia L: *Chest* 2017 Aug 2 [Epub ahead of print].

The goal of treatment is to stop the process of autodigestion and prevent systemic complications. Narcotics, nonsteroidal antiinflammatory drugs, and acetaminophen are used to relieve pain. Hemodynamic monitoring and parenteral fluids are essential to restore blood volume and prevent hypotension and shock, particularly in the first 24 hours. Nasogastric suction may not be necessary with mild pancreatitis but may help relieve pain and prevent paralytic ileus in individuals who are nauseated and vomiting. Feeding is usually initiated within 24 to 48 hours if ileus is not present. In severe acute pancreatitis, enteral nutrition with use of jejunal tube feeding is usually well tolerated and may decrease pancreatic enzyme secretion, prevent gut bacterial overgrowth, and maintain gut barrier function. Parenteral hyperalimentation should be initiated only when enteral feeding is not tolerated.²²² Drugs that decrease gastric acid production (e.g., H₂ receptor antagonists) can decrease stimulation of the pancreas by secretin. Antibiotics are used if there is infection.²²³ Necrotizing pancreatitis requires surgical debridement.²²⁴

Chronic Pancreatitis

Chronic pancreatitis is a process of progressive fibrotic destruction of the pancreas. Forms of the disease include chronic calcifying (most common), chronic obstructive, and steroid-responsive. Chronic alcohol abuse and smoking (nicotine induces oxidative stress in the pancreatic acinar cells) are the most common cause of chronic calcifying pancreatitis because repeated exacerbations of acute pancreatitis can lead to chronic changes. The disease is idiopathic in

about 25% of cases. Obstructive pancreatitis is associated with fibrosis and stricture from trauma endoscopic procedures, abdominal blunt trauma, gallstones, or tumors. In obstructive pancreatitis only the part of the pancreas distal to the obstruction is involved. Steroid-responsive disease is associated with autoimmune pancreatitis. *Autoimmune chronic pancreatitis* has two subtypes: type 1 (lymphoplasmacytic sclerosing pancreatitis) is a multisystem fibro-inflammatory syndrome known as *immunoglobulin G4- (IgG4-) related disease* that affects pancreatic ducts and veins and presents with painless obstructive jaundice; type 2 (idiopathic duct centric pancreatitis) involves a neutrophilic infiltrate in the pancreatic duct epithelium with duct obliteration and is pancreas specific. Both subtypes respond to corticosteroid therapy and immunomodulators.²²⁵

Toxic metabolites and chronic release of inflammatory cytokines contribute to the destruction of acinar cells and islets of Langerhans, fibrosis, strictures, calcification, ductal obstruction, ischemia, and pancreatic cysts. Pancreatic cysts can form, which are walled-off areas or pockets of pancreatic juice, necrotic debris, or blood within or adjacent to the pancreas.

Continuous intermittent abdominal pain is the classic symptom of all forms of chronic pancreatitis with the exception of type 1, steroid-sensitive pancreatitis. Pain is associated with increased intraductal pressure, increased tissue pressure, ischemia, neuritis, ongoing injury, and changes in central pain perception. Weight loss and, less commonly, steatorrhea, malnutrition, fat-soluble vitamin deficiency, and diabetes mellitus (known as *type 3C* to differentiate it from type 1 and type 2 diabetes mellitus) accompany disease progression. Treatment includes oral lipase and insulin. Preventing disease progression includes lifestyle modification to stop alcohol use and smoking. Pain management is complex, with use of analgesics, endoscopic therapy, nerve block, and surgical drainage of cysts or partial resection of the pancreas.²²⁶ Chronic pancreatitis is a risk factor for pancreatic cancer.

Cancer of the Digestive System

Table 42.8 contains information on the various gastrointestinal cancers by organ, percentage of death compared to all cancer deaths, risk factors, type of cell, and common manifestations. The biology of cancer is presented in Chapter 12.

TABLE 42.8

CANCER OF THE GUT, LIVER, AND PANCREAS

ORGAN	PERCENTAGE OF DEATHS OF ALL CANCERS	RISKS	COMMON CELL TYPES	COMMON MANIFESTATIONS
Esophagus	2.6	Malnutrition Alcohol Tobacco Chronic reflux	Squamous cell Adenocarcinoma	Chest pain Dysphagia
Stomach	1.8	Salty food Nitrates and nitrosamines Gastric atrophy	Adenocarcinoma Squamous cell	Anorexia Malaise Weight loss Upper abdominal pain Vomiting Occult blood
Colorectal	8.25	Polyps Ulcerative colitis Diverticulitis High-refined-carbohydrate, low-fiber, high-fat diet	Adenocarcinoma (left colon grows in ring; right colon grows as mass)	Pain Mass Anemia Bloody stool Obstruction Distention
Liver	4	Hepatitis B, C, and D viruses Cirrhosis Intestinal parasite Aflatoxin from moldy peanuts	Hepatomas Cholangiomas	Pain Anorexia Bloating Weight loss Portal hypertension Ascites, ± jaundice
Pancreas	7	Chronic	Adenocarcinoma	

		pancreatitis Cigarette smoking Alcohol (?) Diabetic women	(exocrine part of gland, ductal epithelium)

Cancer of the Gastrointestinal Tract

Cancer of the Esophagus

Carcinoma of the esophagus is a rare disease with an estimated incidence of 16,940 new cases (13,360 males, 3580 females) and 15,690 deaths in 2017 in the United States.²²⁷ Squamous cell carcinoma is more prevalent in China, Iran, South America, and South Africa, and in black men who use alcohol and smoke tobacco in the United States.²²⁸ Squamous cell carcinoma is associated with smoking, chewing tobacco, or betel quid; alcohol, both intrinsic and extrinsic sources of the alcohol metabolite acetaldehyde; irritant drinks; food containing nitrosamines; achalasia; male sex; and older age. Squamous cell carcinomas are more common in the thoracic and cervical areas of the esophagus. Adenocarcinoma is more common in Western countries, accounts for about 58% of esophageal carcinoma cases in the United States, and is increasing. Adenocarcinoma is found in the distal one-third of the esophagus and is associated with risk factors that include reflux esophagitis, Barrett esophagus, abdominal obesity, drugs that decrease lower esophageal pressure, sliding hiatal hernia, and smoking. The *CagA*-positive strain of *H. pylori*, nonsteroidal antiinflammatory drugs, and statins may be a protection against esophageal adenocarcinoma.

◆Pathogenesis.

The pathogenesis of esophageal adenocarcinoma is facilitated by chronic inflammation, intestinal metaplasia, and dysplasia (**Barrett esophagus** [columnar rather than squamous epithelium in the lower esophagus]) caused by gastroesophageal reflux. Long-term exposure

to environmental irritants causes neoplastic transformation for both adenocarcinoma and squamous cell carcinoma (basal and squamous cell hyperplasia). Both genomic and epigenomic events are associated with esophageal cancers, and mutation of the *TP53* gene is an early event. Squamous cell carcinoma progresses from low-grade to high-grade intraepithelial neoplasia and, ultimately, to invasive carcinoma.²²⁹

◆Clinical Manifestations.

Early stages of esophageal carcinoma are asymptomatic. The two frequent symptoms of esophageal carcinoma are chest pain and dysphagia. The most common type of pain is heartburn (pyrosis). It is initiated by eating spicy or highly seasoned foods and assuming the recumbent position. Some individuals with esophageal cancer complain of a constant retrosternal pain that radiates to the back. Dysphagia (pain on swallowing), another common symptom, is usually pressure-like and may radiate posteriorly between the scapulae. Dysphagia usually progresses rapidly. Esophageal cancer metastasizes rapidly and, therefore, has a poor prognosis.

◆Evaluation and Treatment.

Individuals who present with dysphagia undergo endoscopy so that specimens can be examined for neoplastic change and type of carcinoma. Endoscopic ultrasound and CT studies of the thorax are used for diagnosis and staging. Treatment of gastroesophageal reflux is essential for the prevention of Barrett esophagus. Esophageal carcinoma is treated with endoscopic radiofrequency mucosal ablation, cryotherapy, radiotherapy, resection, or combination therapy.²³⁰

Untreated esophageal cancer metastasizes rapidly and has a poor prognosis. At the time of diagnosis, 50% of esophageal cancers present with metastatic disease. The lymphatic vessels of the esophagus are continuous with vital mediastinal structures (trachea, heart, and great vessels) and drain to the celiac lymph nodes, making it impossible to remove all the lymph nodes with the tumor. Removal of the primary

lesion and the local lymph nodes, however, can benefit the individual with esophageal cancer, and cure is likely if there is no metastasis.

Cancer of the Stomach

The incidence of gastric adenocarcinoma is estimated at 28,000 new cases (17,750 men and 10,250 women) and 10,960 deaths in the United States in 2017.²²⁷ Most cases are adenocarcinoma. Squamous cell carcinoma is very rare and accounts for only 0.04% to 0.07% of all gastric carcinomas.²³¹ In countries such as Eastern Asia, Eastern Europe, and South America, the incidence of stomach cancer has remained consistently high.²³² Nonenvironmental risk factors include a family history of gastric adenocarcinoma; blood type (blood group A); type A atrophic gastritis; pernicious anemia, which is associated with atrophy of the gastric mucosa in the same locations where gastric tumors arise; and Epstein-Barr virus- (EBV-) associated gastric carcinoma in some individuals; however, the mechanism is unknown.^{233,234}

The most important environmental risk factors in causing gastric cancer are:

1. Infection with *H. pylori* that carry selected virulence factors (i.e., *CagA* gene product cytotoxin-associated antigen A [80% of cases]) in genetically susceptible individuals. Only about 1% of individuals infected with *H. pylori* develop gastric cancer.^{235,236} Infection with *H. pylori* and severe chronic gastritis change the mucosal cell proliferation pattern, destroy cell junctions, inhibit cell proliferation, and promote cell invasive ability, increasing the risk for gastric and duodenal carcinoma.²³⁷⁻²³⁹ *H. pylori* also is causatively linked to **mucosa-associated lymphoid tissue (MALT) lymphoma** (a low-grade B-cell lymphoma) that can originate in the stomach.
2. Dietary factors, such as salt added to food, food additives (e.g., nitrates) in pickled or salted foods (e.g., bacon), and low intake of fruits and vegetables. Dietary salt enhances the conversion of nitrates to carcinogenic nitrosamines in the stomach. Salt is

also caustic to the stomach and can cause chronic atrophic gastritis. Hypertonic salt solutions delay gastric emptying. Delayed emptying increases the time during which carcinogenic nitrosamines can exert their effects on the stomach mucosa. Nitrates interact with amino acids in the stomach to form nitrosamines. The conversion of these carcinogenic nitrosamines is enhanced at a low pH by iodides and thiocyanates. Nitrates are thought to be active only when converted to nitrites and to cause stomach cancer once atrophic gastritis has occurred.

3. Lifestyle factors, such as alcohol consumption and cigarette smoking. Alcohol is metabolized to the carcinogen acetaldehyde and decreases the production of prostaglandins that maintain gastric mucosal integrity. Smokers have a higher incidence of *H. pylori* infection.²⁴⁰

◆Pathogenesis.

Environmental factors and genetic predisposition combine to cause injury, inflammation, and the progression to gastric adenocarcinoma. Epigenetic alterations (DNA methylation, histone methylation, and histone acetylation) and multiple genes are involved in gastric cancer, including oncogenes, tumor-suppressor genes, DNA repair genes, and cell cycle regulator genes. Genetics also can distinguish well-differentiated (intestinal) from undifferentiated (diffuse) gastric adenocarcinomas. About 1% to 3% of gastric cancers are familial.^{241,242} Gastric adenocarcinoma usually begins in the glands of the stomach mucosa, commonly in the prepyloric antrum (Fig. 42.26). Atrophic gastritis progresses to intestinal metaplasia, dysplasia, and adenocarcinoma.

FIGURE 42.26 Typical Sites of Stomach Cancer. (From del Regato JA, Spjut HJ, Cox JD: *Cancer: diagnosis, treatment, and prognosis*, ed 2, St Louis, 1985, Mosby.)

◆Clinical Manifestations.

The early stages of gastric cancer are generally asymptomatic or produce vague symptoms such as loss of appetite (especially for meat), malaise, and indigestion. Later manifestations include unexplained weight loss, upper abdominal pain, vomiting, change in bowel habits, and anemia caused by persistent occult bleeding. The prognosis is poor because symptoms usually do not occur until the tumor has penetrated the muscle layers of the stomach, spread to surrounding tissues, and entered the draining lymph nodes and veins, causing distant metastases. Generally the first manifestations of carcinoma are caused by distant metastases when the disease is already in an advanced stage.

◆Evaluation and Treatment.

There are no specific biomarkers for gastric cancer. Micro RNAs, circulating tumor cells, and exhaled breath analysis are being evaluated as specific diagnostic and prognostic markers.²⁴³ Most symptoms suggest a problem in the upper gastrointestinal tract, and a barium x-ray film shows the lesion. Direct endoscopic visualization

and biopsy usually establish the diagnosis, or microscopic examination of exfoliated cells obtained by lavage during endoscopy.²⁴⁴

Screening and eradication of *H. pylori* infection are the best preventive approaches to gastric cancer. Vaccines to prevent *H. pylori* infection are under investigation and could eliminate a worldwide cause of gastric cancer death.²⁴⁵ Surgery is the only curative treatment for early stages of disease. Staging is determined by pathologic findings after resection. Early diagnosis and chemotherapy combined with radiation improve postsurgical outcomes. Targeted therapy is being evaluated for molecular subtypes of gastric cancer. Abstinence from alcohol and smoking improves outcomes. Dietary modifications include high intake of fruits and vegetables, vitamin C, carotenoids, and fiber and reduced intake of salt, salted food, and red meat.²⁴⁶

Cancer of the Small Intestine

Small intestine carcinoma is rare and represents less than 3% of gastrointestinal cancers (10,190 estimated new cases and 1390 deaths in 2017).²²⁷ Adenocarcinoma is the most common tumor type, followed by carcinoid tumors (neuroendocrine serotonin-producing tumors), sarcomas, and lymphomas. Carcinoma occurs more frequently in familial adenomatous polyposis and Crohn disease. Symptoms are nonspecific. Screening includes imaging and endoscopic surveillance. Urinary evaluation of 5-hydroxyindoloacetic acid can assist with diagnosis of carcinoid tumors. Treatment is surgical resection followed by tumor types specific treatment.^{113,247}

Cancer of the Colon and Rectum

Colorectal cancer (CRC) is the third most common cause of cancer and cancer death with an estimated 95,520 new colon and 39,910 new rectal cancer cases, and 50,260 deaths (colon and rectal combined) in 2017 in the United States.²²⁷ The incidence has been declining over the past several years because of successful screening programs, removal of polyps, and increased use of nonsteroidal antiinflammatory drugs.

CRC tends to occur in individuals older than 50 years and is rare in children. Worldwide, the prevalence of colorectal cancer is highest in black populations, possibly because of a lack of access to screening and treatment.²⁴⁸ In the United States, higher socioeconomic status was associated with lower incidence and mortality between 1998 and 2010 in a large Medicare cohort.²⁴⁹ CRC develops in individuals with an acquired or inherited genetic predisposition who are exposed to a combination of environmental risk factors (Box 42.6). Lifestyle modifications related to diet, alcohol and tobacco use, exercise, and weight control are the most effective approaches to primary prevention of colorectal cancer. The 5- and 10-year survival rates are 65% and 58%, respectively, with 90% survival at 5 years for localized disease.²⁵⁰

Box 42.6

Selected Risk Factors and Colorectal Cancer

Hereditary and Medical Factors

- Family history of colorectal cancer
- Familial adenomatous polyposis
- Hereditary nonpolyposis colorectal cancer
- Inflammatory bowel disease after 10 years
- Type 2 diabetes mellitus

Modifiable Risk Factors

- Smoking or chewing tobacco
- Obesity
- Physical inactivity
- Moderate to heavy alcohol consumption
- High consumption of processed meat

Red meat consumption (large variations among studies)
High-fat, low-fiber diet

Lower Risk

Diets high in cereal grains, vegetables, milk; fish; folic acid, calcium, and vitamin D; magnesium and selenium; and low in fat

Postmenopausal estrogen use

Physical activity

Use of NSAIDs

Other studies: Alexander DD, et al: *J Am Coll Nutr* 34(6):521-543, 2015; Le NT, et al: *Environ Health Perspect* 124(10):1529-1536, 2016.

Data from American Cancer Society (ACS): *Cancer facts & figures 2017*, Atlanta, 2017, American Cancer Society. Available at: <https://www.cancer.org/research/cancer-facts-statistics/all-cancer-facts-figures/cancer-facts-figures-2017.html>.

◆Pathogenesis.

Genetic and environmental factors (epigenetics) are associated with the development of CRC. CRC can develop through molecular pathways, gene mutations, and genomic instability (the cell cycle loses control of the gene mutation rate). Gene mutations may be inherited or acquired after birth (somatic mutations). Family history of CRC occurs in about 25% of cases, but only 5% to 6% of the 25% with a family history are related to highly penetrating gene mutations, mostly autosomal dominant. Familial adenomatous polyposis (FAP, 100% risk of developing CRC) and hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome, 40% risk of developing CRC) are examples of these types of cancers. The remainder of inherited CRCs are related to less penetrant genes, and environmental interactions increase risk. Most CRC is sporadic (nonhereditary or acquired), and the environment contributes to multiple somatic mutations. Chronic inflammatory bowel disease increases risk of CRC after 10 to 15 years

of disease. Understanding the molecular events associated with CRC is allowing more targeted detection, diagnosis, and prognosis prediction, and more specific and personalized treatment approaches.²⁵¹ Most colorectal cancers arise from adenomatous polyps (Fig. 42.27), with the exception of HNPCC, which arises from apparently normal intestinal epithelial tissue. Other cancers are rare and include carcinoid (neuroendocrine) tumors, gastrointestinal stromal tumors, and lymphomas.

FIGURE 42.27 Development of Cancer of the Colon from Adenomatous Polyps. A, The tumor becomes invasive if it penetrates the muscularis mucosae and enters the submucosal layer. B, Endoscopic image of pedunculated polyp in descending colon. (A from del Regato JA, Spjut HJ, Cox JD: *Cancer: diagnosis, treatment, and prognosis*, ed 2, St Louis, 1985, Mosby. B courtesy David Bjorkman, MD, Department of Gastroenterology, University of Utah School of Medicine, Salt Lake City, UT.)

A **polyp** is a mass or finger-like projection arising from the intestinal mucosal epithelium. Most polyps are benign (nonneoplastic) and composed of normal glandular and stromal cells. Grossly, they are described as pedunculated or tubular (with a stalk) or sessile (flat, without a stalk) (Fig. 42.28). Neoplastic or cancerous polyps have progressed into adenocarcinomas. Histologically, they have different growth patterns and are classified as *tubular adenomas* with a stalk projecting from the intestinal wall (the most prevalent); *villous adenomas* with finger-like projections of the epithelium without stalks and tending to larger than 1 cm (more related to CRC); or *tubulovillous adenomas* with characteristics of both tubular and villous adenomas. *Serrated polyps* are more rare, have a serrated (sawtooth appearance) of the crypt epithelium, and are larger and difficult to remove endoscopically. When polyps are larger than 2 cm, more numerous (greater than 20), and have a villous architecture, they have the most malignant potential. The adenomatous polyp forms in an area of epithelial cell hyperproliferation and crypt dysplasia. Once the adenoma traverses the muscularis mucosae, it becomes invasive and highly malignant. Adenomas can be detected early, however, and the submucosa may not be penetrated for several years. Thus screening colonoscopy with polypectomy is important when polyps are found. Table 42.9 gives other conditions commonly confused with colorectal cancer.

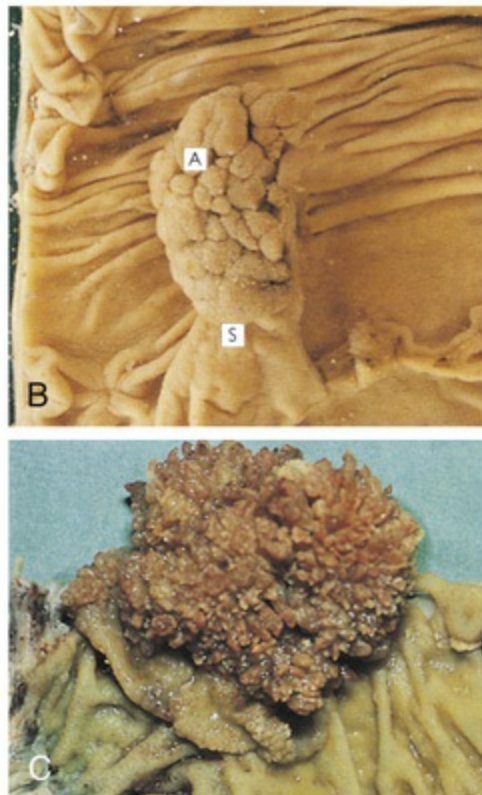

FIGURE 42.28 Signs and Symptoms of Colorectal Cancer by Location of Primary Lesion. A, Clinical manifestations are listed in order of frequency for each region (lymphatics of colon also shown). B, Tubular adenomas (A) are rounded lesions 0.5 to 2 cm in size that are generally red and sit on a stalk (S) of normal mucosa that has been dragged up by traction of the polyp in the bowel lumen. C, Villous adenomas are sessile (frondlike) lesions about 0.6 cm thick that occupy a broad area of mucosa generally 1 to 5 cm in diameter. (B and C from Stevens A, Lowe JS, Scott I: *Core pathology*, ed 3, London, 2009, Mosby.)

TABLE 42.9

CONDITIONS COMMONLY CONFUSED WITH COLORECTAL CANCER

CONDITION	SIGNIFICANT CHARACTERISTICS
Diverticulitis	Left-sided pain similar to that of appendicitis; tender lower left quadrant; associated findings: nausea, vomiting, fever, obstruction, anorexia, and leukocytosis; mucosa is intact, and perforation, peritonitis, and abscesses occur more often than in cancer; ultrasound, CT scan, MRI, and proctosigmoidoscopy are used to distinguish from cancer
Ulcerative colitis	Younger people with chronic attacks of bloody diarrhea, crampy abdominal pain, fever, malnutrition, and dehydration; usually involves the left colon and rectum; endoscopy, barium enema, and biopsy performed for definitive diagnosis
Crohn disease (granulomatous colitis)	Generally involves the right colon; chronic diarrhea with abdominal cramps, fever, weight loss, and often a palpable abdominal mass; difficult at times to distinguish Crohn disease from ulcerative colitis; endoscopic examination and CT scan used to distinguish from cancer
Appendicitis	Vague abdominal symptoms, often with a tender or nontender mass in the lower right quadrant; associated symptoms: mild fever and leukocytosis; CT scan used to distinguish cancer of the cecum from appendiceal abscess
Thrombosed hemorrhoids	Examination shows a tender, swollen, bluish painful mass in the anus; individual has a history of hemorrhoids

CT, Computed tomography; *MRI*, magnetic resonance imaging.

Progression from polyps to colon cancer involves a multistep cascade of genetic mutations that occur over 10 to 15 years (Box 42.7). Gene mutations include

Box 42.7

Common Genes Associated With Colorectal Cancer

APC (adenomatous polyposis coli): tumor suppressor; suppresses cell growth

TP53 (tumor protein 53): prevents gene mutations; a tumor suppressor gene

KRAS (V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog,

proto-oncogene): promotes cell proliferation
BRAF (B-Raf proto-oncogene serine/threonine kinase):
promotes cell proliferation
DCC (deleted in colon cancer): located at chromosome 18q;
tumor suppressor and apoptosis regulation
SMAD4 (Mothers against decapentaplegic homolog 4, proto-
oncogene): promotes cell growth through TGF- β
TGF- β (transforming growth factor-beta): activates signaling
pathways that facilitate tumor growth
EGFR (epidermal growth factor receptor): activates signaling
pathways that facilitate tumor growth
COX-2 (cyclooxygenase-2): promotes cell growth and
inflammation.
BAX: promotes apoptosis and normal cell life cycle
DNA: (mismatch repair genes [HNPCC/Lynch syndrome and
some sporadic colorectal cancers]:
 hMLH1 (human mutator homolog 1)
 hMSH2 (human mutator S protein homolog 2)
 hMSH6 (human mutator S homolog 6)
 PMS2 (postmeiotic segregation increased 2)
LOH (loss of heterozygosity): loss of entire genome and
surrounding chromosomal region

1. loss of tumor-suppressor gene activity (genes that inhibit cell growth, e.g., *APC*, *TP53*, *SMAD4*, and *DCC*);
2. activation of proto-oncogenes (promote cell growth; e.g., *KRAS* [retrovirus-associated DNA sequence] and *BRAF*); and
3. abnormalities in DNA mismatch repair (MMR) genes (genes that fix errors in DNA replication and recombination, e.g., *TGF*, *EGFR*, *hMSH1*, *hMSH2*, and *hMSH6*).

CRC is genetically unique for each individual; three molecular pathways of genomic instability have been recognized and can overlap in tumor development:

1. *Chromosomal instability* (CIN), or the tumor-suppressor pathway (adenoma-to-carcinoma sequence), is initiated by mutations in *APC/Wnt-β-catenin*, *K-RAS*, *DCC*, and *tp53* and includes sporadic (50% to 70%) and the autosomal dominant inherited syndrome known as *familial adenomatous polyposis* (*FAP*) coli (100%). Tumors associated with CIN are primarily located on the left (descending) side in the distal colon.²⁵²
2. *Microsatellite instability* (MSI) pathway (15% of all CRCs) is associated with epigenetic methylation of DNA MMR genes and *APC* mutations. These tumors are located in the right (ascending) colon proximal to the splenic flexure and are associated with autosomal dominant hereditary nonpolyposis colorectal cancer (HNPCC/Lynch syndrome [70%]) and sporadic epigenetic alterations (10% to 15%) of CRCs.²⁵³
3. *CpG (cytosine-phosphate-guanine) island methylator phenotype* (CIMP) pathway (about 15% to 20% of all CRCs) involves epigenetic DNA methylation of promoter CpG islands silencing genes involved in tumor suppression, cell cycle control, DNA repair, apoptosis, and invasion. It is found in about 30% to 40% of CRCs. Serrated adenomas are associated with a progression of steps or a sequence of malignant transformation that moves from a hyperplastic polyp to a serrated polyp to adenocarcinoma, particularly with activation of proto-oncogenes *KRAS* and *BRAF* and methylation of *MLH1*.^{254,255}

[Fig. 42.29](#) provides a summary of common genetic events in the development of CRC.

FIGURE 42.29 Multistage Development of Colonic Cancer. Colorectal carcinoma develops from the sequential progression of genetic abnormalities in different pathways. These pathways overlap in many tumors. 1, Most colonic cancers arise in the chromosomal instability (CIN) pathway with imbalances in chromosomal numbers (aneuploidy) and loss of heterozygosity. Abnormalities in oncogenes and tumor-suppressor genes activate the pathways for CRC initiation and progression. Mutations in the *APC* gene are the earliest known event and inactivation of *APC* accelerates cell cycle progression. *K-ras* (proto-oncogene) overexpression leads to loss of other tumor-suppressor genes *SMAD4*, *DCC*, and *tp53* and transforms an adenoma into a metastatic carcinoma. *tp53* loss occurs in about 35% to 45% of colorectal carcinomas, and occurs less frequently in benign lesions. Growth factors *COX-2* and *EGFR* promote tumor growth and angiogenesis in response to inflammatory cytokines and proto-oncogenes. 2, The microsatellite instability (*MSI*) pathway involves the epigenetic mutation of DNA mismatch repair genes (*MMR*) that encode key molecules that repair DNA, resulting in replication errors and deactivation of proteins from other downstream mutations (*TGF-β*, *IGF2R*, *BAX*). 3, The epigenetic pathway, CpG island methylator phenotype (*CIMP*), involves early hypermethylation of DNA with gene silencing of *MMR* genes (i.e., *MLH1*, *MSH2*, *MSH6*). Proto-oncogenes *KRAS* and *BRAF* also are involved in this pathway. This pathway also can transform into the *MSI* pathway. **NOTE:** definitions for all abbreviations are listed in [Box 42.7](#). (Adapted from National Institutes of Health: Advances in colorectal cancer research. Available at: <https://www.nih.gov/research-training/advances-colorectal-cancer-research>.)

Cyclooxygenase-2 (COX-2) is variably expressed in right-sided and

left-sided colorectal cancer. Platelets are activated with tissue damage, which induces proinflammatory mediators and activates expression of COX-2 and pro-oncogenic prostaglandin E₂.²⁵⁶ Use of aspirin and NSAIDs has shown efficacy in the prevention and treatment of colorectal cancer and may be related to suppression of platelet activation and inflammation and COX-2.²⁵⁷

The stem cell theory of CRC proposes that genetic mutations begin in crypt stem cells with strong oncogenicity. However, cells outside the stem cell zone can be cells of origin, so it is possible that other cells have the plasticity to revert to stemlike cells and acquire genetic mutations that initiate neoplasia.^{258,259} The tumor microenvironment also influences the way mutations develop and progress in CRC. Factors include gut dysbiosis, chronic inflammation, and the cellular composition of the extracellular matrix, including fibroblasts and immune cells. Thus pathogenesis of CRC is promoted by the accumulation of genetic mutations within the context of tumor-promoting factors derived from adjacent tissue.²⁶⁰

Colorectal adenocarcinomas have a long preinvasive phase, and when they invade they tend to grow slowly over 10 to 15 years, with the exception of HNPCC/Lynch syndrome, which can progress more rapidly within 3 to 5 years. Because the lymphatic channels are located underneath the muscularis mucosae, the lesions must traverse this layer before metastasis can occur. Systemic lymphatic spread occurs along the aorta to the mesenteric and pancreatic lymph nodes. Liver metastasis follows invasion from the inferior mesenteric vein (left colon) or superior mesenteric vein (right colon), which drain into the portal circulation.

Rectal carcinomas are defined as tumors occurring up to 15 cm from the anal opening. Most are adenocarcinomas and more rarely squamous cell or neuroendocrine tumors, sarcomas, and lymphomas. Tumors of the rectum can spread through the rectal wall to nearby structures: the prostate in men and the vagina in women. Penetration occurs more readily in the lower third of the rectum because it has no serosal covering. Systemic and pulmonary metastases occur through the hemorrhoidal plexus, which drains into the vena cava.²⁶¹

◆Clinical Manifestations.

Polyps and early stage tumors usually do not have symptoms, making screening important for early detection. Symptoms of colorectal cancer depend on the location, size, shape, and metastasis of the lesion. Tumors of the right and left colon evolve into two distinct types. On the right side the lesions are polypoid and extend along one wall of the cecum and ascending colon. These tumors may be silent, evolving to pain, with a palpable mass in the lower right quadrant, fatigue, dark red or mahogany-colored blood mixed with the stool, and anemia (see Fig. 42.28). These tumors can become large and bulky with necrosis and ulceration, contributing to persistent blood loss and anemia. Obstruction is unusual because the growth does not encircle the colon. These tumors are more common in women.²⁶²

Tumors of the left, or descending, colon are small, elevated, button-like masses. This type grows circumferentially, encircling the entire bowel wall (the left colon has a narrower lumen), and eventually ulcerating in the middle as the tumor penetrates the blood supply. Obstruction is common but occurs slowly, and stools become narrow and pencil shaped. Manifestations include progressive abdominal distention, pain, vomiting, constipation, need for laxatives, cramps, bright blood on the surface of the stool, and anemia. In 8% to 29% of cases, bowel obstruction is the primary symptom at diagnosis.²⁶³ These tumors are more common in men. Rectal tumors also cause obstruction and changes in bowel habits, including constipation, diarrhea, and tenesmus (a constant feeling of needing to pass stool). Other symptoms can develop related to distant organ metastasis.

◆Evaluation and Treatment.

Individuals with hereditary polyposis or a strong family history of CRC should begin screening at an early age (10 to 12 years) using colonoscopy and removal of polyps when they are found. Screening procedures for detection of nonhereditary CRC are summarized in Box 42.8. Specific, sensitive, and affordable molecular markers are being evaluated to assist with early diagnosis and evaluation of therapy. Chromoendoscopy (spraying dye onto the surface of the

colon to make polyps more visible) and magnifying endoscopy help to differentiate between neoplastic and nonneoplastic colonic polyp subtypes.²⁶⁴ Carcinoembryonic antigen (CEA) is evaluated during and after cancer treatment.

Box 42.8

Screening for Colorectal Cancer

Beginning at age 50, both men and women should follow one of these testing schedules:

- Guaiac-based fecal occult blood test (gFOBT) with at least 50% sensitivity
- OR
- Fecal immunochemical test (FIT) with at least 50% sensitivity
- Yearly testing of spontaneously passed stool specimens

Single stool testing during a clinician office visit is not recommended, nor are “throw in the toilet bowl” tests. In comparison with guaiac-based tests for the detection of occult blood, immunochemical tests are more patient-friendly and are likely to be equal or better in sensitivity and specificity. There is no justification for repeating gFOBT in response to an initial positive finding.

OR

Stool DNA test; every 3 years

OR

Flexible sigmoidoscopy (FSIG); every 5 years alone or consideration can be given to combining FSIG performed every 5 years with a highly sensitive gFOBT or FIT performed annually.

OR

Double-contrast barium enema; every 5 years

OR

Colonoscopy; every 10 years

OR

CT colonography, every 5 years

All positive tests (other than colonoscopy) should be followed up with colonoscopy.

Data from American Cancer Society (ACS): Recommendations for early detection of cancer in average risk asymptomatic people. In *Cancer facts & figures 2017*, p. 71, Atlanta GA, 2017, Author. Available at: <https://www.cancer.org/research/cancer-facts-statistics/all-cancer-facts-figures/cancer-facts-figures-2017.html>

The staging of colorectal cancer involves preoperative testing and operative exploration. Preoperative testing begins with physical examination of the abdomen to detect liver enlargement and ascites and palpation of appropriate lymph nodes. Elevations in the level of CEA are often detected in the sera of individuals with colorectal carcinoma. The amount of CEA in the serum is a function of the stage of the disease and the type of tumor. Operative staging consists of careful exploration during surgery and biopsy of possible metastases. The National Cancer Institute²⁶⁵ classification is widely used for staging of colorectal cancer and is as follows (see Fig. 42.29):

Stage 0 (carcinoma in situ): involves only the mucosal lining; also known as *carcinoma in situ*

Stage I: extension of cancer to the middle layers of the colon wall, no spread to lymph nodes; stage I colon cancer is sometimes called *Dukes A colon cancer*

Stage II: extension beyond the colon wall to nearby tissues around the colon or *rectum*, and/or through the *peritoneum*; stage II colon cancer is sometimes called *Dukes B colon cancer*

Stage III: spread beyond the colon into lymph nodes and nearby organs and/or through the *peritoneum*; stage III colon cancer is sometimes called *Dukes C colon cancer*

Stage IV: spread to nearby *lymph nodes* and has spread to other parts of the body, such as the *liver* or *lungs*; stage IV colon cancer is sometimes called *Dukes D colon cancer*

Treatment for cancer of the colon is always surgical. The location and amount of colon resected depend on the site of the cancer. Resection and anastomosis can be performed for early-stage tumors and is usually curative. These surgeries are performed using laparoscopic techniques or through abdominal incisions, and natural defecation is preserved. Growths in the lower portion of the rectum require removal of the entire rectum with formation of a permanent colostomy. Prognosis after surgery depends on the stage and location of the tumor.²⁶⁶

Radiation therapy is often given before surgery in the hope that it will shrink the tumor, alter the malignant cells, or both so that these cells will not survive after surgery. Adjuvant chemoradiotherapy is used to treat metastatic disease and cases with a high risk of recurrence. Monoclonal antibody therapy and other targeted therapies that are gene-specific may be added.²⁶⁷ Vaccines for colon cancer are in clinical trials. Treatment of rectal cancer includes preoperative chemoradiotherapy, total mesorectal excision surgery, and adjuvant chemotherapy.

Anal carcinoma is rare (estimated 8200 cases and 1100 deaths in 2017).²²⁷ The most common tumor type is squamous cell carcinoma, about 80%; other anal cancers are adenocarcinoma, lymphoma, or sarcoma. The most common risk factor is infection with human papillomavirus (93%) and less commonly anal involvement in Crohn disease. Squamous cell anal carcinoma is more common among the human immunodeficiency virus-infected population. Anal carcinomas are treated according to stage and include surgery and combined chemoradiation.^{268,269}

Cancer of the Accessory Organs of Digestion

Cancer of the Liver

Cancer of the liver is a leading cause of cancer death worldwide and is highest in Eastern and Southeastern Asia.²⁷⁰ The estimated number of new cases is 40,710, with 28,920 deaths in the United States in 2017. The overall 5-year survival rate is 18%.²²⁷ In the United States, blacks

and Hispanics are almost twice as likely to develop these cancers as whites.²⁷¹ In the United States, the incidence of primary hepatocellular carcinoma is increasing significantly as a result of chronic hepatitis C infection. Liver cancer is common in densely populated parts of Southeast Asia and sub-Saharan Africa, where hepatitis B virus infection is endemic.²²⁷ Primary liver cancer is rare before the age of 40 years and most common after 60 years. Cancer in the liver is usually caused by metastatic spread from a primary site elsewhere in the body. Risk factors for primary liver cancer include the following:

1. Infection and inflammation associated with HBV, HCV, and HDV, particularly in conjunction with cirrhosis, acts either as a carcinogen or as a co-carcinogen in chronically infected hepatocytes²⁷²; primary liver cancer risks associated with HBV and HCV are decreasing with antiviral therapy and screening
2. Chronic alcoholic liver disease and nonalcoholic fatty liver disease that results in cirrhosis
3. Exposure to mycotoxins; the most significant mycotoxins are the aflatoxins, particularly those produced by *Aspergillus flavus*, a mold found on spoiled corn, peanuts, and grain; aflatoxins cause mutation of the *TP53* suppressor gene and activation of WNT signal transduction pathway
4. Long duration of heavy smoking (greater than 20 years)
5. Hepatic iron overload (hemochromatosis)
6. Obesity

◆Pathogenesis.

Primary carcinomas of the liver are hepatocellular or cholangiocellular. **Hepatocellular carcinoma (hepatocarcinoma) (HCC)** develops in the hepatocytes and can be nodular (consisting of multiple, discrete nodules), massive (consisting of a large tumor mass having satellite nodules), or diffuse (consisting of very small nodules distributed throughout most of the liver). HCC is the type of primary liver cancer that is closely associated with cirrhosis (Fig. 42.30). Chronic hepatitis B and hepatitis C and cirrhosis give rise to HCC

repetitive cellular proliferation that occurs in the inflamed liver in response to growth factor and cytokine stimulation and oxidative stress-induced DNA damage. Numerous genetic and epigenetic alterations, including activation of oncogenes, failure of tumor-suppressor genes, and signaling pathways, combine to promote carcinogenesis.²⁷³ Because carcinoma of the liver invades the hepatic and portal veins, it often spreads to the heart and lungs. Other sites of metastases are the brain, kidney, and spleen.

FIGURE 42.30 Primary Hepatocellular Carcinoma. Macroscopically, hepatocellular carcinomas may be single or multifocal. They usually develop in a liver already affected by cirrhosis as shown in this image. Tumor appears as the light-colored mass within the top part of the liver. (From Connolly AJ, et al, editors: *Autopsy pathology: a manual and atlas*, ed 3, Philadelphia, 2016, Saunders.)

Cholangiocellular carcinomas (cholangiocarcinoma) is rare (less than 1% of liver cancers), develops in the bile ducts, and occurs less often than hepatocellular carcinoma in the United States.²⁷⁴ The disease predominates in men. Incidence demonstrates geographic variation and is common in Southeast Asia, where liver fluke infestation is prevalent. The mechanism by which fluke infestation causes cholangiocellular carcinoma is multifactorial and includes parasite secretions, immunopathology, and mechanical damage. Other risk factors include primary sclerosing cholangitis, hepatolithiasis, and choledochal cysts.²⁷⁴ Intrahepatic

cholangiocellular carcinoma also is associated with cirrhosis, HBV and HCV infection, obesity, and diabetes. However, most individuals diagnosed with cholangiocellular carcinoma do not have an identifiable risk factor except age. Cholangiocellular carcinoma can occur anywhere along the bile duct, both within and outside the liver, and usually is a solitary lesion. It is difficult to distinguish an invasion of cholangiocellular carcinoma from a metastatic adenocarcinoma except by neoplastic changes found in nearby ducts. A combined form of HCC is known as *combined (mixed) hepatocellular-cholangiocellular carcinoma*.

◆Clinical Manifestations.

HCC is usually asymptomatic. Manifestations can develop slowly or abruptly and include vague abdominal symptoms, such as nausea and vomiting; fullness or pressure; dull ache in the right hypochondrium; and weight loss. In individuals with cirrhosis, deepening jaundice or abrupt lack of appetite is a sign of hepatocellular carcinoma. Obstruction by the tumor can cause sudden worsening of portal hypertension and development of ascites. As the tumor enlarges, it causes pain. Cholangiocellular carcinoma more commonly presents insidiously as pain, loss of appetite, weight loss, and gradual onset of jaundice. Some carcinomas of the liver rupture spontaneously, causing hemorrhage. Others are discovered accidentally during laboratory evaluation, imaging, or surgery for other diseases or trauma.

◆Evaluation and Treatment.

There is no specific test or biologic marker to guide diagnosis and treatment of HCC.²⁷⁵

Biopsy is not recommended because of the risk for tumor seeding. For HCC high-risk individuals, alpha fetoprotein associated with HBV (risk of high false-negative and false-positive results) and abdominal ultrasound are common screening tools. Additional serum markers are being evaluated.²⁷⁶ Diagnosis is based on clinical manifestations, laboratory findings, imaging, biopsy findings, and exploratory

laparotomy. In individuals without cirrhosis, liver scans can document filling defects. CT or ultrasonography is used to detect solid tumors, but neither can distinguish benign from malignant tumors. Serum levels of alkaline phosphatase, aspartate aminotransferase (AST), and alanine aminotransferase (ALT) are commonly elevated in individuals with HCC.

Staging of HCC is important for guiding treatment but does not accurately predict postoperative outcome. Surgical resection is possible with solitary tumors localized to a removable lobe of the liver and the absence of portal hypertension.

Radiofrequency (thermal) ablation has emerged as the most effective method for local tumor destruction.²⁷⁷ Tyrosine kinase inhibitors (e.g., sorafenib) and monoclonal antibodies are improving survival; many new therapies are in clinical trials. Transarterial embolization, chemotherapy, and radiation are used for management of pain and to reduce tumor size.²⁷⁸ Surgical resection or liver transplantation is the only alternative for cure; however, very early stage HCC is difficult to diagnose. Primary prevention of HCC is vaccination against HBV and antiviral therapy for HCV.

Cholangiocarcinoma causes duct obstruction. Most tumors are unresectable, and radiotherapy, chemotherapy, photodynamic therapy, and stenting can temporarily relieve the blockage.^{279,280}

Cancer of the Gallbladder

Cancer of the gallbladder and biliary tract is a rare but lethal disease. The estimated number of new cases was 11,740 and 3830 deaths in 2017 in the United States.²²⁷ It rarely occurs before age 40 and is most common between the ages of 50 and 60 years. Risk factors include gallstones, advancing age, female sex (2:1), anomalous pancreaticobiliary ductal junction, and obesity. Native populations in North and South America have greater risk of gallbladder cancer, and it is more common in Chile, Poland, India, Japan, and Israel.²⁸¹⁻²⁸⁴ Most cancerous tumors in the gallbladder are caused by metastasis.

◆Pathogenesis.

Most primary cancers of the gallbladder are adenocarcinomas and, less commonly, squamous cell carcinomas. The pathogenesis is not clear. Chronic inflammation may trigger dysplasia and progression to metaplasia. The molecular mechanisms involve mutation of several genes, including tumor suppressor genes, oncogenes, and alterations in the extracellular matrix.²⁸⁵ Infiltrative tumors are associated with gallstones, and invasion of the liver and lymph nodes occurs early. Spreading extends to the pancreas and retroperitoneal lymph nodes. Direct invasion of the stomach and the duodenum can cause pyloric obstruction. Infection often accompanies cancer of the gallbladder. Generalized peritonitis, gangrene, perforation, and liver abscesses are potential complications of infection.

◆Clinical Manifestations.

Early stages of gallbladder carcinoma are asymptomatic and the disease usually presents at an advanced stage. When symptoms develop, there is usually steady upper right quadrant pain for about 2 months, jaundice, and fever. Other symptoms mimic benign gallbladder disease, including diarrhea, belching, weakness, loss of appetite, weight loss, and vomiting. Obstructive jaundice can occur if an enlarging tumor presses on the extrahepatic ducts.

◆Evaluation and Treatment.

Early diagnosis of gallbladder cancer is rare, and the disease may be found incidentally when removing gallstones. The disease is often in an early stage and resectable.²⁸⁶ Therefore adults with gallstones, particularly older women, are evaluated for gallbladder carcinoma. Inflammatory disorders, such as cholangitis (bile duct inflammation) and peritonitis, often obscure an underlying malignancy. Diagnostic procedures include high resolution ultrasonography, CT, and MRI.²⁸⁷

Complete surgical resection of the gallbladder is the only effective treatment. Because advanced malignancies cannot be resected, gallbladders containing stones are removed as a preventive measure. Palliative chemotherapy or chemoradiation provides symptom improvement but does not improve survival. The prognosis of

gallbladder cancer is extremely poor. Most individuals with advanced-stage disease die within 5 years.²⁸⁸

Cancer of the Pancreas

Pancreatic cancer represents about 2.6% of all new cancers. An estimated 53,670 new cases and 43,090 deaths occurred in 2017 in the United States.²²⁷ The incidence of pancreatic cancer rises steadily with age. Men are affected more often than women, and blacks more often than whites.²²⁷ Mortality is about 95% within 12 months and is related to lack of early diagnosis and ineffective treatment. Risk factors include use of tobacco (smoking and nonsmoking), heavy alcohol use, family history of pancreatic cancer, long-term type 2 diabetes mellitus, chronic pancreatitis, and non-O blood group. Obesity, with centralized fat distribution, is a risk factor, particularly in women, and is associated with decreased response to chemotherapy.^{289,290}

◆Pathogenesis.

Pancreatic cancer is a disease of inherited and multiple acquired mutations in cancer-related genes associated with chronic inflammation and growth factors.²⁹¹ A *K-ras* mutation (a proto-oncogene) is the most common and early genetic alteration; tumor-suppressor gene alterations also are found, including *TP53*, *CDKN2A*, *SMAD4*, *BRCA2*, and *PALB2*.^{290,292}

Pancreatic cancer can arise from exocrine or endocrine cells. Most pancreatic tumors (95%) arise from metaplastic exocrine cells in the ducts and are called *ductal adenocarcinomas*. There is significant expansion of the extracellular matrix (stroma) from activation of pancreatic stellate cells, a type of fibroblast in the pancreas, which also promotes inflammation, angiogenesis, and tumor growth and contributes to therapeutic resistance.²⁹³ Tumors arising in small ducts invade nearby glandular tissue, penetrate the covering of the pancreas, and extend into surrounding tissues. Tumors are staged using the TNM classification.

Ductal adenocarcinomas are the most common tumor and can occur in the head, body, or tail of the pancreas. Tumors of the head quickly

spread to obstruct the common bile duct and portal vein (Fig. 42.31). These tumors can then infiltrate the superior mesenteric artery, the vena cava, and the aorta. Cancer cells that enter the blood vessels can form emboli. Tumors of the body and tail infiltrate the posterior abdominal wall. Lymphatic invasion occurs early and rapidly and involves local and regional lymph nodes. Venous invasion causes metastases to the liver. Tumor implants on the peritoneal surface can obstruct veins and promote development of ascites.

FIGURE 42.31 Pancreatic Carcinoma. Adenocarcinoma of the head of pancreas. Pancreatic adenocarcinoma may arise in the head (60%), body (15%), or tail (5%) of the pancreas; in 20% of cases there is involvement of more than one segment. (From Connolly AJ, et al: *Autopsy pathology: a manual and atlas*, ed 3, St Louis, 2016, Elsevier.)

Ductal adenocarcinomas arising in the head of the pancreas cause biliary obstruction somewhat early in the disease. Individuals with such tumors survive slightly longer than those with cancer of the body and tail, presumably because they seek medical attention earlier.

Tumors of the endocrine pancreas are rare neoplasms of the islets of Langerhans known as *apudomas*. The first four letters in *apudoma* derive from *amine precursor uptake* and *decarboxylation*. The apudomas are so named because they contain neurosecretory granules. Endocrine neoplasms secrete abnormal amounts of hormones, such as insulin.

◀Clinical Manifestations.

Cancer of the body and tail of the pancreas is generally asymptomatic until there is intraductal obstruction or the tumor invades adjacent tissue. Alarm symptoms include lethargy, weight loss, abdominal pain, nausea and vomiting, bloating, dyspepsia, new-onset diabetes, changes in bowel habit, pruritus, lethargy, back pain, shoulder pain, and jaundice. Jaundice develops in most cases, usually caused by obstruction of the bile duct. Distant metastases are found in the cervical lymph nodes, the lungs, and the brain. Most individuals die of hepatic failure, malnutrition, or systemic complications.²⁹⁴

◀Evaluation and Treatment.

Pancreatic cancer is usually diagnosed at an advanced stage after several years of silent tumor progression and has a poor prognosis. The most effective screening method for those at risk is endoscopic ultrasound because it detects small lesions and endoscopic ultrasonography-guided fine-needle aspiration for biopsy. Contrast CT scans or contrast MRI, or both, assist with diagnosis. *Autoimmune pancreatitis* is a rare, fibroinflammatory disorder of the pancreas that mimics radiologic and clinical symptoms (painless obstructive jaundice) of pancreatic cancer and must be differentiated from pancreatic cancer. Symptoms for this disease usually improve with steroid administration.²⁹⁵ CA19-9 tumor antigen is a serum tumor biomarker useful for diagnosis and response to treatment of pancreatic cancer. The measurement of *K-ras* mutations has not been clinically beneficial.²⁹⁶ The search for other biomarkers is continuing.²⁹⁷ Laparotomy is used to establish a definitive diagnosis, evaluate the extent and resectability of disease, and determine whether palliative bypass surgery (i.e., cholecystojejunostomy and gastrojejunostomy) is needed. Laparoscopic and robotic approaches have been used in some centers.^{298,299}

Individuals with small tumors and complete resection have the best possibility of cure (15% to 20% of cases), but 5-year survival is about 25% because of tumor recurrence. Pancreaticoduodenectomy (Whipple procedure) is the most common procedure performed to

decompress duct obstruction. Some surgeons recommend a total pancreatectomy because cancer of the pancreas seldom consists of a single lesion. Islet cell autotransplantation minimizes the development of diabetes mellitus.³⁰⁰ Neoadjuvant chemotherapy has shown encouraging long-term survival in borderline tumor resection. Evaluations are in progress for adjuvant radiation therapy. The dense stromal structure of the tumor impairs chemotherapeutic drug delivery and results in poor response to chemotherapy. Five classes of cytotoxic drugs (gemcitabine, fluoropyrimidines, oxaliplatin, irinotecan-nanoliposomal, or nanoparticle albumin-bound paclitaxel) are showing efficacy in disease treatment.³⁰¹ Chemoradiation therapy is used for advanced disease in some centers. Treatments with molecular targets are in clinical trials, including immune-modifying agents and vaccines, and combination agents.³⁰² Palliative care, including pain management and nutrition, is important.³⁰³

Summary Review

Disorders of the Gastrointestinal Tract

1. Anorexia (loss of appetite), vomiting, constipation, diarrhea, abdominal pain, and evidence of gastrointestinal bleeding are clinical manifestations of many disorders of the gastrointestinal tract.
2. Vomiting is the forceful emptying of the stomach effected by gastrointestinal contraction and reverse peristalsis of the esophagus. It is usually preceded by nausea and retching with the exception of projectile vomiting, which is associated with direct stimulation of the vomiting center in the brain.
3. Primary constipation is defined in three categories: functional, associated with low-residue, low-fluid diet; slow-transit, related to impaired colonic motor function; and pelvic floor dyssynergia-anismus. Secondary constipation results from a neurogenic disease, drugs that decrease intestinal motility, endocrine or metabolic disorders, or obstruction.

4. Diarrhea can be caused by excessive fluid drawn into the intestinal lumen by osmosis (osmotic diarrhea), excessive secretion of fluids by the intestinal mucosa (secretory diarrhea), or excessive gastrointestinal motility (motility diarrhea).
5. Abdominal pain is caused by stretching, inflammation, or ischemia and originates in the peritoneum (parietal pain) or in the organs themselves (visceral pain). Visceral pain is often referred to the back.
6. Gastrointestinal bleeding can occur in the upper or lower gastrointestinal tract. Obvious manifestations of gastrointestinal bleeding are hematemesis (vomiting of blood), melena (dark, tarry stools), and hematochezia (frank bleeding from the rectum). Occult bleeding can be detected only by testing stools or vomitus for the presence of blood.
7. Dysphagia is difficulty in swallowing or perception of obstruction during swallowing. It can be caused by a mechanical or functional obstruction of the esophagus. Functional obstruction is an impairment of esophageal motility.
8. Achalasia is a form of functional dysphagia caused by loss of esophageal innervation or relaxation of the lower esophageal sphincter.
9. Gastroesophageal reflux disease is the regurgitation of chyme from the stomach into the esophagus, causing esophagitis from repeated exposure to acids, enzymes, or bile salts in the regurgitated gastric contents.
10. Hiatal hernia is the protrusion of the upper part of the stomach through the hiatus (esophageal opening in the diaphragm) at the gastroesophageal junction. Hiatal hernia can be sliding, paraesophageal, or mixed.
11. Gastroparesis is delayed gastric emptying in the absence of mechanical gastric outlet obstruction.
12. Pyloric obstruction is the narrowing or blockage of the pylorus, which is the opening between the stomach and the

duodenum. It can be caused by a congenital defect, inflammation and scarring secondary to a gastric ulcer, or tumor growth.

13. Intestinal obstruction can occur in the small or large intestine and prevents the normal movement of chyme through the intestinal tract. It is usually mechanical—that is, caused by torsion, herniation, or tumor. Functional obstruction is caused by paralytic ileus.
14. The most severe consequences of intestinal obstruction are fluid and electrolyte losses, hypovolemia, shock, intestinal necrosis, and perforation of the intestinal wall.
15. Gastritis is an acute or a chronic inflammation of the gastric mucosa.
16. Regurgitation of bile, use of antiinflammatory drugs or alcohol, *H. pylori* infection, and some systemic diseases are associated with gastritis.
17. Chronic fundal gastritis is rare and associated with autoantibodies to parietal cells and intrinsic factor, resulting in gastric atrophy and causing pernicious anemia.
18. Chronic antral gastritis is the most common gastritis and is associated with *H. pylori* and NSAIDs.
19. Alkaline reflux gastritis is stomach inflammation caused by the reflux of bile and pancreatic secretions from the duodenum into the stomach. These substances disrupt the mucosal barrier and cause inflammation.
20. A peptic ulcer is a circumscribed area of mucosal inflammation and ulceration caused by excessive secretion of gastric acid, disruption of the protective mucosal barrier, or both.
21. The three types of peptic ulcers are duodenal, gastric, and stress ulcers. Duodenal and gastric ulcers are associated with *H. pylori* infection and chronic use of NSAIDs.
22. Duodenal ulcers, the most common peptic ulcers, are associated with increased numbers of parietal (acid-secreting) cells in the stomach, elevated gastrin levels, and rapid gastric emptying. Pain occurs when the stomach is empty, and pain is

relieved with food or antacids. Duodenal ulcers tend to heal spontaneously and recur frequently.

23. Gastric ulcers develop near parietal cells, generally in the antrum, and tend to become chronic. Gastric secretions may be normal or decreased, and pain may occur after eating.
24. Zollinger-Ellison syndrome is associated with a gastrinoma, chronic secretion of gastric acid, and gastric and duodenal ulcers.
25. Stress ulcer (stress-related mucosal disease) is an acute form of peptic ulcer associated with severe illness or extensive trauma.
26. Ischemic stress ulcers develop suddenly after severe illness, systemic trauma, neural injury, or burns (Curling ulcer). Ulceration follows mucosal damage caused by ischemia (decreased blood flow to the gastric mucosa).
27. Cushing ulcer is a stress ulcer caused by head trauma. Ulceration follows hypersecretion of hydrochloric acid caused by overstimulation of the vagal nuclei.
28. Postgastrectomy syndromes are a group of signs and symptoms that occur after gastric resection for the treatment of peptic ulcer, gastric carcinoma, or bariatric surgery for extreme obesity.
29. Dumping syndrome causes malabsorption by the rapid emptying of hypertonic chyme from the surgically created residual stomach into the small intestine. It causes an osmotic shift of fluid from the vascular compartment to the intestinal lumen, which decreases plasma volume.
30. Malabsorption syndromes result in impaired digestion or absorption of nutrients.
31. Pancreatic insufficiency causes malabsorption associated with insufficient amounts of the enzymes that digest protein, carbohydrates, and fats into components that can be absorbed by the intestine.
32. Deficient lactase production in the brush border of the small intestine inhibits the breakdown of lactose. This prevents lactose absorption and causes osmotic diarrhea.

33. Bile salt deficiency causes fat malabsorption, including fat-soluble vitamins, and steatorrhea (fatty stools). Bile salt deficiency can result from inadequate secretion of bile, excessive bacterial deconjugation of bile, or impaired reabsorption of bile salts caused by ileal disease.
34. Ulcerative colitis is an inflammatory bowel disease that causes ulceration, abscess formation, and necrosis of the colonic and rectal mucosa. Cramping pain, bleeding, frequent diarrhea, dehydration, and weight loss accompany severe forms of the disease. A course of frequent remissions and exacerbations is common.
35. Crohn disease is similar to ulcerative colitis but it affects entire GI tract, including the large and small intestines. Ulceration tends to involve all layers of the lumen. "Skip lesion" fissures and granulomas are characteristic of Crohn disease. Abdominal tenderness, nonbloody diarrhea, and weight loss are the usual symptoms.
36. Microscopic colitis involves two histologic forms of the disease, lymphocytic and collagenous, with both resulting in frequent diarrhea.
37. Irritable bowel syndrome is a disorder of brain-gut interaction characterized by abdominal pain with altered bowel habits (diarrhea, constipation, or both).
38. Diverticula are outpouchings of colonic mucosa through the muscle layers of the colon wall. Diverticulosis is the presence of these outpouchings; diverticulitis is inflammation of the diverticula.
39. Appendicitis is caused by obstruction of the lumen and leads to increased pressure, ischemia, and inflammation of the appendix. Without surgical resection, inflammation may progress to gangrene, perforation, and peritonitis.
40. Vascular insufficiency in the intestine is associated most often with acute or chronic occlusion or obstruction of the mesenteric vessels or insufficient mesenteric arterial blood flow. The resulting ischemia and necrosis produce abdominal

pain, fever, bloody diarrhea, hypovolemia, and shock.

Disorders of the Accessory Organs of Digestion

1. Portal hypertension, ascites, hepatic encephalopathy, jaundice, and hepatorenal syndrome are complications of many liver disorders.
2. Portal hypertension is an elevation of portal venous pressure to at least 10 mmHg. It is caused by increased resistance to venous flow in the portal vein and its tributaries, including the sinusoids and hepatic vein.
3. Portal hypertension is the most serious complication of liver disease because it can cause fatal complications, such as bleeding varices, ascites, hepatic encephalopathy, and renal failure.
4. Varices are distended, tortuous, collateral veins associated with portal hypertension.
5. Splenomegaly is an enlargement of the spleen resulting from increased splenic vein pressure caused by portal hypertension.
6. Hepatopulmonary syndrome is pulmonary hypertension related to the release of vasodilators that affect pulmonary arterioles and is associated with portal hypertension and severe liver disease.
7. Ascites is the accumulation and sequestration of fluid in the peritoneal cavity, often as a result of portal hypertension, decreased concentrations of plasma proteins, and sodium retention.
8. Hepatic encephalopathy (portosystemic encephalopathy) is impaired cerebral function caused by blood-borne toxins (particularly ammonia) not metabolized by the liver.
9. Jaundice (icterus) is a yellow or greenish pigmentation of the skin or sclera of the eyes caused by increases in plasma bilirubin concentration (hyperbilirubinemia).
10. Obstructive jaundice is caused by obstructed bile canaliculi (intrahepatic obstructive jaundice) or obstructed bile ducts

outside the liver (extrahepatic obstructive jaundice). Bilirubin accumulates proximal to sites of obstruction, enters the bloodstream, and is deposited in the skin and other connective tissues.

11. Hemolytic jaundice is caused by destruction of red blood cells at a rate that exceeds the liver's ability to metabolize unconjugated bilirubin.
12. Hepatorenal syndrome is functional renal failure caused by advanced liver disease, particularly cirrhosis with portal hypertension. Renal failure is caused by a sudden decrease in blood flow to the kidneys, usually as a result of massive gastrointestinal hemorrhage or liver failure. Its chief clinical manifestation is oliguria.
13. Acute liver failure can be caused by toxic overdose of acetaminophen or complications of viral hepatitis.
14. Autoimmune hepatitis is T-cell mediated inflammatory liver disease with hypergammaglobulinemia, elevated transaminases, and absence of viral hepatitis.
15. Viral hepatitis is an infection of the liver caused by strains of the hepatitis virus. Modes of transmission are HAV and HEV, fecal-oral route; and HAV, HBV, HCV, HDV, and HEV, parenteral and sexual transmission. The hepatitis viruses can cause hepatic cell necrosis, Kupffer cell hyperplasia, and infiltration of liver tissue by mononuclear phagocytes. These changes obstruct bile flow and impair hepatocyte function.
16. The clinical manifestations of viral hepatitis depend on the stage of infection. Fever, malaise, anorexia, and liver enlargement and tenderness characterize the prodromal phase (stage 1). Jaundice and hyperbilirubinemia mark the icteric phase (stage 2). During the recovery phase (stage 3), symptoms resolve. Recovery takes several weeks.
17. Chronic active hepatitis can occur with HBV and HCV with predisposition to cirrhosis and hepatocellular carcinoma.
18. Fulminant hepatitis is a complication of hepatitis B (with or without hepatitis D infection) or hepatitis C. It causes

widespread hepatic necrosis and is often fatal.

19. Cirrhosis is an irreversible inflammatory disease of the liver that causes disorganization of lobular structure, fibrosis, and nodular regeneration. Bile obstruction causes jaundice. Vascular obstruction causes portal hypertension, shunting, and varices. Cirrhosis can result from hepatitis or exposure to toxins, such as acetaldehyde (a product of alcohol metabolism). The disease causes progressive irreversible liver damage, usually over a period of years.
20. Alcoholic liver disease results from formation of acetaldehyde impairing the hepatocytes' ability to oxidize fatty acids, synthesize enzymes and proteins, degrade hormones, and clear portal blood of ammonia and toxins. The disease is progressive and includes steatosis, steatohepatitis, and alcoholic cirrhosis.
21. Nonalcoholic fatty liver disease and nonalcoholic steatohepatitis is fat infiltration and inflammation of hepatocytes associated with obesity.
22. Primary biliary cirrhosis is an autoimmune disease with inflammatory destruction of intrahepatic bile ducts. Mitochondrial autoantibodies are found in this disease.
23. Secondary biliary cirrhosis develops from prolonged obstruction of bile flow (e.g., gallstones) with increased pressure in the hepatic bile ducts that causes pooling of bile and necrosis of tissue. Relief of obstruction alleviates symptoms of jaundice and pruritus. Continued obstruction causes cirrhosis and liver failure.
24. Primary sclerosing cholangitis is a fibrotic disease of medium- and large-sized bile ducts outside the liver.
25. Cholelithiasis (the formation of gallstones) is a result of bile aggregation of cholesterol crystals (cholesterol stones) or precipitates of unconjugated bilirubin (pigmented stones). Gallstones that fill the gallbladder or obstruct the cystic, or common, bile duct cause abdominal pain and jaundice.
26. Cholecystitis is an inflammation of the gallbladder. It is

usually associated with obstruction of the cystic duct by gallstones.

27. Acute pancreatitis (pancreatic inflammation) is a serious but relatively rare disorder associated with biliary obstruction and alcoholism. Injury permits leakage of digestive enzymes into pancreatic tissue, where they become activated and begin the process of autodigestion, inflammation, and destruction of tissues. Release of pancreatic enzymes into the bloodstream or abdominal cavity causes damage to other organs.
28. Chronic pancreatitis results from structural or functional impairment of the pancreas usually related to alcoholism or recurrent acute pancreatitis. It causes recurrent abdominal pain and digestive disorders.

Cancer of the Digestive System

1. Cancer of the esophagus is rare and tends to occur in people older than 60 years. Alcohol and tobacco use, reflux esophagitis, radiation exposure, and nutritional deficiencies are associated with esophageal carcinoma. There are two types, squamous cell and adenocarcinoma.
2. Dysphagia and chest pain are the primary manifestations of esophageal cancer. Early treatment of tumors that have not spread into the mediastinum or lymph nodes results in a good prognosis.
3. Gastric carcinoma is associated with *H. pylori* (*CagA*), high salt intake, food preservatives (nitrates and nitrites), and atrophic gastritis.
4. Gastric cancers are commonly located in the prepyloric antrum. Clinical manifestations (weight loss, upper abdominal pain, vomiting, hematemesis, anemia) develop only after the tumor has penetrated the wall of the stomach.
5. Cancer of the colon and rectum (colorectal cancer) is the third most common type of cancer and cancer death in the United States. Small intestinal cancers are rare. Familial adenomatous

polyposis coli and hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome) are inherited forms of colon cancer. Preexisting large and numerous polyps are highly associated with sporadic (acquired) adenocarcinoma of the colon.

6. Tumors of the right (ascending) colon are usually large and bulky; tumors of the left (descending, sigmoid) colon develop as small button-like masses. Manifestations of colon tumors include pain, bloody stools, and change in bowel habits.
7. Rectal carcinoma is located up to 15 cm from the opening of the anus. The tumor spreads transmurally to the vagina in women or to the prostate in men.
8. Metastatic invasion of the liver is more common than primary cancer of the liver.
9. Primary liver cancers are associated with chronic liver disease (cirrhosis and hepatitis B and C). Hepatocellular carcinomas arise from the hepatocytes, whereas cholangiocellular carcinomas arise from the bile ducts. Primary liver cancer spreads to the heart, lungs, brain, kidney, and spleen through the circulation.
10. Cancer of the gallbladder is relatively rare and tends to occur in women older than 50 years. Adenocarcinoma is most common. Because clinical manifestations occur late in the disease, metastases to lymph channels have usually occurred by the time of diagnosis, and the prognosis is poor.
11. Cancer of the pancreas represents about 2.6% of all cancers in the United States. Most tumors are adenocarcinomas that arise in the exocrine cells of ducts in the head, body, or tail of the pancreas. Symptoms may not be evident until the tumor has spread to surrounding tissues. Treatment is palliative, and mortality is nearly 100% for advanced tumors.

Key Terms

Achalasia, 1326
Acute colonic pseudo-obstruction (Ogilvie syndrome), 1329
Acute gastritis, 1331
Acute liver failure (fulminant liver failure), 1347
Acute mesenteric ischemia, 1342
Acute pancreatitis, 1354
Alcoholic cirrhosis, 1350
Alcoholic fatty liver (steatosis), 1350
Alcoholic hepatitis (steatohepatitis), 1350
Alkaline reflux gastritis, 1332
Anal carcinoma, 1362
Anorexia, 1321
Appendicitis, 1341
Ascites, 1343
Barrett esophagus, 1357
Biliary cirrhosis, 1351
Cholangiocellular carcinoma (cholangiocarcinoma), 1363
Cholecystitis, 1354
Cholelithiasis, 1353
Chronic active hepatitis, 1350
Chronic gastritis, 1331
Chronic mesenteric ischemia, 1342
Chronic pancreatitis, 1355
Cirrhosis, 1350
Constipation, 1322
Crohn disease (CD), 1338
Curling ulcer, 1334
Cushing ulcer, 1334
Diarrhea, 1323
Diverticula (*sing.*, diverticulum), 1340
Diverticulitis, 1340
Diverticulosis, 1340
Dumping syndrome, 1335
Duodenal ulcer, 1332
Dysphagia, 1325

Eosinophilic esophagitis, 1327
Esophageal varices, 1343
Esophagitis, 1326
Gallstone, 1353
Gastric ulcer, 1334
Gastritis, 1331
Gastroesophageal reflux disease (GERD), 1326
Gastroparesis, 1327
Hematemesis, 1324
Hematochezia, 1324
Hemolytic jaundice (prehepatic jaundice, nonobstructive jaundice), 1346
Hepatic encephalopathy, 1344

CHAPTER 43

Alterations of Digestive Function in Children

Sara J. Fidanza, Sharon Sables-Baus

CHAPTER OUTLINE

Disorders of the Gastrointestinal Tract, 1373

Congenital Impairment of Motility, 1373

Obstructions of the Duodenum, Jejunum, and Ileum, 1376

Meconium Syndromes, 1378

Acquired Impairment of Motility, 1379

Impairment of Digestion, Absorption, and Nutrition, 1380

Diarrhea, 1385

Disorders of the Liver, 1386

Disorders of Biliary Metabolism and Transport, 1386

Inflammatory Disorders, 1387

Portal Hypertension, 1388

Metabolic Disorders, 1389

Disorders of the gastrointestinal tract, liver, and pancreas in children

include congenital anomalies with structural and functional alterations, enzyme deficiencies, and infections. These disorders lead to impairment of motility, digestion, nutrition, and normal growth and development.

Disorders of the Gastrointestinal Tract

Congenital Impairment of Motility

Cleft Lip and Cleft Palate

Cleft lip (CL) and cleft palate (CLP) are embryonic developmental anomalies of the first branchial arch (Fig. 43.1). The incidence of CL with or without CLP is estimated at 1 in 940 live births and the incidence of CLP without CL is estimated at 1 in 1574 live births in the United States between 2004 and 2006.¹ Incidence is lower in black populations and higher in Asian populations.² Cleft lip, with or without cleft palate, is more common in males and isolated cleft palate is more common in females. Both anomalies can be unilateral or bilateral, partial or complete, and may also be associated with other malformations. *Nonsyndromic (isolated) CLP* is a malformation with an incomplete separation between nasal and oral cavities without any associated anomaly (70% of cases). Syndromic CLP is associated with other malformations (e.g., Crouzon syndrome [craniofacial dysostosis], Treacher Collins syndrome [mandibulofacial dysostosis], hemifacial microsomia).³

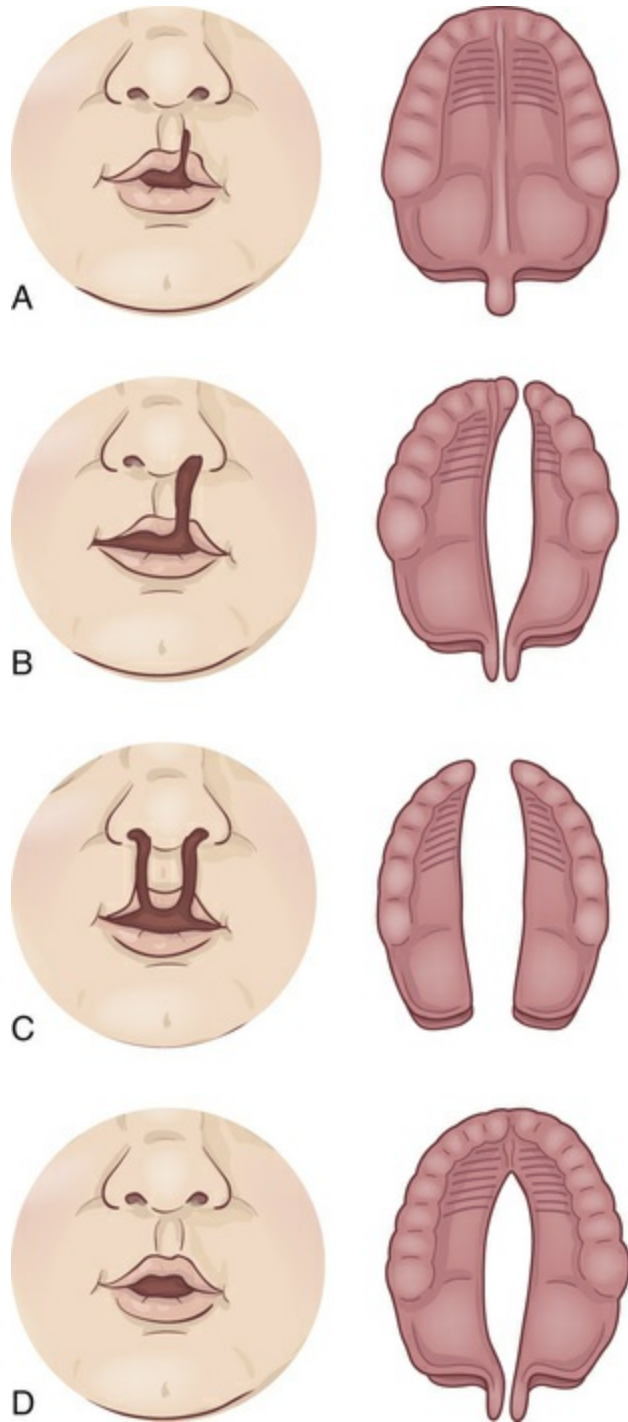

FIGURE 43.1 Variations in Clefts of the Lip and Palate. A, Notch in vermilion border. B, Unilateral cleft lip and palate. C, Bilateral cleft lip and cleft palate. D, Cleft palate.

In most cases, cleft lip and cleft palate are caused by multiple gene-environmental interactions, including maternal deficiency of B vitamins (B_6 , folic acid, and B_{12}), maternal smoking and alcohol intake,

steroid or statin use, maternal hyperhomocysteinemia, and maternal diabetes mellitus as well as many gene mutations.⁴ (This phenomenon, called *multifactorial inheritance*, is discussed in [Chapter 5](#).) Together these factors reduce the amount of neural crest mesenchyme that migrates into the area that will develop into the face of the embryo.⁵

◆Pathophysiology.

Cleft lip is caused by the incomplete fusion of the nasomedial and intermaxillary processes beginning during the fourth week of embryonic development, a period of rapid fetal growth. The cleft causes structures of the face and mouth to develop without the normal restraints of encircling lip muscles. The facial cleft may affect not only the lip but also the external nose, the nasal cartilages, the nasal septum, and the alveolar processes (bony ridge of the maxilla that contains the tooth sockets). The cleft is usually just beneath the center of one nostril. The defect may occur bilaterally and may be symmetrical or asymmetrical. The cleft can range in severity from a slight indentation of the lip to a fissure that extends to the nostril, causing a sagging and flattening of the nose. The failure of lip fusion by 35 days' gestation may impair closure of the palatal shelves. The more complete the cleft lip, the greater the chance that teeth in the line of the cleft will be missing or malformed.

Cleft palate is often associated with cleft lip but may occur without it. Cleft palate results from the failure of the primary palatal shelves, or processes, to fuse during the third month of gestation. The fissure may affect only the uvula and soft palate, or it may extend forward to the nostril and involve the hard palate and the maxillary alveolar ridge. It may be unilateral or bilateral, with the cleft occupying the midline posteriorly and as far forward as the alveolar process, where it deviates to the involved side. Clefts involving the palate only are usually but not necessarily in the midline. In some cases the vomer process and nasal septum are partly or completely undeveloped. When these facial bones are involved, the nasal cavity may freely communicate with the oral cavity. Teeth in the cleft palate area may

be missing or deformed.⁶

◆Clinical Manifestations.

Clefts of the lip or palate, or both, are immediately recognizable disruptions of normal facial structure. Feeding difficulty is the most significant clinical manifestation because of the oronasal communication and the inability to generate negative pressure needed for normal sucking.⁷ There also may be swallowing difficulty.

◆Evaluation and Treatment.

Prenatal diagnosis is made by ultrasound, and postnatal imaging confirms the extent of bone deformity. Soft tissue alterations are evaluated by history and physical examination. The nature and extent of the cleft, the infant's condition, and the method of surgical correction proposed determine the course of treatment. Surgical correction is planned at about the third to sixth month and may be performed in stages and may include preoperative nasal alveolar molding.⁸ There are limited long-term outcome studies.⁹

Feeding the infant with cleft lip usually presents no difficulty if the cleft lip is simple and the palate intact. A baby with a complete cleft palate requires consultation with a feeding and swallowing specialist to ensure adequate and safe nutritional intake. Bottles with nipples specialized for feeding an infant with a cleft palate are required. Breast-feeding may be possible for some infants.⁷ An orthodontic prosthesis for the roof of the mouth may facilitate sucking for some infants. Parental education and support is required for the long-term care of children with cleft palate. Longitudinal monitoring requires a cleft/orofacial multidisciplinary team including a plastic surgeon, speech therapist, orthodontist, and nurse.¹⁰ The child should be evaluated for hearing loss.

Esophageal Malformations

The estimated incidence of congenital malformations of the esophagus is 1 in 3500 live births.¹¹ Other congenital malformations are present in up to 50% of cases. **Esophageal atresia (EA)** is the most common,

where the esophagus ends in a blind pouch. EA is usually accompanied by a fistula between the esophagus and the trachea (**tracheoesophageal fistula [EA/TEF]**). Either defect can occur alone (**Fig. 43.2**). Environmental risk factors include maternal exposure to methimazole, exogenous sex hormones, infectious diseases, alcohol, or cigarette smoke; maternal diabetes; advanced maternal age; and maternal employment in agriculture.¹² There is a high frequency of anomalies and syndromes associated with esophageal atresias.¹³ Two syndromes in particular are associated with esophageal atresia¹⁴:

FIGURE 43.2 Five Types of Esophageal Atresia and Tracheoesophageal Fistulae. **A**, Simple esophageal atresia. Proximal esophagus and distal esophagus end in blind pouches, and there is no tracheal communication. Nothing enters the stomach; regurgitated food and fluid may enter the lungs. **B**, Proximal and distal esophageal segments end in blind pouches, and a fistula connects the proximal esophagus to the trachea. Nothing enters the stomach; food and fluid enter the lungs. **C**, Proximal esophagus ends in a blind pouch, and a fistula connects the trachea to the distal esophagus. Air enters the stomach; regurgitated gastric secretions enter the lungs through the fistula. **D**, Fistula connects proximal and distal esophageal segments to the trachea. Air, food, and fluid enter the stomach and the lungs. **E**, Simple tracheoesophageal fistula between otherwise normal esophagus and trachea. Air, food, and fluid enter the stomach and the lungs from the mouth through the fistula; and regurgitated gastric secretions enter the lungs through the fistula. Between 85% and 90% of esophageal anomalies are type C; 6% to 8% are type A; 3% to 5% are type E; and less than 1% are type B or D. **NOTE:** Type F, esophageal stenosis, is not shown.

- VACTERL (Vertebral anomalies, Anal atresia, Cardiac malformations, Tracheoesophageal fistula, Esophageal atresia, Renal anomalies and radial

aplasia, and *Limb anomalies*)

- CHARGE (*Coloboma, Heart defects, Atresia of the choanae, Retardation of mental and/or physical development, Genital hypoplasia, and Ear abnormalities*)

◆Pathophysiology.

The pathogenesis of esophageal abnormalities is unknown, but postviral, infectious, environmental, and genetic factors have been suggested.¹⁵ Defective growth of endodermal cells and impaired embryonic foregut development of the trachea and esophagus¹⁶ lead to atresia.¹⁶

◆Clinical Manifestations.

Antenatal diagnosis of EA/TEF increases with the findings of polyhydramnios (excessive amniotic fluid) on ultrasound.¹⁷ Swallowed amniotic fluid is usually absorbed into the placental circulation; therefore if the fetus cannot swallow, amniotic fluid accumulates in the uterus. EA will be diagnosed at birth on the basis of drooling, inability to swallow secretions or choking with feeding, respiratory distress, and inability to pass an orogastric tube. Confirmation is established by a radiopaque catheter, which determines the location of the atresia on x-ray. If a fistula connects the trachea with the distal esophagus, the abdomen fills with air and becomes distended, possibly interfering with breathing (see [Fig. 43.2, C to E](#)). Intermittent cyanosis may result.

Pulmonary complications are compounded by reflux of air and gastric secretions into the tracheobronchial tree through the fistula, causing severe chemical irritation. Infants with esophageal atresia but no fistulae have scaphoid (boat-shaped), gasless abdomens. In infants with fistulae but without atresia (see [Fig. 43.2, E](#)), the usual symptoms are recurrent aspiration, pneumonia, and atelectasis that remains unexpressed for days or even months. Late complications of esophageal atresia or tracheal esophageal fistula include stricture,

reflux, dysphagia, chronic cough, and dyspnea on exertion.¹⁸

◆Evaluation and Treatment.

Infants presenting with esophageal atresia are evaluated with ultrasound, echocardiogram, and vertebral and limb radiographs. Following diagnosis, a tube should be placed into the upper pouch and continuous suction should be applied to decrease the risk of aspiration. The head of the bed should be elevated slightly to assist drainage of the upper pouch. The infant should not be fed orally. Surgical repair is completed in the majority of cases and may be done in stages.¹⁹ The overall survival rate for infants with esophageal defects is 95%.²⁰

Infantile Hypertrophic Pyloric Stenosis

Infantile hypertrophic pyloric stenosis (IHPS) is the most common cause of intestinal obstruction in infancy. It is an acquired narrowing and distal obstruction of the pylorus and a common cause of postprandial vomiting. Its presentation most commonly occurs in the first few weeks or months of life.²¹ The incidence of pyloric stenosis is approximately 2 to 5 in 1000 live births for males and 1 in 1000 live births for females.²²

The causes of IHPS are multifactorial and may include environmental and hereditary factors. Potential etiologic factors include deficiency of nitric oxide synthase containing neurons, abnormal innervation of the myenteric plexus, the presence of infantile hypergastrinemia, and exposure to macrolide antibiotics. Whites are affected more often than blacks or Asians, and full-term infants are affected more often than premature infants. The cause is unknown but increased gastrin secretion by the mother in the last trimester of pregnancy raises the likelihood of pyloric stenosis in the infant. The overproduction of gastric secretions in the infant may be caused by stress-related factors in the mother. Exogenous administration of prostaglandin E is associated with an increased incidence of pyloric stenosis. There is an increased incidence of pyloric stenosis in those children who have a family member with pyloric

stenosis, suggesting a genetic predisposition.²³

◆Pathophysiology.

Individual muscle fibers thicken, particularly the circular and longitudinal muscular layers of the pylorus, so the entire pyloric sphincter becomes enlarged and inflexible.²³ The mucosal lining of the pyloric opening is folded and the lumen is narrowed by the encroaching muscle. Because of the extra peristaltic effort necessary to force the gastric contents through the narrow pylorus, the muscle layers of the stomach may become hypertrophied as well.

◆Clinical Manifestations.

Between 2 and 3 weeks after birth, an infant who has fed well and gained weight begins forceful, nonbilious vomiting immediately after feeding.^{24,25} The infant then demands to be refed. Constipation occurs because little food reaches the intestine.

In severe untreated cases, increased gastric peristalsis and vomiting lead to severe fluid and electrolyte imbalances (hypokalemic, hypochloremic metabolic alkalosis), malnutrition, and weight loss that can be fatal within 4 to 6 weeks. Infants with pyloric stenosis are irritable because of hunger, and they may have esophageal discomfort caused by repeated vomiting and esophagitis. The vomitus may be blood streaked because of rupture of gastric and esophageal vessels.

◆Evaluation and Treatment.

Diagnosis is based on the history and clinical manifestations, such as nonbilious vomiting or regurgitation, which often is described as projectile, after which the infant is still hungry. The force and timing of the vomiting can help distinguish IHPS from gastroesophageal reflux, for which episodes of vomiting are not forceful and occur 10 minutes or more after feeding. The hypertrophied pylorus is palpable as a firm, small, movable mass, approximately the size of an olive, and is felt in the right upper quadrant in 70% to 90% of infants with pyloric stenosis. A visible gastric peristaltic wave after eating is observed in some infants. Ultrasound will show the hypertrophied

pyloric muscles and narrowed pyloric channel.

The standard treatment for hypertrophic pyloric stenosis is corrective surgery, specifically a laparoscopic pyloromyotomy, in which the muscles of the pylorus are split and separated. Preoperative and postoperative medical management to correct fluid and electrolyte imbalance has been the key to the high success rate and low complication rates associated with this surgery.²⁶ Children usually can tolerate feeding several hours after surgery.²⁶

Obstructions of the Duodenum, Jejunum, and Ileum

High intestinal obstruction should be considered whenever persistent vomiting occurs. With duodenal obstruction there will be upper abdominal distention, visible peristaltic waves, a decrease in the size and frequency of meconium stools, progressive weight loss, persistent vomiting, and dehydration. Congenital obstruction of the duodenum can be caused by intrinsic malformations, such as atresia (complete blockage), stenosis (partial obstruction or narrowing), or external pressure by a choledochal cyst or annular pancreas, and occurs in 2.5 to 10 per 100,000 live births.²⁷ Duodenal atresia is the third most common atresia of the gastrointestinal tract and is the failure of canalization during embryonic development because of an ischemic event or genetic factors. Duodenal obstruction may be partial or complete and is usually located at or near the major duodenal papilla. The classic “double bubble” sign is seen on imaging of the abdomen and represents duodenal obstruction. The larger, proximal “bubble” is air in a dilated stomach. The more distal, smaller “bubble” is air in a dilated proximal duodenum. There is usually little or no air in the bowel distal to the obstruction. Double bubble also may be seen on prenatal ultrasounds. An annular pancreas—a defect in which the head of the pancreas surrounds part of the duodenum—can obstruct the duodenum. Congenital obstructions of the jejunum and ileum can be attributable to atresia, stenosis, meconium ileus, megacolon (Hirschsprung disease), intussusception, Meckel diverticulum,

intestinal duplication, or strangulated hernia. In ileal or jejunal atresia, the intestine ends blindly, proximal and distal to an interruption in its continuity, with or without a gap in the mesentery. Stenosis (narrowing of the lumen) causes dilation proximal to the obstruction and luminal collapse distal to it.

Intestinal Malrotation

Intestinal malrotation is the most common congenital anomaly of the small intestine. It has an estimated incidence of about 0.5%. Associated abnormalities are common and include duodenal, jejunal, or biliary atresia; pancreatic malformations; and heart defects.²⁸

◆Pathophysiology.

In malrotation, the small intestine lacks a normal posterior fixation because it has only a rudimentary attachment near the origin of the superior mesenteric artery (Fig. 43.3). When rotation does not occur, the colon remains in the upper right quadrant where an abnormal membrane or band called a **periduodenal band (Ladd band)** may press on and obstruct the duodenum (Fig. 43.3, D). The mobile loops of intestine can twist upon themselves (volvulus) from the duodenojejunal junction to the middle of the transverse colon. The twisting can partly or completely occlude the superior mesenteric artery, causing infarction and necrosis of the entire midgut.

FIGURE 43.3 Variations of Intestinal Malrotation. A, Nonrotation. B, Incomplete rotation. C, Midgut volvulus with duodenal obstruction and obstruction of superior mesenteric artery blood flow. D, Incomplete rotation with Ladd bands extending from the lateral and posterior abdominal wall to the subhepatic cecum. *LB*, Ladd band; *SMA*, superior mesenteric artery. (From Gilbert-Barness E et al: *Potter's pathology of the fetus, infant and child*, ed 2, Philadelphia, 2007, Mosby.)

◆Clinical Manifestations.

Most cases of malrotation-associated volvulus and infarction develop during the neonatal period (90% of cases involve children younger than 1 year). Some develop during childhood or even adulthood.²⁹ Classic symptoms in infants are intermittent or persistent bile-stained vomiting after feeding and epigastric distention as the stomach and duodenum are dilated. Dehydration and electrolyte imbalance may occur rapidly with vomiting. Fever usually ensues with pain and

scanty stools. Diarrhea and bloody stools are associated with progressive volvulus, vascular compression, and infarction of the intestine. Intermittent or partial volvulus may be seen in older children and adults. It may be asymptomatic or cause minor abdominal discomfort and be discovered during unrelated abdominal surgery.³⁰

◆Evaluation and Treatment.

Diagnosis of malrotation with volvulus and infarction is based on clinical manifestations, upper gastrointestinal contrast imaging, and explorative laparoscopy. Treatment includes laparoscopic or open Ladd procedure to reduce the volvulus.³¹ Necrotic bowel is resected and a primary anastomosis performed. An enterostomy may be created. Most children have a good outcome; however, there is risk for adhesion-related bowel obstruction in about 15% of cases and its long-term sequelae.³²

Meckel Diverticulum

Diverticula are small outpouches, or sacs, that have formed and pushed outward through weak spots of the intestinal wall. **Meckel diverticulum** is a true diverticulum in that it contains all layers of the intestinal wall and is a remnant of the embryonic yolk sac. It is the most prevalent congenital abnormality of the small bowel and is usually located in the distal ileum. Ectopic gastric mucosal cells are contained in the diverticuli and may cause peptic ulcer and painless bleeding or mimic colonic diverticulitis. Often referred to as *the rules of 2s*, a Meckel diverticulum occurs in approximately 2% of the general population, is typically located within 2 feet of the ileocecal valve (on the antimesenteric border of the ileum), is an average 2 inches in length, and its clinical symptomatology often occurs before 2 years of age. Meckel diverticulum develops when there is failure to obliterate the omphalomesenteric duct, which normally leaves a fibrous band that connects the small intestine to the umbilicus during the first months of fetal development. Ectopic gastric mucosal cells are contained in the diverticuli and may cause peptic ulcer. Although

most Meckel diverticuli are asymptomatic, the most common symptom is painless rectal bleeding. Intestinal obstruction, intussusception, and volvulus occur more commonly in adults. Diagnosis is made by symptom presentation and imaging studies. Radionucleotide scintigraphy shows the gastric mucosal cells in the diverticuli. Treatment in those with symptoms is surgical resection.³³

Hirschsprung Disease

Hirschsprung disease, congenital aganglionic megacolon, is a functional obstruction of the colon. It is the most common cause of colon obstruction, accounting for about one-third of all gastrointestinal obstructions in infants. The incidence is approximately 1 in 5000 live births with an increased incidence in males, siblings of children with Hirschsprung disease, and children with Down syndrome or other congenital malformations.³⁴ Familial occurrence is 5% to 20%. The exact cause is unknown but multiple interacting factors, including gene mutations and epigenetic mechanisms, have been described.³⁵

◆Pathophysiology.

Hirschsprung disease is a congenital malformation resulting from failure of neural crest cells to migrate into the gastrointestinal (GI) tract. There is an absence of parasympathetic nervous system intrinsic ganglion cells in the submucosal and myenteric plexuses (Meissner and Auerbach plexuses) along variable lengths of the colon, and there may be skipped segments. Lacking neural stimulation, the muscle layers of the colon wall fail to propel feces through the colon, leading to functional obstruction. In 80% of cases the aganglionic segment is limited to the rectosigmoid region (short-segment Hirschsprung disease); in about 5% of cases the entire colon lacks ganglion cells and the ileum may be involved. The abnormally innervated colon impairs fecal movements, causing the proximal colon to become distended, hence the term *megacolon* (Fig. 43.4). In rare cases the entire bowel can be involved, known as *total intestinal Hirschsprung disease*.

FIGURE 43.4 Congenital Aganglionic Megacolon (Hirschsprung Disease).

◆Clinical Manifestations.

The infant typically becomes symptomatic during the first 24 to 72 hours after birth with delayed passage of meconium. Mild to severe constipation is the usual manifestation of Hirschsprung disease with poor feeding, poor weight gain, and progressive abdominal distention. However, diarrhea may be the first sign because only water can travel around the impacted feces. With “ultrashort-segment” Hirschsprung disease, mild constipation is generally the only symptom. These children may not be diagnosed until adulthood.

The most serious complication in the neonatal period is Hirschsprung-associated enterocolitis (HAEC) and it can occur both preoperatively and postoperatively. The intestinal inflammation is related to fecal impaction, alterations in intestinal microbiota, impaired mucosal barrier function, and innate immunity with bacterial translocation.^{36,37} Bowel dilation stretches and partly occludes the encircling blood and lymphatic vessels, causing edema, ischemia, infarction of the mucosa, and significant outflow of fluid into the bowel lumen. Copious liquid stools result. Infarction and destruction

of the mucosa enable enteric microorganisms to penetrate the bowel wall. Frequently, gram-negative sepsis occurs, accompanied by fever and vomiting. Severe and rapid fluid and electrolyte changes may take place, causing hypovolemic or septic shock or death.

◆Evaluation and Treatment.

Radiocontrast enema and anorectal manometry are screening tools for the diagnosis of Hirschsprung disease. The definitive diagnosis is made by rectal biopsy showing an absence of ganglion cells in the submucosa of the colon. Surgery is the definitive treatment in all cases of Hirschsprung disease with resection of the aganglionic segment and anastomosis of the proximal bowel to the anus, known as a “pull-through” procedure. Laparoscopic or open approaches may be used.³⁸ In general, the prognosis of Hirschsprung disease is satisfactory for children who undergo surgical treatment. Bowel training may be prolonged; however, most children achieve bowel continence before puberty whereas others have long-term constipation or fecal incontinence.^{39,40}

Idiopathic Intestinal Pseudo-Obstruction

Idiopathic intestinal pseudo-obstruction is a rare condition characterized by repetitive episodes or continuous symptoms of intestinal obstruction without an obstructing lesion and can occur at any age. Alterations or atrophy of enteric nerves and/or muscles, or of the interstitial cells of Cajal, prevents normal contractions of the intestines and prevents the movement of food, fluid, and air through the intestines. It may have an acute or chronic onset and can be a cause of intestinal failure.⁴¹

Distal Intestinal Obstruction Syndrome

Distal intestinal obstruction syndrome (DIOS), formerly called *meconium ileus equivalent*, is the partial or complete obstruction of the colon of the terminal ileum by abnormally viscous intestinal contents, particularly after episodes of dehydration or lack of pancreatic

enzymes. It is characterized by complete or incomplete intestinal obstruction of viscous fecal accumulation in the terminal ileum and proximal colon and affects approximately 7.4% of children and adults with cystic fibrosis.⁴²

Anorectal Malformations

Anorectal malformations (ARMs) represent a spectrum of rare anomalies of the anus and rectum, including anorectal stenosis, imperforate anus, anorectal atresia, and rectal atresia (Fig. 43.5). Persistent cloaca is the most severe type of anorectal malformation and occurs primarily in girls. The rectum, urethra, and vagina fail to develop separately; instead, they drain through a single, common channel onto the perineum.⁴³ Approximately 40% of infants with anorectal malformations have other developmental anomalies (i.e., Down syndrome, Hirschsprung disease and duodenal atresia, neurogenic bladder, and spinal malformations).^{44,45} ARMs occur in approximately 1 in 2500 to 1 in 5000 newborns.⁴⁶ The cause is unknown but may be associated with altered expression of the sonic hedgehog (*SHH*) gene, which is involved in anorectal development.⁴⁷

FIGURE 43.5 Anorectal Stenosis and Imperforate Anus.

Most ARMs are identified in routine physical examination during the neonatal period. Ultrasound and magnetic resonance imaging (MRI) can assist prenatal diagnosis. Types of **imperforate anus** include the following: the anal opening may be narrow or misplaced; a membrane (covering) may be present over the anal opening; the rectum may not connect to the anus; the rectum may connect to part of the urinary tract or to the reproductive system through an opening called a *fistula*; or the anal opening may not be present. Treatment recommendations depend on the type of imperforate anus, the presence and type of associated abnormalities, and the child's overall health status. Anal stenosis can be treated by dilation. Infants with an imperforate anus and other anorectal malformations require surgical correction. Children with lower lesions and those with an intact sacrum and normal sacral vertebrae and spinal cord have better functional outcomes.⁴⁸

Meconium Syndromes

Meconium is a substance that fills the entire intestine before birth. It is a dark greenish, odorless mass of desquamated cells, mucus, free fatty acids, pancreatic phospholipases, and bile that accumulates in the bowel of a fetus and is typically discharged during the first 12 to 48 hours after birth. **Meconium plug syndrome**, also termed *functional immaturity of the colon*, is a benign cause of bowel obstruction and a transient disorder of the newborn colon. It is more common in premature infants and characterized by delayed passage of meconium during the first 24 to 48 hours after birth with dilation of the intestine. Meconium plug syndrome is a diagnosis of exclusion. Contrast enema usually excludes congenital small bowel obstruction and rare colon abnormalities, such as atresia or duplication. The main differential consideration is Hirschsprung disease, which is eventually diagnosed in approximately 10% to 30% of children with apparent meconium plug syndrome.⁴⁹

Meconium aspiration syndrome occurs following intestinal peristalsis, meconium release, and contamination of amniotic fluid associated with fetal hypoxia. Gasping respirations cause aspiration of the contaminated amniotic fluid deep into the fetal lung. Infants present with respiratory distress with expiratory airway obstruction, air trapping, surfactant inactivation, atelectasis, and chemical pneumonitis. Meconium aspiration also predisposes to infection and the development of persistent pulmonary hypertension of the newborn with shunting through the patent ductus arteriosus and foramen ovale.⁵⁰ The presence of meconium-stained amniotic fluid and the clinical presentation help confirm the diagnosis. Treatment includes surfactant administration (by bolus or lavage), oxygen, inhaled nitric oxide, and ventilator support.⁵¹

Meconium ileus (MI) is intestinal obstruction in the neonatal period caused by meconium formed in utero that is abnormally sticky. There are two forms of MI: simple and complex. In simple MI, thickened meconium accumulates and obstructs the ileum causing proximal dilatation, bowel wall thickening, and congestion. Complex MI is associated with bowel atresia, volvulus, necrosis, or perforation and is a surgical emergency. MI occurs in up to 20% of infants with

cystic fibrosis, and is thought to result from abnormal mucus production in the intestine or impaired pancreatic enzymes, or both.⁵² In the cases *not* associated with cystic fibrosis, genes other than *CFTR* mutations have been identified.⁵³ The cause usually is unknown.

The terminal ileum in MI is plugged with thick, viscous meconium resulting from the formation of an insoluble, calcium-glycoprotein compound in abnormal mucus. The segment of the ileum proximal to the obstruction is distended with liquid contents, and its walls may be hypertrophied. The segment distal to the obstruction is collapsed and filled with small pellets of pale-colored stool. Meconium in the obstructed segment has the consistency of thick syrup or glue. Peristalsis fails to propel this viscous material through the ileum, so it becomes impacted. Volvulus, atresia, or perforation of the bowel occurs in complicated MI.

Abdominal distention usually develops during the first few days after birth. The infant does not pass meconium and begins to vomit within hours or days of birth. Infants with cystic fibrosis may have signs of pulmonary involvement, such as tachypnea, intercostal retractions, and grunting respirations. The distended abdomen shows patterns of dilated intestinal loops that feel doughlike when palpated. Some of the loops contain scattered, firm, movable masses. Despite hyperactive peristalsis, the rectal ampulla is empty.

All women of reproductive age should be offered preconception and prenatal cystic fibrosis (CF) carrier screening (see [Chapter 37](#)). Prenatal diagnosis of MI can be made by ultrasound or MRI.⁵⁴ The treatment of choice for cases not complicated by volvulus or perforation is a hyperosmolar enema (e.g., meglumine diatrizoate [Gastrografin]) performed under fluoroscopy. A warm saline enema containing 4% *N*-acetylcysteine may be given to help complete the evacuation. Surgical management includes tube enterostomy (a percutaneous drain), open enterostomy, or resection to remove the meconium mass. Survival of infants with meconium ileus is improving, with survival rates approaching 100%.⁵² Mortality increases if the obstruction is complicated by peritonitis.

Acquired Impairment of Motility

Gastroesophageal Reflux Disease

Gastroesophageal reflux (GER) is the passage of gastric contents into the esophagus independent of swallowing. GER is normal and nonpathologic in healthy infants and may be asymptomatic or exhibited by regurgitation and vomiting because of relaxation or incompetence of the lower esophageal sphincter. In newborns, gastroesophageal reflux or regurgitation is normal (physiologic reflux) because neuromuscular control of the gastroesophageal sphincter is not fully developed. The frequency of reflux is highest in premature infants and decreases during the first 6 to 12 months of life. Children usually outgrow their reflux. **Gastroesophageal reflux disease (GERD)** is different from GER and occurs when it is the cause of troublesome symptoms or complications, or both, described as esophageal or extraesophageal in nature. Children at greatest risk for complicated GERD are those with prematurity, neurologic impairment, esophageal atresia, obesity, hiatal hernia, achalasia, chronic lung diseases, and certain genetic disorders, including cystic fibrosis.

◆Pathophysiology.

GERD is influenced by genetic, environmental, anatomic, hormonal, and neurogenic factors. Although transient lower esophageal sphincter relaxations (TLESRs) are the most common pathophysiologic cause of GER, inadequate adaptation of sphincter tone to changes in abdominal pressure also may be implicated. Factors that maintain lower esophageal sphincter integrity in children include the location of the gastroesophageal junction in a high-pressure zone within the abdomen, mucosal gathering within the sphincter, and the angle at which the esophagus is inserted into the stomach. Reflux persists if any one of these pressure-maintaining factors is altered. Other mediators of GER are esophageal peristalsis or clearance, mucosal resistance that mediates the noxiousness of the refluxate, and delayed gastric emptying. Reflux of acidic gastric contents results in

inflammation of the esophageal epithelium (esophagitis) and stimulation of the vomiting reflex.

Eosinophilic esophagitis is differentiated from GERD (see [Chapter 42](#)) and can occur in children. It is thought to be an allergic esophageal disease involving reactions to food antigens. A mast cell, eosinophil, and T lymphocyte infiltrate are associated with inflammation of the entire esophagus that is nonresponsive to acid-suppression therapy. Eosinophilic inflammation may lead to *progressive subepithelial fibrosis* with esophageal strictures, narrowing, and dysphagia.⁵⁵ Dysphagia, food impaction, and vomiting are common symptoms and other atopic diseases, such as asthma and eczema, may be present. Treatment includes elimination of aggravating foods and administration of oral corticosteroids.⁵⁶

◆Clinical Manifestations.

The clinical manifestations of GERD include excessive regurgitation or vomiting; food refusal/anorexia; unexplained crying, choking, or gagging; sleep disturbance; dysphagia; and abdominal or epigastric pain, or both.⁵⁷ Esophageal complications of GER can be significant, such as esophagitis, hemorrhage, stricture, Barrett esophagus (metaplasia; see [Chapter 42](#)) and, rarely, adenocarcinoma. Extraesophageal symptoms include cough and wheezing, laryngitis, pharyngitis, dental erosions, sinusitis, recurrent otitis media, and Sandifer syndrome (a neurologic disorder).⁵⁸ This constellation of symptoms is often indistinguishable from those of cow's milk protein allergy, which may coexist with or overlap GERD.

◆Evaluation and Treatment.

The clinical manifestations are often adequate to confirm a diagnosis of GERD. However, irritability, crying, feeding refusal, and regurgitation can be common problems in infants and not specific to GERD. Esophageal pH monitoring with or without impedance using a 24-hour pH probe and endoscopy with biopsy are used for diagnosis when there are unusual symptoms or treatment failure. Mild GER resolves without treatment usually within 12 months. Techniques for

managing infant reflux include small, frequent feedings; prolonged feeding duration and slower flow rate; frequent burping and position changes; and thickened feedings.^{59,60} Lifestyle changes for children and adolescents include weight loss, smoking cessation, sleeping position changes, and avoidance of caffeine, chocolate, alcohol, and spicy foods.

Medications are used to treat erosive esophagitis, including gastric acid suppression therapy with proton pump inhibitors (e.g., esomeprazole) and prokinetic agents (e.g., bethanechol).⁶¹ Routine use of medications requires caution because of adverse side effects.⁶² If no improvement is seen with medical management or if the child has life-threatening events with reflux, an antireflux surgical procedure, including gastropexy and fundoplication, is performed. A fundoplication re-creates a valve by wrapping the fundus of the stomach around the lower esophagus and can be completed using laparoscopic techniques.⁶³

Intussusception

Intussusception is the telescoping of a proximal segment of intestine into a distal segment, causing an obstruction. It is the most common cause of small bowel obstruction in children with rates of hospitalization at about 4.0 to 5.5 per 10,000 children yearly in the United States.⁶⁴ Most cases occur between 5 and 7 months of age with seasonal peaks between fall and winter. Intussusception is more common in males and can be idiopathic, can be associated with lead points (polyps or tumors, Meckel diverticulum, intestinal adhesions) or cystic fibrosis, or can develop immediately after abdominal surgery. The health benefits of rotavirus vaccination far exceed the risk of intussusception.⁶⁴

◆Pathophysiology.

In intussusception, the ileum commonly telescopes into the cecum and part of the ascending colon by collapsing through the ileocecal valve (ileocolic intussusception), although it can occur anywhere from the duodenum to the rectum. The proximal portion of the intestine (the

intussusceptum) collapses into the distal portion (intussusciens) in the direction of peristaltic flow (Fig. 43.6). The intussusceptum then drags its mesentery into the enveloping lumen, causing an intussusception. Initially, the mesentery is constricted, obstructing venous return. Compression of the mesenteric vessels between the two layers of intestinal wall and at the U-shaped angle at either end of the intussusceptum leads within hours to venous stasis, engorgement, edema, exudation, and further vascular compression. The tension of the mesentery on the intussusceptum tends to arch the bowel in a curve with its center at the mesenteric root. Edema and compression obstruct the flow of chyme through the intestine. Unless the intussusception is treated, bleeding, necrosis, and bowel perforation ensue.

FIGURE 43.6 Ileocolic Intussusception.

◆Clinical Manifestations.

The classic symptoms of intussusception include colicky abdominal pain, irritability, knees drawn to the chest, abdominal mass, vomiting, and bloody (currant-jelly) stools. A single normal stool may be passed, evacuating the colon distal to the apex of the intussusception. All of these symptoms may not occur and intussusception has been discovered incidentally by computed tomography (CT) or magnetic resonance imaging (MRI) scan for other indications.

◆Evaluation and Treatment.

Diagnosis is based on clinical manifestations and onset of symptoms. Ultrasound of the abdomen and radiographic imaging studies are commonly completed for diagnosis.⁶⁵ For large bowel intussusception, an enema reduction is usually effective and avoids the progression to ischemia and perforation. Surgical reduction is done on children who fail or, in rare cases, have perforation.⁶⁶ Untreated intussusception in infants is nearly always fatal. Most infants recover if the intussusception is reduced within 24 hours. Spontaneous reduction of intussusception may occur in symptomatic or asymptomatic children.⁶⁷

Appendicitis

Appendicitis is common in children between the ages of 10 and 11 years.⁶⁸ The mechanisms of disease, symptoms, and treatment are similar to those for adults and can be reviewed in [Chapter 42](#).

Impairment of Digestion, Absorption, and Nutrition

Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive disease of the exocrine glands that involves multiple organ systems but primarily the gastrointestinal and respiratory systems. Prognosis is mainly determined by the degree of pulmonary involvement, with death

caused by a combination of respiratory failure and cor pulmonale. This section focuses on gastrointestinal complications of CF ([Chapter 37](#) discusses epidemiology and pulmonary involvement).

◆Pathophysiology.

The gastrointestinal presentation of CF is caused by a dysfunction of the CF transmembrane regulator (CFTR) protein, which is located on epithelial membranes and regulates chloride and sodium ion channels. It is found throughout the airways, sweat glands, digestive tract, pancreas, hepatobiliary system, and reproductive system (also called *mucoviscidosis* or *fibrocystic disease of the pancreas*). The hallmark pathophysiologic triad of CF includes obstruction, infection, and inflammation that are evident throughout the gastrointestinal tract and within the airways. The full spectrum of involvement is summarized in [Table 43.1](#).

TABLE 43.1

PATHOPHYSIOLOGY, CLINICAL MANIFESTATIONS, AND COMPLICATIONS OF CYSTIC FIBROSIS

ORGAN INVOLVED	SECRETORY DYSFUNCTION	CLINICAL MANIFESTATIONS	COMPLICATIONS
Sweat glands	Elevated concentrations of sodium and chloride in sweat	Hyponatremia; hypochloremia	Heat prostration; shock
Esophagus	None	Gastroesophageal reflux	Risk for aspiration events
Intestine			
Newborn	Viscid meconium	Meconium ileus with intestinal obstruction	Meconium peritonitis
Older child and adult	Inspissated (dried out) mucofecal masses (intestinal sludging)	Partial intestinal obstruction with severe cramping pains	Gastroesophageal reflux Volvulus (obstruction), intussusception (prolapse) Distal intestinal obstruction syndrome
Pancreas	Inspissation and precipitation	Absence of pancreatic	Hypoproteinemia; iron

(enzyme deficiency)	of pancreatic secretions, causing obstruction of pancreatic ducts	enzymes, causing malabsorption of food; fatty, bulky stools	deficiency anemia; malnutrition Recurrent pancreatitis, pancreatic cysts
		Decreased vitamins A, D, E, and K absorption Growth failure	Vitamins A, D, E, and K deficiency and rectal prolapse Decreased bone density and risk of fractures in adolescents and adults
	Insulin deficiency	Glucose intolerance	Diabetes mellitus
Liver	Inspissation and precipitation of bile in biliary system	Focal biliary cirrhosis; shrunken, "hobnail" liver	Portal hypertension with esophageal varices, hematemesis and hypersplenism Hepatic steatosis Focal biliary cirrhosis Steatorrhea from lack of bile salts
Salivary glands	Inspissation and precipitation of secretions in small ducts of submaxillary and sublingual salivary glands	Mild patchy fibrosis of salivary glands	None
Paranasal structures	Viscid mucus	Retention of mucus; clouding seen on sinus roentgenograms	Mucopyoceles (pus accumulations) with nasal deformity or orbital cavity extension
Nose	Nasal polyps	Obstruction of nasal airflow	None
Lungs	Viscid mucus in bronchioles and bronchi	Obstruction of bronchioles causing bronchiolectasis, bronchiectasis, and chronic lung infection	Hemoptysis; pneumothorax; cor pulmonale; atelectasis; chronic bacterial infection; respiratory failure
Reproductive tract			
Male	Viscid genital tract secretions during embryologic development, causing failure of formation of	Delayed puberty Sterility	None

	normal vas deferens		
Female	Distention of endocervical epithelial cells with cytoplasmic mucin	Delayed puberty Decreased fertility	Polypoid cervicitis (cervical inflammation) while taking oral contraceptives

Data from Assis DN, Freedman SD: *Clin Chest Med* 37(1):109–118, 2016; Lavelle LP et al: *Radiographics* 35(3):680–695, 2015; Leeuwen L, Fitzgerald DA, Gaskin KJ: *Paediatr Respir Rev* 15(1):69–74, 2014; Marcdante KJ, Kliegman RM, editors: *Nelson essentials of pediatrics*, ed 7, Philadelphia, 2014, Saunders; Stalvey MS, Clines GA: *Curr Opin Endocrinol Diabetes Obes* 20(6):547–552, 2013.

Dysfunction of the CFTR protein results in altered sodium, chloride, and potassium resorption, all of which remain external to the surface of the epithelial membrane with reduced clearance from tubular structures lined by affected epithelia. Maldigestion of proteins, carbohydrates, fats, and fat-soluble vitamins occurs because mucus obstruction of the pancreatic ducts blocks the flow of pancreatic enzymes, causing intestinal malabsorption and degenerative and fibrotic changes in the pancreas and gastrointestinal tract. Diabetes mellitus commonly develops as CFTR protein mutation results in dysregulation of beta-cell insulin secretion.⁶⁹

◆Clinical Manifestations.

Clinical manifestations are presented in [Table 43.1](#). Gastrointestinal symptoms often precede pulmonary manifestations. Approximately 85% of those with CF present early in life with pancreatic insufficiency (PI). PI is the cause of nutrient malabsorption and failure to thrive (FTT) in children with CF. Steatorrhea and abdominal distention are common symptoms with potential sequelae that include distal intestinal obstruction syndrome (DIOS) (see [the Obstructions of the Duodenum, Jejunum, and Ileum section](#)), fibrotic colonopathy, intussusception, and focal biliary cirrhosis. Children who are pancreatic sufficient (PS) are at greater risk of developing pancreatitis in addition to many other gastrointestinal complications, including gastrointestinal cancers and hepatobiliary abnormalities, which may lead to pancreatic transplant or death.^{70,71}

◆ Evaluation and Treatment.

All states in the United States screen newborns for cystic fibrosis using a blood test to detect immunoreactive trypsinogen. Genetic screening and the sweat test are required for diagnosis. To determine the extent of pancreatic function, 72-hour fecal fat measurements are used, which are not easily obtained. Therefore the most common measurement of fat malabsorption is the level of fecal elastase. A serum test for trypsinogen level also can be used to detect pancreatic insufficiency in children older than 8 years of age.

The goal of treatment for PI is to reduce malabsorption of nutrients and improve growth. Most children with CF take pancreatic enzyme replacement therapy (PERT) for the rest of their lives. PERT is administered before or with every meal, snack, or enteral feeding supplementation. High doses of PERT are associated with DIOS; therefore minimal effective doses are indicated. High-caloric, high-protein diets with frequent snacks and vitamin supplements are used to treat malnutrition. Enteral supplements are used as needed.⁷² Nutritional status and growth should be carefully monitored, and growth hormone may be included with nutritional supplements.⁷³

Celiac Disease (CD)

Celiac disease (CD also known as *celiac sprue* or *gluten-sensitive enteropathy*), is an autoimmune disease that damages the small intestinal villous epithelium when there is ingestion of gluten (gliadin), which is commonly found in the wheat, rye, barley, and oats of cereal grains. CD is a multiorgan disease with a strong genetic predisposition associated with human leukocyte antigen DQ2 (HLA-DQ2) and HLA-DQ8. The disease has a prevalence of about 1% worldwide although evidence suggests only 10% to 15% of the population have been diagnosed and treated.⁷⁴ **Nonceliac gluten sensitivity (GS)** should not be confused with CD. Although it presents similarly after the ingestion of gluten. The individual does not have positive autoantibodies or classic intestinal villous atrophy but instead has variable HLA status with similar symptoms as CD. The cause is unknown and there is not a biologic marker for the

disease.⁷⁵ IgE-mediated wheat allergy is a gluten-related disorder with gastrointestinal manifestation in younger children (vomiting and/or diarrhea) and dermatitis and wheezing in older children.⁷⁶

The pathogenesis of CD is complex and involves genetic and both cellular and humoral immunologic factors. Environmental factors include early infections, gut microbiota in infants, feeding patterns, and timing and amount of gluten. CD presents with greater frequency in children with type 1 diabetes mellitus, autoimmune thyroid or liver disease, Down syndrome, Turner syndrome, Williams syndrome, selective immunoglobulin A (IgA) deficiency, Addison disease, and first-degree relatives with CD. Individuals with CD are also at greater risk for non-Hodgkin's lymphoma and rarely, small intestinal adenocarcinoma.⁷⁷

◆Pathophysiology.

The major pathophysiologic characteristic is an HLA-DQ2- or HLA-DQ8-induced CD4+ T-cell-mediated autoimmune injury to the small intestinal epithelial cells of genetically susceptible individuals. There are increased numbers of intraepithelial lymphocytes, atrophy and flattening of villi, crypt hyperplasia in the upper small intestine, and malabsorption of most nutrients in the presence of cereal gluten, particularly wheat, rye, and barley (Figs. 43.7 and 43.8). The levels of transglutaminase 2 IgA (TG2) and endomysial IgA autoantibodies closely correlate with the acute phase of the disease in the presence of gluten.⁷⁸ The atrophy is caused by accelerated shedding of epithelial cells from the villi. To compensate for this loss, epithelial cell production increases, causing hypertrophy of the crypts of Lieberkühn. Increased cell production is not sufficient to keep pace with cell loss, and the cells are not mature enough to sustain absorptive functions. The microvilli and brush border disappear, leaving patches of bald mucosa. The loss of mucosal surface area and brush-border enzymes leads to severe malabsorption. The pathologic process is most pronounced in the duodenum and jejunum. The ileum may be spared. The severity of disease correlates with the length of the small intestinal mucosa involved.⁷⁹

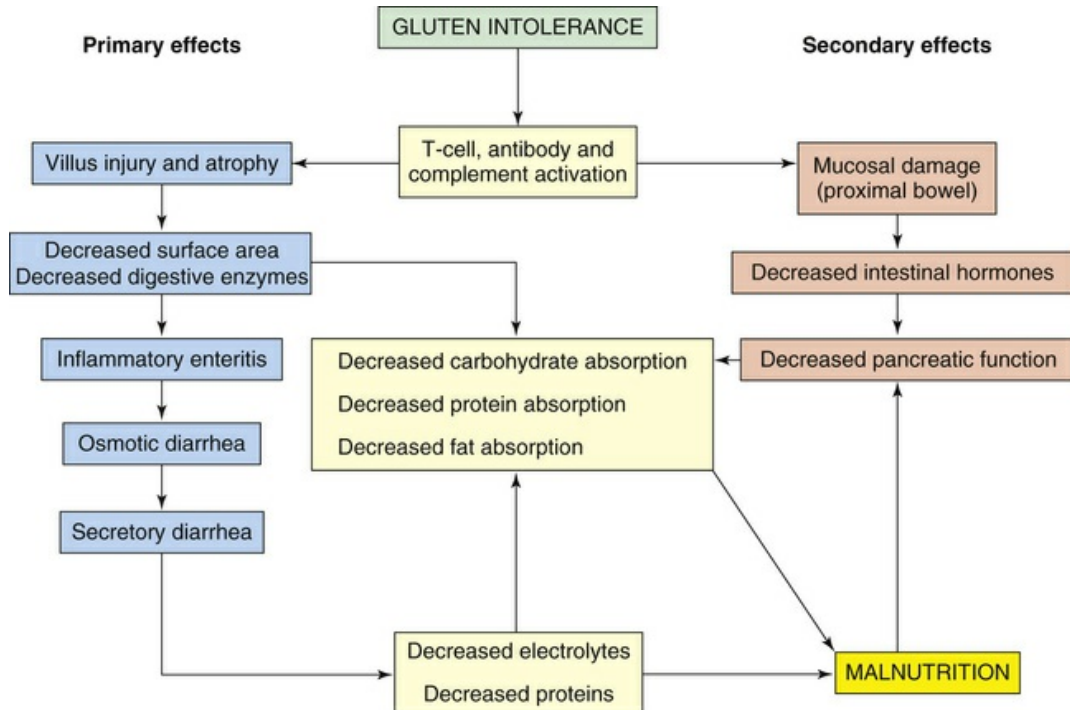

FIGURE 43.7 Pathophysiology of Gluten-Sensitive Enteropathy.

FIGURE 43.8 Gluten-Sensitive Enteropathy. A, Atrophy of villi and elongation of crypts that result in reduced surface area, loss of digestive enzymes, and malabsorption (arrows). B, Recovery of normal villous structure after 6 months of gluten-free diet. (From Damjanov I, Linder J:

Damage to the mucosa of the duodenum and jejunum exacerbates malabsorption. The secretion of intestinal hormones, such as secretin and cholecystokinin, may be diminished. Consequently, secretion of pancreatic enzymes and expulsion of bile from the gallbladder are reduced, contributing to malabsorption. Destruction of mucosal cells causes inflammation, and water and electrolytes are secreted, leading to watery diarrhea. Potassium loss leads to muscle weakness. Magnesium and calcium malabsorption can cause seizures or tetany. Unabsorbed fatty acids combine with calcium, and secondary hyperparathyroidism increases phosphorus excretion, resulting in bone reabsorption. Calcium is no longer available to bind oxalate in the intestine and is absorbed, which causes hyperoxaluria. Gallbladder function may be abnormal, and bile salt conjugation may decrease.

Fat malabsorption in the jejunum is the major cause of steatorrhea (fatty stools). Deficiencies of fat-soluble vitamins are common in children with CD. Vitamin K malabsorption leads to hypoprothrombinemia. In one-third of cases, iron and folic acid malabsorption is manifested as cheilosis; anemia; and a smooth, red tongue. Vitamin B₁₂ absorption is impaired in those with extensive ileal disease. Because the absorption of folate and iron is greatest in the proximal small intestine, deficiencies of these substances are common.

◆Clinical Manifestations.

The onset of clinical manifestations of CD depends on the age of the infant when gluten-containing substances are added to the diet. In 50% of affected children, onset occurs by 18 months of age; it is not uncommon to be diagnosed later in life. Severity of symptoms can vary tremendously, and children older than 3 years of age can present with mild to severe gastrointestinal symptoms or no symptoms.

Abdominal pain, abdominal distention, and diarrhea are early signs in most infants accompanied by failure to thrive and anemia. The stools are pale, bulky, greasy, and foul smelling, and may contain oil

droplets. Three to five such movements occur daily. As early as 3 or 4 months of age, growth failure, anorexia, and constipation can begin. Some children present with constipation. Vomiting and abdominal pain are prominent in infants but unusual in older children. Anorexia is prevalent. The classic physical manifestations of organic failure to thrive, such as abdominal protuberance, wasted buttocks and limbs, and hypotonia, occur in less than 50% of infants with gluten-sensitive enteropathy. Growth is usually diminished.

Extraintestinal manifestations of malabsorption, such as rickets, tetany, frank or occult bleeding, or anemia, may be obvious. Some children urinate more at night. The tongue is smooth and red, and the child may bruise and bleed easily. Hypomagnesemia and hypocalcemia cause irritability, tremor, convulsions, tetany, bone pain, osteomalacia, and dental abnormalities. If vitamin D deficiency is prolonged, rickets and clubbing of the terminal phalanges are likely. **Dermatitis herpetiformis** is a cutaneous manifestation of itchy blister formation that presents with a symmetrical distribution on the extensor surfaces of the elbows (90%), knees (30%), shoulders, midline of the back, or buttocks. The sacral region, scalp, nuchal area, face, and groin also may be involved. Eighty-six percent of older children have fingerprint changes (ridge atrophy). In older children, delayed puberty and infertility may be a manifestation of otherwise subtle gluten-sensitive enteropathy. There is an increased incidence of malignant disease, particularly T-cell lymphoma, in individuals who have refractory celiac disease (failure to heal after 6 to 12 months of a strict gluten-free diet).⁸⁰

◆Evaluation and Treatment.

Diagnosis includes confirmation of clinical findings with serologic measurements of antiendomysial and antitransglutaminase IgA antibodies and HLA-DQ2 or HLA-DQ8 (human leukocyte antigen class II haplotypes that regulate immunity). Duodenal biopsy detects the classic mucosal changes caused by gluten-sensitive enteropathy and confirms the diagnosis. The initial biopsy may be followed by a second intestinal biopsy to demonstrate regeneration of intestinal villi

after treatment with a gluten-free diet. Later age diagnosis is associated with younger age gluten avoidance. Many children with celiac disease remain undiagnosed.^{81,82}

Treatment consists of lifelong adherence to a gluten-free diet (GFD), which includes elimination of wheat, rye, barley, and malt. Lactose (milk sugar) intolerance may be present because of damage to the villi; therefore lactose is excluded from the diet but should be resumed after treatment. Infants are routinely given fat-soluble vitamins, iron, and folic acid supplements to treat deficiencies. Breast-feeding at the time of gluten introduction in the diet delays the appearance of celiac disease. Most children have complete remission of symptoms with clearing of serologic markers and an excellent prognosis. Refractory CD is resistant to treatment with a gluten-free diet and is rare. Steroids or immunosuppressants may be required for treatment.⁸⁰

Malnutrition

Pediatric malnutrition is an imbalance between nutrient requirements and intake that results in energy, protein, and micronutrient deficits that negatively impact growth and development. Malnutrition also involves impaired absorption and altered nutrient utilization. Kwashiorkor and marasmus (all forms of inadequate nutrient intake) are the two most common types of malnutrition in children. Collectively, they are known as **protein-energy malnutrition (PEM)**. PEM describes the effects of malnutrition but not the etiology or interactions that contribute to nutrient depletion.

Both Kwashiorkor and marasmus are states of severe long-term starvation and are the result of widespread nutritional deficiencies among children in developing countries and economically destitute populations, particularly when associated with human immunodeficiency virus (HIV) infection.⁸³ **Kwashiorkor** refers to edematous malnutrition and usually occurs in infants or children from 1 to 4 years of age who have been weaned from breast milk to a high-starch, protein-deficient diet. The death rate of kwashiorkor is higher than that for marasmus.

Marasmus can occur at any age but it is common in children

younger than 1 year. In marasmus, starvation is attributable to lack of protein and carbohydrates, and in neglected children it can have a psychogenic basis. In developing countries and impoverished populations, early weaning of breast-fed infants to overdiluted commercial formulas is a risk factor for marasmus.

Although PEM is common in developing countries, it is underestimated in hospitalized children. A new paradigm used to define pediatric malnutrition includes the concepts of etiology (illness or environmental), identification of pathogenesis and chronicity, associations with inflammation, and resulting impact on functional outcomes.⁸⁴

PEM is a known complication of chronic diseases, such as chronic fever; infectious diseases like tuberculosis; malignancy; digestive and malabsorption disorders; cardiac, pulmonary, renal, and neurologic diseases; burns or hypermetabolic states; anorexia and bulimia; and psychogenic illness. Treatments, such as radiation therapy and chemotherapy, also can contribute to malnutrition. PEM contributes to hospital-acquired conditions (HACs), longer time on mechanical ventilation, increased hospital length of stay, and increased morbidity and mortality.⁸⁵

◆Pathophysiology.

The pathogenesis of kwashiorkor is uncertain but includes inadequate dietary protein, leaky gut syndrome (compromised gut barrier), and intestinal inflammation. The lack of sufficient plasma proteins results in generalized edema with a substantial loss of potassium. The liver swells with stored fat because no hepatic proteins are synthesized to form and release lipoproteins. Pancreatic atrophy and fibrosis may be present. Kwashiorkor also causes malabsorption, reduced bone density, and impaired renal function. If the condition is not reversed, the prognosis is very poor.

The metabolic response in marasmus is different, allowing sustained protein and lipid supply during periods of decreased dietary intake. Metabolic processes, including liver function, are preserved, but growth is severely retarded. Caloric intake is too low to

support protein synthesis for growth or the storage of fat. Muscle and fat wasting occur, and anemia is common and can be severe.

Recent studies are now implicating alterations in gut microbiota in the pathophysiology of malnutrition.⁸⁶ Children with malnutrition show stunting of gut microbiota maturation, which may delay normal development of the gut, depress intestinal immune function, and promote inflammation and infection. Healthy gut bacteria also produce short-chain fatty acids, B vitamins, and vitamin K, and promote the absorption of minerals important for maintaining intestinal epithelium.⁸⁷

◆Clinical Manifestations.

Children with kwashiorkor have marked generalized edema, dermatoses, hypopigmented hair, distended abdomen, hepatomegaly, and almost normal weight for age (because of edema). Children with marasmus demonstrate greater wasting of protein and fat stores yet have improved survival. Marasmus is characterized by muscle wasting, fatty liver and hepatomegaly, diarrhea, dermatosis, low hemoglobin level, and infection. There is loss of subcutaneous fat and an absence of edema. Both conditions lead to delays in physical, behavioral, and cognitive development and academic performance. Lastly, micronutrient deficiencies, especially with zinc, selenium, iron, and antioxidant vitamins, can lead to immune deficiency and infections. Severe vitamin A deficiency commonly results in blindness.⁸⁸

◆Evaluation and Treatment.

Evaluation of PEM is based on nutritional history and clinical manifestations, including anthropometric measurements. Laboratory monitoring is used to assess for macro- and micronutrient deficiencies, aminotransaminase alterations, and refeeding response. The provision of deficient nutrients will resolve clinical symptoms in 4 to 6 weeks. Use of antibiotics has been shown to improve recovery of PEM and decrease mortality.⁸⁹ Developmental sequelae of PEM may be irreversible; therefore early intervention is recommended.

Nutritional rehabilitation with appropriate environmental stimulation for infants and young children resolves or improves cerebral shrinkage, physical growth, and psychomotor development. Advances are being made in the preparation of ready-to-use therapeutic food for both home- and community-based malnutrition management.⁹⁰ Breast-feeding needs to be encouraged and some infants and children require intensive inpatient treatment.⁹¹ High morbidity and mortality occur in some regions of the world.

Failure to Thrive or Growth Faltering

Failure to thrive (FTT), or **growth faltering**, is a physical sign demonstrating that a child is receiving inadequate nutrition for optimal growth and development. It is manifested as a deceleration in weight gain, a low weight/height ratio, a low weight/height/head circumference ratio, or a low body mass index (BMI). FTT is a common problem and can present at any time in childhood. Approximately 80% of children present with FTT before 18 months of age.⁹²

◆Pathophysiology.

Currently, there is a move away from describing FTT as organic versus nonorganic; instead, it is considered a multifactorial condition that includes biologic, psychosocial, and environmental contributions that are illness related or nonillness related (Box 43.1). An underlying medical condition is never found in more than 80% of cases of FTT. Categories of FTT include inadequate caloric intake, inadequate caloric absorption, or excessive caloric expenditure. Infants and children are at risk for FTT if their parents or primary caregivers are unable to provide nurturance.

Box 43.1

Factors Associated With Failure to Thrive or Growth Faltering

Poverty: food insecurity related to lack of money
Premature birth; low birth weight
Inadequate caloric intake or caloric absorption: infant feeding problems, underlying chronic disease, chronic infection, or malabsorption syndromes
Incorrect preparation of formula (too diluted, too concentrated)
Mechanical feeding difficulties (oromotor dysfunction, congenital anomalies, central nervous system disorders)
Unsuitable feeding habits (food fads, excessive juice)
Behavior problems affecting eating
Disturbed parent-child relationship; parental stress, parental lack of knowledge; child neglect

Data from Krishna A et al: *Glob Health Action* 8:26523, 2015; Kyle UG et al: *Nutr Clin Pract* 30(2):227–238, 2015; Mehta NM et al: *JPEN J Parenter Enteral Nutr* 37(4):460–481, 2013.

◆Clinical Manifestations.

Clinical manifestations of FTT are delayed growth accompanied by manifestations of malnutrition or an underlying disease (e.g., diarrhea or infectious disease, or both). Symptoms include delayed growth; pallid or dry, cracked skin and sparse hair; poorly developed musculature; decreased subcutaneous fat; swollen abdomen with malabsorption, diarrhea, or anorexia; and signs of vitamin deficiencies, such as rickets. Social or emotional manifestations include reduced energy level, reduced responsiveness and interaction with the environment, social isolation, spasticity or rigidity when held or touched, inability to make eye contact or smile, refusal to eat, and rejection of foods.⁹³

◆Evaluation and Treatment.

FTT is suggested if a child falls below the third percentile on the growth curve or shows stagnation in length or weight measurements. Underlying medical conditions are evaluated. If illness is ruled out, a thorough review of psychosocial, emotional, and environmental

components of care is necessary. Screening tools are available to assist with evaluation of nutrition status and to guide therapy, particularly in hospitalized children.⁹⁴

Treatment of FTT includes treating an underlying illness if found, increasing volume or caloric density of formula, increasing frequency of breast-feeding (if found to be insufficient), structuring meals and snacks, and adding high-calorie foods and additives. Eliminating fruit juice, soda, or excessive milk also will improve appetite and absorption of nutrients. Medications are used to stimulate appetite. Nutrient deficiencies are supplemented. If unable to gain weight, an oral enteral supplement may be added to the diet or a nasogastric or gastrostomy tube can be used to supplement oral intake.

If the cause is not medical, management then involves the immediate total care of the child and measures to address (1) the psychosocial and emotional problems of the caregivers and (2) parent-child interactions. Counseling, parental modeling, and long-term family support are sometimes required.⁹⁵ Hospital admission and evaluation is recommended if the diagnosis is unclear or the child is in nutritional or emotional jeopardy. Eating patterns, food preferences, caloric intake, and family interactions can be assessed and treatment plans implemented during the hospital stay.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is an acquired disease associated with an ischemic, inflammatory condition that causes bowel necrosis and perforation, and infant death if untreated. NEC is not a specific diagnosis but a constellation of signs and symptoms with several proposed etiologies. It is the most common severe neonatal gastrointestinal emergency that predominantly affects the smallest and most premature infants. Approximately 11% of infants born weighing less than 1500 g will develop NEC; of those, about 30% will not survive.⁹⁶ Isolated or focal intestinal perforation is sometimes confused with NEC and generally is not accompanied by an inflammatory component or by diffuse necrosis.⁹⁷ The risk of NEC decreases as the gastrointestinal tract matures.

◆Pathophysiology.

The exact etiology of NEC is unclear. Factors contributing to the development of NEC include infections, abnormal bacterial colonization, intestinal ischemia, immature immune responses, increases in proinflammatory mediators, immature intestinal motility, altered microcirculatory blood flow and barrier function, perinatal stress, effects of medications and formula feeding, and genetic predisposition.⁹⁷ The immature mucosal barrier delays digestion and motility is slower, allowing for the accumulation of noxious substances that damage the intestine, increase permeability, and increase risk for infection. Translocation of intestinal bacteria and other substances contributes to injury, inflammation, development of systemic inflammatory disease, and multiple organ failure and death. Immature intestinal innate immunity and an unfavorable balance between normal and pathogenic bacteria promote intestinal inflammation and release of proinflammatory mediators.⁹⁸ Accumulation of gas in the intestine can cause pressure that decreases blood flow, and an imbalance between vasodilator and vasoconstrictor inputs in the immature gut may lead to vasoconstriction, promoting ischemia and oxidative stress, reperfusion injury, necrosis, and perforation. Injury to Paneth cells located in the intestinal crypts has also been proposed.⁹⁹ The terminal ileum and proximal colon are most often involved.^{100,101}

◆Clinical Manifestations.

Manifestations of NEC appear suddenly and usually within weeks of premature birth and sooner for term neonates. Signs and symptoms of “classic” NEC include feeding intolerance, abdominal distention and bloody stools after 8 to 10 days of age, septicemia with elevated white blood cell count, and falling platelet levels. Unstable temperature, bradycardia, and apnea are nonspecific signs. In late preterm infants, NEC is more likely to be associated with other predisposing factors, such as low Apgar scores, chorioamnionitis, exchange transfusions, prolonged rupture of membranes, congenital heart defects, and neural tube defects.

◆ Evaluation and Treatment.

Diagnosis is based on clinical manifestations, laboratory results, and plain films of the abdomen. Symptoms usually progress rapidly, often within hours, from subtle signs to abdominal discoloration, intestinal perforation, and peritonitis or even death. Abdominal radiographs show pneumoperitoneum, pneumatosis intestinalis (gas in the bowel wall), or unchanging “rigid” loops of small bowel. Systemic hypotension requires intensive medical support or bowel resection, or both. Efforts are in progress to identify predictive biologic markers for early diagnosis including urinary intestinal fatty acid-binding protein; a marker for intestinal cell wall integrity damage; and fecal calprotectin, a marker for intestinal inflammation.¹⁰²

Preventive strategies include awareness of risk factors, encouragement of breast milk feeding, preferential feeding of human milk, judicious fluid management to prevent vascular fluid overload, and confirmation of patent ductus arteriosus (see [Chapter 34](#)). Additional treatments include avoidance of H₂-receptor antagonists, administration of amino acids (i.e., arginine and glutamine supplements) to support intestinal epithelial cell growth, and utilization of enteral probiotics to support normal gut bacteria.^{103,104} The rapid onset of symptoms makes primary prevention difficult.

Treatments include cessation of feeding, implementation of gastric suction to decompress the intestines, maintenance of fluid and electrolyte balance, and administration of antibiotics to control sepsis. Surgical resection is the treatment of choice for perforation, and peritoneal drainage may be used as an adjunct to laparotomy. Overall mortality is high, particularly for infants who have surgery.⁹⁶

Diarrhea

Diarrhea is an increase in the water content, volume, or frequency of stools and can be acute or chronic. Diarrhea is usually defined as three or more watery or loose stools in 24 hours.¹⁰⁵ Children with acute gastroenteritis often remain mildly symptomatic for up to 4 weeks; therefore diarrhea that persists longer than 4 weeks is considered chronic. Diarrhea is a common gastrointestinal problem during

infancy and early childhood, and infectious diarrhea is the leading cause of death in young children, particularly among preterm infants and in developing countries.¹⁰⁶ Severe, acute infectious diarrhea occurs one to three times during the first 3 years of life. Most episodes are self-limiting and resolve within 72 hours.

The pathophysiologic mechanisms of diarrhea in children are similar to those described for adults: osmotic, secretory, intestinal dysmotility, or inflammatory (see [Chapter 42](#)). Prolonged diarrhea is more dangerous in infants and children because they have much smaller fluid reserves and more rapid peristalsis and metabolism than adults. Therefore dehydration can develop rapidly if any disturbance increases fluid secretion into the gastrointestinal lumen (secretory diarrhea), draws fluid into the lumen by osmosis (osmotic diarrhea), reduces intestinal transit time with luminal fluid retention (intestinal dysmotility), or causes inflammation that results in malabsorption and increased luminal osmotic load from nutrients, fluid, and blood, which may increase gut motility (inflammatory diarrhea).¹⁰⁷

Diarrhea in Infants and Children

There are numerous causes of **diarrhea** in infants and young children, including viral, bacterial, and systemic infections; malabsorption syndromes; autoimmune disorders; congenital malformations; and genetic disorders. Acute infection is a common cause of childhood diarrhea worldwide.¹⁰⁶

Acute infectious diarrhea in infants and young children is usually associated with acute viral or bacterial gastroenteritis, and contaminated food or water is often the source of infection. Viral causes of diarrhea include rotaviruses, noroviruses, and adenoviruses. Rotavirus is the most common cause in young children and is associated with a higher death rate in low-income countries. Rotavirus invades enterocytes of the intestinal mucosa and releases an enterotoxin that damages these cells. Damage decreases viable absorptive surface area, causing an imbalance of secretion and absorption, and increases motility, resulting in diarrhea and dehydration. Recovery from mucosal damage may take several weeks.

Rotavirus is transmitted by the fecal-oral route among humans.

Numerous bacteria or parasites can contaminate food or water and cause diarrhea. Specific bacteria can be identified using molecular analysis or stool culture. Bacterial causes of diarrhea have geographical variation and include *Cryptosporidium*, *Shigella* spp., and heat-stable toxin-producing enterotoxigenic *Escherichia coli* (ST-EPEC), *Vibrio cholerae*, *Campylobacter jejuni*, adenovirus 40/41, and *Aeromonas* spp.¹⁰⁸ *Clostridium difficile* is often associated with previous antibiotic therapy.

Infectious diarrhea has a rapid onset, with watery stools sometimes mixed with blood, abdominal cramping, fever, vomiting, and weight loss. Severe dehydration, acidosis, and shock can occur quickly from diarrhea and vomiting. Hemolytic uremic syndrome and renal failure can develop when diarrhea is associated with *Shigella* toxin and *Escherichia coli* infection (see [Chapter 40](#)). Other causes of acute diarrhea in the older child include antibiotic therapy, appendicitis, chemotherapy, inflammatory bowel disease, parasitic infestation, parenteral infections, and ingestion of toxic substances.

Treatment of diarrhea requires evaluation of cause by taking the individual's history, testing the stool for common pathogens, and performing laboratory analysis. Treatment of underlying illness is warranted when identified. Other treatments include hydration, electrolyte replacement, nutrition maintenance, and antibiotics if a pathogen is found. Antispasmodics may relieve abdominal cramping, and probiotics can reduce duration and improve morbidity and mortality.¹⁰⁹ Intravenous solutions are used only when oral solutions are not tolerated. Prevention includes clean water, environmental sanitation, and good hygiene. Licensed vaccines are available for rotavirus, cholera, and typhoid fever^{110,111} (see [What's New? Pediatric Inflammatory Bowel Disease](#)).

What's New?

Pediatric Inflammatory Bowel Disease

Pediatric inflammatory bowel disease (IBD) includes Crohn disease (CD), ulcerative colitis (UC), and IBD unspecified (see [Chapter 42](#)). The incidence in children is 10 per 100,000 children in the United States and Canada, and appears to be rising across the world with approximately 25% of children diagnosed before the age of 20. It is often diagnosed in late childhood or during adolescence, although 4% present before 4 years and 18% before age 10 years. Risk factors that predispose IBD include Western lifestyle, cesarean delivery, lack of exposure to breast milk, high dietary fat intake, and early exposure to antibiotics. The etiology of IBD is unknown, but there are host genetic, epigenetic, microbial, and environmental factors that together result in a dysregulated mucosal immune response to commensal intestinal microbiota. Children with IBD are more likely to have a family member with the disease. UC is described as diffuse, continuous inflammation of the colon that extends upward from the rectum proximally and can involve the entire colon (pancolitis), and may or may not have extension into the ileum, known as *backwash ileitis*. Male children more commonly develop CD. The disease is more extensive and progressive than in adults, commonly involving both the ileum and the colon but can be located anywhere from the mouth to the anus. Growth failure, anemia, perianal disease, and other extraintestinal symptoms, such as mouth ulcers, uveitis, fevers, arthritis, and vascularities such erythema nodosum or pyoderma gangrenosum, are associated with CD. Because of the transmural nature of the inflammation in CD, complications can include fistulae, intraabdominal abscesses, and strictures. Hospitalization and surgery are more common in CD, with 14% of children requiring intraabdominal surgery within 5 years of diagnosis. Evaluation may include laboratory monitoring, such as inflammatory markers, stool cultures, endoscopy, colonoscopy, videocapsule endoscopy, magnetic resonance enterography (MRE), and computer tomography (CT) scan. Fecal calprotectin (FC) level is elevated in IBD and can be used as a marker for IBD identification and response to treatment in children. Treatment for childhood IBD is currently the same as that for adults

except treatments are FDA approved for adults only; new treatment approaches are being investigated including fecal transplants. Enteral nutrition therapy is a novel use of nutrition therapy in CD and has been found to be equally effective in producing a remission as corticosteroids and improves growth and development. Many children with IBD have nutritional deficiencies, which include iron, vitamin D, and calcium attributable to the disease and side effects of medications used for treatment. Supplementation of nutrients is required. The risk of cancer and death is low in children with IBD.

Data from Conrad MA, Rosh JR: *Pediatr Clin North Am* 64(3):577-591, 2017; D'Arcangelo G, Alois M: *Paediatr Drugs* 19(2):113-120, 2017; Oliveira SB, Monteiro IM: *BMJ* 357;j2083, 2017; Wang AY, Popov J, Pai N: *World J Gastroenterol* 22(47):10304-10315, 2016.

Primary Lactose Intolerance.

Lactose intolerance (lactose malabsorption) is the inability to digest lactose (milk sugar) and is caused by inadequate production or impaired activity of the enzyme lactase. It is a common cause of diarrhea in children, particularly nonwhite children younger than 7 years of age. The congenital form is a rare autosomal recessive disorder that manifests at birth. The malabsorption of lactose results in osmotic diarrhea accompanied by abdominal pain, bloating, and flatulence. Fluids move by osmosis from the vascular compartment into the intestinal lumen. The undigested sugar is processed by the colonic bacteria, and intestinal gas and short-chain fatty acids are produced.¹¹² Systemic manifestations include skin disease, rheumatologic complaints, chronic fatigue, and failure to thrive.

Diagnosis can be made by eliminating dietary lactose or by performing hydrogen lactose breath testing or an oral lactose tolerance test.¹¹³ Treatment consists of reducing milk consumption or supplementing the diet with oral lactase. Some children can tolerate lactose in fermented forms, such as cheese and yogurt, or by adding soy food. Utilization of a diet low in fermentable oligo-, di-, and monosaccharides and polyols (FODMAPs) or administration of probiotics to alter intestinal flora has been found to be effective in

children with lactose-intolerant irritable bowel syndrome who have persistent symptoms. Other sources of dietary calcium or supplements need to be provided if dairy products are eliminated.

Disorders of the Liver

Disorders of Biliary Metabolism and Transport

Neonatal Jaundice

Jaundice (icterus) is a yellow pigmentation of the skin caused by an increased level of bilirubin in the bloodstream (i.e., total serum bilirubin [TSB] level that exceeds the 95th percentile for the infant's age in hours or is greater than 20 mg/dL, except in the low birth weight population). Jaundice usually becomes clinically apparent when the serum bilirubin concentration is greater than 2 mg/dL (34 μ mol/L). **Physiologic jaundice (hyperbilirubinemia) of the newborn** is usually a transient, benign icterus that occurs during the first week of life in otherwise healthy full-term infants. It is caused by mild unconjugated (indirect-reacting) hyperbilirubinemia. **Pathologic jaundice** appears within 24 hours after birth with total serum bilirubin level greater than 20 mg/dL or an indirect bilirubin level greater than 15 mg/dL. Risk factors include fetal-maternal blood type incompatibility (ABO and Rh incompatibility), prematurity, exclusive breast-feeding, maternal age greater than or equal to 25 years, an infant of male gender, delayed meconium passage, and excessive birth trauma such as bruising or cephalohematomas.¹¹⁴ Prediction tools for hyperbilirubinemia are available to reduce risk associated with early hospital discharge (within 48 hours) when hyperbilirubinemia may not yet be evident.

◆Pathophysiology.

Pathologic jaundice results from the complex interaction of factors that cause (1) increased bilirubin production (e.g., hemolysis), (2) impaired hepatic uptake or excretion of unconjugated bilirubin, and (3) delayed maturation of liver conjugating mechanisms. The most

common cause is hemolytic disease of the newborn, also known as *erythroblastosis fetalis*¹¹⁵ (ABO blood incompatibility; see [Chapters 9](#) and [31](#)), and all pregnant women should be tested for ABO and Rh incompatibility. Unconjugated bilirubin (indirect bilirubin) is lipid soluble and bound to albumin in the blood, and in the free form readily crosses the blood-brain barrier in infants. Bilirubin encephalopathy (**kernicterus**) is caused by the deposition of toxic, unconjugated bilirubin in brain cells and usually does not occur in healthy full-term infants. An elevated level of conjugated bilirubin is a sign of underlying disease (e.g., neonatal cholestasis). A late, acute rising indirect bilirubin level also may be a manifestation of **glucose-6-phosphate dehydrogenase** (an enzyme important in red blood cell metabolism) **deficiency**, a hereditary X-linked genetic defect.¹¹⁵

◆Clinical Manifestations.

Physiologic jaundice develops during the second or third day after birth and usually subsides in 1 to 2 weeks in full-term infants and in 2 to 4 weeks in premature infants. After this, increasing bilirubin values and persistent jaundice indicate pathologic hyperbilirubinemia. Manifestations include yellowing skin, dark urine, light-colored stools, and weight loss. Premature infants with respiratory distress, acidosis, or sepsis are at greater risk for kernicterus and the development of bilirubin-induced neurologic dysfunction (BIND) (e.g., neuromotor signs, hyperexcitable neonatal reflexes, and speech and hearing impairment).¹¹⁶

◆Evaluation and Treatment.

Jaundice is detected by clinical assessment. Both total and direct (conjugated) bilirubin levels are monitored, and the bilirubin/albumin ratio is being evaluated as a corollary to unbound serum bilirubin level for predicting neurotoxicity, particularly in premature infants.¹¹⁷ Transcutaneous bilirubin monitoring is readily available.¹¹⁸ Pathologic jaundice should be suspected with serum bilirubin values that increase greater than 5 mg/dL per day, persistent jaundice (more than 7 to 10 days in the full-term infant), or conjugated bilirubin values

greater than 2 mg/dL. Other causes of jaundice must be eliminated to confirm physiologic jaundice.

Treatment depends on the degree of hyperbilirubinemia. Physiologic jaundice is usually treated by phototherapy (ultraviolet light) with good eye protection; several techniques are available. Phototherapy produces isomers of bilirubin that are water soluble, can be more rapidly excreted in the stools and urine, and do not cross the blood-brain barrier. Pathologic jaundice requires high-intensity phototherapy, exchange transfusion, and treatment of the underlying cause.¹¹⁹ Treatment with tin-mesoporphyrin (a heme oxygenase inhibitor) is useful in severe hyperbilirubinemia.¹²⁰

Biliary Atresia

Biliary atresia (BA) is a rare congenital malformation characterized by the absence or obstruction of extrahepatic bile ducts, resulting in neonatal cholestasis. The etiology of duct injury is not clear but is thought to be related to either an embryonic (or congenital) abnormality or an acquired anomaly (e.g., perinatal viral-induced progressive inflammation with innate autoimmune destruction in genetically susceptible individuals). There is phenotypic variation in the timing of disease onset (embryonic or perinatal—80% of cases) and the association with other anomalies. The disease expression is a continuum in which the principal process is one of bile duct destruction. The atresia of the bile ducts is associated with inflammation, fibrosis, loss of epithelial cells, and obstruction of the bile canaliculi. Progressive obstruction leads to cholestasis and secondary biliary cirrhosis (see [Chapter 42](#)), portal hypertension, and liver failure, which can develop within a few weeks after birth. Liver failure can lead to death within 2 years without surgical intervention.¹²¹

Jaundice is the primary clinical manifestation of BA along with hepatomegaly and acholic (clay-colored) stools. Fat absorption is impaired because of the lack of bile salts. Abdominal distention caused by hepatomegaly and ascites may cause anorexia and FFT. Fat-soluble vitamin (A, D, E, K) deficiencies require supplementation.

Manifestations of cirrhosis and liver failure include ascites, hypoalbuminemia, hypercoagulation, pruritus, esophageal varices, and gastrointestinal bleeding that may lead to death.

Early diagnosis of BA is essential with the best outcome occurring when diagnosed and treated in the first 30 to 45 days of life. Late diagnosis of BA does not respond well to current surgical treatment. Diagnosis of BA is based on clinical manifestations, abnormal liver function tests, liver biopsy results, and intraoperative cholangiogram. Serum aminotransaminase and alkaline phosphatase levels are elevated and conjugated (direct) serum bilirubin levels increase progressively. Surgical intervention removes the atretic biliary remnants and creates a Roux-en-Y intestinal conduit for bile drainage, also known as the *Kasai hepatportoenterostomy* (Fig. 43.9). Even with initial restoration of bile flow, however, obliteration of intrahepatic bile ducts can continue and cirrhosis results. Liver transplantation is performed for 80% of children with BA and is the only long-term therapeutic option.¹²²

FIGURE 43.9 Kasai Procedure. Surgical correction for extrahepatic biliary atresia. The jejunal segment between the liver and the bowel may be externalized, creating a double-barrel portoenterostomy.

Inflammatory Disorders

Hepatitis

Details related to viral hepatitis are presented in [Chapter 42](#), including differentiation of types of viruses (see [Table 42.7](#)).

Hepatitis A.

Approximately one-third to one-half of the reported cases of **hepatitis A virus (HAV)** occur in children, particularly children of nursery school age.¹²³ Outbreaks tend to occur in daycare centers with large numbers of children who are not toilet trained and with staff members who practice poor handwashing techniques. Vertical transmission

from mother to newborn or from a transfusion is rare. HAV replicates in the liver and is excreted through the biliary system into the stool. HAV in young children is usually mild and asymptomatic but may include nausea, vomiting, and diarrhea. Older children have jaundice and elevated serum aminotransferase levels. Almost all children recover from hepatitis A without residual liver damage. Relapse HAV occurs in 3% to 20% of individuals. Vaccination programs for children 1 year and older have successfully reduced the incidence of HAV in the United States by 95%.¹²⁴

Hepatitis B.

Risk factors for **hepatitis B virus (HBV)** include infants of mothers who are chronic **hepatitis B surface antigen (HBsAg)** carriers, children from families that immigrated to the United States or are adopted from endemic areas, children who have been infected by HBsAg-positive household contacts, and children who abuse parenteral drugs or engage in unprotected sex. Ninety percent of newborns are infected by their mothers (vertical transmission); 25% to 50% of children between the ages of 1 and 5 years who are acutely infected will develop chronic infection, and 25% will develop cirrhosis or hepatocellular carcinoma.¹²⁵ Chronic hepatitis may develop more often in young children because of their immature immune systems. The most serious consequence of HBV infection is fulminant hepatitis, which occurs in 1% of cases. **Hepatitis D virus (HDV)** infection depends on active infection with HBV. Exacerbation of HBV is more common in children with superinfected HDV. There is evidence that the risk of fulminant hepatitis is higher in individuals with combined infections of HBV, HDV, hepatitis C virus (HCV), or human immunodeficiency virus (HIV) than in those with HBV infection alone. There also is a higher risk of hepatocellular carcinoma and increased mortality in this group. Aggressive HBV vaccination programs have reduced the incidence of HBV; HDV reduction has mirrored this response and there is decreased risk of hepatocellular carcinoma.¹²⁶ To prevent perinatal transmission of HBV, immunoprophylaxis and HBV vaccination within the first 12 hours of

birth are recommended with close follow-up visits. Treatment is conservative and antivirals are used for chronic disease. Children ages 2 to 17 years who are hepatitis B surface antigen (HBsAg) seropositive for more than 6 months with elevated serum alanine transaminase (ALT) and HBV DNA levels for more than 3 months respond to treatment with antivirals.¹²⁷ Maternal antiviral therapy during pregnancy and lactation reduces the hepatitis B virus mother-to-child transmission rate.¹²⁸

Hepatitis C.

Hepatitis C virus (HCV) in children is most commonly transmitted vertically and is enhanced with maternal coinfection with HIV. Risk factors for vertical transmission include internal fetal monitoring, prolonged rupture of membranes, and fetal anoxia. HCV transmission also can occur through exposure to infected blood or contaminated materials (as in injection drug use or tattooing and body piercing) and, less commonly, following sexual encounters with HCV-infected partners. Transmission from blood transfusions has become a negligible risk with universal HCV screening of blood. With vertical transmission, spontaneous resolution of HCV is high, up to 40%; otherwise, the disease is usually mild in children and cirrhosis is rare. Treatment is genotype specific with high sustained viral response in children treated with pegylated interferon (Peg-IFN) + ribavirin with HCV genotypes 2 or 3 and about 45% to 55% in those infected with genotypes 1 or 4. Efforts are in progress to develop affordable direct-acting antiviral treatments with fewer adverse drug-related events.¹²⁹ Maternal antiviral therapy reduces vertical transmission. There is currently no vaccination available for hepatitis C and only those children with persistently elevated serum aminotransferase levels or progressive liver disease are treated with antiviral drugs.

Chronic Hepatitis.

HBV and HCV are the main causes of chronic hepatitis in children. Manifestations of chronic hepatitis include malaise, anorexia, fever, gastrointestinal bleeding, hepatomegaly, edema, and transient joint

pain. Often there are no symptoms. Serum alanine aminotransferase and bilirubin levels are elevated. There may be evidence of impairment of synthetic functions of the liver: prolonged prothrombin time, thrombocytopenia, and hypoalbuminemia. Diagnosis is based on the clinical manifestations and liver biopsy. There is no curative therapy for chronic HBV or HCV; hence children are treated with antiviral drugs and should continue to be monitored. About 3% develop cirrhosis or hepatocellular carcinoma before adulthood.¹³⁰ Liver transplant may ultimately be required for chronic hepatitis.¹³¹

There also is an autoimmune form of chronic hepatitis, known as *autoimmune hepatitis (AIH)* or *autoimmune primary sclerosing cholangitis (PSC)*, with unknown etiology. The pathogenic mechanism is thought to be immunologic, environmental, or genetic in nature. PSC is associated with a diagnosis of inflammatory bowel disease (IBD). Advances are being made in identifying serologic markers to guide diagnosis and treatment.¹³² Elevations in the levels of aminotransferases, autoantibodies, and immunoglobulin G (IgG) are seen in both AIH and PSC. AIH is more common in female children, and both are treated with prednisone and/or immunosuppressive therapy; about 50% to 80% will achieve remission and long-term survival.¹³³

Cirrhosis

Cirrhosis is fibrotic scarring of the liver in response to inflammation and tissue damage, resulting in obstruction to the flow of blood and bile (see [Chapter 42](#)). Most forms of chronic liver diseases in children can progress to cirrhosis, but they seldom do. The complications of cirrhosis in children are the same as those in adults: portal hypertension, the opening of collateral vessels between the portal and systemic veins, and varices. In addition, children with cirrhosis experience growth failure caused by nutritional deficits and developmental delay, particularly in gross motor function because of ascites and weakness. The cause of cirrhosis may influence its severity and course. Some types of cirrhosis can be stabilized if the cause is identified and treated early. The risk of cirrhosis is increased in obese

children with nonalcoholic fatty liver disease (see [What's New? Childhood Obesity and Nonalcoholic Fatty Liver Disease](#)).

What's New?

Childhood Obesity and Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease in children and is associated with obesity, insulin resistance, genetic predisposition, ethnicity, the gut microbiome, and environmental factors (diet and lack of exercise). NAFLD is associated with dyslipidemia, hypertension, and early cardiac dysfunction in children. The rise in childhood obesity worldwide is contributing to the increasing prevalence of NAFLD. The disease usually presents in prepubertal children and is predominant in males and in children of Hispanic origin. Diagnosis is made by exclusion of other causes of the disease, usually by 12 to 13 years of age in the United States. Liver biopsy is required for definitive diagnosis of nonalcoholic steatohepatitis (NASH). Compared to adults, there are differences in the extent of fat, inflammation, and fibrosis in children and there is no standard scoring system. There is no consensus regarding treatment. Exercise and slow, consistent weight loss with a low glycemic index diet have been shown to be more effective than a low-fat diet in lowering body weight. Pharmacologic agents are being evaluated to control insulin resistance and prevent progression of liver disease and cirrhosis. Omega-3 fatty acids, probiotics, and vitamin E may delay disease progression. Research is in progress to define the pathophysiology of NAFLD, measures that can help prevent this disease, and also noninvasive diagnostic procedures.

Data from Clemente MG et al: *World J Gastroenterol* 22(36):8078-8093, 2016; Selvakumar PKC et al: *Pediatr Clin North Am* 64(3):659-675, 2017; Temple JL et al: *Int J Mol Sci* 17(6):E947, 2016.

Portal Hypertension

Portal hypertension is increased pressure in the portal venous system and a major cause of morbidity and mortality in children with liver disease. There are two basic causes of **portal hypertension** in children: (1) increased resistance to blood flow within the portal system, and (2) increased volume of portal blood flow. The second cause is rare in children and is not discussed here. Increased resistance to flow can occur anywhere in the portal circulatory system. Portal hypertension can accompany cirrhosis, intraabdominal infections, portal vein thrombosis, congenital anomalies of the portal vein, and congenital hepatic fibrosis.

Types of Portal Hypertension

Extrahepatic Portal Hypertension.

Extrahepatic (prehepatic) portal venous obstruction causes 50% to 70% of extrahepatic portal hypertension in children. No specific cause can be found in approximately two-thirds of these children. Obstruction is almost always in the portal vein and is usually caused by thrombosis as a complication of abdominal trauma, pancreatitis, abdominal infections, and some systemic disorders; however, these causes are rare. Umbilical infection with or without a history of catheterization of the umbilical vein may be a cause in neonates. It also has been associated with neonatal dehydration, inflammatory bowel disease, and hypercoagulable states, such as protein C and protein S deficiencies.¹³⁴ Life-threatening bleeding and coagulation disorders can occur. Mesoportal bypass (anastomosis of the mesenteric vein to the portal vein) restores normal physiologic portal flow to the liver and corrects portal hypertension.¹³⁵

Intrahepatic Portal Hypertension.

Liver fibrosis is the primary cause of **intrahepatic portal hypertension**. The fibrosis can lead to cirrhosis with increased resistance to portal blood flow by constricting and reducing the

compliance of hepatic sinusoids. Chronic hepatitis, biliary atresia, nonalcoholic fatty liver disease, and congenital hepatic fibrosis are causes of liver fibrosis in children.

The clinical manifestations of portal hypertension are (1) splenomegaly, (2) upper gastrointestinal tract bleeding, (3) ascites, (4) hepatopulmonary syndrome, (5) hepatorenal syndrome, and (6) hepatic encephalopathy (see [Chapter 42](#)).

The objectives of the clinical investigation are to (1) locate the site of the venous block and (2) identify the disease responsible for the portal hypertension. Thorough physical examination; laboratory evaluation of liver function, white blood count, and platelet count; ultrasonographic imaging (e.g., sonoelastography); endoscopic evaluation; and biopsy may be included in the diagnostic evaluation. Treatment in children is the same as that in adults (see [Chapter 42](#)). The outcome of portal hypertension depends almost entirely on its cause. Children with extrahepatic disease are expected to recover with little morbidity. For children with intrahepatic disease, the prognosis varies.

Metabolic Disorders

More than 5000 genetically determined metabolic pathways have been identified in liver tissue. The earliest possible identification of metabolic disorders is essential because (1) early treatment may prevent permanent damage to vital organs, such as the liver or brain; (2) precise genetic counseling may be possible with prenatal diagnosis; and (3) complications can be minimized, even if cure is not possible. Galactosemia,¹³⁶ fructosemia, and Wilson disease are rare treatable metabolic disorders that have hepatic clinical manifestations. These disorders are summarized in [Table 43.2](#); Wilson disease is summarized here.

TABLE 43.2

GALACTOSEMIA, FRUCTOSEMIA, AND WILSON DISEASE

GALACTOSEMIA	FRUCTOSEMIA	WILSON DISEASE
--------------	-------------	----------------

Mechanism of disease	<p>Deficiency of galactose and phosphate, uridyl transferase</p> <p>An autosomal recessive trait</p> <p>Cannot convert galactose to glucose</p> <p>Toxic accumulation of galactose in body tissues, liver, and brain</p>	<p>Deficiency of fructose-1-phosphate aldolase</p> <p>An autosomal recessive trait</p> <p>Cannot metabolize fructose, sucrose, or honey; occurs when breast milk is replaced with cow's milk</p> <p>Toxic accumulation of fructose in body tissues</p>	<p>Autosomal recessive: <i>ATP7B</i> gene mutation on chromosome 13</p> <p>Defect in copper excretion by liver</p> <p>Impaired transport of copper in blood caused by diminished transport protein (ceruloplasmin)</p> <p>Toxic accumulations of copper in liver, brain, kidney, corneas</p>
Clinical manifestations	<p>High levels of blood galactose</p> <p>Vomiting</p> <p>Hypoglycemia</p> <p>May have failure to thrive</p> <p>Symptoms of cirrhosis at 2 to 6 months— jaundice</p> <p>Intellectual disability if not treated</p> <p>Cataracts if not treated</p>	<p>High levels of blood fructose</p> <p>Vomiting</p> <p>Hypoglycemia</p> <p>May have failure to thrive</p> <p>Hepatomegaly</p> <p>Jaundice</p> <p>Seizures</p>	<p>Intention tremors</p> <p>Indistinct speech</p> <p>Dystonia</p> <p>Greenish yellow rings in cornea</p> <p>Hepatomegaly</p> <p>Jaundice</p> <p>Anorexia</p> <p>Renal tubular defects</p>
Evaluation	<p>Presence of reducing substances in urine when infant is receiving lactose</p>	<p>Detailed dietary history</p> <p>Liver or intestinal mucosa biopsy</p>	<p>Low plasma ceruloplasmin</p>
Treatment	<p>Galactose-free diet</p>	<p>Fructose-, sucrose-, honey-free diet</p> <p>Vitamin C supplementation</p>	<p>Chelation therapy to remove copper from body</p> <p>Decreased dietary intake of copper</p> <p>Liver transplant</p>

Wilson Disease

Wilson disease (hepatolenticular degeneration) is an autosomal

recessive defect of copper metabolism related to loss of *ATP7B* gene expression that causes toxic amounts of copper to accumulate in the liver, brain, kidneys, and corneas. *ATP7B* is localized on chromosome 13 and encodes copper-transporting P-type adenosinetriphosphatase (ATPase) membrane-spanning protein. It is highly expressed in the liver, kidney, and placenta and is expressed in lower levels in the brain, heart, muscle, and pancreas. This defect in the uptake and excretion of copper by hepatocytes is an important cause of progressive liver disease in children and young adults. Wilson disease is very rare, with an incidence of 1 in 30,000 to 1 in 100,000 live births worldwide. About 1 in 90 persons are carriers.¹³⁷

◆Pathophysiology.

Two major abnormalities in copper metabolism have been identified: (1) diminished biliary excretion of copper and (2) failure to insert copper into ceruloplasmin (a glycoprotein that transports copper in the blood). A positive copper balance is present from birth in children with Wilson disease, despite increased excretion of copper in the urine. Copper toxicity with accumulation in the liver and brain is the major abnormality. Excesses of copper generate free radicals that disrupt cellular organelles, deoxyribonucleic acid (DNA), microtubules, enzymes, and proteins. Copper overload is related to impaired biliary excretion of copper and may be related to failure of hepatocyte lysosomes to eliminate copper by exocytosis.¹³⁸

Early in the disease, intestinal absorption of copper is normal, as is hepatic clearance of albumin-bound absorbed copper. As copper-binding proteins in the liver become saturated, hepatic uptake of copper diminishes, with elevated serum copper levels and biochemical and clinical evidence of liver damage caused by copper accumulation. In later stages of the disease, copper accumulates in extrahepatic tissues, including the eyes, brain, and kidneys.

When cerebral copper-binding proteins become saturated, a characteristic pattern of brain damage develops, particularly in the basal ganglia. Neural effects include intention tremor, unsteady gait, dystonia, and behavioral changes. Manifestations of renal tubular

injury usually appear simultaneously. The uptake of copper by red blood cells is thought to cause hemolytic anemia, a condition sometimes seen early in the clinical course of Wilson disease.

◆Clinical Manifestations.

The clinical manifestations of Wilson disease may begin as young as 4 years of age, when control mechanisms responsible for copper homeostasis and biliary excretion should have matured. The classic clinical presentation of Wilson disease is a triad of neuromuscular abnormalities, intention tremors, dysarthria (indistinct speech), and dystonia (disordered muscular tonicity): (1) Kayser-Fleischer rings (accumulation of copper in the limbus of the cornea, causing a greenish yellow ring), (2) cirrhosis associated with elevated serum copper levels, and (3) low ceruloplasmin levels.¹³⁹ Initial symptoms vary from malaise and abdominal pain to jaundice. Changes in mental and motor performance may develop at age 6 years or into adult life. The earliest signs of liver involvement include enlargement of the liver and spleen, jaundice, and anorexia. Edema and ascites may develop suddenly, or gastrointestinal hemorrhage may be the initial sign of the disease. Occasionally Wilson disease begins with a hemolytic crisis caused by the toxic effects of copper on the red blood cells. Cirrhosis develops in all untreated cases. Copper deposition in the kidneys causes a proximal renal tubular defect that results in losses of glucose, amino acids, phosphate, and uric acid in the urine and renal tubular acidosis. All untreated individuals will develop behavioral or psychiatric disorders.

◆Evaluation and Treatment.

Because Wilson disease is rare and has broad clinical manifestations, it may not be diagnosed until older childhood or adulthood. Laboratory tests detect a serum ceruloplasmin concentration less than 30 mg/dL. Serum copper values may be normal or high, and urine copper values are elevated. Liver biopsy confirms structural changes and measures copper concentrations. *ATP7B* gene sequencing can avoid the need for liver biopsy.¹⁴⁰ The goal of therapy is to decrease copper accumulation

by decreasing dietary copper intake and intestinal copper absorption, and increasing renal excretion of copper. Medical treatments include D-penicillamine and trientine (copper chelating agents), and zinc and ammonium tetrathiomolybdate (reduces intestinal copper absorption).¹⁴¹ Liver transplantation is the only therapy for Wilson disease, and gene therapy and hepatocyte cell transplantation are being investigated.¹³⁷

Summary Review

Disorders of the Gastrointestinal Tract

1. Most alterations of digestive function in children are caused by congenital anomalies of the intestinal tract; disorders of digestion, absorption, or nutrition; or liver disease.
2. Cleft lip and cleft palate may occur separately or together, and both defects are associated with multiple gene-environmental interactions and deficiency of B vitamins. The fissure may affect the uvula, soft palate, hard palate, nostril, and maxillary alveolar ridge.
3. *Nonsyndromic (isolated) CLP* is the most common malformation with an incomplete separation between nasal and oral cavities without any associated anomaly.
4. Esophageal atresia, a condition in which the esophagus ends in a blind pouch, may occur with or without tracheoesophageal fistula, a connection between the esophagus and the trachea. As the infant swallows oral secretions or ingests milk, the pouch fills, causing either drooling or aspiration into the lungs.
5. Infantile hypertrophic pyloric stenosis, an obstruction of the pyloric outlet caused by hypertrophy and hyperplasia of circular muscles in the pyloric sphincter, is more common in male infants and may require surgical correction.
6. Intestinal malrotation occurs with failure of the colon to rotate during fetal development, and an obstructing band or volvulus (twisting of the bowel on itself) may partly or

completely occlude the gastrointestinal tract and its blood vessels.

7. Meckel diverticulum is an outpouching of all layers of the small intestine caused by failure of the fibrous band that connects the small intestine to the umbilicus.
8. Hirschsprung disease (aganglionic megacolon) is caused by an absence of enteric ganglia and malformation of the parasympathetic nervous system in a segment of the colon, resulting in inadequate colon motility and functional obstruction.
9. Idiopathic intestinal pseudo-obstruction is repetitive episodes or continuous symptoms of intestinal obstruction without an obstructing lesion and may be associated with atrophy of enteric nerves and/or muscles.
10. DIOS, formerly called *meconium ileus equivalent*, can occur when intestinal contents become abnormally thick and obstruct the intestinal lumen. CF, pancreatic enzyme deficiency, and dehydration are common causes.
11. Duodenal, jejunal, and ileal obstructions can be caused by meconium ileus, atresia, peritoneal bands, or acquired obstructive disorders.
12. Malformations of the anus and rectum range from mild congenital stenosis of the anus to complex deformities, all of which are classified as imperforate anus.
13. Meconium aspiration syndrome is a type of newborn respiratory distress caused by fetal inspiration of meconium-contaminated amniotic fluid associated with fetal hypoxic distress and in utero gasping respirations.
14. Meconium ileus is a condition in the newborn in which intestinal secretions and amniotic waste products produce a thick tarry plug that obstructs the intestine, usually from lack of fetal digestive enzymes. From 10% to 15% of neonates with CF have meconium ileus as neonates.
15. GERD is caused by the relaxation or incompetence of the lower esophageal sphincter. Infants are susceptible to reflux because

the sphincter is not fully mature, their diet consists of liquids, and they are seldom in an upright position.

16. Eosinophilic esophagitis involves an eosinophilic inflammation of the esophagus with dysphagia and vomiting that can be associated with asthma and eczema.
17. The most common cause of acquired intestinal obstruction in infants is intussusception, a condition in which one portion of the bowel telescopes or invaginates into another. It occurs most commonly in the area of the ileocecal junction.
18. CF is an inherited disease caused by a dysfunction of the CF transmembrane regulator (CFTR) protein with a pathophysiologic triad that includes pancreatic enzyme deficiency (which causes maldigestion), overproduction of mucus in the respiratory tract, and abnormally elevated sodium and chloride concentrations in sweat.
19. Celiac disease is an immune-mediated lifelong disease with a genetic predisposition characterized by the loss of mature villous epithelium in the presence of a gluten-containing diet. It results in malabsorption and growth failure. Nonceliac gluten sensitivity is wheat allergy without the autoantibodies associated with celiac disease.
20. Severe acute malnutrition is a group of disorders resulting from a severe dietary deficiency of proteins (kwashiorkor), carbohydrates, or both (marasmus). Starvation causes stunted mental and physical development. Kwashiorkor occurs most often in toddlers who have stopped breast-feeding and subsist on a high-carbohydrate diet.
21. Failure to thrive or growth faltering is inadequate physical growth of a child associated with multifactorial conditions that include biologic, psychosocial, and environmental contributions resulting in delayed growth and malnutrition.
22. Necrotizing enterocolitis is a disorder in neonates, particularly low birth weight or premature infants, thought to result from stress and anoxia of an immature bowel wall and immature intestinal innate immunity. Bacteria invade the mucosa and

can cause colitis, necrosis, intestinal perforation, sepsis, and death.

23. Acute diarrhea in infants and children is often caused by infection from contaminated food and/or water and can rapidly cause dehydration and electrolyte imbalances because fluid reserves are relatively small. The most common cause of acute diarrhea in children is bacterial or viral enterocolitis.
24. Chronic diarrhea (diarrhea persisting longer than 4 weeks) can be caused by a wide variety of underlying conditions and often leads to growth failure and delayed development.
25. Lactose malabsorption and intolerance causes diarrhea when failure to produce lactase results in osmotic diarrhea with ingestion of lactose-containing dairy products.

Disorders of the Liver

1. Physiologic jaundice of the newborn is caused by mild hyperbilirubinemia that subsides in 1 to 2 weeks. Pathologic jaundice is caused by severe hyperbilirubinemia and can cause brain damage (kernicterus).
2. Biliary atresia is a congenital malformation of the bile ducts that obstructs bile flow. Atresia causes jaundice, biliary cirrhosis, portal hypertension, and liver failure. Biliary atresia is the most common reason for liver transplantation in children.
3. Acute hepatitis has the same clinical course in children and adults but children have milder cases of the disease. Hepatitis A is the most common form of childhood hepatitis and is spread by contact with contaminated stool and poor handwashing.
4. Young children more readily develop chronic HBV or HCV hepatitis because of their immature immune system. HBV and HCV can be acquired by maternal vertical transmission in newborns or by parenteral (i.e., use of shared needles) transmission in older children.

5. Cirrhosis is fibrotic scarring of the liver and is rare in children but can develop from most forms of chronic liver disease.
6. Portal hypertension in children usually is caused by extrahepatic obstruction. Thrombosis of the portal vein is the most common cause of portal hypertension in children and splenomegaly is the most common sign.
7. The three most common metabolic disorders that cause liver damage in children are galactosemia, fructosemia, and Wilson disease. All are rare, are inherited as genetic traits, and permit the accumulation of toxins in the liver.
8. Wilson disease causes defective copper uptake and metabolism. Copper that is not excreted accumulates in the liver, brain, kidney, and corneal cells. Damage from accumulated copper is gradual; the disease is usually not diagnosed before age 4 or 5 years.

CHAPTER OUTLINE

Structure and Function of Bones, 1395

- Elements of Bone Tissue, 1396
- Types of Bone Tissue, 1402
- Characteristics of Bone, 1402
- Maintenance of Bone Integrity, 1403

Structure and Function of Joints, 1406

- Fibrous Joints, 1406
- Cartilaginous Joints, 1406
- Synovial Joints, 1407

Structure and Function of Skeletal Muscles, 1410

- Whole Muscle, 1411
- Components of Muscle Function, 1414

Tests of Musculoskeletal Function, 1418

- Tests of Bone Function, 1418
- Tests of Joint Function, 1418
- Tests of Muscular Function, 1418
 - AGING and the Musculoskeletal System, 1418*
- Aging of Bones, 1418

The way an individual functions in daily life, moves, or manipulates objects physically depends on the integrity of the musculoskeletal system. The musculoskeletal system actually consists of the following two systems: (1) the skeleton composed of bones and joints and (2) soft tissues (skeletal muscles, tendons, and ligaments). Each of the systems contributes to mobility. The skeleton supports the body and provides leverage to the skeletal muscles so that movement of various parts of the body is possible. Contraction of the skeletal muscles and bending or rotation at the joints facilitate movement of the various body parts.

Structure and Function of Bones

Bones give form to the body, support tissues, and permit movement by providing points of attachment for muscles. Many bones meet in movable joints that determine the type and extent of movement possible. Bones also protect many of the body's vital organs. For example, the bones of the skull, thorax, and pelvis are hard exterior shields that protect the brain, heart, lungs, and reproductive and urinary organs.

Bone marrow is one of the sources of **mesenchymal stem cells (MSCs)** (Fig. 44.1). These nonhematopoietic stem cells consist of a small proportion of the stromal cell population in the bone marrow, and can generate bone cells, cartilage cells, and fat cells that support the formation of blood and fibrous connective tissue. Within certain bones, the marrow cavities also serve as a storage site for the hematopoietic stem cells that form both blood and immune cells. In adults, blood cells originate exclusively in the marrow cavities of the skull, vertebrae, ribs, sternum, shoulders, and pelvis. Bones also have a crucial role in mineral homeostasis (storing minerals [i.e., calcium,

phosphate, carbonate, magnesium]) that is essential for the performance of many delicate cellular mechanisms, have a role in hormone homeostasis, and assist in maintaining normal immunologic function.

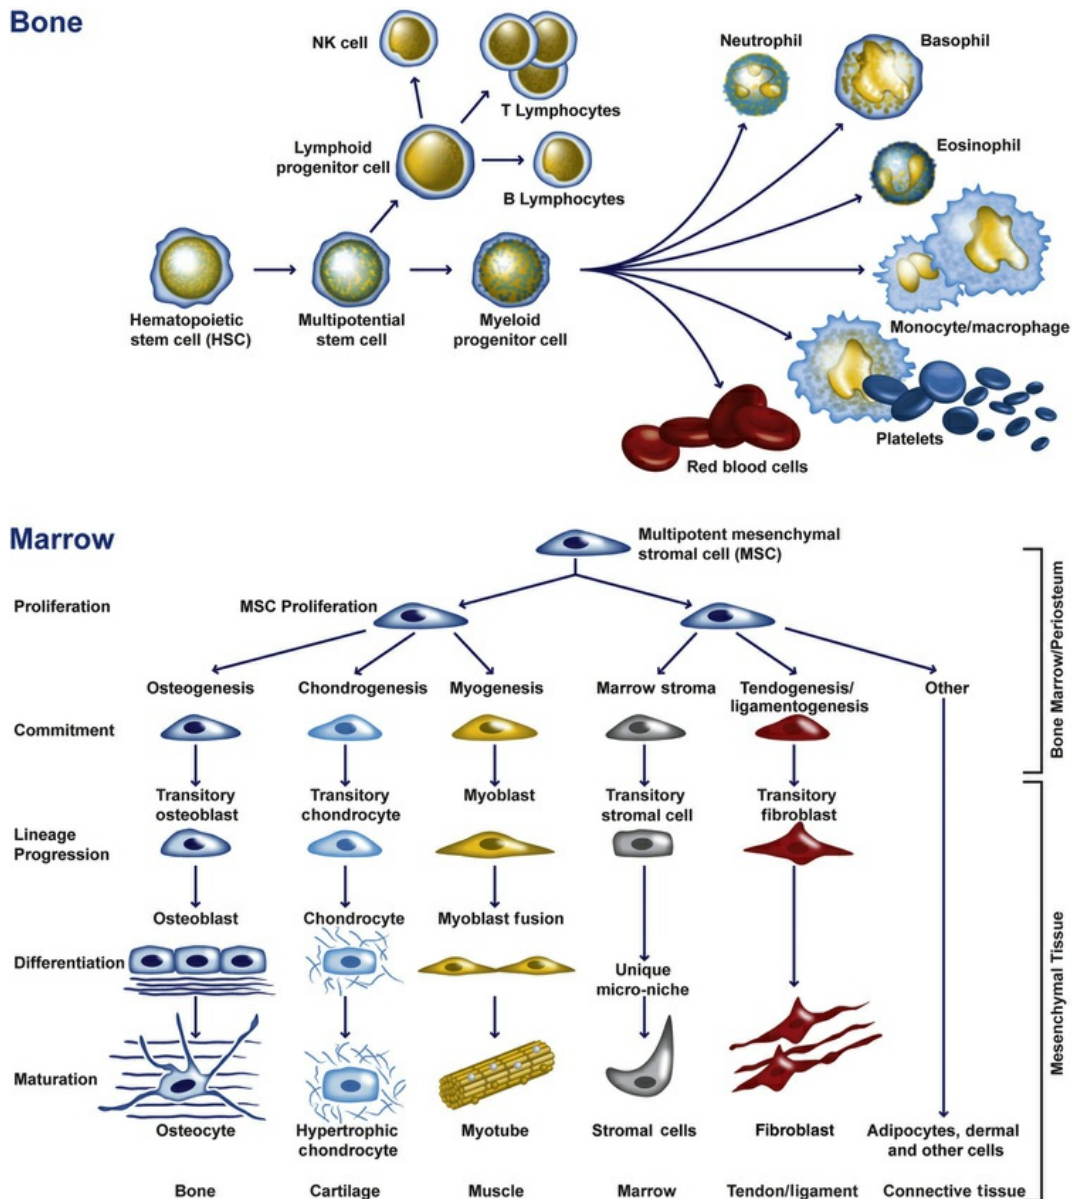

FIGURE 44.1 Hematopoietic and Mesenchymal Stromal Cell Differentiation. Undifferentiated hematopoietic and mesenchymal multipotential cells give rise to a variety of cell types with distinct functions. *NK*, Natural killer cell. (Adapted from abcam.com.)

Elements of Bone Tissue

Mature bone is a rigid yet flexible connective tissue consisting of cells, fibers, a homogeneous gelatinous medium termed **ground substance**, and large amounts of crystallized minerals, mainly calcium, that give bone its rigidity. Ground substance consists of proteoglycans and hyaluronic acid secreted by chondroblasts. The structural elements of bone are summarized in [Table 44.1](#).

TABLE 44.1

STRUCTURAL ELEMENTS OF BONE

STRUCTURAL ELEMENT	FUNCTION
Bone Cells	
Osteoblasts	Synthesize collagen and proteoglycans; stimulate bone formation and are also involved in some osteoclast resorptive activity
Osteocytes	Maintain bone matrix; act as mechanoreceptors; influence osteoblasts and osteoclasts
Osteoclasts	Resorb bone; major role in mineral homeostasis
Bone Matrix	
Collagen fibers	Lend support and tensile strength
Proteoglycans	Control transport of ionized materials through matrix
Bone morphogenic proteins (BMPs)*	Induce cartilage, bone, tendon, and ligament formation and repair
Glycoproteins	
Sialoprotein	Promotes calcification
Osteocalcin	Inhibits calcium phosphate precipitation; promotes bone resorption
Laminin	Stabilizes basement membranes in bones
Osteonectin	Binds calcium in bones
Albumin	Transports essential elements to matrix; maintains osmotic pressure of bone fluid
α -Glycoprotein	Promotes calcification
Minerals (elements)	Crystallize to lend rigidity and compressive strength
Calcium	Regulates vitamin D and thereby promotes mineralization
Phosphate	Balance of organic and inorganic phosphate required for proper bone mineralization; regulates vitamin D

Alkaline phosphatase	Promotes mineralization
Vitamins	
Vitamin D	Assists with differentiation, mineralization of osteoblasts
Vitamin K	Increases bone calcification; reduces serum osteocalcin level

*See [Table 44.2](#) for BMP functions.

Bone cells enable bone to grow, repair itself, change shape, and continuously synthesize new bone tissue and resorb (dissolve or digest) old tissue. The fibers in bone are made of collagen, which gives bone its tensile strength (the ability to hold itself together). Ground substance acts as a medium for the diffusion of nutrients, oxygen, metabolic wastes, biochemicals, and minerals between bone tissue and blood vessels.

Bone formation begins during embryonic development when mesenchymal stem cells begin differentiating into either chondrocytes or preosteoblasts. Endochondral ossification and intramembranous ossification are the two major mechanisms responsible for normal bone development.

Endochondral ossification occurs when mesenchymal (**mesenchyme**, or loose tissue found during embryonic development) stem cells begin differentiating into chondrocytes (see [Fig. 44.1](#)), which in turn develop a mineralized cartilage scaffold that allows formation of osteoblasts. Long bones and most other bone elements are formed this way. **Intramembranous ossification** is responsible for the development of skull and flat bones.^{1,2} With intramembranous ossification, mesenchymal stem cells differentiate into a preosteoblast line that forms osteoblasts without any cartilage framework.^{2,3}

Multiple factors influence normal bone formation, maintenance, and remodeling. Bone morphogenic proteins (BMPs) are members of the transforming growth factor-beta (TGF- β) superfamily, and BMPs play a major role in bone formation.³ This group is primarily responsible for initiation, differentiation, and commitment of precursor cells into osteoblasts. TGF- β signals are transmitted across the plasma membrane, combine with certain proteins that act as transcription factors (Smads), and then form specific receptors known as *R-Smads*.³ These receptors, in turn, initiate intracellular signaling,

interact with other transcription factors, and regulate other factors that are important in osteoblast formation, function, and maintenance.³ Crosstalk between signaling pathways (including TGF- β , BMPs, fibroblast growth factors [FGFs], Wnt, Notch, MAPK, and Indian Hedgehog) is critical in regulating osteoblasts.

BMPs have multiple crucial functions in the skeletal system. BMP activities are regulated at different molecular levels. [Table 44.2](#) summarizes the role of several important BMPs.

TABLE 44.2

BONE MORPHOGENIC PROTEINS (BMPs) AND THEIR KNOWN FUNCTIONS

BMP	KNOWN FUNCTION
BMP1	Involved in cartilage development; is actually a metalloprotease; key role in extracellular matrix (ECM) formation
BMP2	Induces bone and cartilage formation, osteoblast differentiation, bone healing
BMP3 (osteogenin)	Induces bone formation
BMP4	Regulates formation of teeth, limbs, and bone
BMP5	Involved in cartilage development
BMP6	Found in osteoblasts; helps maintain adult joint integrity; accelerates bone repair
BMP7	Has major role in osteoblast differentiation, chondrocyte formation, fracture healing; important in renal development and repair
BMP8a	Involved in bone and cartilage development; up-regulated in fracture nonunion
BMP9	Induces osteogenesis in mature osteoblasts
BMP10	Plays role in development of the heart
BMP12 (cartilage-derived morphogenic protein-3; CDMP-3)	Involved in tendon and ligament formation
BMP13	Involved in cartilage development; tendon and ligament repair
BMP14	Assists in bone and tendon healing; cartilage formation

Data from Caetano-Lopes J, Canhão H, Fonseca JE: *Arthritis Res Ther* 9(Suppl 1):S1, 2007; Hojo H et al: *J Bone Miner Metab* 28(5):489–502, 2010; Fajardo M, Liu C-J, Egol K: *Clin Orthop Relat Res* 467(12):3071–3078, 2009; Li Y et al: *Zhong Nan Da Xue Xue Bao Yi Xue Ban* 37(1):1–5, 2012.

Wnt genes belong to a large family of protein-signaling factors that are required for the development of body systems, including the musculoskeletal system. They play a significant role in forming bone, developing bone mass, remodeling bone, and healing fractures. Wnt signaling regulates production and differentiation of osteoblasts and osteoclasts, and affects bone mass and density, joint formation, fracture repair, bone remodeling, and some bone diseases. Other important elements responsible for bone formation and homeostasis are presented in [Table 44.3](#).

TABLE 44.3

SELECTED FACTORS AFFECTING BONE FORMATION AND HOMEOSTASIS

FACTOR	FUNCTION
Transforming growth factor-beta (TGF- β)	Superfamily of polypeptides; regulates bone formation, many other cellular processes through signaling
Platelet-derived growth factor (PDGF)	Increases number of osteoblasts
Fibroblast growth factor-2 (FGF-2)	FGF-2 increases osteoblast population, but not function; inhibits alkaline phosphatase activity, osteocalcin, type I collagen, and osteopontin
Insulin-like growth factor (IGF)	
IGF-1	Increases peak bone mass during adolescence; decreases osteoblast apoptosis; maintains bone matrix
IGF-2	Increases BMP-9–induced endochondral ossification
Smad proteins	Mediate the signaling cascade of transforming growth factor-beta (TGF- β), especially in embryonic bone development; play a role in crosstalk between BMP/TGF- β and Wnt signaling pathways
Bone morphogenic proteins (BMPs)	Members of transforming growth factor-beta (TGF- β) superfamily of polypeptides; have many functions outside skeletal system; stimulate endochondral bone and cartilage formation and function, promote osteoblast maturation; augment bone remodeling by affecting both osteoblasts and osteoclasts
Tumor necrosis factors (TNFs)	Superfamily of cytokines; play major role in regulating bone metabolism, especially osteoclast function
Osteoprotegerin (OPG)	Inhibits bone remodeling/resorption; produced by several cells, including osteoblasts; is a decoy receptor for RANKL (binds to RANKL, inhibiting RANK/RANKL interactions, suppressing osteoclast formation and bone resorption)

Receptor activator of nuclear factor $\kappa\beta$ (RANK)	Stimulates differentiation of osteoclast precursors; activates mature osteoclasts
Bone morphogenic protein antagonists	Prevent BMP signaling
Noggin	Binds BMP-2 and BMP-4, reducing osteoblast function
Gremlin	Multiple effects in and out of skeletal system, but also binds BMP-2, -4, and -7; may play a role in development of osteoporosis
Twisted gastrulation	Acts as either a BMP agonist or an antagonist
Activin (a BMP-related protein)	Affects both osteoblasts and osteoclasts; may promote bone formation and fracture healing; expressed by both osteoblasts and chondrocytes; helps regulate bone mass
Inhibin	Dominant over activin and BMPs; helps regulate bone mass and strength by affecting formation of osteoblasts and osteoclasts
Leptin	Plays role in bone formation and resorption
Wnt (a signaling pathway)	Important in differentiating osteoblasts and bone formation; has overlapping effects with BMPs; helps regulate bone formation and remodeling
Wnt antagonists	
Dickkopf family (Dkk)	Disrupts Wnt signaling, leading to reduced bone mass
Sclerostin	Protein secreted by osteocytes, osteoblasts, and osteoclasts; binds to BMP-6 and BMP-7; interferes with Wnt signaling pathway, inhibiting bone formation by osteoblasts
Transcription Factors	
Nuclear factor of activated $\kappa\beta$ cells (NF- $\kappa\beta$)	Affects embryonic osteoclastogenesis; plays a role in certain osteoclast, osteoblast, and chondroblast functions
Matrix metalloproteinases (MMPs)	
Family of endopeptidases (enzymes) that includes collagenases, gelatinases, stromelysins, matrilysins	Help maintain equilibrium of extracellular matrix (ECM); break down almost all components of ECM
A disintegrin and metalloproteinase (ADAM)	Proteolytic enzymes; also have cell-signaling functions, usually linked to cell membrane
A disintegrin and metalloproteinase with thrombospondin	Similar to ADAMs but are secreted into circulation, are found around cells; various subgroups affect multiple tissues

motifs (ADAMTS)	
Cysteine Protease	
Cathepsin	K-expressed by osteoclasts; assists in bone remodeling by cleaving proteins, such as collagen type I, collagen type II, and osteonectin
Mmp Inhibitors	
Tetracyclines (especially doxycycline), bisphosphonates	Block enzymatic function of MMPs
Tissue inhibitors of metalloproteinases (TIMPs)	Balance effect of MMPs in maintaining ECM equilibrium

From Boyce GC, Zhenqiang, Zing L: *Ann N Y Acad Sci* 1192:367–375, 2010; Canalis E: *J Cell Biol* 108(4):769–777, 2009; Kim Y-S et al: *J Korean Med Sci* 25:985–991, 2010; Moester MJ et al: *Calcif Tissue Int* 87(2):99–107, 2010; Nicks KN et al: *Mol Cell Endocrinol* 310(1–2):11–20, 2009; Pasternak B, Aspenberg P: *Acta Orthopaedica* 80(6):693–703, 2009; Stewart A, Guan H, Yang K: *J Cell Physiol* 223(3):658–666, 2010; Tat SK et al: *Keio Med J* 58(1):29–40, 2009.

In mature bone the formation of new tissue begins with the production of an organic matrix by the bone cells. This **bone matrix** consists of ground substances, collagen, and other proteins (see [Table 44.1](#)) that take part in bone formation and maintenance.

The next step in bone formation is **calcification**, when minerals are deposited and crystallize. Minerals bind tightly to collagen fibers, producing tensile and compressional strength in bone, and withstand pressure and weightbearing.

Bone Cells

Bone contains three types of cells: osteoblasts, osteocytes, and osteoclasts ([Fig. 44.2](#)). Osteoblasts are the bone-forming cells, whose primary function is to lay down new bone. Once this function is complete, osteoblasts become osteocytes that are embedded in bone. Comprising 90% to 95% of bone cells, osteocytes develop dendritic processes that extend either to the bone surface or to the bone's vascular space.⁴ Osteocytes help maintain bone by signaling osteoblasts and osteoclasts to form and resorb bone.⁵ Osteoclasts are the major bone-resorbing cells responsible for remodeling.

FIGURE 44.2 Bone Cells. A, Osteoblasts are responsible for the production of collagenous and noncollagenous proteins that compose osteoid. Active osteoblasts are aligned on the osteoid. Note the eccentrically located nuclei. B, Osteocyte. Scanning electron micrograph showing an osteocyte within a lacuna. The cell is surrounded by collagen fibers and mineralized bone. C, Osteoclasts actively resorb mineralized tissue. The scalloped surface in which the multinucleated osteoclasts rest is termed the *Howship lacuna*. (A and C from Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby. B from Erlandsen S, Magney J: *Color atlas of histology*, St Louis, 1992, Mosby.)

Osteoblasts.

Osteoblasts originate from mesenchymal stem cells (MSCs). Bone formation is initiated by osteoblasts. Mature osteoblasts produce inorganic calcium phosphate, which is converted to hydroxyapatite, and an organic matrix that is comprised mainly of type I collagen.⁶ Once this process is complete, osteoblasts deposit new bone in response to the bone resorbed by osteoclasts.⁶ Osteoblasts and osteocytes control osteoclast differentiation and bone resorption by producing **receptor activator of nuclear factor $\kappa\beta$ ligand (RANKL)** and osteoprotegerin. Osteoclasts trigger an osteoblastic response to couple bone formation to bone resorption during bone remodeling.⁷ The net result is continuous renewal of the skeletal system. Bone modeling and bone remodeling are the processes that allow the skeleton to adapt to environmental challenges and to regulate mineral metabolism.⁷ Osteoblasts cause the formation of new bone and the orderly mineralization of bone matrix by concentrating some of the plasma proteins (growth factors) found in the bone matrix and by facilitating the deposit and exchange of calcium and other ions at the site. Enzymes, signaling proteins, and growth factors, including bone

morphogenic proteins (BMPs) and other members of the transforming growth factor-beta (TGF- β) superfamily, are critical components of bone formation, maintenance, and remodeling (Table 44.4).

TABLE 44.4

EFFECTS OF SELECTED CYTOKINES (GROWTH FACTORS) ON SKELETAL TISSUES (BONE OR CARTILAGE)

CYTOKINE (GROWTH FACTOR)	BONE		CARTILAGE	
	FORMATION	RESORPTION	FORMATION	RESORPTION
Transforming growth factor-beta	+, -	+, -	+, -	-
Transforming growth factor-alpha or epidermal growth factor	+, -	+	+	0
Insulin-like growth factor	-	?	-	0
Fibroblast growth factor	+, -	?	-	0
Platelet-derived growth factor	0	+	?	?
Colony-stimulating factors	?	?	-	-
Interferon-gamma	-	?	-	+
Tumor necrosis factor	-	+	+, -	+
Interleukins-1, -3, and -6	-	+	?	?

+, -, Both stimulatory and inhibitory properties on the specific cell listed; 0, no effects presently known; ?, possible effects on the cell listed.

Osteoblasts are active on the outer surface of bones, where they form a single layer of cells. They are responsive to parathyroid hormone (PTH) and produce a protein called *osteocalcin* when stimulated by 1,25-dihydroxy-vitamin D₃.⁸ Osteoblasts initiate the formation of new bone by their synthesis of **osteoid** (nonmineralized bone matrix). The mechanism of osteoblast stimulation is reported to be the production of so-called coupling factors generated during the resorption process. Osteoblasts alter levels of RANKL and osteoprotegerin (OPG); the balance of these two cytokines determines overall osteoclast formation⁹ (see Fig. 45.11). As new bone is formed, it is shaped and remodeled through TGF- β , as well as other plasma

proteins (growth factors) found in the bone marrow (see [Table 44.4](#)).

Osteocytes.

Osteocytes, the most abundant cells in bone, are transformed osteoblasts that become trapped or surrounded in osteoid as it hardens because of minerals that enter during ossification (see [Fig. 44.2, B](#)). It is the final differentiation stage for an osteoblast. The osteocyte is within a space in the hardened bone matrix called a **lacuna**. Within the mineralized matrix, osteocytes are interconnected by a network of dendritic cytoplasmic processes through tunnels known as *canaliculi*.^{1,4} These canaliculi radiate from each lacuna and contain cell processes from the resident osteocyte, thereby enabling it to form gap junctions with adjacent osteocytes.¹⁰ Within this microenvironment, osteocytes detect mechanical forces and help to control calcium and phosphate levels.¹

One of the osteocyte's primary functions is to act as a mechanoreceptor, responding to changes in weightbearing or other stressors ("loading") on bone. Lying within the lacunae are the osteocyte's primary cilia, which are likely the primary mechanoreceptors in bone.^{11,12} Once changes, such as mechanical stress, hormonal imbalance, loading, or unloading, in bone are detected by the osteocyte's mechanoreceptors, multiple molecular signals are produced and the process of bone remodeling begins.^{6,13} Osteocytes communicate with other bone cells and instruct both osteoblasts and osteoclasts about when and where to form and resorb bone; concentrate nutrients in the matrix; regulate bone mass and minerals (especially calcium and phosphorus); and secrete other proteins, such as sclerostin and fibroblast growth factor-23 (FGF-23), that influence mineral metabolism.^{4,14-16} Sclerostin inhibits osteoblasts, thus reducing bone formation. Additionally, osteocytes seem to function as endocrine receptors in regulating bone metabolism and are prime target cells of parathyroid hormone (PTH).¹⁶⁻¹⁸ Through exchanges between these cells, hormone catalysts, and minerals, optimal levels of calcium, phosphorus, and other minerals are maintained in blood plasma. (Remodeling is described under

Maintenance of Bone Integrity.)

Osteoclasts.

Derived from the hematopoietic monocyte-macrophage lineage, **osteoclasts** are terminally differentiated multinucleated bone cells and are responsible for bone resorption.¹ Osteoclasts migrate over bone surfaces to resorption areas that have been prepared and stripped of osteoid by enzymes, such as collagenases produced by osteoblasts in the presence of parathyroid hormone (PTH), which are necessary for the resorptive process. Osteoclasts travel over the prepared bone surfaces, creating irregular, scalloped cavities, known as *Howship lacunae* or *resorption lacunae*, as they resorb bone areas and then acidify hydroxyapatite in order to dissolve it.¹⁹

A specific area of the cell membrane adjacent to the bone surface forms deep and irregular foldings. These foldings, known as the **ruffled border**, greatly increase the surface areas of cells under their scalloped or ruffled borders. Osteoclasts resorb bone by secretion of hydrochloric acid, acid proteases (such as cathepsin K), and matrix metalloproteinases (MMPs) that help digest collagen, along with the action of cytokines (see [Table 44.3](#)). Osteoclasts also resorb bone through the action of lysosomes (digestive vacuoles) filled with hydrolytic enzymes in their mitochondria.¹⁹

Osteoclasts bind to the bone surface through attachments called **podosomes**, which are footlike structures that cluster together along a sealing membrane that forms a “belt” containing multiple proteins, enzymes, and integrin receptors.¹⁹⁻²⁰ Once resorption is complete, the osteoclasts retract and loosen from the bone surface under the ruffled border through the action of calcitonin. Calcitonin binds to receptor areas of the osteoclasts' cell membranes to effectively loosen the osteoclasts from the bone surfaces. Once resorption is completed, osteoclasts disappear by the process of degeneration either by reverting to the form of their parent cells or by undergoing cell movements away from the site, in which the osteoclast becomes an inactive or resting osteoclast.

In addition to resorption of bone, osteoclasts assist the endocrine

and renal systems in maintaining appropriate serum calcium and phosphorus levels. Osteoclasts also appear to have a role in the body's immune response.¹⁹

The OPG/RANKL/RANK System.

Osteoprotegerin (OPG) is a glycoprotein belonging to the tumor necrosis factor superfamily and inhibits bone remodeling/resorption by inhibiting osteoclast formation. Numerous cells, including osteoblasts and osteocytes, produce it. OPG is key in the interaction between osteoblasts and osteoclasts.²¹ Osteoblasts and osteoclasts cooperate (a term called *coupling*) to maintain normal bone homeostasis. RANKL is an essential cytokine needed for the formation and activation of osteoclasts. RANKL increases bone loss. OPG decreases bone loss because when it is activated it promotes bone formation. When RANKL binds to its receptor RANK on osteoclast precursor cells, it triggers their proliferation and increases bone resorption. OPG, secreted by osteoblasts and B lymphocytes, serves as a decoy by binding to RANK, preventing RANKL binding to RANK and thereby preventing bone resorption.²² Therefore the overall balance between RANKL and OPG determines the amount of bone loss and is regulated by cytokines and hormones.²³

Alterations of the RANKL/RANK/OPG system can lead to dysregulation and pathologic conditions, including primary osteoporosis, immune-mediated bone diseases, malignant bone disorders, and inherited skeletal diseases. It is worth noting that dimethyl sulfoxide (DMSO), an FDA-approved organosulfur solvent, is reported to have osteoclast-inhibiting properties.²⁴ In a recent study, data showed that 1% DMSO significantly inhibited RANKL-induced osteoclastogenesis.²⁴ Specifically, DMSO inhibited both differentiation and function of osteoclasts. This is an important finding because it presents the potential use of DMSO for treatment of bone diseases related to increased osteoclast proliferation, such as osteoporosis.²⁴ One study demonstrated that daily injections of DMSO inhibited estrogen deficiency-induced osteopenia in rats by inhibiting the function of osteoclasts.²⁵

Bone Matrix

Bone matrix is made of the extracellular elements of bone tissue. Bone matrix is composed of an organic component known as *osteoid* (35%) and a mineral component (65%). Osteoid is comprised of predominantly type I collagen with small amounts of glycosaminoglycans and other proteins¹ (Box 44.1).

The major inorganic components are the calcium and phosphate minerals. Other parts of the bone matrix are the proteins,

carbohydrate-protein complexes, and ground substances. Water comprises 5% to 8% of the matrix.

Collagen Fibers.

Collagen fibers make up the bulk of bone matrix. They are formed as follows:

1. Osteoblasts synthesize and secrete type I collagen and osteocalcin.
2. Collagen molecules assemble into three thin chains (alpha chains) to form **fibrils**.
3. Fibrils organize into the staggered pattern, with each fibril overlapping its nearest neighbor by about one-fourth its length; this creates gaps into which mineral crystals are deposited.
4. After mineral deposition, fibrils interlink and twist to form ropelike fibers.
5. The fibers then join to form the framework that gives bone its tensile and supportive strength.

Collagen is the most abundant macromolecule in the body, accounting for approximately one-third of all protein and providing the structural framework for nearly all tissues. Collagen is one of the extracellular components, along with proteoglycans and noncollagenous matrix proteins, of articular cartilage. To date, more than 20 types of collagen have been identified, though all their functions are not yet known. Cartilage-specific collagens include types II (the principal component), VI, IX, X, and XI. Type IX collagen is thought to be the “glue” that holds together the type II collagen scaffold of articular cartilage, helps maintain the structural integrity of cartilage, and resists tensile forces on joint cartilage. Type XI regulates the fibril diameter of type II cartilage. Degradation of type IX collagen by proteolytic enzymes has been seen in the early stages of osteoarthritis and rheumatoid arthritis. Researchers have proposed that this degradation, or “unplugging,” may be the mechanism for the

degenerative changes seen in osteoarthritic and rheumatoid cartilage. [Table 44.5](#) gives the musculoskeletal distribution of other types of collagen.

TABLE 44.5

TYPES OF COLLAGEN IN MUSCULOSKELETAL TISSUES

TYPE OF COLLAGEN	DISTRIBUTION IN MUSCULOSKELETAL TISSUES
I	Bone, tendon, ligament, intervertebral disk, muscle*
II	Cartilage, intervertebral disk
III	Skin, muscle, often with type I
IV	Basement cell membrane, muscle
V	Codistributed with type I muscle, most interstitial tissues
VI	Ubiquitous, muscle
IX	Codistributed with type II muscle
X	Cartilage growth plate
XI	Cartilage, muscle
XII	Codistributed with type I and type III muscle
XIII	Molecule has not been isolated in connective tissues to date
XIV	Codistributed with type I muscle
XV	Muscle; contains heparin sulfate proteoglycans (HSPGs)
XVII	Muscle; contains HSPGs

*Refers specifically to skeletal muscle.

Proteoglycans.

Proteoglycans are large complexes of numerous polysaccharides attached to a common protein core. They strengthen bone by forming compression-resistant networks between the collagen fibrils. Proteoglycans also control the transport and distribution of electrically charged particles (ions), particularly calcium, through the bone matrix, thereby playing a role in bone calcium deposition and calcification.

Glycoproteins.

Glycoproteins are carbohydrate-protein complexes of bone. Glycoproteins control the collagen interactions that lead to fibril formation. They also may play a role in calcification.

Some of the glycoproteins in bone matrix include bone sialoprotein, osteocalcin, osteonectin, laminin, albumin, and α -glycoprotein. Other proteins found in bone matrix are the compounds currently called **bone morphogenic proteins (BMPs)** (see [Table 44.2](#)). **Sialoprotein (osteopontin)** comprises about 8% of the noncollagenous matrix of bone and easily binds with calcium.

Osteocalcin is also a calcium-binding protein that binds preferentially to calcium that has already crystallized. The roles of osteocalcin may be to inhibit calcium phosphate precipitation and to play a part in bone resorption by recruiting osteoclasts.

Osteonectin is a bone-specific protein that binds selectively to both hydroxyapatite and collagen in the bone matrix. **Laminin** is an abundant bone matrix protein in humans that stabilizes basement membranes in bones and is important in neurite and axon growth.

Bone albumin is identical to serum albumin. In calcified matrix, bone albumin is permanently fixed to bone mineral crystals and remains so until the bone is resorbed. Bone albumin transports essential elements such as hormones, ions, and other metabolites to and from the bone cells and maintains the osmotic pressure of **bone fluid** (fluid surrounding mineral crystals and osteoblasts).

Bone Minerals

After collagen synthesis and fiber formation, the final step in bone formation is mineralization. Mineralization has two distinct phases: (1) formation of hydroxyapatite crystals within matrix vesicles that bud from the surface membrane of chondrocytes, osteoblasts, and odontoblasts; and (2) proliferation or accretion of hydroxyapatite into the extracellular matrix and its deposition between collagen fibrils.²⁶

[Table 44.6](#) lists the sequence in which calcium and phosphate form amorphous (fluid) calcium phosphate compounds that are converted, in stages, to solid hexagonal crystals of **hydroxyapatite (HAP)**. As the calcium and phosphorous concentrations increase in the bone matrix,

the first precipitate to form is dicalcium phosphate dihydrate (DCPD). Once DCPD precipitation begins, the remaining phases of bone crystal formation proceed until insoluble HAP is produced, with approximately 80% to 90% of the HAP being incorporated into the collagen fibers. Amorphous calcium phosphate is distributed throughout the bone matrix.

TABLE 44.6

SEQUENCE OF CALCIUM AND PHOSPHATE COMPOUND FORMATION AND CRYSTALLIZATION*

FORMULA	NAME	ABBREVIATION
$\text{Ca}(\text{HPO}_4) \times 2\text{H}_2\text{O}$	Dicalcium phosphate dehydrate	DCPD
$\text{Ca}_4\text{H}(\text{PO}_4)_3$	Octacalcium phosphate	OCP
$\text{Ca}_9(\text{PO}_4)_6$ (var.)	Amorphous calcium phosphate	ACP
$\text{Ca}_3(\text{PO}_4)_2$	Tricalcium phosphate	TCP
$\text{Ca}_5(\text{PO}_4)_3\text{OH}$	Hydroxyapatite	HAP

*NOTE: Compounds are listed in order in which precipitation and crystal formation occur.

Types of Bone Tissue

Bone is composed of two types of bony (osseous) tissue: **compact bone (cortical bone)** and **spongy bone (cancellous bone)** (Fig. 44.3). Compact bone constitutes approximately 85% of the skeleton; spongy bone comprises the remaining 15%. Both types of bone tissue contain the same structural elements, and, with a few exceptions, both compact tissue and spongy tissue are present in every bone. The major difference between the two types of tissue is the organization of the elements.

FIGURE 44.3 Cross Section of Bone. Longitudinal section of long bone (tibia) showing cancellous and compact bone. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

Compact bone is highly organized, solid, and extremely strong. The basic structural unit in compact bone is the haversian system (Fig. 44.4). Each **haversian system** is made up of the following:

FIGURE 44.4 Structure of Compact and Spongy Bone. A, Longitudinal section of a long bone showing cancellous and compact bone. B, A magnified view of compact bone. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

1. A central canal called the **haversian canal**
2. Concentric layers of bone matrix called **lamellae**
3. Tiny spaces (lacunae) between the lamellae
4. Bone cells (osteocytes) within the lacunae
5. Small channels or canals called **canaliculi**

Each haversian system is a separate cylindrical entity that looks like

a set of concentric rings. In the center of the haversian system is the haversian canal that runs through the long axis of bone and contains one or two blood vessels and nerve fibers. The blood vessels in the canal communicate with blood vessels in the periosteum (surface cover) and marrow cavity to transport nutrients and wastes to and from the osteocytes contained within the lacunae. Surrounding each haversian canal are the concentric lamellae. Between the lamellae are the lacunae, each of which contains one osteocyte. The lacunae are connected to each other and to the haversian canal by the canaliculi, which run parallel to the horizontal axis of the bone. Each canaliculus encloses a small extension (cytoplasmic process) from the osteocyte contained in the lacuna. The canaliculi transport both nourishment and molecular signals into the lacunae, a mechanism essential for osteocyte survival.

Spongy bone is less complex and lacks haversian systems. In spongy bone the lamellae are not arranged in concentric layers but in plates or bars termed **trabeculae** that branch and unite with one another to form an irregular meshwork. The pattern of the meshwork is determined by the direction of stress on the particular bone. The spaces between the trabeculae are filled with red bone marrow. The osteocyte-containing lacunae are distributed between the trabeculae and interconnected by canaliculi. Capillaries pass through the marrow to nourish the osteocytes.

All bones are covered with a double-layered connective tissue called the **periosteum**. The outer layer of the periosteum contains blood vessels and nerves, some of which penetrate to the inner structures of the bone through channels called *Volkman canals* (see [Fig. 44.4](#)). The inner layer of the periosteum is anchored to the bone by collagenous fibers (Sharpey fibers) that penetrate the bone. Sharpey fibers also help hold or attach tendons and ligaments to the periosteum of bones.²⁷

Characteristics of Bone

The human skeleton consists of 206 bones that constitute the axial skeleton and the appendicular skeleton ([Fig. 44.5](#)). The **axial skeleton**

consists of 80 bones that make up the skull, vertebral column, and thorax. The **appendicular skeleton** consists of 126 bones that make up the upper and lower extremities, the shoulder girdle (pectoral girdle), and the pelvic girdle (os coxae). The skeleton contributes about 14% of the weight of the adult body.

FIGURE 44.5 Anterior View of Skeleton. (From Drake R et al: *Gray's atlas of anatomy*, ed 2, Philadelphia, 2015, Churchill Livingstone.)

Bones can be classified by shape as long, flat, short (cuboidal), or irregular. **Long bones** are longer than they are wide and consist of a narrow tubular midportion (**diaphysis**) that merges into a broader neck (**metaphysis**) and a broad end (**epiphysis**) (see [Fig. 44.3](#)).

The diaphysis consists of a shaft of thick, rigid compact bone that can tolerate bending forces. Contained within the diaphysis is the elongated marrow (medullary) cavity. The marrow cavity of the diaphysis contains primarily fatty tissue, which is referred to as *yellow marrow*. The yellow marrow assists red bone marrow in hematopoiesis only during times of stress. The yellow marrow cavity of the diaphysis is continuous with marrow cavities in the spongy bone of the metaphysis and diaphysis. The marrow contained within the epiphysis is red because it contains primarily blood-forming tissue (see [Chapter 28](#)). A layer of connective tissue, the **endosteum**, lines the outer surfaces of both types of marrow cavity.

The broadness of the epiphysis allows weightbearing to be distributed over a wide area. The epiphysis is made up of spongy bone covered by a very thin layer of compact bone. In a child the epiphysis is separated from the metaphysis by a cartilaginous **growth plate**, the **epiphyseal plate**. After puberty the epiphyseal plate calcifies and the epiphysis and metaphysis merge. By adulthood the line of demarcation between the epiphysis and metaphysis is undetectable.

In **flat bones**, such as the ribs or scapulae, two plates of compact bone are roughly parallel to each other. Between the compact bone plates is a layer of spongy bone. **Short bones (cuboidal bones)**, such as the bones of the wrist or ankle, are often cuboidal in shape. They consist of spongy bone covered by a thin layer of compact bone.

Irregular bones, such as the vertebrae, mandible, or other facial bones, have various shapes that include thin and thick segments. The thin part of an irregular bone consists of two plates of compact bone with spongy bone between the plates. The thick part consists of spongy bone surrounded by a layer of compact bone.

Maintenance of Bone Integrity

Remodeling

The integrity of bone is maintained by bone remodeling, a three-phase process in which existing bone is resorbed and new bone is laid down

to replace it. Osteoclasts and osteoblasts work together as a **basic multicellular unit (BMU)** to remove old bone by osteoclast activity and to deposit new bone by osteoblast activity.⁶ The basic multicellular units are made up of bone precursor cells that differentiate into osteoclasts and osteoblasts. Precursor cells are located on the free surfaces of bones and along the vascular channels (especially the marrow cavities).

In phase 1 (activation) of the remodeling cycle, a stimulus (e.g., hormone, drug, vitamin, physical stressor) activates programmed osteocyte cell death (apoptosis). The distribution of these apoptotic osteocytes provides the osteoclasts with information about where to begin resorbing damaged bone. In phase 2 (resorption), the osteoclasts form a “cutting cone,” which gradually resorbs bone, leaving behind an elongated cavity termed a *resorption cavity*. Osteoclasts attach to the bone matrix by actin microfilaments and multiple other proteins that form footlike structures called *podosomes*. Once attached, the osteoclasts' integrin receptors anchor their microfilaments to the extracellular matrix, thus providing receptor pathways between the osteocyte and bone matrix. Lysosomal enzymes produced by osteoclasts “digest” bone; the osteoclasts then release the degraded bone products into the vascular system.¹⁹

In phase 3 (formation), new bone formation begins as osteoblasts lining the walls of the resorption cavity express osteoid and alkaline phosphatase, forming sites for calcium and phosphorus deposition. New bone is formed as the osteoid mineralizes. Successive layers (lamellae) in compact bone are laid down until the resorption cavity is reduced to a narrow haversian canal around a blood vessel. In this way, old haversian systems are destroyed and new haversian systems are formed. New trabeculae are formed in spongy bone. The formation phase takes 4 to 6 months in humans.²⁸

Repair

The remodeling process can repair microscopic bone injuries, but gross injuries, such as fractures and surgical wounds (osteotomies), heal by the same stages as soft tissue injuries, except that new bone,

instead of scar tissue, is the final result (see [Chapter 7](#)). In bone the stages of wound healing are as follows:

1. *Hematoma formation*: This process occurs if vessels have been damaged, causing hemorrhage. Fibrin and platelets within the hematoma form a meshwork that is the initial framework for healing with the help of hematopoietic growth factors such as platelet-derived growth factor and TGF- β (see [Table 44.3](#)).
2. *Procallus formation*: Fibroblasts, capillary buds, and osteoblasts move into the wound to produce granulation tissue called **procallus**. Cartilage is formed as a precursor of bone, and types I, II, and III collagen are formed. Enzymes and growth factors, such as insulin and insulin-like growth factors, plus bone morphogenic protein and osteogenin, aid in this stage of healing.
3. *Callus formation*: Osteoblasts in the procallus form membranous or **woven bone (callus)**. Enzymes increase the phosphate content and permit the phosphate to join with calcium to be deposited as mineral to harden the callus.
4. *Replacement*: Basic multicellular units of the callus are replaced with lamellar bone or trabecular bone ([Fig. 44.6](#)).

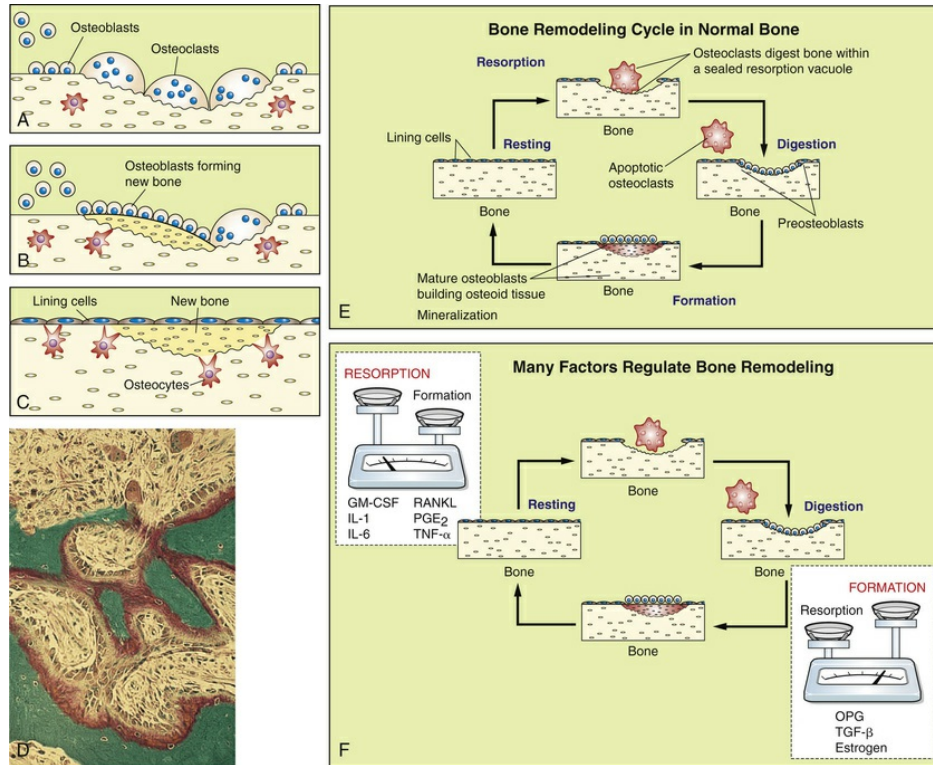

FIGURE 44.6 Bone Remodeling. All bone cells participate in bone remodeling. In the remodeling sequence bone sections are removed by bone-resorbing cells (osteoclasts) and replaced with a new section laid down by bone-forming cells (osteoblasts). Bone remodeling is necessary because it allows the skeleton to respond to mechanical loading, maintains quality control (repair and prevent microdamage), and allows the skeleton to release growth factors and minerals (calcium and phosphate) stored in bone matrix to the circulation. The cells work in response to signals generated in the environment (see F). Only the osteoclastic cells mediate the first phase of remodeling. They are activated, scoop out bone (A), and resorb it; then the work of the osteoblasts begins (B). They form new bone that replaces bone removed by the resorption process (C). The sequence takes 4 to 6 months. D, Micrograph of active bone remodeling seen in the settings of primary or secondary hyperparathyroidism. Note the active osteoblasts surmounted on red-stained osteoid. Marrow fibrosis is present. E, Bone remodeling cycle in normal bone (F). Numerous signaling factors are necessary for remodeling. Factors most important for resorption include granulocyte-macrophage colony-stimulating factor (*GM-CSF*), interleukins-1 and -6 (*IL-1* and *IL-6*), receptor activator for nuclear factor $\kappa\beta$ ligand (*RANKL*), prostaglandin E_2 (*PGE_2*), and tumor necrosis factor-alpha (*TNF- α*). Important factors for bone formation include osteoprotegerin (*OPG*), transforming growth factor-beta (*TGF- β*), and estrogen. (Adapted from Nucleus Medical Art. D from Damjananov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

5. *Remodeling*: The periosteal and endosteal surfaces of the bone are remodeled to the size and shape of the bone before injury. Synthesis of

other types of collagen recedes in favor of type I, which is the collagen found in bone. This final stage of healing, or **remodeling**, is vital because bone that has not been remodeled does not have good mechanical properties for weightbearing and mobility.

The speed with which bone heals depends on the severity of the bone disruption; the type and amount of bone tissue that must be replaced (spongy bone heals faster); the blood supply and oxygen content at the site; the presence of growth and thyroid hormones, insulin, vitamins, and other nutrients; the presence of systemic disease; the effects of aging; and the effectiveness of treatment, including immobilization and the prevention of complications such as infection. In general, however, hematoma formation occurs within hours of fracture or surgery; formation of procallus by osteoblasts occurs within days; callus formation occurs within weeks; and replacement and contour modeling occur within years—up to 4 years in some cases.

Structure and Function of Joints

The site where two or more bones meet is called a **joint (articulation)** (Fig. 44.7). The primary function of joints is to provide stability and mobility to the skeleton. Whether a joint provides stability or mobility depends on its location and its structure. Generally, joints that stabilize the skeleton have a simpler structure than those that enable movement of the skeleton. Most joints provide stability and mobility to some degree (Fig. 44.8).

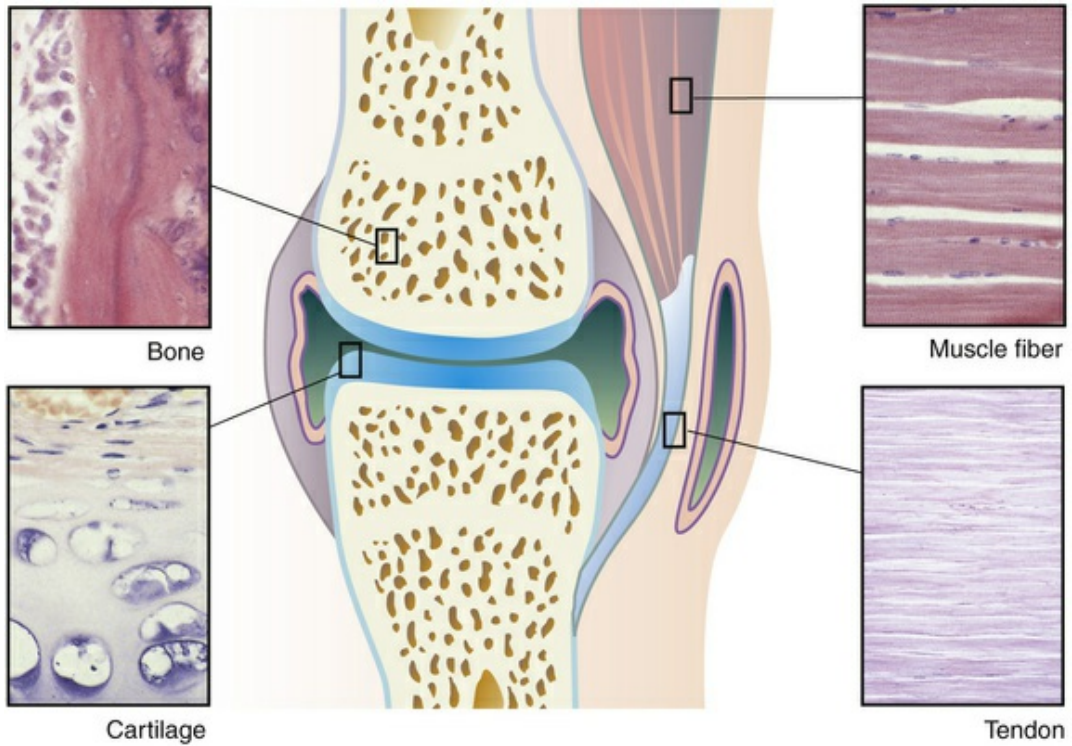

FIGURE 44.7 Main Tissues of a Joint. (Micrographs from Erlandsen SL, Magney JE: *Color atlas of histology*, St Louis, 1992, Mosby.)

FIGURE 44.8 Types of Joints. Cartilaginous (amphiarthrodial) joints, which are slightly movable, include (A) a synchrondrosis that attaches ribs to costal cartilage; (B) a symphysis that connects vertebrae; and (C) the symphysis that connects the two pubic bones. Fibrous (synarthrodial) joints, which are immovable, include (D) the syndesmosis between the tibia and fibula; (E) sutures that connect the skull bones; and the gomphosis (not shown), which holds teeth in their sockets. The synovial joints include (F) the spheroid type at the shoulder; (G) the hinge type at the elbow; and (H) the gliding joints of the hand.

Joints are classified based on the degree of movement they permit or on the connecting tissues that hold them together. Based on movement, a joint is classified as a **synarthrosis (immovable joint)**, an

amphiarthrosis (slightly movable joint), or a **diarthrosis (freely movable joint)**. On the basis of connective structures, joints are classified broadly as fibrous, cartilaginous, and synovial. Each of these three structural classifications can be subdivided according to the shape and contour of the articulating surfaces (ends) of the bones and the type of motion the joint permits.

Fibrous Joints

A joint in which bone is united directly to bone by fibrous connective tissue is called a **fibrous joint**. Generally, fibrous joints are synarthroses (immovable), but many fibrous joints allow some movement. The degree of movement depends on the distance between the bones and the flexibility of the fibrous connective tissue.

Fibrous joints are further subdivided into three types: sutures, syndesmoses, and gomphoses. A **suture** has a thin layer of dense fibrous tissue that binds together interlocking flat bones in the skulls of young children. Sutures form an extremely tight union that permits no motion. By adulthood the fibrous tissue has been replaced by bone. A **syndesmosis** is a joint in which the two bony surfaces are united by a ligament or membrane. The fibers of ligaments are flexible and stretch, permitting a limited amount of movement. The paired bones of the lower arm (radius and ulna) and the lower leg (tibia and fibula) and their ligaments are syndesmotic joints. A **gomphosis** is a special type of fibrous joint in which a conical projection fits into a complementary socket and is held there by a ligament. The teeth held in the maxilla or mandible are gomphosis joints.

Cartilaginous Joints

The two types of cartilaginous joints are symphyses and synchondroses. A **symphysis** is a cartilaginous joint in which bones are united by a pad or disk of fibrocartilage. A thin layer of hyaline cartilage usually covers the articulating surfaces of the two bones, and the thick pad of fibrocartilage acts as a shock absorber and stabilizer. Examples of symphyses are the symphysis pubis, which joins the two

pubic bones, and the intervertebral disks, which join the bodies of the vertebrae. A **synchondrosis** is a joint in which hyaline cartilage, rather than fibrocartilage, connects the two bones. The joints between the ribs and the sternum are synchondroses. The hyaline cartilage of these joints is called *costal cartilage*. Slight movement at the synchondroses between the ribs and the sternum allows the chest to move outward and upward during breathing.

Synovial Joints

Structure

Synovial joints (diarthroses) are the most movable and the most complex joints in the body (Fig. 44.9). A synovial joint consists of the following parts:

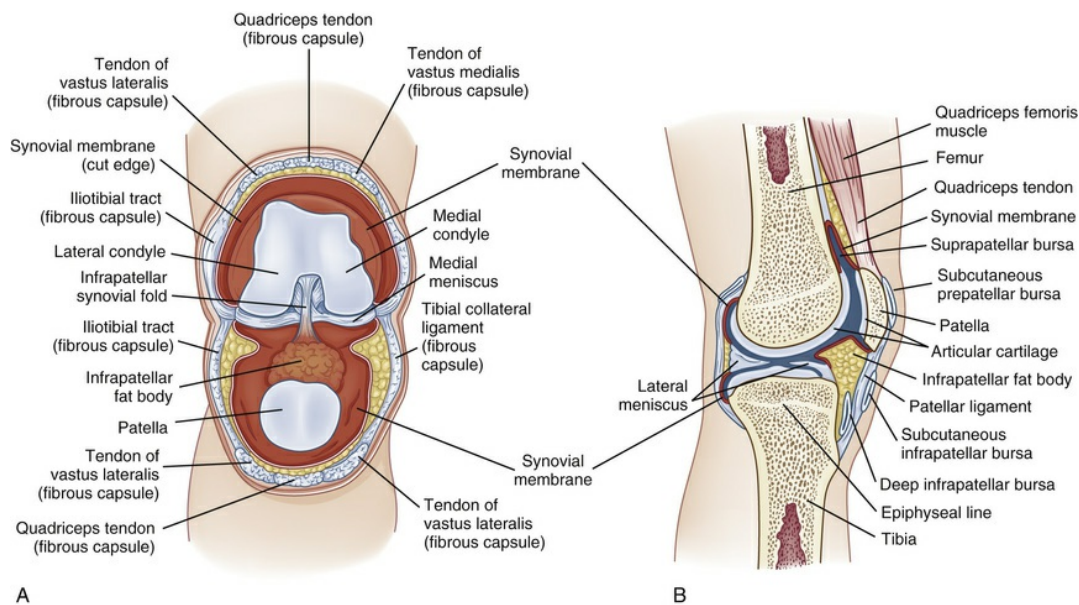

FIGURE 44.9 Knee Joint (Synovial Joint). A, Frontal view. B, Lateral view.

1. A fibrous joint capsule (articular capsule)
2. A synovial membrane that lines the inner surface of the joint capsule
3. A joint cavity (synovial cavity), a space formed by the capsule

4. Synovial fluid, which fills the joint cavity and lubricates the joint surface
5. Articular cartilage, which covers and pads the articulating bony surfaces

Joint Capsule.

The fibrous **joint capsule (articular capsule)** is connective tissue that covers the ends of the bones where they meet in the joint. Sharpey fibers firmly attach the proximal and distal capsules to the periosteum and ligaments and tendons, which also reinforce the capsule. The joint capsule consists of parallel, interlacing bundles of dense, white fibrous tissue. It is richly supplied with nerves, blood vessels, and lymphatic vessels. The nerves in and around the joint capsule are sensitive to the rate and direction of motion, compression, tension, vibration, and pain.

Synovial Membrane.

The **synovial membrane (synovium)** is the smooth, delicate inner lining of the joint capsule ([Fig. 44.10](#)). It lines the nonarticular portion of the synovial joint and any ligaments or tendons that traverse the joint cavity. It is made up of two layers—a vascular layer (**subintima**) and a thin cellular layer (**intima**). The vascular subintima merges with the fibrous joint capsule and is composed of loose fibrous connective tissue, elastin fibers, fat cells, fibroblasts, macrophages, and mast cells. The intima consists of rows of synovial cells embedded in a fiber-free intercellular matrix. The intima contains two types of synovial cells: type A and type B. **Type A synovial cells** ingest and remove bacteria and particles of debris by phagocytosis in the joint cavity. (Phagocytosis is described in [Chapter 7](#).) **Type B synovial cells** secrete **hyaluronate**, a binding agent that gives synovial fluid its viscous quality. The synovial membrane is richly supplied with blood and lymphatic vessels; therefore it is capable of rapid repair and regeneration.

FIGURE 44.10 Synovium. Note the delicate synovial lining resting on a fibroadipose subintimal lining rich in capillaries, lymphatics, and nerve endings. (Modified from Hochberg MC et al: *Rheumatology*, ed 4, Philadelphia, 2008, Mosby.)

Joint Cavity.

The **joint cavity (synovial cavity)** is an enclosed fluid-filled space between the articulating surfaces of the two bones. This small cavity, often called the *joint space*, enables the two bones to move “against” one another. The synovial cavity is surrounded by the synovial membrane and filled with a clear, viscous, slick fluid called the *synovial fluid*.

Synovial Fluid.

Synovial fluid is superfiltrated plasma from blood vessels in the synovial membrane. Synovial fluid lubricates the joint surfaces, nourishes the pad of the articular cartilage that covers the ends of the bones, and contains free-floating synovial cells and various leukocytes that phagocytize joint debris and microorganisms. Loss of synovial fluid leads to rapid deterioration of articular cartilage.

Articular Cartilage.

Articular cartilage is a layer of hyaline cartilage that covers the end of each bone (Fig. 44.11). It ranges from 2 to 5 mm thick, depending on

the size of the joint, the fit of the two bone ends, and the amount of weight and shearing force the joint normally withstands. Cartilage strength and its biologic properties are due to an extensive network of cross-linked collagen fibers. Fig. 44.12 illustrates how collagen cross-links form cartilage. The function of articular cartilage is to reduce friction in the joint and to distribute the forces of weightbearing. Articular cartilage is composed of **chondrocytes** (cartilage cells) (making up about 2% of the tissue) and an intercellular matrix made up of collagen (making up about 10% to 30% of weight), protein polysaccharides (making up 5% to 10% of weight), and water. The water content ranges from 60% to almost 80% of the net weight of the cartilage, and individual molecules rapidly enter or exit the articular cartilage to contribute to the resiliency of the tissue.

FIGURE 44.11 Collagen Zones. The three collagen zones (reserve, proliferative, and hypertrophic) are distinctly shown in a growth plate. (From Hjorten R et al: *Bone* 41[4]:535, 2007.)

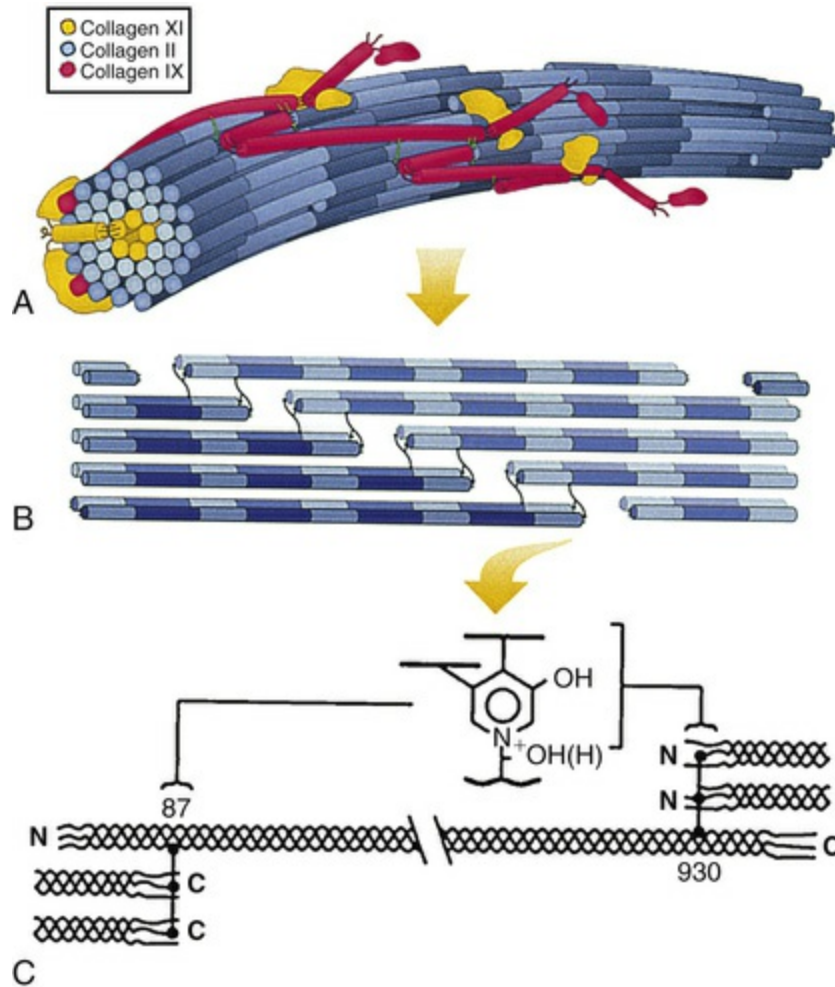

FIGURE 44.12 Heterotypic Collagen Fibril. Hierarchical depiction of heterotypic collagen fibril, emphasizing the internal axial relationships required for mature cross-link formation. A, Three-dimensional concept of the type II/IX/XI heterotypic fibril of developing cartilage matrix. B, Detail illustrating required nearest neighbor axial relationships for trifunctional intermolecular cross-links to form in collagens of cartilage, bone, and other high-tensile strength tissue matrices. The exact three-dimensional spatial pattern of cross-linking bonds is still unclear for any tissue. C, Detail of the axial stagger of individual collagen molecules required for pyridinoline cross-linking. (From Eyre DA, Weiss MA, Wu JJ: *Methods* 4[1]:65, 2008.)

The intercellular matrix is produced by the chondrocytes, which synthesize and extrude collagen that, like the collagen produced by bone cells, is distributed throughout the cartilage in a highly organized system of fibers. Collagen fibers in cartilage are made up of many fine fibrils that, like bone fibrils, are assembled in an orderly fashion that makes them resistant to physical, metabolic, or chemical breakdown. The main differences between bone collagen and cartilage

collagen are the amino acid content of the α chains and the composition of the fibrils. Bone collagen fibrils are made up of two type I chains and one type II chain. Approximately 90% of the cartilage collagen fibrils are made up of three identical type II chains, with the remaining 10% consisting of types V, VI, IX, X, and XI.

At the surface of articular cartilage, the collagen fibers run parallel to the joint surface and are closely compacted into a dense, protective mat. (Loss of this dense, compacted configuration at the surface subjects the underlying fibers to splitting and thinning, in which case the cartilage is unable to tolerate weightbearing.) In the middle layer (the proliferative zone) of the cartilage, the fibers are arranged tangential to the surface, which allows them to deform and absorb some of the force of weightbearing (see Fig. 44.11). In the bottom layer (the hypertrophic zone) of the cartilage, the fibers are perpendicular to the joint surface, allowing them to resist shear forces, and are embedded in a calcified layer of cartilage called the **tidemark**. The tidemark anchors the collagen fibers to the underlying (subchondral) bone and represents the zone between calcified and noncalcified cartilage. Collagen fibers are important components of the cartilage matrix because they account for approximately 60% of the dry weight and because they (1) anchor the cartilage securely to underlying bone, (2) provide a taut framework for the cartilage, (3) control the loss of fluid from the cartilage, and (4) prevent the escape of protein polysaccharides (proteoglycans) from the cartilage.

The proteoglycans are macromolecules consisting of proteins, carbohydrates (**glycosaminoglycans**), and hyaluronic acid. One subgroup of proteoglycans, known as *heparin sulfate proteoglycans* (*HSPGs*), binds to many proteins involved in musculoskeletal development and homeostasis, including FGF, BMPs, Wnts, chemokines, interleukins, and extracellular matrix (ECM) proteins.^{29,30} The glycosaminoglycans (keratan sulfate and chondroitin sulfate) are attached to the **protein core**, and several protein cores (with their attached glycosaminoglycans) are bound to a hyaluronic acid chain by a special protein called **link protein**. The proteoglycans give articular cartilage its stiff quality and regulate the movement of synovial fluid

through the cartilage. Without proteoglycans, normal weightbearing would rapidly and completely press all the synovial fluid out of the cartilage. Proteoglycans act as a pump, permitting enough fluid to be pressed out to ensure that a fluid film is always present on the surface of the cartilage, even after hours of weightbearing. The pumping action of proteoglycans also draws synovial fluid back into the cartilage after a weightbearing load is released. Mobility and weightbearing are necessary for the pumping action of proteoglycans to occur. Nonuse of a joint quickly reduces the pumping action, which changes the composition of the matrix and interferes with the nutrition of the chondrocytes.

Normal articular cartilage has no blood vessels, lymph vessels, or nerves. Therefore it is insensitive to pain and regenerates slowly and minimally after injury.^{31,32} Regeneration occurs primarily at sites where the articular cartilage meets the synovial membrane, where blood vessels and nutrients are available. In general, it has been difficult to enhance cartilage repair, but that may be changing.

Progress in Rebuilding Cartilage.

Although much research is needed, recent evidence suggests that mesenchymal stem cell therapies may be a potential solution to rebuilding articular cartilage.³³ Multipotent adult stem cells are largely available and accessible. It is theorized that bone marrow mesenchymal stem cells secrete proliferative and regenerative factors in the lesion site of articular cartilage (AC), thereby retarding osteoarthritis progression and promoting AC regeneration locally by trophic effects.³³⁻³⁵

Gene therapy (GT) also represents a novel approach to managing joint degradation. The principle of gene therapy is the overexpression of desired gene products. Gene therapy can support articular cartilage generation by targeting different genes involved in different cellular processes, such as inhibiting inflammatory and catabolic pathways, stimulating anabolic pathways, or preventing cell senescence and apoptosis.³³ Candidate transgene studies are currently in the exploratory phases, generally using animal models. Candidate

transgenes with antiinflammatory action include interleukin-1 (IL-1) receptor antagonist and soluble tumor necrosis factor (sTNF). Gene therapy strategies also may target the catabolic effect of matrix metalloproteinases by the delivery of tissue inhibitor of metalloproteinase.^{33,36-38}

The overexpression of growth factors has been shown to enhance matrix formation. TGF- β , in particular, was reported to aid cartilage regeneration and enhance meniscal tissue healing in vitro.³³ GT shows promise for the future; however, to ensure safety and efficacy, thorough evaluation of the technique is necessary.

Movement

Synovial joints are described as uniaxial, biaxial, or multiaxial according to the shapes of the bone ends and the type of movement occurring at the joint (Fig. 44.13). Usually one of the bones is stable and serves as an axis for the motion of the other bone. The body movements made possible by various synovial joints are either circular or angular (Fig. 44.14).

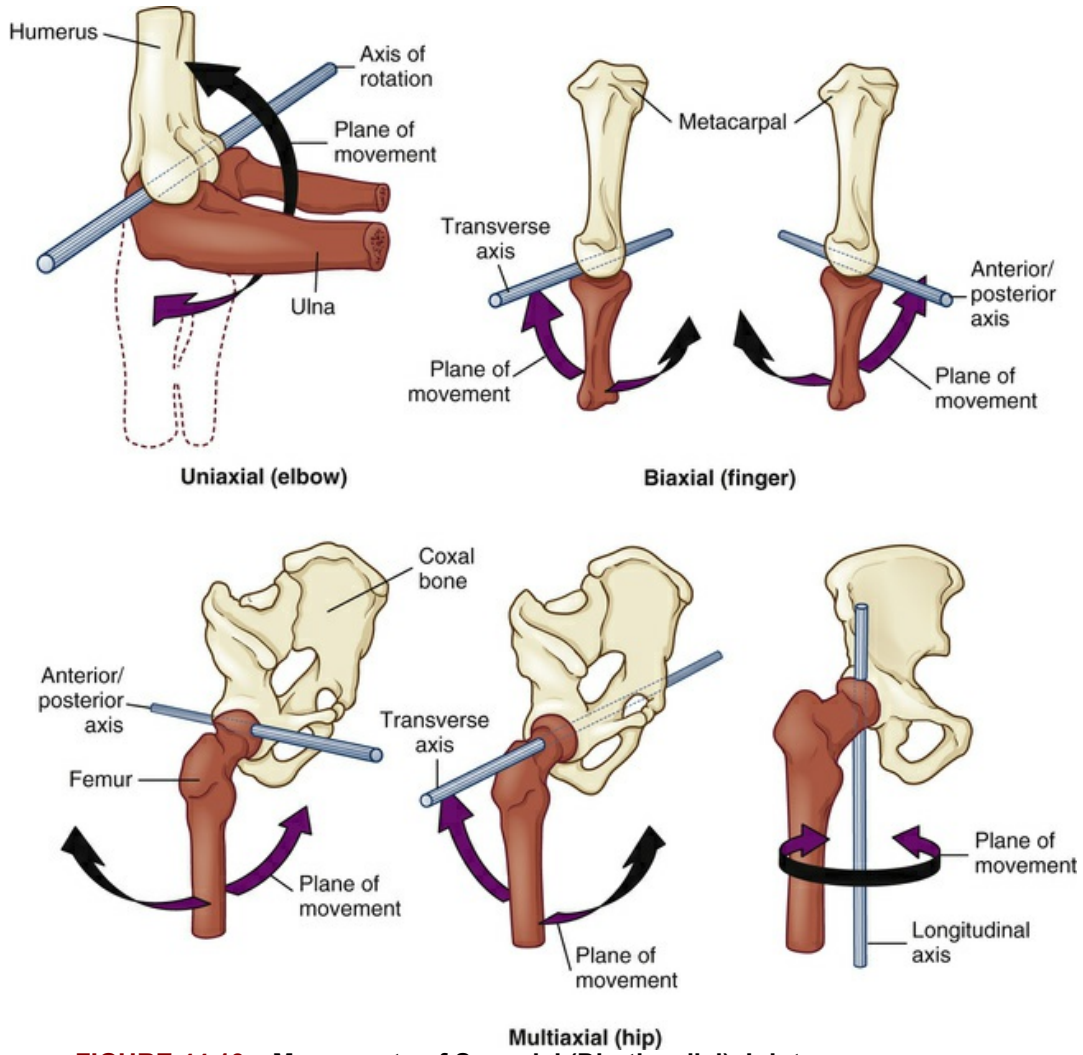

FIGURE 44.13 Movements of Synovial (Diarthrodial) Joints.

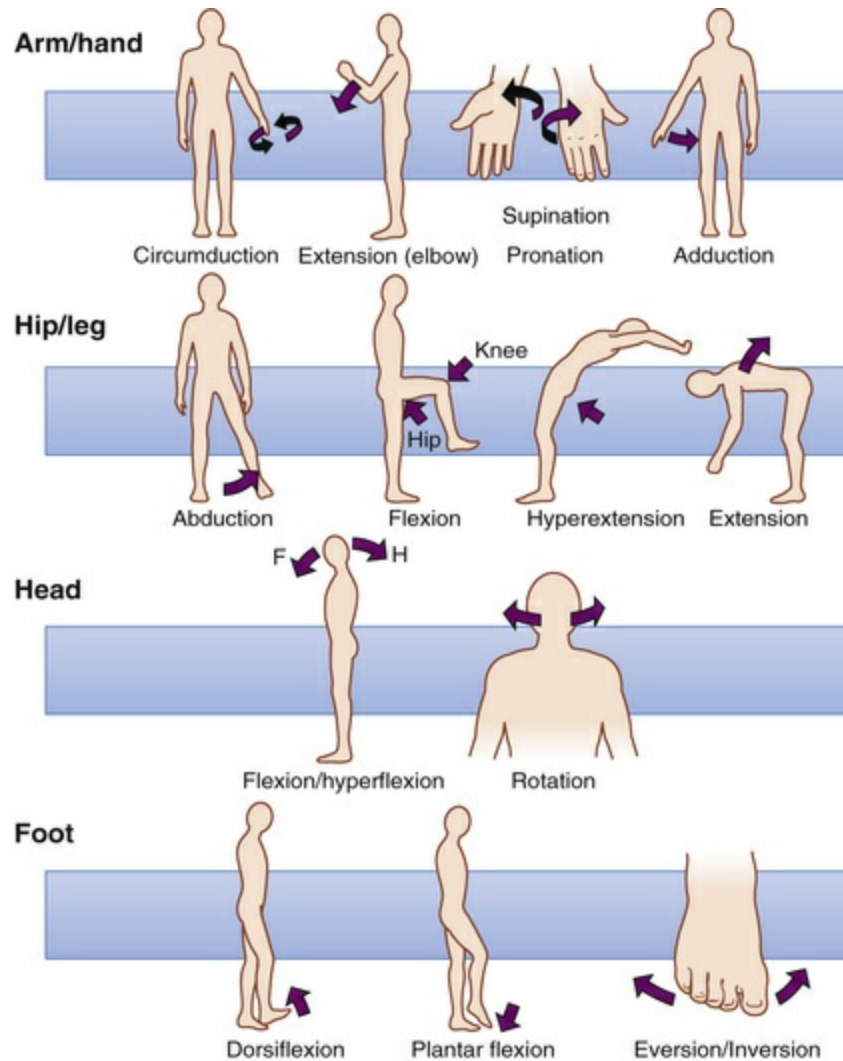

FIGURE 44.14 Body Movements Provided by Synovial (Diarthrodial) Joints.

Structure and Function of Skeletal Muscles

Skeletal muscles arise from mesodermal progenitor cells; the most numerous are the somites. Actual formation of skeletal muscle is a complex process controlled by multiple signaling factors. A critical component of successful embryonic muscle formation (myogenesis) is protein kinase, an enzyme that adds phosphate groups to substrate proteins, thereby directing cell processes.³⁹ In muscle, these factors

direct formation of myoblasts. Once myoblasts are formed, they fuse with other myoblasts and form myotubes, eventually developing into muscle fibers. At birth, the muscle fibers have completed development from myoblasts. Final muscle type is determined by transcription factors that regulate both pre- and postnatal muscle development.⁴⁰

All **voluntary muscles** are derived from the mesodermal layer of the embryo. Genetic transcription factors, most notably myoblast determination protein (MyoD), induce skeletal muscle differentiation. Myoblasts are the main cells responsible for muscle growth and regeneration. Myoblasts are termed *satellite cells* when in a dormant state and are crucial in muscle growth, maintenance, repair, and regeneration. Once muscle is injured, satellite cells become activated and increase the number of transcriptional factors necessary to form myoblasts and assist in repair.

Skeletal muscles are made up of millions of individual fibers that by the processes of contraction and relaxation do the work necessary to complete movements as varied as a ballerina's pirouette or an artist's deft stroke (Fig. 44.15). Muscle constitutes 40% of adults' body weight and 50% of children's body weight. Muscle is 75% water, 20% protein, and 5% organic and inorganic compounds; 32% of all protein stores for energy and metabolism is contained in muscle.

FIGURE 44.15 Skeletal Muscles of the Body. **A**, Anterior view. **B**, Posterior view.

Whole Muscle

There are more than 350 named muscles; almost all are paired. The body's muscles vary dramatically; they range from 2 to 60 cm in length and are shaped according to function.⁴¹ **Fusiform muscles** are elongated muscles shaped like straps and can run from one joint to another. **Pennate muscles** are broad, flat, and slightly fan shaped, with fibers running obliquely to the muscle's long axis. The multipennate deltoid muscle, which flexes and extends the arm, is a good example of a muscle shaped according to its function.

Each skeletal muscle is a separate organ encased in a three-part connective tissue framework called **fascia**. The layers of connective tissue protect the muscle fibers, attach the muscle to bony prominences, and provide a structure for a network of nerve fibers, blood vessels, and lymphatic channels.

The outermost layer, the **epimysium**, is located on the surface of the muscle and tapers at each end to form the **tendon** (Fig. 44.16).

Tendons allow a short muscle to exert power on a distant joint, whereas a thick muscle interferes with joint mobility. The next layer, the **perimysium**, further subdivides the muscle fibers into bundles of connective tissue, or **fascicles**. The **endomysium** surrounds the muscle fascicles, the smallest unit of muscle fibers visible without a microscope. The ligaments, tendons, and fascia are made up of connective tissue that also serves to buffer the limbs from the effects of sudden strains or changes in speed. The rapid recovery necessary for strenuous exercise is supported by the elastic property of muscle and its connective tissue.

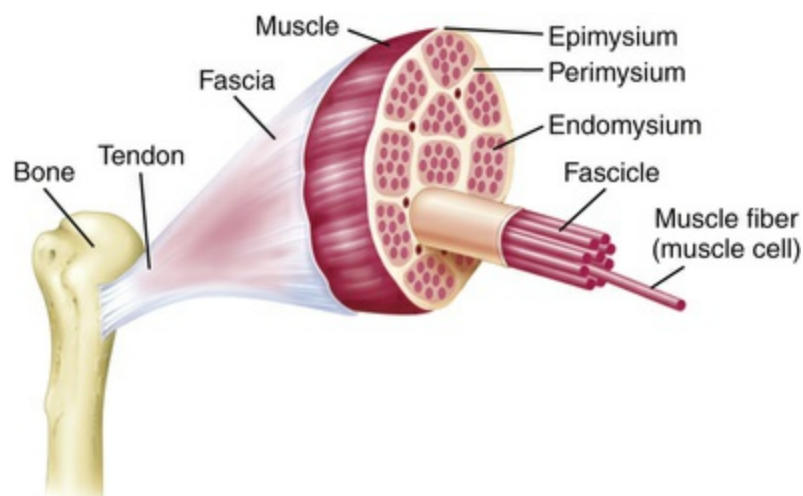

FIGURE 44.16 Cross Section of Skeletal Muscle Showing Muscle Fibers and Their Coverings. (Thibodeau GA, Patton KT: *Anatomy & physiology*, ed 5, St Louis, 2003, Mosby.)

Skeletal muscle is described, almost interchangeably, as **voluntary**, **striated**, or **extrafusal**. “Voluntary” indicates that the muscle is controlled directly by the central nervous system. “Striated” describes the striated, or striped, pattern of skeletal muscle viewed under a light microscope. The striations result from the organization of the muscle fibers into the contractile units called *sarcomeres*. “Extrafusal” distinguishes the skeletal muscle fibers from other contractile fibers located within the sensory organs of the muscle.

Other components that are visible on gross inspection of the whole muscle include the motor and sensory nerve fibers. These function

together with the muscle, innervating portions of it and providing the electrical impulses needed for motor function.

Motor Unit

From the anterior horn cell of the spinal cord, the axons of motor nerves branch out to innervate a specific group of muscle fibers. Each anterior horn cell, its axon (part of a lower motor neuron; see [Chapter 15](#)), and the muscle fibers innervated by it are called a **motor unit** ([Fig. 44.17](#)). The motor units are composed of lower motor neurons, which extend to skeletal muscles. Often termed the *functional unit* of the neuromuscular system, the motor unit behaves as a single entity and contracts as a whole when it receives an electrical impulse.

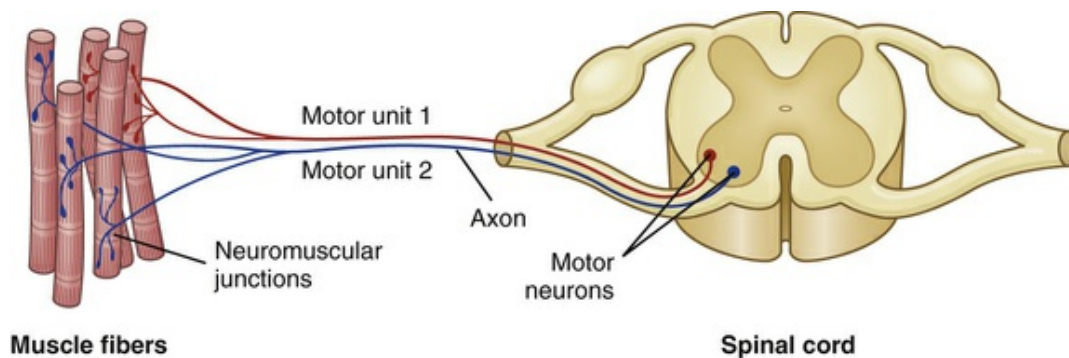

FIGURE 44.17 Motor Units of a Muscle. Each motor unit consists of a somatic motor neuron and all the muscle fibers (cells) supplied by the neuron and its axon branches.

The whole muscle may be controlled by several motor nerve axons. These branch out to innervate many motor units within the muscle. The whole muscle then may consist of many motor units. The number of motor units per individual muscle varies greatly. In the calf, for example, 1 motor axon will innervate approximately 2000 muscle fibers, out of a total of 1,200,000 muscle fibers. This is a high innervation ratio of muscle fibers to axons, and it contrasts markedly with the low innervation ratio in the laryngeal muscles, where two or three muscle fibers constitute each motor unit, and the innervation ratio can be of great functional significance. The greater the

innervation ratio of a particular organ, the greater its endurance. Higher innervation ratios prevent fatigue, and lower innervation ratios allow for precision of movement.

Sensory Receptors.

Although muscles function as effector organs, they also contain sensory receptors and are involved in sending different signals to the central nervous system. Among these are the muscle spindles and Golgi tendon organs. **Spindles** are mechanoreceptors that lie parallel to muscle fibers and respond to muscle stretching. **Golgi tendon organs** are dendrites that terminate and branch to tendons near the neuromuscular junction. Motor and sensory neurons secrete a proteoglycan called *neuregulin (NRG)* that increases the number of acetylcholine receptors and helps in the formation of muscle spindle fibers. Muscle spindles, Golgi tendon organs, and free nerve endings provide a means of reporting changes in length, tension, velocity, and tone in the muscle. This system of afferent signals is responsible for the muscle stretch response and maintenance of normal muscle tone.

Muscle Fibers.

Each **muscle fiber** is a single **muscle cell**. This long cell is cylindrical and surrounded by a membrane capable of excitation and impulse propagation. The muscle fiber contains bundles of **myofibrils**, the fiber's functional subunits, in a parallel arrangement along the longitudinal axis of the muscle (Fig. 44.18). At birth the muscle fibers have completed development from precursor cells called **myoblasts**. All voluntary muscles are derived from the mesodermal layer of the embryo.

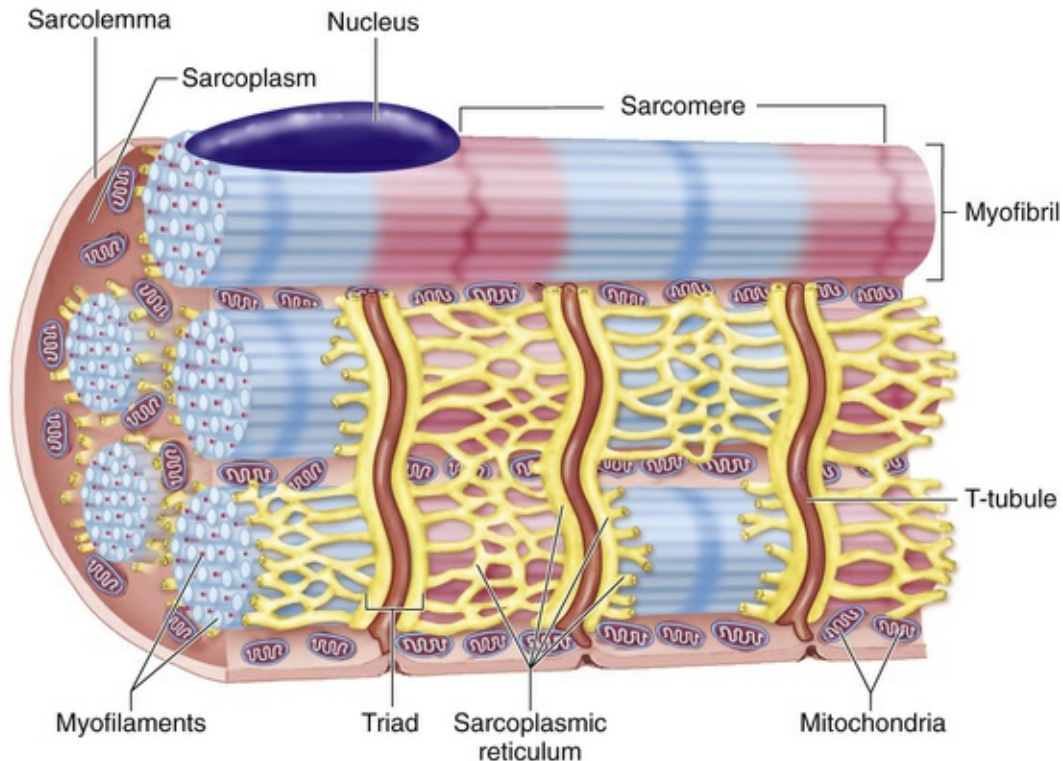

FIGURE 44.18 Myofibrils of a Skeletal Muscle Fiber (Cell) and Overall Organization of Skeletal Muscle. (Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

The type of peripheral nerve influences the muscle fiber and motor unit considerably; that is, the type of muscle fiber in the motor unit is determined by whether the motor nerve is fast or slow. Type II fibers, also called *white fast-motor fibers*, are innervated by relatively large type II alpha motor neurons with fast conduction velocities. These fibers rely on a short-term anaerobic glycolytic system for rapid energy transfer, whereas type I fibers depend on aerobic oxidative metabolism. Histochemical stains are now routinely used to describe the structure of muscle fibers and contractile elements of muscle biopsy specimens. White muscle (**type II fibers**) stains dark with the enzyme stain adenosinetriphosphatase (ATPase) at a pH of 9.4. Red muscle (**type I fibers**) appears lightly stained.

The overlap of muscle fibers that appear with staining gives the checkerboard appearance of muscle biopsy specimens and provides an equal distribution of fiber types throughout the muscle. This overlap also helps compensate for muscle fiber loss and fatigue of individual motor units during activity. In spite of this, some muscles

contain proportionally more of one fiber type than another. The postural muscles have more type I fibers, allowing them the high resistance to fatigue that is necessary to maintain the same position for extended periods. Ocular muscles have more type II muscle fibers, allowing them to respond rapidly to visual changes. (Table 44.7 describes the specific characteristics of type I and type II fibers.)

TABLE 44.7

CHARACTERISTICS OF MUSCLE FIBERS

CHARACTERISTIC	TYPE I (RED)	TYPE II (WHITE)
Anatomic location	Deep axial portion of surface muscle	Surface portion of surface muscle
Contraction speed	Slow	Fast
Motor neuron type	Type I, small alpha	Type II, large alpha
Firing frequency	Low, long duration	Rapid, short duration
Resistance to fatigue	High	Low
Myoglobin	High	Low
Capillary supply	Profuse	Intermediate to sparse
Metabolism	Oxidative	Glycolysis
Mitochondria	Many	Few
Enzymes	Lactate dehydrogenase, types 1 to 3	Lactate dehydrogenase, types 4 and 5
Creatine kinase	Cardiac type	Fast, skeletal
Example (most muscles are mixed)	Greater proportion of slow-contracting fibers in soleus	Greater proportion of fast-contracting fibers in laryngeal and ocular muscles
Glycogen content	Low	High
Intensity of contraction	Low	High
Aerobic metabolic capacity	High	Low
Fiber diameter	Small	Large
Myosin-adenosinetriphosphatase (ATPase) activity	Low	High

From Spence AP, Mason EE: *Human anatomy and physiology*, ed 4, St Paul, MN, 1992, West Publishing.

The number of muscle fibers varies according to location. Large muscles, such as the gastrocnemius, have more fibers (1,200,000) than smaller muscles, such as the lumbrical muscles in the hand (10,000). The diameter of muscle fibers also varies. The closely packed polygons are small (10 to 20 μm) until puberty, when they attain the normal adult diameter of 40 to 80 μm . Women usually have smaller-diameter fibers than men. Small muscles, such as the ocular muscles, are 15 μm in diameter; larger, more proximal muscles are 40 μm in diameter. Both fiber size and muscle length have functional significance. Studies have shown that larger fiber diameter is associated with generation of greater forces. Fiber diameter can be increased by activities that cause hypertrophied muscle, such as exercise or occupational overuse.

The major components of the muscle fiber include the muscle membrane, myofibrils, sarcotubular system, sarcoplasm, and mitochondria (Fig. 44.18). The **muscle membrane** is a two-part membrane. It includes the **sarcolemma**, which contains the plasma membrane of the muscle cell, and the cell's **basement membrane**. The sarcolemma is 7.5 μm thick and is capable of propagating electrical impulses to initiate contraction. At the motor nerve end plate, where the nerve impulse is transmitted, the sarcolemma forms the highly convoluted synaptic cleft. The sarcolemma is comprised of lipid molecules and protein systems. The protein systems perform special functions, such as transport of nutrients and synthesis of proteins. They also provide the sodium-potassium pump and include the cell's cholinergic receptor. The basement membrane is 50 μm thick and is composed primarily of proteins and polysaccharides. It serves as the cell's microkeleton and maintains the shape of the muscle cell. The basement membrane also may function in some way to restrict further diffusion of electrolytes once they have crossed the sarcolemma.

The **sarcoplasm** is the cytoplasm of the muscle cell and contains the intracellular components that are common to all cells (see Chapter 1). The sarcoplasm is an aqueous substance that provides a matrix that surrounds the myofibrils. It contains numerous enzymes and proteins that are responsible for the cell's energy production, protein synthesis,

and oxygen storage. The mitochondria house enzyme systems for energy production, particularly those that regulate such processes as the citric acid cycle and adenosine triphosphate (ATP) formation. Many other structures are present in the sarcoplasm. The ribosomes are composed primarily of ribonucleic acid (RNA) and participate in the process of protein synthesis. The cell nucleus, satellite cells, glycogen granules, and lipid droplets are suspended in the sarcoplasmic matrix. Blood vessels, nerve endings, muscle spindles, and Golgi tendon organs are also directly located within this structure.

Unique to the muscle is the **sarcotubular system**, a network that includes the transverse tubules and the sarcoplasmic reticulum, which crosses the interior of the cell. The **sarcoplasmic reticulum** is made in the same manner as the endoplasmic reticulum in other cells. In the muscle cells the sarcoplasmic reticulum is involved in calcium transport, which initiates muscle contraction at the **sarcomere**, a portion of the myofibril. The sarcoplasmic reticulum is composed of tubules that run parallel to the myofibrils. The longitudinal tubules are termed **sarcotubules**. The **transverse tubules**, which are closely associated with the sarcotubules, run across the sarcoplasm and communicate with the extracellular space. Together, the tubules of this membrane system allow for intracellular calcium uptake, regulation, and release during muscle contraction, and for the storage of calcium during muscle relaxation.

Myofibrils.

Myofibrils, the most abundant subcellular muscle components, are the functional units of muscle contraction. Each myofibril contains sarcomeres, which, in turn, consist of repeating protein filaments⁴² (see [Fig. 44.18](#)). Sarcomeres are chiefly composed of the proteins **actin**, **myosin**, **titin**, and **nebulin**. The sarcomere is responsible for converting chemical energy into movement.

On cross section they are irregular polygons with a mean diameter of less than 1 μm . Each myofibril is composed of serially repeating sarcomeres, separated by Z lines that give the muscle its striped,

cross-striated appearance. Each sarcomere has a dark A band and is flanked by two light I bands (Fig. 44.19). Titin functions as a molecular spring that plays a significant role in determining muscle stiffness and elasticity.⁴³ The A band is 1.5 to 1.6 μm long and contains thick myosin filaments. Included in the A band is a lighter zone called the *H band*, and in the center of the H band is the dark M band, or M line. The I band, which contains actin, is divided at the midpoint of each sarcomere by the Z line. Its length varies with the start of muscle contraction.

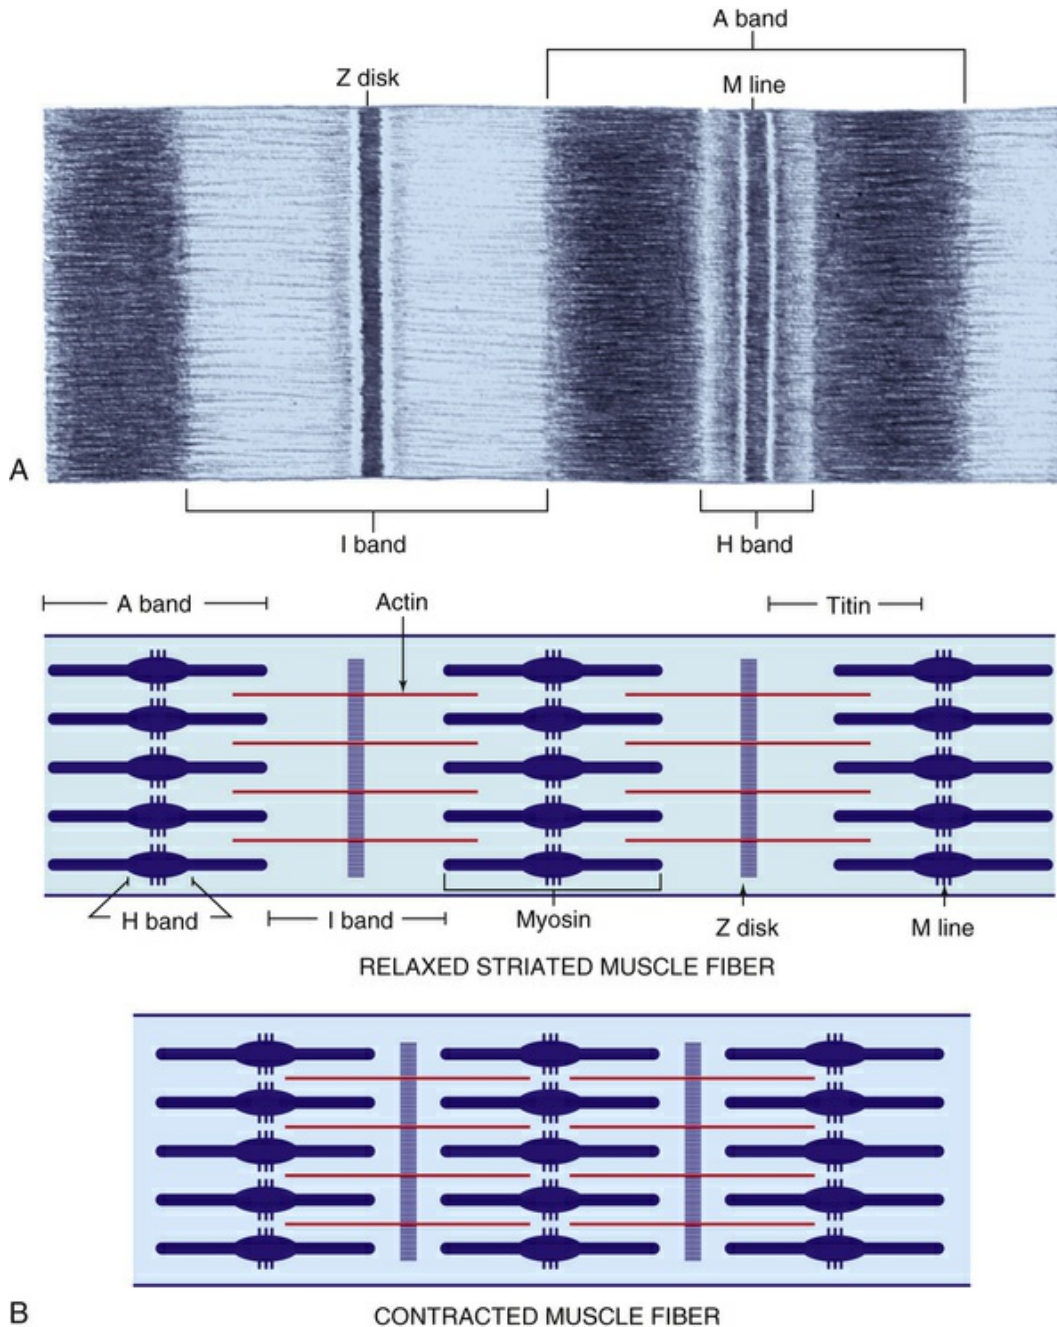

FIGURE 44.19 Muscle Fibers. **A**, The Z disks define the end of an individual sarcomere. The M line (which lies within the H band) is made of cross-connecting elements of the cytoskeleton. **B**, Actin is the primary protein of the I band (thin filament). Nebulin (not shown) also extends along the I band and contains binding sites for actin and myosin. Myosin (thick filament) extends through the A band. Titin extends from the Z disk to the M line, binding with myosin; strong titin anchoring within the I band is necessary for proper muscle function. During contraction, the I bands and H bands shorten, moving the Z disks closer together. (A modified from Thompson JM et al: *Mosby's clinical nursing*, ed 5, St Louis, 2002, Mosby.)

Myofibrils are composed of myofilaments. Each myofilament is structured in a closely packed hexagonal arrangement, with two thin filaments for every thick filament. The thick filament, along with C protein and M line protein, is made up of myosin. Myosin has two subunits, heavy and light meromyosin, which resemble twisted golf club shafts. The thin filaments are twisted double strands made up of actin, troponin, and tropomyosin (see [Chapter 32](#) and [Fig. 32.15](#)).

Muscle Proteins.

[Table 44.8](#) summarizes muscle protein distribution, location, and possible functional significance. The contractile and regulatory functions of actin, myosin, and the troponin-tropomyosin complex (associated with actin) are the most commonly known. They also account for most of the protein found in the myofibril. The structural and regulatory processes of muscle proteins are less well understood. Alpha actin and beta actin are known to link the filaments. M protein contains the enzyme creatine kinase (CK). Creatine is released when muscle cells are damaged, making the serum creatine value an important measurement of pathologic conditions of muscles.

TABLE 44.8

CONTRACTILE PROTEINS OF SKELETAL MUSCLE FIBRILS

NAME	APPROXIMATE PERCENTAGE OF MYOFIBRILLAR PROTEIN	LOCATION	FUNCTION
Myosin	55	A band (thick filament)	Contraction; hydrolyzes ATP and develops tension
Actin	20	I band (thin filament)	Contraction; activates myosin ATPase and interacts with myosin
Troponin	7	Thin filament	Regulatory protein; in presence of Ca^{++} , promotes actin-myosin activation
Tropomyosin	5-7	Thin filament	Regulatory and structural function; links filaments, controls filament length

Alpha (α) actin	10	Z band	Regulatory and structural function; links filaments, controls filament length
Beta (β) actin	2	Z band	Regulatory and structural function; links filaments, controls filament length
M protein	2	M line (center of thick filaments)	Regulatory and structural function; provides enzyme creatine kinase
C protein	2	A band (thick filaments)	Possible structural role
Titin	Unknown	Z line (thick filament)	Interconnects thin filaments in Z line
Creatine kinase	Unknown	M line	Catalyzes the phosphorylation of ADP to form ATP
Desmin	Unknown	Z line	Interconnects thin filaments in Z line
Filamin*	Unknown	Z line	Interconnects thin filaments in Z line; stabilizes membrane
Nebulin*	Unknown	Z line	Determines filament length

The most abundant proteins, actin and myosin, are also found in other cells, particularly motile cells such as platelets. The complete amino acid sequences of actin and myosin have been identified. Noteworthy is the presence of the amino acid 3-methylhistidine, found only in the thin filament, actin; 85% to 90% of 3-methylhistidine is found in skeletal muscle. The amino acids lysine and histidine, in addition to leucine, have been used to study protein synthesis by means of stable isotope infusion and muscle biopsy analysis.

Nonprotein Constituents of Muscle.

Nitrogen, creatine, creatinine, phosphocreatine, purines, uric acid, and

amino acids serve in the complex process of muscle metabolism. Phosphocreatine concentration is an extremely sensitive indicator of muscle fiber activity.⁴⁴ Glycogen and its derivatives are present as energy sources.

Creatine metabolism and creatinine metabolism have been used to measure muscle mass. Plasma creatine is taken up by muscle and converted into the high-energy phosphate compound *phosphocreatine* by the enzyme **creatine kinase**. Creatinine is formed in muscle from creatine at a constant rate of 2% per day. Creatine excretion is increased in muscle wasting. This change reflects the reduction in total body creatine stores and loss of muscle mass.

Inorganic compounds, anions (phosphate, chloride), and cations (calcium, magnesium, sodium, potassium) are important in regulating protein synthesis, muscle contraction, enzyme systems, and membrane stabilization. Intracellular calcium levels influence the force and duration of muscle contraction. Total body potassium (TBK) level, measured by the K_{40} method, has been used to measure muscle mass, also called *lean body mass*. TBK levels reflect changes in muscle mass seen during growth, malnutrition, and muscle wasting.

Components of Muscle Function

The ultimate function of muscle is to accomplish work. Although variously expressed in such measures as foot-pounds or kilogram-meters, work usually refers to the amount of energy liberated or force exerted over a distance (work = force \times distance). Muscles usually contract or tense while doing work. Muscle contraction occurs on the molecular level and leads to the observable phenomenon of muscle movement.

Muscle Contraction at the Molecular Level

Muscle contraction is a four-step process: excitation, coupling, contraction, and relaxation. The initial contraction process is the excitation-contraction coupling (ECC) series, which involves the electrical properties of all cells and the movement of ions across the

plasma membrane (see [Chapter 1](#)). At rest an electrical charge of -90 mV is continually maintained across the muscle sarcolemma. This resting potential, generated by the separation of positive and negative charges on either side of the membrane, creates an electrochemical equilibrium caused by the selective permeability of the sarcolemma to electrolytes in the intracellular and extracellular fluids, particularly potassium and sodium.

Specific intracellular receptors within the skeletal muscle sarcoplasmic reticulum, called **ryanodine receptors (RyRs)**, are the primary ion channels that control calcium release. RyRs are the largest known ion channels, allowing for rapid movement of calcium. Three RyRs have been identified: RyR1 is predominantly found in skeletal muscle; RyR2 is found mostly in cardiac muscle; and RyR3 is in the diaphragm, smooth muscle, and brain.⁴⁵⁻⁴⁷

Excitation, the first step of muscle contraction, begins with the spread of an action potential from the nerve terminal to the neuromuscular junction. The rapid depolarization of the membrane initiates an electrical impulse in the muscle fiber membrane called the **muscle fiber action potential**. As the action potential advances along the sarcolemmal membrane, it spreads to the transverse tubules (T-tubules). (The velocity of conduction is much slower in muscle fibers than in myelinated nerve fibers—only 3 to 5 m/second compared with 54 to 90 m/second in nerve fibers.)

The generated action potential then triggers voltage-sensitive receptors in the T-tubule wall; in turn, these receptors open the RyR channels, causing release of calcium from the sarcoplasmic reticulum.⁴⁵

Following depolarization of the T-tubules, the second stage, **coupling**, occurs. This stage consists of the migration of calcium ions to the myofilaments. Calcium affects troponin and tropomyosin, muscle proteins that bind with actin when the muscle is at rest. In the presence of calcium, however, both of these proteins are attracted to calcium ions, leaving the actin free to bind with myosin.

Contraction begins as the calcium ions combine with troponin, a reaction that overcomes the inhibitory function of the troponin-

tropomyosin system. The thin filament *actin* then slides toward the thick filament *myosin*. The two ends of the myofibril shorten after contraction when the myosin heads attach to the actin molecules, forming a cross-bridge that constitutes an actin-myosin complex. ATP, located on the actin-myosin complex, is released when the cross-bridges attach. This is the **sliding filament theory** and was first described by A. F. Huxley in the 1950s; however, it is now called the **cross-bridge theory** because of the formation of the actin-myosin cross-bridges. The process is so named because the actin actually slides onto the myosin, causing the sarcomere to shorten. The useful distance of contraction of a skeletal muscle is approximately 25% to 35% of the muscle's length. When actin and myosin filaments have maximal interactions, the muscle generates maximal force.⁴¹

The last step, **relaxation**, begins as the sarcoplasmic reticulum absorbs the calcium molecules, removing them from interaction with troponin. Calcium is pumped back into the sarcoplasmic reticulum by means of an active transport process. The cross-bridges detach, and the sarcomere lengthens. (The cross-bridge theory of muscle contraction is discussed in [Chapter 32](#).)

Muscle Metabolism

Skeletal muscle requires a constant supply of ATP and phosphocreatine. These substances are necessary to fuel the complex processes of muscle contraction, driving the cross-bridges of actin and myosin together and transporting calcium from the sarcoplasmic reticulum to the myofibril. Other internal processes of the muscular system that require ATP include protein synthesis, which replenishes muscle constituents and accommodates growth and repair. The rate of protein synthesis is related to hormone levels (particularly insulin), amino acid substrates, and overall nutritional status. At rest the rate of ATP formation by oxidation of glucose or acetoacetate is sufficient to maintain internal processes, given normal nutritional status. During activity the need for ATP increases 100-fold. The metabolic pathways for muscle activity in [Table 44.9](#) show reactions to the immediate need for increased ATP caused by contraction. Activity lasting longer than

5 seconds expends the available stored ATP and phosphocreatine.

TABLE 44.9

ENERGY SOURCES FOR MUSCULAR ACTIVITY

SOURCES	REACTIONS
Short-term (anaerobic) sources	Adenosine triphosphate (ATP) → Adenosine diphosphate (ADP) + Inorganic phosphate (Pi) + Energy
	Phosphocreatine + ADP ⇌ Creatine + ATP
	Glycogen/glucose + Pi + ADP → Lactate + ATP
Long-term (aerobic) sources	Glycogen/glucose + ADP + Pi + O ₂ → H ₂ O + CO ₂ + ATP
	Free fatty acids + ADP + Pi + O ₂ → H ₂ O + CO ₂ + ATP
	Creatine kinase catalyzes the reversible reaction of ATP to ADP: Creatine phosphate + ADP $\xrightleftharpoons{\text{Creatine kinase}}$ Creatine + ATP

From Spence AP, Mason EE: *Human anatomy and physiology*, ed 4, St Paul, MN, 1992, West Publishing.

Stored glycogen and blood glucose are converted anaerobically to sustain brief activity without increasing the demand for oxygen. Anaerobic glycolysis is much less efficient than aerobic glycolysis, using six to eight times more glycogen to produce the same amount of ATP. With increased activity, such as intense exercise, or ischemia, an increase in the level of lactic acid occurs because of the breakdown of glycogen, thus causing a shift in muscle pH (see [Table 44.9](#)). This short-term mechanism “buys time” by allowing ATP formation in spite of inadequate energy stores or oxygen supply. When the anaerobic threshold is reached and more oxygen is required, physiologic changes occur, including an increase in lactic acid concentration and increases in oxygen consumption, heart rate, respiratory rate, and muscle blood flow.

Strenuous exercise requires oxygen, which activates the aerobic glycogen pathway for ATP formation. During maximal exercise, free fatty acid mobilization and the aerobic glycogen pathways provide ATP over an extended time. These pathways require oxygen to maintain maximal activity and return the muscle to the resting state.

Maximal exercise increases oxygen uptake 15 to 30 times over the resting state.⁴⁸ When this system becomes exhausted or unable to respond to the need for ATP, fatigue and weakness finally force the muscle to reduce activity, with a resultant buildup of lactic acid in muscle fibers.

The ability to sustain maximal muscular activity leads to the accumulation of oxygen debt. **Oxygen debt** is the amount of oxygen needed to convert the buildup of lactic acid to glucose and replenish ATP and phosphocreatine stores. For example, after running at maximal speed for 10 seconds, the average person has consumed 1 L of oxygen. At rest, oxygen consumption for the same period is approximately 40 mL. As the person recovers, the measured oxygen debt is 4 L greater than the amount used during activity.

Oxygen consumption is measured to calculate the metabolic cost of activity in normal and diseased muscle. It is an indirect measure of energy expenditure, along with timed tests of activity, heart rate, and respiratory quotient (ratio of carbon dioxide to expired oxygen consumed). Energy expenditure is measured directly by heat production because heat is released whenever work is accomplished.

Another factor that changes energy requirements is muscle fiber type. Type II fibers rely on anaerobic glycolytic metabolism and fatigue readily. Type I fibers can resist fatigue for longer periods because of their capacity for oxidative metabolism.

Muscle Mechanics

Muscle contraction cannot be viewed in isolation. Several factors determine how force is transmitted from the cross-bridges on individual muscle fibers to accomplish whole-muscle contraction. First, when a motor unit responds to a single nerve stimulus, it develops a phasic contraction, also called *twitch*. Because the motor unit contracts in an “all or nothing” manner, the contraction that is generated will be a maximal contraction. The central nervous system smoothly grades the force generated by “recruiting” additional motor units and varying the discharge frequency of each active motor unit. This adding of motor units within the muscle is called **repetitive**

discharge.

Recruitment and repetitive discharge of motor units allow the muscle to activate the number of motor units needed to generate the desired force. The total force developed is the sum of the force generated by each motor unit. As the strength, speed, and duration of stimuli increase, the summation of contractions reaches a critical frequency called **tetanus**. When tetanus is reached, no further increase in force can be achieved.

Other variables, such as fiber type, innervation ratio, muscle temperature, and muscle shape, influence the efficiency of muscular contraction. The two muscle fiber types differ in their responses to electrical activity. Tetanus and duration of phasic contractions, which take microseconds to accomplish, are achieved more rapidly in type II than in type I muscle fibers. Low-innervation ratios promote control and coordination, whereas high ratios promote strength and endurance. Muscles work best at normal body temperature (37°C [98.6°F]). Finally, muscles with a large cross-sectional area, such as the fan-shaped pennate muscles, develop greater contractile forces than smaller-diameter muscles. The initial length of a muscle and the range of shortening that occur when the muscle contracts also determine the forces it can generate. The long fusiform muscles have a greater range of shortening and can contract up to 57% of their resting length. A certain amount of elongation is necessary to generate sufficient tension and muscular force. The elongation that occurs during the swing of a golf club or tennis racquet is an example of how stretch improves contractile force.

Types of Muscle Contraction

During **isometric contraction (static or holding contraction)**, the muscle maintains constant length as tension is increased. Isometric contraction occurs, for example, when the arm or leg is pushed against an immovable object. The muscle contracts, but the limb does not move.

During dynamic contraction, formerly known as *isotonic contraction*, the muscle maintains a constant tension as it moves. The terms

“eccentric” for lengthening and “concentric” for shortening are technically inaccurate descriptions of muscle movement; the respective terms “lengthening” and “shortening” are more precise. Positive work is accomplished during shortening, and energy is released to exert force or lift a weight. In contrast, during lengthening the muscle lengthens and absorbs energy. Negative work is accomplished on the muscle by the load. Lengthening requires less energy to accomplish and may result in the development of pain and stiffness after unaccustomed exercise.

Movement of Muscle Groups

Muscles do not act alone but rather in groups, often under automatic control. When a muscle contracts it acts as a “prime mover,” or **agonist**, and its reciprocal muscle, or **antagonist**, relaxes. This is easily tested by holding the right arm in the horizontal position in front of the body and then bending the elbow while feeling the upper arm, biceps in the front and the triceps in the back, with the other hand. The biceps is firm, and the triceps is soft. As the arm is extended, the muscles change. When the elbow is completely extended, the biceps is soft and the triceps firm. Completing this movement causes the agonist and antagonist to change automatically; only the movement is commanded, not the alternate contraction and relaxation of the specific muscle groups.

Other associated actions may be seen during walking; as the foot leaves the ground, the paravertebral and gluteal muscles on the opposite side of the body contract to maintain balance. One notices the loss of the associated muscle's action when paralysis offsets this process and decreases balance. If a person is paralyzed, difficulty in maintaining balance is noticeable.

Tests of Musculoskeletal Function

Tests of Bone Function

Diagnostic procedures to evaluate bone function include gait analysis,

measurement of serum calcium and phosphorus levels, and imaging studies. Most imaging techniques provide morphologic rather than functional information about bone. Plain radiographs (x-rays) remain the standard initial imaging tool for bone evaluation because bone absorbs x-ray beams better than soft tissue. Computed tomography (CT) provides multiple images that are then processed into single (two-dimensional) or multiple images taken around a single axis to form (three-dimensional) pictures. Dual-energy computed tomography (DECT) utilizes x-ray beams at two different energy levels to determine different chemical compositions of tissues, thereby expanding CT imaging to include soft tissues, bone marrow, and crystals.⁴⁹ Advances in CT technology allow for detailed visualization of bone microstructure.⁵⁰

Magnetic resonance imaging (MRI) provides detailed anatomic information and is useful for evaluating primary or metastatic bone lesions, infection, marrow edema, bony erosions, osteonecrosis, fractures, and other pathologic changes of bone. Magnetic resonance arthrography (MRa) involves injection of a contrast agent into the area of interest but allows better visualization of small abnormalities. Detailed functional imaging of bone can be attained with positron emission tomography (PET) scanning. A relatively new technology, MRI-PET combines MRI with functional imaging of molecular events seen with PET.

Nuclear medicine studies also provide imaging about metabolic activity in bone and soft tissue. After a small amount of radioactive tracer is injected, a special camera is used to identify bone absorption of the tracer. Bone scanning is very sensitive, but not specific about the cause of increased metabolic activity.

Dual-photon absorptiometry (DXA) is often used to measure the density of bones in the extremities and the fracture risk of vertebral bodies, femoral neck, and distal radius. Dual-photon absorptiometry allows the soft tissue components to be subtracted. New technology promises more accurate evaluation of bone.

Serum bone-specific alkaline phosphatase (BAP) is a marker of bone formation. Bone resorption is evaluated with urinary and serum

measurements of cross-linked N-terminal telopeptides (NTx), a product of osteoclast bone resorption. NTx is specific for bone because the cross-links assessed are characteristic of bone collagen alone. Urine NTx is a more sensitive and specific biochemical marker of bone resorption than serum NTx.^{51,52}

Tests of Joint Function

Procedures used to diagnose joint function include arthrography, arthroscopy, magnetic resonance imaging, and synovial fluid analysis. **Arthrography** (the injection of dye into the joint) is particularly useful to diagnose tears in the fibrocartilage of the knee (meniscus) and the rotator cuff of the shoulder. **Arthroscopy** is the direct visualization of a joint through an arthroscope. **Magnetic resonance imaging (MRI)** produces images of body tissues through the use of electromagnetic (radio) waves that alter the atoms (hydrogen ions) in the nuclei of cells being examined. When the polarized radio waves are stopped, the nuclear atoms return to their original positions, emitting energy as signals as they move back. The signals produce visible images for examination and diagnosis. MRI produces excellent contrast of soft tissues for evaluation of musculoskeletal conditions. Magnetic resonance arthroscopy (MRa) is injection of contrast into a joint, followed by MRI evaluation.

Analysis of synovial fluid may reveal inflammatory, septic, and noninflammatory joint diseases, which cause characteristic changes in the color, clarity, viscosity, and cellular elements of the fluid. The presence of blood in the joint fluid (hemarthrosis) usually indicates joint trauma. Normal synovial fluid is sterile, so the presence of bacteria in the fluid always indicates disease. Cell fragments and fibrous tissue in the fluid are the result of inflammation or wear-and-tear on the articular surfaces.

Tests of Muscular Function

When the individual's history and physical examination disclose abnormalities, such as weakness, atrophy, muscle tenderness, cramps,

and stiffness, specific tests of muscle function are in order. One of the most useful tests is the serum creatine kinase (CK) concentration. CK is found in large quantities in the muscle fibers, and when these fibers are diseased or damaged, CK leaks into the serum. Myoglobin is also detectable in the urine after acute muscle damage caused by crush injury, ischemic disorders, extreme exertion, and some inherited diseases.

Because the muscle membrane tissue is excitable and carries an electrical charge, its capacity to function can be assessed by electromyography. Using sensitive needle electrodes, the **electromyogram (EMG)** records the summation of action potentials of the muscle fibers in each motor unit. The EMG is often compared with the electrocardiogram (ECG), but the activity recorded on the EMG is on a much smaller scale. The amplitude of the ECG is measured in volts, the duration of impulse is recorded in seconds, and both are recorded as the heart rate (e.g., 80 V/60 seconds). EMG amplitude is recorded in millivolts and the duration is measured in milliseconds, with a frequency of about 5 to 50 action potentials per second. Motor unit potentials are measured to determine rate of firing, duration, and amplitude. Abnormalities in EMG and nerve conduction velocities help differentiate muscle diseases (myopathy) from peripheral nerve (neuropathy) and neuromuscular junction disorders. The muscle biopsy (using histologic, histochemical, and electron microscopic studies) is used to further define the presence of myopathic and neuropathic disorders, many of which can be diagnosed only by muscle biopsy. Complex myography, a relatively new technique, allows a noninvasive way to gather information on the mechanical characteristics of muscle.

A new area of evaluation is genetics. Recent advances in molecular genetics, deoxyribonucleic acid (DNA) libraries, genetic probes, and gene localization techniques have enhanced the knowledge of neuromuscular diseases, including types of muscular dystrophy, Charcot-Marie-Tooth disease, and familial amyotrophic lateral sclerosis.

Aging and the Musculoskeletal System

Aging of Bones

Aging is accompanied by the loss of bone tissue. Bones become less stiff, less strong, and more brittle with aging. The bone remodeling cycle takes longer to complete, and the rate of mineralization also decelerates. Studies have shown that an individual's bone mass at the end of the growth period helps determine the significance of bone loss as the person ages. With aging, women experience loss of bone density, accelerated by rapid bone loss during early menopause from increased osteoclastic bone resorption, fewer osteocytes, and decreased numbers of osteoblasts.⁵³ By age 70 years, susceptible women have, on average, lost 50% of their peripheral cortical bone mass.¹ Bone mass loss to this extent can lead to deformity, pain, stiffness, and high risk for fractures. Men also experience bone mass loss but at later ages and much slower rates than women. Also, peak bone mass in men is higher than that in women. Therefore bone loss in men causes less risk of disability than for women.⁵⁴ In general, age-related bone loss is caused by genetics, hormonal factors (decreased estrogen and estradiol levels), decreased bone formation, vitamin and mineral deficiencies (vitamin D, magnesium, and calcium), underlying conditions (malignancy, autoimmune diseases, hyperthyroidism), and lifestyle choices (physical inactivity, smoking, certain medications, and alcohol intake). Men's peak bone mass is related to race, heredity, hormonal factors (testosterone and estradiol levels), physical activity, and calcium intake during childhood.⁵⁵ Height also is lost with aging because of intervertebral disk degeneration and, sometimes, osteoporotic spinal fractures.

Bone mass can be gained in healthy young women up to the third decade through physical activity and intake of dietary calcium and magnesium. In postmenopausal women, aerobic exercises and strength training in particular have proven to be effective in improving and maintaining bone mass during the aging process.^{56,57} In addition to the positive effects of exercise on bone mineral density (BMD), exercise has been shown to improve balance, coordination,

muscle strength, lean body mass, and mobility, all of which may decrease the incidence of falls.^{58,59}

Aging of Joints

With aging, cartilage becomes more rigid, fragile, and susceptible to fraying because of increased cross-linking of collagen and elastin, decreased water content in the cartilage ground substance, and decreased concentrations of glycosaminoglycans. Changes in collagen result in cartilage calcification and muscle stiffness. Decreased range of motion of the joint is related to the changes in ligaments and muscles. Bones in joints develop evidence of osteoporosis with fewer trabeculae and thinner, less dense bones, making them prone to fractures. Intervertebral disk spaces decrease in height.

Aging of Muscles

The function of skeletal muscle depends on many factors that are affected by aging, including the nervous, vascular, and endocrine systems. Mitochondrial dysfunction within cells contributes to oxidative stress and results in increased bone resorption and apoptosis of muscle cells.^{60,61} In the young child, development of muscle tissue is highly dependent on continuing neurodevelopmental maturation. Muscle function remains trainable even into advanced age. Muscle diseases have a definite association with specific age groups. Muscular dystrophies occur in children, and muscle disabilities related to rheumatic diseases usually occur in advancing age.

Age-related loss in skeletal muscle is referred to as **sarcopenia** and is a direct cause of the age-related decrease in muscle strength. By 50 years of age, approximately 10% of muscle area is lost.⁶² Parallel to sarcopenia, muscle strength declines by 15% per decade in the sixties and seventies and doubles to 30% after 80 years of age.⁶² As the body ages, muscle bulk and strength decline slowly, beginning as early as age 50, with loss of about 1% per year thereafter. Muscle strength declines faster than muscle mass.⁶¹ Type II fibers decrease to a greater

extent than the slower-acting type I fibers. Loss of satellite cells appears to play a major role in the development of sarcopenia. Although muscle's regenerative function remains largely intact, satellite cell numbers are decreased.⁶³ Reduced RNA synthesis, loss of mitochondrial volume, shortening of telomeres, and reduction in the size of motor units contribute to sarcopenia. As much as 30% to 40% of skeletal muscle mass and strength may be lost from the third to ninth decades.

Maximal oxygen intake decreases with age. Reduced basal metabolic rate and decreased lean body mass are also seen in the older adult population.

Summary Review

Structure and Function of Bones

1. Bones provide support and protection for the body's tissues and organs and are important sources of minerals and blood cells.
2. Bone formation begins during embryonic development with the differentiation of mesenchymal cells into either chondrocytes or preosteoblasts. Bone minerals then either crystallize on a cartilage framework or become bone-forming cells without cartilage.
3. Bone tissue is continuously being resorbed and synthesized by bone-remodeling units of osteoclasts and osteoblasts.
4. RANKL induces osteoclast activation and bone resorption. OPG, a protein, binds to a protein called *OPG ligand*. This attachment serves as a decoy receptor for RANKL and blocks osteoclast activity, thus decreasing bone resorption. The balance between RANKL and OPG determines the quality of bone.
5. Bones in the body are made up of compact bone tissue and spongy bone tissue. Compact bone is highly organized into haversian systems that consist of concentric layers of

crystallized matrix surrounding a central canal that contains blood vessels and nerves. Dispersed throughout the concentric layers of crystallized matrix are small spaces containing osteocytes. Smaller canals, called *canaliculi*, interconnect the osteocyte-containing spaces. The crystallized matrix in spongy bone is arranged in bars or plates. Spaces containing osteocytes are dispersed between the bars or plates and interconnected by canaliculi.

6. BMPs are part of the TGF- β superfamily and are involved in multiple crucial functions in the skeletal system.
7. There are 206 bones in the body, divided into the axial skeleton and the appendicular skeleton. Bones are classified by shape as long, short, flat, or irregular. Long bones have a broad end (epiphysis), broad neck (metaphysis), and narrow midportion (diaphysis) that contains the medullary cavity.
8. Bone injuries are repaired in stages. Hematoma formation provides the fibrin framework for formation and organization of granulation tissue. Granulation tissue provides a cartilage model for the formation and crystallization of bone matrix. Remodeling restores the original shape and size to the injured bone.

Structure and Function of Joints

1. A joint is the site of attachment of two or more bones. Joints provide stability and mobility to the skeleton.
2. Joints are classified as synarthroses, amphiarthroses, or diarthroses, depending on the degree of movement they allow. Joints also can be classified by the type of connecting tissue holding them together. Fibrous joints are connected by dense fibrous tissue, ligaments, or membranes. Cartilaginous joints are connected by fibrocartilage or hyaline cartilage. Synovial joints are connected by a fibrous joint capsule. Within the capsule is a small fluid-filled space. The fluid in the space nourishes the articular cartilage that covers the ends of the

- bones meeting in the synovial joint.
3. Articular cartilage is a highly organized system of collagen fibers and proteoglycans. The fibers firmly anchor the cartilage to the bone, and the proteoglycans control the loss of fluid from the cartilage.
 4. Joints help move bones and muscle.

Structure and Function of Skeletal Muscles

1. Skeletal muscle is the largest organ in the body and is made up of millions of individual fibers.
2. Whole muscles vary in size (2 to 60 cm in length) and shape (fusiform and pennate). Each skeletal muscle is encased in a three-part connective tissue framework. The fundamental concept of muscle function is the *motor unit*, defined as all muscle fibers innervated by a single motor nerve.
3. Muscle fibers contain bundles of myofibrils arranged in parallel along the longitudinal axis and include the muscle membrane, myofibrils, sarcotubular system, aqueous sarcoplasm, and mitochondria. There are two types of muscle fibers, type I and type II, determined by motor nerve innervation.
4. Myofibrils and myofilaments contain the major muscle proteins actin and myosin, which interact to form cross-bridges during muscle contraction. The nonprotein muscle constituents provide an energy source for contraction and regulate protein synthesis, enzyme systems, and membrane stabilization.
5. Muscle contraction includes excitation, coupling, contraction, and relaxation.
6. Muscle strength is graded by the “all or nothing” phenomenon and recruitment. Speed of contraction is affected by several factors: muscle fiber type, temperature, stretch, and weight of the load.
7. The two types of muscle contraction are isometric and isotonic.

Muscle shortening occurs during contraction but can be seen also during pathologic and physiologic contracture.

8. Actin and myosin filaments form cross-bridges that cause the sarcomere to shorten, a process now known as the *cross-bridge theory of muscle contraction*.
9. Skeletal muscle requires a constant supply of ATP and phosphocreatine to fuel muscle contraction and for growth and repair. ATP and phosphocreatine can be generated aerobically or anaerobically. Phosphocreatine concentration is an extremely sensitive indicator of muscle fiber activity.
10. Several factors determine how force is transmitted from the actin-myosin cross-bridges on individual muscle fibers to accomplish whole-muscle contraction. When a motor unit responds to a single nerve stimulus, it develops a phasic contraction. The central nervous system smoothly grades the force generated by “recruiting” additional motor units and varying the discharge frequency of each active motor unit.

Tests of Musculoskeletal Function

1. Procedures used to evaluate bone function include analysis of gait, evaluation of urinary bone resorption markers, measurement of serum calcium and phosphorus levels and serum bone-specific alkaline phosphatase (BAP) level, x-ray films, angiography, bone scanning, and MRI.
2. Procedures used to evaluate joint function include arthrography, arthroscopy, MRI, and synovial fluid analysis.
3. Serum creatine kinase concentration is useful in detecting muscle damage. Electromyography is used to assess the muscle membrane's capacity to function. Genetic evaluation is useful in detecting, diagnosing, and developing specific treatment for certain inheritable muscle diseases such as muscular dystrophy.

Aging and the Musculoskeletal System

1. Muscle bulk and strength slowly decline with aging, although not to a pathologic degree. The bone remodeling cycle takes longer to complete, and the rate of mineralization slows.
2. Exercise in older adults improves muscle strength, helps increase bone mineral density, and improves balance, coordination, lean body mass, and mobility.
3. Age-related loss in skeletal muscle is referred to as *sarcopenia*. Loss of satellite cells appears to play a major role in the development of sarcopenia.

Inflammatory Muscle Diseases: Myositis, 1463

Myopathy, 1464

Muscle Tumors, 1464

The musculoskeletal system is comprised of the bones, muscles, cartilage, tendons, ligaments, and other connective tissues. This system provides structure, support, stability, and movement to the body. Injuries to the musculoskeletal system include fractures (traumatic and nontraumatic), dislocations, sprains, and strains. Additionally, alterations in bones, joints, and muscles may be caused by metabolic disorders, infections, inflammatory or noninflammatory diseases, or tumors. The most common disease affecting bones is osteoporosis and the incidence increases with age.¹

Musculoskeletal Injuries

Trauma has been termed “the neglected disease of modern society.”² Unintentional traumatic injuries are the number one cause of death for people ages 1 to 44.³ Fractures are most commonly caused by falls, car accidents, and athletic injuries. For those who survive traumatic injuries, the impact is significant. Injury affects their families, and impacts society because of related loss or limitation of daily activities and mobility, pain, and a decreased quality of life. Significant direct care costs are associated with diagnosis and treatment; indirect care costs are related to time away from work, loss of employment, and decreased productivity. Several national organizations in the United States are collaborating to develop a centralized national resource for injury prevention.⁴

Skeletal Trauma

Fractures

A **fracture** is a break in the continuity of a bone. A break occurs when force is applied that exceeds the tensile or compressive strength of the bone. Fracture incidence varies depending on the bone involved, age, and gender. The highest incidence of fractures occurs in young males ages 15 to 24 and in adults 65 years and older. Rates of hip and wrist fractures tended to be higher in women. An estimated 158 million hip fractures occurred worldwide in 2015; this number is expected to

increase to 316 million by 2040.⁵

Classification.

Fractures are classified as complete or incomplete and open or closed (Fig. 45.1). In a **complete fracture**, the integrity of the bone is broken into two pieces, whereas in an **incomplete fracture** the bone is damaged but still in one piece. Complete or incomplete fractures are further classified as open or closed. An **open fracture**, formerly referred to as a *compound fracture*, is characterized by a concurrent break in the skin in the area of the fracture. A **closed fracture**, formerly referred to as a *simple fracture*, has no break in the surrounding skin. Fractures are classified according to the direction of the fracture line. A **linear fracture** runs parallel to the long axis of the bone. An **oblique fracture** is a slanted fracture of the shaft of the bone. A **spiral fracture** encircles the bone, and a **transverse fracture** occurs straight across the bone. A fracture in which a bone breaks into more than two fragments is termed a **comminuted fracture**.

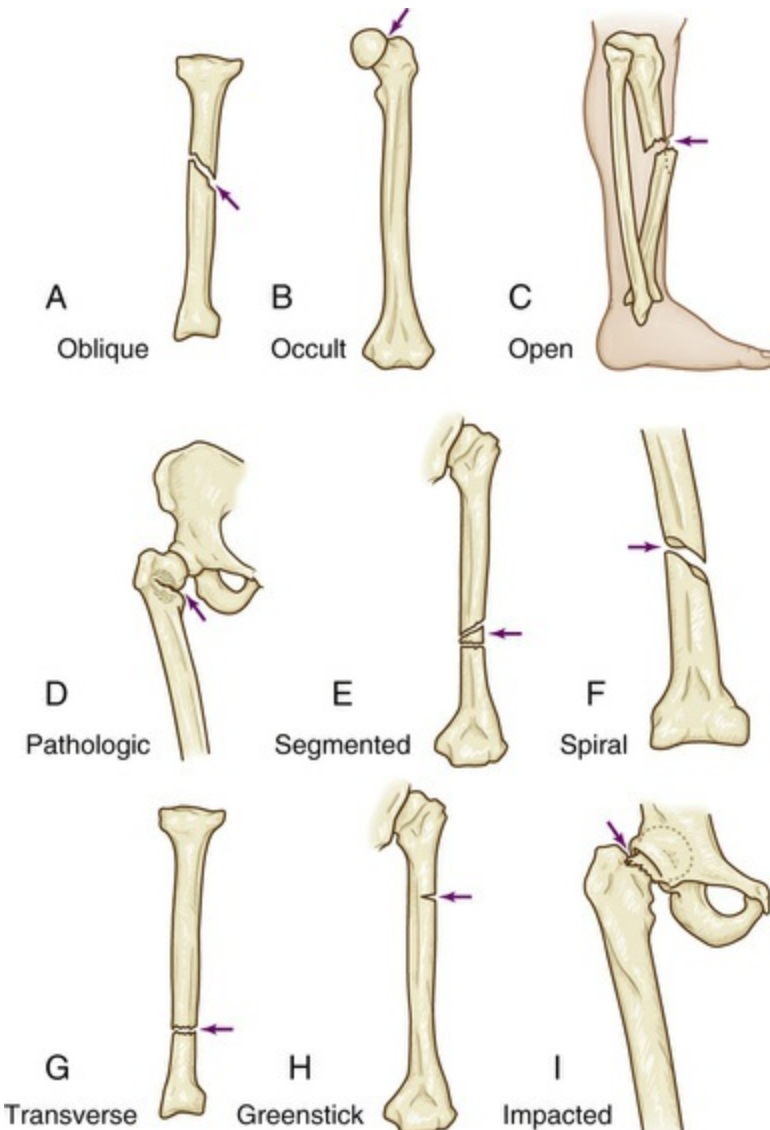

FIGURE 45.1 Examples of Types of Bone Fractures. A, *Oblique*: fracture at oblique angle across both cortices. *Cause*: direct or indirect energy, with angulation and some compression. B, *Occult*: fracture that is hidden or not readily discernible. *Cause*: minor force or energy. C, *Open*: skin broken over fracture; possible soft tissue trauma. *Cause*: moderate to severe energy that is continuous and exceeds tissue tolerances. D, *Pathologic*: transverse, oblique, or spiral fracture of bone weakened by tumor pressure or presence. *Cause*: minor energy or force, which may be direct or indirect. E, *Segmented*: fracture with two or more pieces or segments. *Cause*: direct or indirect moderate to severe force. F, *Spiral*: fracture that curves around cortices and may become displaced by twist. *Cause*: direct or indirect twisting energy or force with distal part held or unable to move. G, *Transverse*: horizontal break through bone. *Cause*: direct or indirect energy toward bone. H, *Greenstick*: break in only one cortex of bone. *Cause*: minor direct or indirect energy. I, *Impacted*: fracture with one end wedged into opposite end of inside fractured fragment. *Cause*: compressive axial energy or force directly to distal fragment. (Redrawn from Mourad L: Musculoskeletal system. In Thompson JM et al, editors: *Mosby's clinical nursing*, ed 7, St Louis, 2002, Mosby.)

The three main types of incomplete fractures are greenstick, buckle or torus, and bowing. A **greenstick fracture** perforates one cortex and splinters the spongy bone and is relatively unstable. The term *greenstick* is derived from the damage sustained by a young tree branch (a green stick) when it is bent sharply. The outer surface of the bone (or tree branch) is disrupted, but the inner surface remains intact. Greenstick fractures typically occur in the metaphysis or diaphysis of the tibia, radius, and ulna. In a buckle or **torus fracture**, the cortex of the bone buckles but does not break, thus making it a relatively stable fracture. **Bowing fractures** usually occur when longitudinal force is applied to bone. This type of fracture is common in children and usually involves the paired radius-ulna or fibula-tibia. A complete diaphyseal fracture occurs in one bone of the pair, which disperses the stress sufficiently to prevent a complete fracture of the second bone, which bows. Treatment of a bowing fracture is difficult because the bowed bone interferes with the reduction of the fractured bone. In addition, a bowing fracture resists correction (reduction) because the force necessary to reduce it must be equal to the force that caused the initial injury. A fracture that results from a trauma that would not normally cause a fracture (a low-level trauma) is termed a **fragility fracture**. Fragility fractures are often a sequela of osteoporosis. Types of fractures are summarized in [Table 45.1](#).

TABLE 45.1

TYPES OF FRACTURES

TYPE	DEFINITION
Typical Complete Fractures	
Closed fracture	Skin overlying the bone is intact
Open fracture	Communicating wound between bone and skin
Comminuted fracture	Multiple bone fragments
Linear fracture	Fracture line parallel to long axis of bone
Oblique fracture	Fracture line at an angle to long axis of bone
Spiral fracture	Fracture line encircling bone (as in a spiral staircase)

Transverse fracture	Fracture line perpendicular to long axis of bone
Impacted	Fracture fragments are pushed into each other
Pathologic	Fracture occurs at a point in the bone weakened by disease (e.g., bones with tumors or osteoporosis)
Avulsion	A fragment of bone connected to a ligament or tendon breaks off from the main bone
Compression	Fracture is wedged or squeezed together on one side of bone
Displaced	Fracture with one, both, or all fragments out of normal alignment
Extracapsular	Fragment is close to the joint but remains outside the joint capsule
Intracapsular	Fragment extends into or is within the joint capsule
Fragility	Fracture caused by low-level trauma
Typical Incomplete Fractures	
Greenstick fracture	Break on one cortex of bone with splintering of inner bone surface (commonly occurs in children and older adults)
Torus fracture	Buckling of cortex
Bowing fracture	Bending of the bone
Stress fracture	Microfracture
Transchondral fracture	Separation of cartilaginous joint surface (articular cartilage) from main shaft of bone

Fractures may be further classified by cause as pathologic, stress, or transchondral fracture. A **pathologic fracture** is a break at the site of a preexisting abnormality (such as a tumor), usually by force that would not fracture a healthy bone. Any disease process that weakens a bone (especially the cortex) predisposes the bone to pathologic fracture. This type of fracture is most commonly associated with tumors, infections, osteoporosis, and other metabolic bone disorders.

A **stress fracture** is caused by the cumulative effects of repeated forces over time, such as occurs during athletics. Fatigue and insufficiency fractures are subtypes of stress fractures. **Fatigue fractures** are caused by abnormal stress or torque applied to a bone with normal ability to deform and recover (e.g., joggers, dancers, military recruits). **Insufficiency fractures** include fragility fractures of osteoporosis and osteomalacia, and occur in bones lacking normal ability to deform and recover (i.e., normal weightbearing or activity fractures the bone).

A **transchondral fracture** consists of fragmentation and separation

of a portion of the articular cartilage that covers the end of a bone at a joint. (Joint structures are defined in [Chapter 44](#).) The fragments may consist of cartilage alone or cartilage and bone. Typical sites of transchondral fractures are the distal femur, the ankle, the kneecap, the elbow, and the wrist. Transchondral fractures are most prevalent in adolescents.

◆Pathophysiology.

When a bone is broken the periosteum and blood vessels in the cortex, marrow, and surrounding soft tissues are disrupted. Bleeding occurs from the damaged ends of the bone and from the neighboring soft tissue. A hematoma forms within the medullary canal, between the fractured ends of the bone, and beneath the periosteum. Bone tissue immediately adjacent to the fracture dies. This necrotic tissue and any debris in the fracture area stimulate an intense inflammatory response characterized by vasodilation, exudation of plasma and leukocytes, and infiltration by inflammatory leukocytes and mast cells. Cytokines, including transforming growth factor-beta (TGF- β), platelet-derived growth factor (PDGF), prostaglandins, and other factors that promote healing, are released. Within 48 hours after the injury, vascular tissue invades the fracture area from the surrounding soft tissue and marrow cavity, and blood flow to the entire bone is increased. Osteoblasts and osteoclasts (or bone-forming cells) in the periosteum, endosteum, and marrow are activated to produce subperiosteal procallus along the outer surface of the shaft and over the broken ends of the bone ([Fig. 45.2](#)). Healing generally occurs in three overlapping phases. The initial inflammatory phase of healing lasts 3 to 4 days. During the next few days, the repair phase begins and capillary ingrowth, together with mononuclear cells and fibroblasts, begins the transformation of a hematoma into granulation tissue. Next, osteoblasts within the procallus synthesize collagen and matrix, which becomes mineralized to form callus. As the repair process continues, remodeling occurs, during which unnecessary callus is resorbed and trabeculae are formed along lines of stress; at the end of this stage, bone can withstand normal stresses. The last phase, remodeling, lasts

for months to years. Except for the liver, bone is unique among all body tissues in that after a fracture it will heal with normal, not scar, tissue.

FIGURE 45.2 Exuberant Callus Formation Following Fracture. (From Rosai J: *Ackerman's surgical pathology*, ed 8, St Louis, 1996, Mosby.)

◆Clinical Manifestations.

Clinical manifestations of a fracture can vary according to the type of fracture, site of the fracture, and associated soft tissue injury. In general, the signs and symptoms of a fracture include impaired function, unnatural alignment (deformity), swelling, muscle spasm, tenderness, pain, and impaired sensation. The position of the bone segments is determined by the pull of attached muscles, gravity, and the direction and magnitude of the force that caused the fracture. One or both segments of the fractured bone may be rotated inward or outward on the bone's long axis (rotation), misaligned at an angle (angulation), or slide over the other segment (overriding) or out of normal position (displaced).

Fractures are usually caused by trauma and immediate, often severe pain at the site of injury occurs. Subsequent pain is produced by muscle spasm, overriding of the fracture segments, or damage to adjacent soft tissues. Numbness also is common and caused by swelling, pinching, or severing of a nerve caused by the trauma or bone fragments. Pathologic fractures can cause angular deformity, painless swelling, or generalized bone pain. Stress fractures usually occur in weightbearing bones. Stress fracture symptoms can vary, but the most common is pain. The pain of a stress fracture is often gradual in onset and can be relieved with rest. Other symptoms of stress fractures include local tenderness and soft tissue swelling. Transchondral fractures may be entirely asymptomatic or painful during movement. Range of motion in the joint is limited and movement may evoke crepitation, a crunching sensation felt when bones rub against each other.

◆Evaluation and Treatment.

Treatment of a displaced fracture involves manipulating the bone to realign bone fragments (reduction) to the correct anatomic position and holding the fragments in place (immobilization) so bone healing can occur. Many fractures heal without manipulation and require only adequate immobilization. Several methods of manipulation are available to reduce a fracture that will not heal with simple immobilization, including closed manipulation, traction, and open reduction. Maligned fractures require the most aggressive treatment of all types of fractures.

Fractures can be reduced by closed manipulation if the skin is not opened and the bone is able to be moved or manipulated into place. Appropriate use of closed manipulation occurs when the contour of the bone is well aligned and the alignment can be maintained with immobilization.

Traction is another option used to accomplish or maintain reduction of a fracture. When bone fragments are displaced (not in their anatomic position), weights are used to apply firm, steady traction (pull) and countertraction to the long axis of the bone. Traction

stretches and fatigues muscles that pull the bone fragments out of place, allowing the distal fragment to align with the proximal fragment. Traction can be applied to the skin (skin traction), directly to the involved bone, or distal to the involved bone (skeletal traction). Skin traction is used when only a few pounds of pulling force are needed to realign the fragments or when the traction will be used for only a brief time, such as before surgery or for a few days before applying a cast. In skeletal traction, a pin or wire is drilled through the bone below the fracture site, and a traction bow, rope, and weights are attached to the pin or wire to apply tension by providing the pulling force needed to overcome the muscle spasm and helping realign the fracture fragments.

Open reduction is a surgical procedure that exposes the fracture site; the fragments are brought into alignment under direct visualization. Some form of hardware, such as a screw, plate, nail, or wire, is used to maintain the reduction (internal fixation). External fixation is a procedure used to reduce and immobilize significantly displaced open fractures. Pins are placed in the bone proximal and distal to the break and then stabilized by an external frame of clamps and rods (Fig. 45.3). Bone grafts also are used to repair fractures and filling voids in the bone. These grafts are from the injured individual (autograph), a cadaver (allograft), or a bone substitute (ceramic composites, bioactive cement).

FIGURE 45.3 Example of an External Fixation Device on the Right Leg. The left leg is in a splint.

Improper reduction or immobilization of a fractured bone may result in nonunion, delayed union, or malunion. **Nonunion** is failure of the bone ends to grow together (Fig. 45.4). The gap between the broken ends of the bone fills with dense fibrous and fibrocartilaginous tissue instead of new bone. Occasionally, the fibrous tissue contains a fluid-filled space that resembles a joint, termed a *false joint*, or *pseudarthrosis*. **Delayed union** is union that does not occur until approximately 8 to 9 months after a fracture. **Malunion** is the healing of a bone in a nonanatomic position. Treatment of delayed union and nonunion includes use of various modalities designed to stimulate new bone formation. Physical modalities, such as implantable or external electric current devices, electromagnetic field generations, and low-density ultrasound, have been effective in stimulating bone formation.⁶ Stem cells and gene therapy also show promise in promoting formation of new bone.^{7,8} Large defects in bone can be filled with bone graft or synthetic materials, such as calcium phosphate cement.

FIGURE 45.4 Nonunion of Old Fracture of Tibia and Fibula in a 53-Year-Old Man. Multiple fractures had occurred in 2 years previously and necessitated bone grafting. (From Rosai J: *Ackerman's surgical pathology*, ed 8, St Louis, 1996, Mosby.)

Dislocation and Subluxation

Dislocation and subluxation are caused by trauma, but also can be caused by ligamentous laxity, nerve injury, rheumatoid disease, or genetic problems. **Dislocation** is the temporary displacement of a bone from its normal position in a joint. If a dislocation does not involve a fracture, it is a simple dislocation; if there is an associated fracture, it becomes a complex dislocation. If the contact between the two joint surfaces is only partially lost, the injury is called a **subluxation**.

Dislocation and subluxation are most common in persons younger than 20 years and are generally associated with fractures. Dislocation and subluxation, however, may result from congenital or acquired disorders that cause (1) muscular imbalance, as occurs with congenital hip dislocation or neurologic disorders; (2) incongruities in the articulating surfaces of the bones, such as with rheumatoid arthritis

(see [Classic Inflammatory Joint Disease](#)); or (3) joint instability.

Most often dislocated or subluxated are the joints of the shoulder, elbow, wrist, finger, hip, and knee ([Fig. 45.5](#)). The shoulder's glenohumeral joint is a relatively unstable joint because the articular surface of the glenoid cavity is only one-third as large as the surface of the humeral head. As a result, the glenohumeral joint is often injured. Physical trauma to the shoulder can cause anterior, posterior, superior, or inferior dislocation. Anterior dislocation is the most common and is usually the result of an indirect force that places the shoulder in extreme external rotation. Posterior dislocations usually occur because of trauma. A superior dislocation is rare and usually the result of an extreme forward and upward force on an adducted arm. Inferior displacement is seen in persons with neurologic injuries of the brachial plexus and is believed to be caused by stretching of the supporting muscles or by joint effusion.

FIGURE 45.5 Displaced Fracture. An x-ray showing a displaced fracture of the base of the first metacarpal, also known as a *Bennett fracture*.

Traumatic dislocation of the elbow joint is common in the immature skeleton. In adults, however, an elbow dislocation is usually associated with a fracture of the ulna or head of the radius. Posterior dislocations occur when the individual falls on an outstretched hand with the elbow extended. Anterior dislocations are usually the result of a direct blow to the flexed elbow.

Traumatic dislocation of the wrist usually involves the distal ulna and carpal bones. Any one of the eight carpal bones can be dislocated after an injury. The most common cause is a fall on the hyperextended hand.

Dislocation in the hand usually involves the metacarpophalangeal and interphalangeal joints. Dislocation of the metacarpophalangeal joint is often the result of a fall on the outstretched hand that forces the joint into hyperextension. Dislocation of the interphalangeal joint occurs because of injury to the fingers in a hyperextended position.

Considerable trauma is needed to dislocate the hip. Anterior hip dislocation is rather rare and caused by forced abduction, for example, when an individual lands on the feet from a high fall. Posterior dislocation of the hip can occur in an automobile accident in which the flexed knee strikes the dashboard.

The knee is a relatively unstable joint that depends heavily on the soft tissue structures around it for support. Because the knee is an unstable weightbearing joint exposed to many different types of motion (flexion, extension, rotation), it is one of the most commonly injured joints. A knee dislocation can be anterior, posterior, lateral, medial, or rotary. It is often the result of a hyperextension injury that occurs during sports activities.

◆Pathophysiology.

Dislocations and subluxations are often accompanied by fracture because stress is placed on areas of bone not normally subjected to stress. In addition, as the bone separates from the joint, it may bruise or tear adjacent nerves, blood vessels, ligaments, supporting structures, and soft tissue. Dislocation of the shoulder may damage the shoulder capsule and the axillary nerve. Damage to the axillary

nerve causes anesthesia in the sensory distribution of the nerve and paralysis of the deltoid muscle. Torn periosteum, ligaments, and muscle frequently accompany elbow dislocations. Bleeding from the damaged periosteum and muscle puts pressure on adjacent arteries that stops circulation to and from the forearm and hand. If the pressure is not promptly relieved, ischemic paralysis develops. Dislocations of the hand often result in permanent disability because of damage to the tendons and intricate mechanisms that allow smooth gliding in the joints. In the hip, avascular necrosis of the femoral head is a complication seen with dislocations. Knee dislocation usually tears both the collateral and the cruciate ligaments.

◆Clinical Manifestations.

Signs and symptoms of dislocations or subluxations include pain, swelling, limitation of motion, and joint deformity. Pain is caused by effusion of inflammatory exudate into the joint or associated tendon and injury to the ligament. Joint deformity is caused by muscle contractions that exert pull on the dislocated or subluxated joint or fluid within the joint. Limitation of motion may be a result of effusion into the joint or the displacement of bones.

Tenderness and deformity are prominent in dislocations of the fingers. Unusual muscle pull and pain often result in abnormal posturing of the fingers; for example, the fingers or thumb may be abnormally flexed. A dislocated elbow is often held in a flexed position, and the joint resists active or passive movement. Pain is the key symptom of shoulder injuries. Attempts to lift the arm aggravate the pain. In most shoulder dislocations, the ability to elevate the arm is minimal and the individual supports the injured arm with the opposite hand. Pain and an abnormal gait or limp or inability to bear full weight usually accompanies traumatic dislocation of the hip. The pain is constant and severe and is felt in the inguinal region or thigh. The thigh and leg may assume a position of inward rotation, adduction, or flexion and appear shortened. In a rare anterior dislocation, the limb is not shortened and the joint is fixed in abduction, outward rotation, and flexion.

◆ Evaluation and Treatment.

Evaluation of dislocations and subluxations is based on clinical manifestations and roentgenograms. Treatment consists of reduction and immobilization for 2 to 6 weeks and exercises to maintain normal range of motion in the joint. Depending on the joint, healing is usually complete within months to years.

Support Structure Trauma

Sprains and Strains of Tendons and Ligaments

Tendon and ligament injuries can accompany fractures and dislocations. A **tendon** is fibrous connective tissue that attaches skeletal muscle to bone. A **ligament** is a band of fibrous connective tissue that connects bones where they meet at a joint. Tendons and ligaments support the bones and joints and either facilitate or limit motion. Tendons and ligaments can be torn, ruptured, or completely separated from bone at their points of attachment.

A tear in a tendon is known as a **strain**. Major trauma can tear or rupture a tendon at any site in the body. Most often injured are the tendons of the hands and feet, the knee (patellar), the upper arm (biceps and triceps), the thigh (quadriceps), the ankle, and the heel (Achilles). Lifting excessive weight with the arms can cause traumatic rupture of the biceps tendon. Rupture of the Achilles tendon occurs when forced dorsiflexion is applied to the foot when it is in plantar flexion. Spontaneous tendon ruptures can occur in individuals receiving local corticosteroid injections or fluoroquinolones and in persons with rheumatoid arthritis or systemic lupus erythematosus.

Ligament tears are known as **sprains**. Ligament tears and ruptures can occur at any joint, but are most common in the wrist, ankle, elbow, and knee joints. A complete separation of a tendon or ligament from its bony attachment site is known as an **avulsion**. An avulsion is the result of abnormal stress on the ligament or tendon and is commonly seen in young athletes, especially sprinters, hurdlers, and runners.

Strains and sprains are classified as first degree (least severe), second degree, and third degree (most severe).

◆Pathophysiology.

When a tendon or ligament is torn, an extensive inflammatory cascade process begins. Inflammatory mediators include cytokines, nitric oxide, prostaglandins, and lipoxins. An inflammatory exudate develops between the torn ends. Later, granulation tissue containing macrophages, fibroblasts, and capillary buds grows inward from the surrounding soft tissue and cartilage to begin the repair process. Within 3 to 4 days after the injury, collagen formation begins. At first, collagen formation is random and disorganized. As the collagen fibers interweave and connect with preexisting tendon fibers, they organize parallel to the lines of stress. Eventually, vascular fibrous tissue fuses the new and surrounding tissues into a single mass. As reorganization takes place, the healing tendon or ligament separates from the surrounding soft tissue. Usually, a healing tendon or ligament lacks sufficient strength to withstand strong pull for 4 to 5 weeks after the injury. If strong muscle pull does occur during this time, the tendon or ligament ends may separate again, which causes the tendon or ligament to heal in a lengthened shape with an excessive amount of scar tissue that renders the tendon or ligament functionless. Scar remodeling may take months to years before it is complete.⁹

◆Clinical Manifestations.

Tendon and ligament injuries are painful and cause functional limitation. These injuries are usually accompanied by soft tissue swelling, changes in tendon or ligament contour, and dislocation or subluxation of bones. The pain is generally sharp and localized, and tenderness persists over the distribution of the tendon or ligament. Painful joint swelling usually can be seen in finger and elbow sprains. Flexion deformities of the fingers and thumb occur in injuries to the extensor tendons. Crepitus may accompany tendon injury in the wrist. Tendon or ligament pain in the elbow is accentuated by flexion, supination, and extension of the elbow or by extension of the wrist. Lifting small objects requires extension of the wrist and therefore aggravates the pain. Tendon injuries in the upper arm cause weakness when the individual tries to flex the forearm. Pain is often the key

symptom of shoulder injuries with pain radiating to the deltoid muscle or extending down the arm and is aggravated by attempts to actively raise the arms. Depending on the ligament or tendon involved, injuries to the knee may produce pronounced immobility, absence of lateral movement, instability when walking down stairs, flexion deformity, crepitus, or an upward or downward shift of the patella.

◆ Evaluation and Treatment.

Evaluation is based on clinical manifestations, stress radiography, arthroscopy, or arthrography. When possible, treatment consists of protection of the involved structures (splinting), promotion of early motion, and rehabilitation. Surgical intervention that sutures the tendon or ligament ends in close approximation may be necessary to treat complete rupture. If this is not possible because of the extent of damage, tendon or ligament grafting may be necessary. Prolonged rehabilitation exercises help ensure that the individual regains nearly normal functions.

Tendinopathy and Bursitis

Trauma and overuse injuries can cause painful degradation of collagen fibers (**tendinosis**), inflammation of tendons (**tendinitis**), or inflammation in bursal sacs (**bursitis**). The term *tendinopathy* includes tendinitis, tendinosis, and paratendinitis. Studies have shown that vascular ingrowth in tendinopathy (neovascularization) is accompanied with nerve ingrowth, facilitating pain transmission in Achilles and patellar tendinopathies.¹⁰ Other causes of tendinopathy include crystal deposits, postural misalignment, and hypermobility in a joint. [Table 45.2](#) summarizes classes of tendinopathies.

TABLE 45.2

HISTOPATHOLOGIC CLASSIFICATION OF TENDON DISORDERS

PATHOLOGIC DIAGNOSIS	MACROSCOPIC PATHOLOGY	HISTOPATHOLOGIC FINDINGS
----------------------	-----------------------	--------------------------

Tendinosis	Intratendinous degeneration (commonly due to aging, microtrauma, muscular compromise)	Collagen disorientation, disorganization, and fiber separation by an increase in mucoïd ground substance, increased preponderance of cells and vascular spaces with or without neovascularization and focal necrosis or calcification
Tendinitis	Symptomatic degeneration of the tendon with vascular disruption and inflammatory repair response	Degenerative changes as noted above with superimposed evidence of tear, including fibroblastic and myofibroblastic proliferation, hemorrhage, and organizing granulation tissue
Paratenonitis	“Inflammation” of the outer layer of the tendon (paratenon) alone, whether or not the paratenon is lined by synovium	Mucoïd degeneration if the areolar tissue is seen; a scattered mild mononuclear infiltrate with or without focal fibrin deposition and fibrinous exudate
Paratenonitis with tendinosis	Paratenonitis associated with intratendinous degeneration	Degenerative changes as noted in tendinosis with mucoïd degeneration with or without fibrous and scattered inflammatory cells in the paratenon alveolar tissue

From Maffulli N, Wong J, Almekinders LC: *Clin Sports Med* 22(4):675–692, 2003.

Epicondylitis is inflammation of a tendon where it attaches to a bone (at its origin). Most tendon pathology, however, is caused by tissue degeneration rather than inflammation.¹¹ Epicondylar areas of the humerus, radius, or ulna and the area around the knee are most often involved. **Lateral epicondylopathy**, commonly called **tennis elbow**, is the result of tissue degeneration or irritation of the extensor carpi radialis brevis tendon at its origin. **Medial epicondylopathy**, referred to as **golfer's elbow**, is a degenerative process of the pronator teres, flexor carpi radialis, and palmaris longus tendons at the medial humeral condyle (Fig. 45.6). Epicondylopathy is also related to smoking, obesity, and work activities that involve forceful or repetitive cyclic flexion and extension of the elbow, or cyclic pronation, supination, extension, and flexion of the wrist that generates loads to the elbow and forearm region.

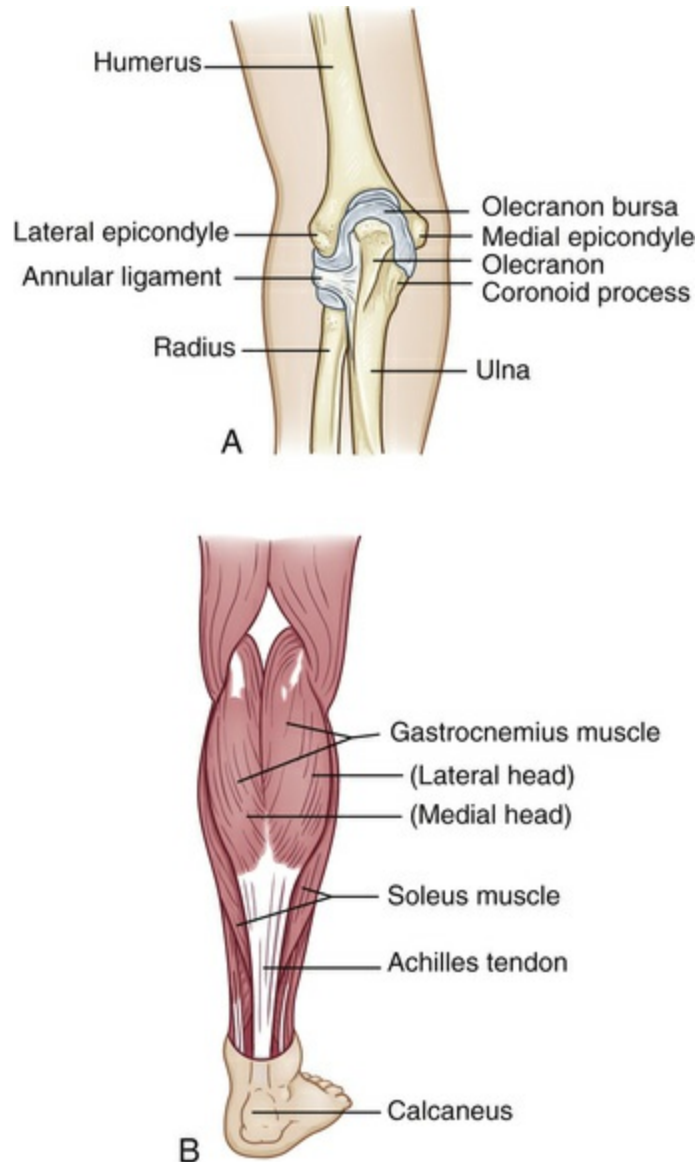

FIGURE 45.6 Tendinitis and Epicondylitis. A, Medial or lateral epicondyles of humerus, site of epicondylitis. B, Achilles tendon, site of commonly occurring tendinitis.

Bursae are small sacs lined with synovial membrane and filled with synovial fluid; they are located between tendons, muscles, and bony prominences. Their primary function is to separate, lubricate, and cushion these structures. When irritated or injured, these sacs become inflamed and swell. Because most bursae lie outside joints, joint movement is rarely compromised with bursitis. Acute bursitis occurs primarily in the middle years and is often caused by trauma; repetitive irritation can cause chronic bursitis. Septic bursitis is caused

by wound infection or bacterial infection of the skin overlying the bursae. Bursitis commonly occurs in the shoulder, hip, knee, and elbow.

◆Pathophysiology.

In tendinitis, inflammatory fluid accumulates, causing swelling of the tendon and its enclosing sheath. Inflammatory changes cause thickening of the sheath, which limits movements and causes pain. Microtears cause bleeding, edema, and pain in the involved tendons or surrounding structures. At times, after repeated inflammations, calcium may be deposited in the tendon origin area, causing a calcific tendinitis.

The typical bursitis is an inflammation that is reactive to overuse or excessive pressure. The inflamed bursal sac becomes engorged, and the inflammation can spread to adjacent tissues (Fig. 45.7). The inflammation may decrease with rest, heat, and aspiration of the fluid. (Inflammation is discussed in Chapter 7.)

FIGURE 45.7 Olecranon Bursa. A case of olecranon bursitis in a patient with rheumatoid arthritis. A rheumatoid nodule is also shown. (From Hochberg MC et al: *Rheumatology*, ed 6, Philadelphia, 2015, Elsevier.)

◆Clinical Manifestations.

Tendinopathy may be asymptomatic, but generally there is localized

pain that worsens with active more than passive motion. With symptomatic tendinopathy, the pain is localized over the involved tendon and movement in the affected joint is limited. In bursitis, onset of pain may be gradual or sudden, but movement of the joint itself is normal. Shoulder bursitis impairs arm abduction because of pain and swelling of the bursa. Bursitis in the knee produces pain when climbing stairs, and crossing the legs is painful in bursitis of the hip. Lying on the side of an inflamed trochanteric bursa is also very painful. [Table 45.3](#) summarizes common sites of bursitis. Signs of infectious bursitis may include the presence of a puncture site, prior corticosteroid injection, severe inflammation, or an adjacent source of infection.

TABLE 45.3

COMMON SITES AND CAUSES OF BURSTITIS

SITE	COMMON CAUSES
Shoulder (subacromial)	Repetitive overhead activities
Elbow (olecranon)	Rheumatoid arthritis (RA), gout, tuberculosis, leaning on elbow
Hip (greater trochanter)	Acute trauma, chronic stress
Ischial (weaver's bottom)	Overuse (runner, ballet dancers), lumbosacral disease, RA, osteoarthritis (OA)
Knee	
Prepatellar (housemaid knee)	Trauma, frequent kneeling, infection
Pes anserine (medial knee)	Obesity, long-distance runner, OA, type 2 diabetes
Heel (calcaneal)	Poorly fitting footwear, Achilles tendinitis

◆ Evaluation and Treatment.

Evaluation of tendinopathy, epicondylopathy, and bursitis is based on clinical manifestations, physical examination, arthroscopy, arthrography, ultrasound, and possibly magnetic resonance imaging (MRI). Treatment includes administration of systemic analgesics, application of ice or heat, or local injection of an anesthetic and a corticosteroid to reduce inflammation. Bursitis may require aspiration

to drain excess fluid. Physical therapy to prevent loss of function begins after acute symptoms subside.

Muscle Strains

Mild injury such as **muscle strain** is usually seen after traumatic or sports injuries. *Muscle strain* is a general term for local muscle damage. It is often the result of sudden, forced motion causing the muscle to become stretched beyond normal capacity. Strains often involve the tendon as well. Muscles are ruptured more often than tendons in young people; the opposite is true in older adults. Muscle strain may be chronic when the muscle is repeatedly stretched beyond its usual capacity. There is evidence of tissue disruption with subsequent signs of muscle regeneration and connective tissue repair when a biopsy is performed. Hemorrhage into the surrounding tissue and signs of inflammation also may be present. Knife and gunshot wounds also cause traumatic rupture. Regardless of the cause of trauma, muscle cells usually can regenerate. Regeneration may take up to 6 weeks, and the affected muscle should be protected during this time. Types of muscle strain, together with their manifestations and treatment, are summarized in [Table 45.4](#).

TABLE 45.4

MUSCLE STRAIN

TYPE	MANIFESTATIONS	TREATMENT
First degree (e.g., bench press in untrained athlete)	Muscle overstretched, painful	Ice should be applied 5 or 6 times in the first 24–48 hr; complete rest for up to 2 weeks, followed by weightbearing 3 times per week and range of motion daily
Second degree (e.g., any muscle strain with bruising and pain)	Muscle intact with some tearing pain, mild bruising; fascia is intact	Treatment similar to that for first-degree strains, with added mild analgesia; cryokinetics (a treatment system of alternating applications of cold with progressive exercise)
Third degree (e.g., traumatic injury)	Caused by tearing of fascia; muscle rupture palpable,	Surgery to approximate ruptured edges; immobilization and rest for 6 weeks, followed by an individualized rehabilitation regimen of strengthening exercises

A late complication of localized muscle injury is abnormal bone formation in soft tissue, often called **myositis ossificans** or **heterotopic ossification (HO)**. Its exact pathophysiology remains unknown, but the basic problem seems to be the inability of mesenchymal cells to differentiate into osteoblastic stem cells and the improper development of fibroblasts into bone-forming cells. Though uncommon, HO is associated with burns, joint surgery, and trauma to the musculoskeletal system or central nervous system. HO may involve muscle or tendons, ligaments, or bones near a muscle.¹² Examples include “rider's bone,” in which the adductor muscle of the thigh of equestrians becomes calcified, as well as in football players after muscle injury to thigh muscles; and “drill bone,” in which the same complication is seen in the deltoid and pectoral muscles of fencers and infantry soldiers.

Rhabdomyolysis

Once used interchangeably with the term *myoglobinuria*, **rhabdomyolysis** is the rapid breakdown of muscle that causes the release of intracellular contents, including protein pigment myoglobin, into the extracellular space and bloodstream. Physical interruptions in the sarcolemmal membrane, called *delta lesions*, suggest that the sarcolemmal membrane is the route through which muscle constituents are released. Myoglobinuria, first described in victims of crush injuries in London during World War II, refers to the presence of the muscle protein myoglobin in the urine. More recently, myoglobinuria has been reported in individuals found unresponsive and immobile for long periods, such as drug and alcohol overdoses.

◆Pathophysiology.

Rhabdomyolysis is sometimes incorrectly used interchangeably with *crush injury* (a description of injuries resulting from crushing of a body part), *compartment syndrome* (the consequences of increased intracompartmental pressures of a muscle), or *crush syndrome* (the

pathophysiologic events caused by rhabdomyolysis, primarily involving the kidneys and coagulation syndrome).¹³ Although relatively rare, rhabdomyolysis has many causes (Box 45.1) and can result in serious complications, including hyperkalemia (because of the release of intracellular potassium into the circulation), metabolic acidosis (from liberation of intracellular phosphorus and sulfate), acute renal failure (myoglobin precipitates in the tubules, obstructing flow through the nephron and producing injury), and even disseminated intravascular coagulation (DIC) (likely caused by activation of the clotting cascade by sarcolemma damage and release of intracellular components from the damaged muscles). Even the weight of a limp extremity can generate enough pressure to produce muscle ischemia (Fig. 45.8).

Box 45.1

Selected Causes of Rhabdomyolysis

Medications and Toxic Substances That Increase the Risk of Rhabdomyolysis

Direct Myotoxicity

HMG-CoA reductase inhibitors (statins), especially in combination with fibrate-derived lipid-lowering agents such as niacin (nicotinic acid; Nicolar)
Cyclosporine (Sandimmune)
Itraconazole (Sporanox)
Erythromycin
Colchicine
Zidovudine (Retrovir)
Corticosteroids

Other Medications and Toxins

Amphetamines
Anesthetic and paralytic agents (halothane, propofol, succinylcholine – malignant hyperthermia syndrome)
Antihistamines (diphenhydramine, doxylamine)
Anti-hyperlipidemic agents (statins, clofibrate, bezafibrate)
Antipsychotics and antidepressants (amitriptyline, doxepin, fluoxetine, haloperidol, lithium, protriptyline, perphenazine, promethazine, chlorpromazine, trifluoperazine)
Caffeine
Cocaine
HIV integrase inhibitor (raltegravir)
Hypnotics and sedatives (benzodiazepines, barbiturates)
Heroin
LSD
Methamphetamine
Methadone
Methylenedioxymethamphetamine (MDMA; “ecstasy”)
Miscellaneous medications (amphotericin B, azathioprine, ϵ -aminocaproic acid, quinidine, penicillamine, salicylates, theophylline, terbutaline, thiazides, vasopressin)
Phencyclidine
Protease inhibitors

Indirect Muscle Damage

Alcohol
Central nervous system depressants
Cocaine
Amphetamines
Ecstasy (MDMA)
LSD
Neuromuscular-blocking agents

Traumatic, Heat-Related, Ischemic, and Exertional

Causes

Traumatic Causes

- Direct trauma
- Lightning strike
- Immobilization
- Extensive third-degree burn
- Crush injury

Heat-Related Causes

- Heat stroke
- Malignant hyperthermia
- Neuroleptic malignant syndrome

Ischemic Causes

- Ischemic limb injury

Exertional Causes

- Marathon running
- Physical overexertion in untrained athletes
- Pathologic muscle exertion
- Severe dystonia
- Tetanus
- Status epilepticus
- Delirium tremens
- Heat dissipation impairment
- Physical overexertion in persons with sickle cell disease

Genetic Causes

Lipid Metabolism

Carnitine palmitoyltransferase deficiency
Carnitine deficiency
Short-chain and long-chain acetyl-coenzyme A dehydrogenase deficiency

Carbohydrate Metabolism

Myophosphorylase deficiency (McArdle disease)
Phosphorylase kinase deficiency
Phosphofructokinase deficiency
Phosphoglycerate mutase deficiency
Lactate dehydrogenase deficiency (characteristic elevation of creatine kinase level with normal lactate dehydrogenase level)

Purine Metabolism

Myoadenylate deaminase deficiency
Duchenne muscular dystrophy

Infectious, Inflammatory, Metabolic, and Endocrinologic Causes

Infectious Causes

Viruses: influenza virus B, parainfluenza virus, adenovirus, coxsackievirus, echovirus, herpes simplex virus, cytomegalovirus, Epstein-Barr virus, human immunodeficiency virus
Bacteria: *Streptococcus*, *Salmonella*, *Legionella*, *Staphylococcus*, and *Listeria* species

Inflammatory Causes

Polymyositis
Dermatomyositis
Capillary leak syndrome
Snake bites (mostly in South America, Asia, and Africa)

Metabolic and Endocrinologic Causes

Electrolyte imbalances: hyponatremia, hypernatremia, hypokalemia, hypophosphatemia, hypocalcemia
Hypothyroidism
Thyrotoxicosis
Diabetic ketoacidosis
Nonketotic hyperosmolar syndrome

Herbal Supplements

Red yeast rice (*Monascus purpureus*)
Compounds containing ma huang, guarana, and garcinia cambogia
Ephedra-based compounds, especially weight-loss supplements

HMG-CoA, 3-Hydroxy-3-methylglutaryl coenzyme A; *LSD*, lysergic acid diethylamide; *MDMA*, 3,4-methylenedioxymethamphetamine.

Data from Acharya S et al: *Ann Indian Acad Neurol* 13(3):221–222, 2010; Cervelin G, Comelli I, Lippe G: *Clin Chem Lab Med* 48(6):749–756, 2010; Croce F et al *Int J STD AIDS* 21(11):783–785, 2010; Halpern P et al: *Hum Exp Toxicol* 29(5):259–266, 2010; Mammen AL, Amato AA: *Curr Opin Rheumatol* 22(6):644–650, 2010; Sauret JM, Narinides G, Wang GK: *Am Fam Physician* 65(3):907, 2002.

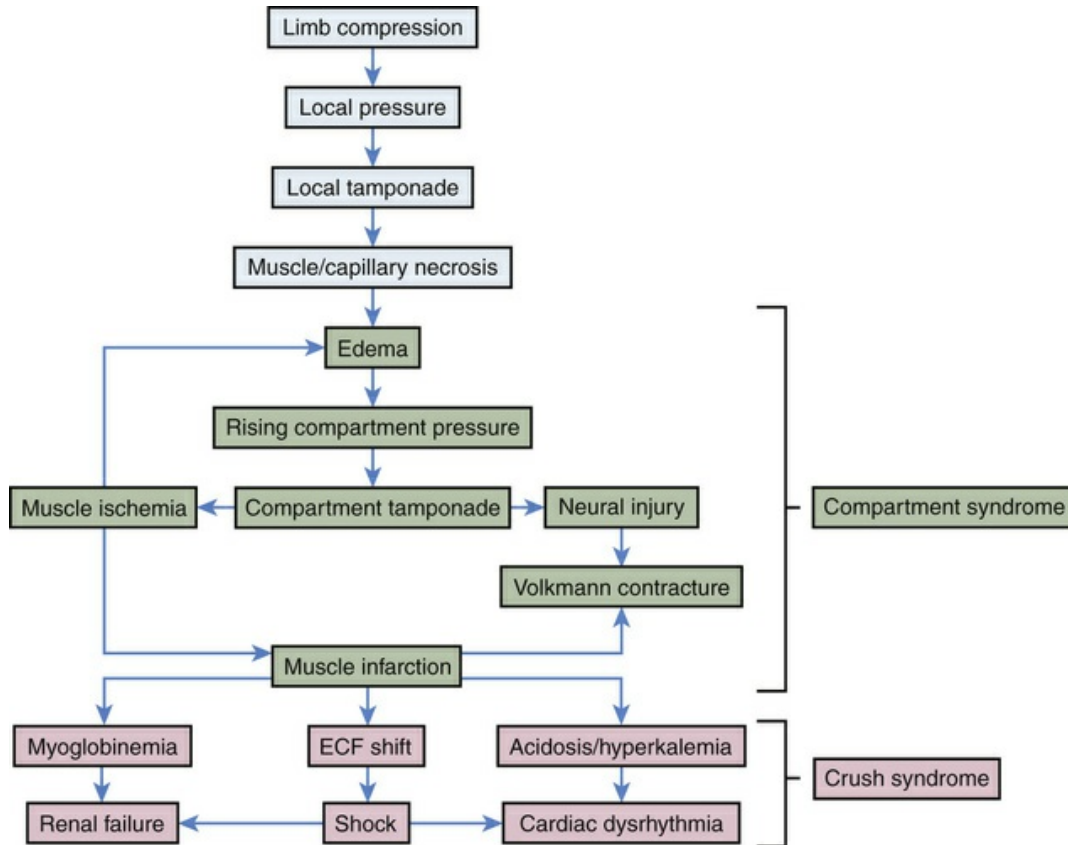

FIGURE 45.8 Pathogenesis of Compartment Syndrome and Crush Syndrome Caused by Prolonged Muscle Compression. *ECF*, Extracellular fluid.

Malignant hyperthermia (MH) is a potentially life-threatening hereditary disorder of skeletal muscle ryanodine receptors (RyR1), allowing large quantities of calcium to be released from the sarcoplasmic reticulum (SR) after exposure to certain volatile anesthetics. The sustained elevation of calcium concentration allows excessive stimulation of aerobic and anaerobic glycolytic metabolism, causing a hypermetabolic state resulting in respiratory and metabolic acidosis, muscle rigidity, altered cell permeability, and hyperkalemia.¹⁴ Dantrolene, a skeletal muscle relaxant, inhibits calcium release from the SR and is used to reverse the effects of MH.

Compartment syndromes occur when blood flow to the affected area is compromised because of increased venous pressure, leading to decreased arterial inflow, ischemia, and edema. Emergency treatment may be required to save an affected limb. Classic symptoms of compartment syndrome are (1) pain out of proportion to the injury,

(2) paresthesia, (3) pallor, (4) pulselessness (uncommon), and (5) paralysis (a late finding). Of these symptoms, pain is the most sensitive clinical sign.¹⁵

When clinical evaluation is inconclusive, the rising compartment pressure can be directly measured by inserting a wick catheter, needle, or slit catheter into the muscle. Immediate fasciotomy and débridement are advocated for reducing elevated intracompartmental pressures.¹⁵ Those frequently affected are the compartments of the leg, the volar compartment of the hand, the abdomen, and the gluteal compartments.

◆Clinical Manifestations.

A *classic triad* of muscle pain, weakness, and dark urine is considered typical of rhabdomyolysis, but those affected may have no complaint of pain or muscle weakness.¹³ Abnormally dark urine caused by myoglobinuria may be the first and only symptom. The renal threshold for myoglobin is low (approximately 0.5 mg/dL of urine), so only 200 g of muscle needs to be damaged to cause visible changes in the urine. Myoglobin is rapidly cleared and levels may return to normal within 24 hours of injury. Along with the release of myoglobin, creatine kinase (CK) and other serum enzymes are released in massive quantities. The efflux of proteins and enzymes also includes loss of potassium, phosphate, nucleotides, creatinine, and creatine. Serum hypocalcemia is seen early in the course of myoglobinuria and is followed by late hypercalcemia.

◆Evaluation and Treatment.

The most important and clinically useful measurement in rhabdomyolysis is serum creatine kinase (CK) level. With normal CK serum levels of 5 to 25 units/L for women and 5 to 35 units/L for men, a level five times the upper limit of normal (about 1000 units/L) is used to identify rhabdomyolysis. Once CK levels exceed 5000 units/L, acute renal failure is likely. A recent study evaluated the ultrasonographic appearance of rhabdomyolysis in damaged muscle from earthquake victims and found abnormalities in muscle texture

and subcutaneous tissue, as well as areas of liquid in the damaged tissue.¹⁶

Maintaining adequate urinary flow and prevention of kidney failure are goals of treatment. Rapid intravenous hydration maintains adequate kidney flow. Other issues, such as hyperkalemia, may require temporary hemodialysis. Other treatments, such as using mannitol to cause an osmotic diuresis or bicarbonate to alkalinize the urine, have not been shown to consistently improve outcomes.

Disorders of Bones

Metabolic Bone Diseases

Metabolic bone disease is characterized by abnormal bone structure that is caused by altered or inadequate biochemical reactions resulting in disorders of bone strength. Abnormalities include genetic, mineral, vitamin, hormone, and structural abnormalities.

Osteoporosis

Osteoporosis, or porous bone, is the most common bone disease in humans. It is characterized by low bone mineral density (BMD), impaired structural integrity of the bone, decreased bone strength, and the risk of fracture.¹⁷ There are two types of osteoporosis: *primary* or *idiopathic osteoporosis*, which is the most common; and secondary osteoporosis. *Secondary osteoporosis* is caused by other conditions, including endocrine diseases (hormone imbalances, diabetes, hyperparathyroidism, hyperthyroidism), medications (such as heparin, corticosteroids, phenytoin, barbiturates, lithium), and other substances (including tobacco and ethanol). Other conditions (including rheumatoid disease, human immunodeficiency virus [HIV], malignancies, malabsorption syndromes, liver or kidney disease) also increase the risk for developing osteoporosis (Box 45.2). Cortical bone becomes more porous and thinner, making bone weaker and prone to fractures (Fig. 45.9). The World Health Organization

(WHO) has defined osteoporosis on the basis of bone density:

Box 45.2

Risk Factors for Osteoporosis

Genetic

- Family history of osteoporosis
- White/Asian race
- Increased age
- Female gender

Anthropometric

- Small stature
- Fair or pale skinned
- Thin build

Hormonal and Metabolic

- Early menopause (natural or surgical)
- Late menarche
- Nulliparity
- Obesity
- Hypogonadism
- Gaucher disease
- Cushing syndrome
- Weight below healthy range
- Acidosis

Dietary

Low dietary calcium and vitamin D
Low endogenous magnesium
Excessive protein*
Excessive sodium intake
High caffeine intake
Anorexia
Malabsorption

Lifestyle

Sedentary
Smoker
Alcohol consumption (excessive)

Concurrent

Hyperparathyroidism

Illness and Trauma

Renal insufficiency, hypocalciuria
Rheumatoid arthritis
Spinal cord injury
Systemic lupus erythematosus

Liver Disease

Marrow disease (myeloma, mastocytosis, thalassemia)

Drugs

Corticosteroids
Dilantin

Gonadotropin-releasing hormone agonists
Loop diuretics
Methotrexate
Thyroid
Heparin
Cyclosporine
Depo-medroxyprogesterone acetate
Retinoids

*Low levels of protein intake also have been reported.

FIGURE 45.9 Vertebral Body. Osteoporotic vertebra (*right*) shortened by compression fractures compared with normal vertebral body (*left*). Note that the osteoporotic vertebra has characteristic loss of horizontal trabeculae and thickened vertebral trabeculae. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

1. Normal bone mass is greater than 833 mg/cm^2 .
2. **Osteopenia**, or decreased bone mass, is 833 to 648 mg/cm^2 .
3. Osteoporosis is bone mass less than 648 mg/cm^2 .

Osteoporosis is a complex, multifactorial chronic disease that often progresses silently for decades until fractures occur. It is the most common disease that affects bone. It is not necessarily a consequence

of the aging process because some older adults retain strong, relatively dense bones. In osteoporosis, old bone is being reabsorbed faster than new bone is being made, causing the bones to lose density, becoming thinner and more porous. A progressive loss of bone mass may continue until the skeleton is no longer strong enough to support itself. Eventually, bones can fracture spontaneously. As bone becomes more fragile, fractures occur from falls or bumps that would not previously have caused fracture.

Severe or established osteoporosis is identified when there has been a fragility fracture. The disease can be (1) generalized, involving major portions of the axial skeleton, or (2) regional, involving one segment of the appendicular skeleton.

Throughout a lifetime, old bone is removed (resorption) and new bone is added (formation) to the skeleton. During childhood and teenage years, new bone is added faster than old bone is removed. Consequently, bones become larger, heavier, and denser. Bone formation continues at a pace faster than resorption until **peak bone mass**, or maximum bone density and strength, is reached, around age 30, after which bone resorption slowly exceeds bone formation. In women, bone loss begins before menopause, and is most rapid in the first years after menopause but persists throughout the postmenopausal years. Osteoporosis is most common in women at a rate of one in two women.¹⁸ Men also are at risk, with an estimated one in four men experiencing an osteoporosis-related fracture at some point in one's lifetime.¹⁸ In adults older than age 50, the prevalence of osteoporosis at either the spine or the femoral neck by age ranges from 3% to 10% in men and from 7% to 35% in women. One study showed that in men the prevalence of osteoporosis did not increase with age until age 80 years and older, but in women it increased for each decade after age 50 years.¹⁹

Approximately 52 million people in the United States are affected by osteoporosis or low bone density.²⁰ The major risks for persons with osteoporosis are fractures. Men lose bone density with aging; but because they begin with a higher bone density, they reach osteoporotic levels at an older age than do women.²¹ In 2011 the

United States Preventive Services Task Force (USPSTF) issued a recommendation that women age 65 and older be routinely screened for osteoporosis.²² Hip fractures, in particular, can have devastating effects on an individual's life. In addition to direct medical costs, studies have shown decreased quality of life as well as excess loss of life-years for those experiencing hip or osteoporotic fractures.^{23,24}

Vertebral fractures are the most common osteoporotic fracture but may be asymptomatic. Even if the fracture does not cause pain, vertebral fractures can cause deformity, reduced pulmonary function, and loss of height. The degree of compression necessary to define a vertebral fracture has not been standardized.

Osteoporosis affects all races and both sexes. Recent data from the National Health and Nutrition Examination Survey (NHANES) showed that Mexican-Americans had higher risk for osteoporosis, whereas non-Hispanic black persons had lower risk of osteopenia or osteoporosis at the lumbar spine or femoral neck.¹⁹ Multiple genetic factors also influence development of osteoporosis.²⁵

Whites are more susceptible than other races to osteoporosis caused by loss of bone density with age. Blacks have only about half the fractures found in whites, probably related to their higher peak bone mass, but black women remain at a high risk because of factors such as decreased dietary calcium intake, a high percentage of lactose intolerance, and increased prevalence of diseases, such as sickle cell disease and lupus, that increase the risk of developing osteoporosis.²⁶ Both black women and black men have generally been undertreated for osteoporosis.²⁶ Decreased bone strength with aging is partly due to lower bone mass, but other factors such as deterioration of type I collagen likely contribute to increased fracture risk.²⁷

Measuring bone mineral density (BMD) by using dual x-ray absorptiometry (DXA) continues to be the most common method of estimating bone mass. Bone quality relates not just to bone mass (as measured by bone density) but also to the microarchitecture of the bone. Other variables include crystal size and shape, brittleness, vitality of the bone cells, structure of the bone proteins, water volume, integrity of the trabecular network, vascular supply, and the ability to

repair tiny cracks.²⁸

Because bone density relates to *quantity* of bone, bone *quality* is not accurately identified by bone density testing. Therefore bone density testing may or may not accurately identify individuals with increased fracture risk. An online tool called Fracture Risk Assessment (FRAX) (Fig. 45.10) incorporates clinical risk factors with BMD at the femoral neck to predict an individual's 10-year probability of fracture. This tool is available at <http://www.shef.ac.uk/FRAX>.

The image shows a screenshot of the FRAX Fracture Risk Assessment Tool. At the top, it displays 'Country: Canada' and a 'Name/ID:' field. Below this is a 'Questionnaire:' section with 12 numbered items. Items 1-4 are input fields for age, sex, weight, and height. Items 5-9 are radio button questions about previous fractures, parent hip fractures, smoking, glucocorticoids, and rheumatoid arthritis. Items 10-12 are radio button questions about secondary osteoporosis, alcohol consumption, and femoral neck BMD. A 'Select BMD' dropdown menu is next to item 12. 'Clear' and 'Calculate' buttons are at the bottom right.

FIGURE 45.10 Fracture Risk Assessment Tool: FRAX. (Available at: <http://www.shef.ac.uk/FRAX/tool.aspx?country=19>.)

Postmenopausal osteoporosis occurs in middle-aged and older women. It can occur because of estrogen deficiency as well as estrogen-independent age-related mechanisms (e.g., secondary causes such as hyperparathyroidism and decreased mechanical stimulation). Recent studies indicate that increased oxidative stress (OS) and increased intracellular reactive oxygen species (ROS) play a significant role in the development of age-related bone loss, as well as other age-related changes in the body.²⁸ Hormonal deficiency also can increase with stress, excessive exercise, and low body weight. Postmenopausal

changes include a substantial increase in bone turnover—that is, an imbalance between the remodeling activity of osteoclasts and osteoblasts. Increased formation and longevity of osteoclasts result in increased bone resorption and is associated with a cascade of proinflammatory cytokines. Increased cytokine activation, especially tumor necrosis factor (TNF), can occur with declining estrogen levels.²⁸ In addition, estrogen helps protect against the effects of OS and osteoclast apoptosis. Biologically, these processes involve the receptor activator of nuclear factor $\kappa\beta$ ligand (RANKL), transcription factors such as Forkhead proteins, the Wnt and osteoprotegerin (OPG) signaling pathways (see the following [Pathophysiology](#) section), and insulin-like growth factor (IGF). Other causes may include a combination of inadequate dietary calcium intake and lack of vitamin D, possibly decreased magnesium level, lack of exercise, low body mass, and family history. IGF is known to help in fracture healing and collagen synthesis and improves conditions for bone mineralization. IGF levels significantly decline by age 60.

The levels of sex hormones, especially estradiol (estrogen) and testosterone, are significant in premenopausal bone maintenance; however, when estrogen levels drop after menopause, it appears that circulating androgens become significant effectors on bone metabolism. In clinical studies of women, data have suggested that serum androgens influence bone density in pre-, peri-, and postmenopausal women. Androgens (i.e., testosterone and dihydrotestosterone) have long been recognized to stimulate bone formation. Other risk factors are identified in [Box 45.2](#).

Poor nutrition and insufficient intake or malabsorption of dietary minerals, particularly calcium, are factors in the development of osteoporosis. Calcium absorption from the intestine decreases with age, and studies of individuals with osteoporosis show that their calcium intake is lower than that of age-matched controls. Deficiencies of vitamins, particularly vitamins C, D, E, and K, also contribute to bone loss.²⁹

Skeletal homeostasis depends on a very narrow range of plasma calcium and phosphate concentrations, which are maintained by the

endocrine system.³⁰ Therefore endocrine dysfunction ultimately can cause metabolic bone disease. In addition to declining levels of sex steroids, the hormones most commonly associated with osteoporosis are parathyroid hormone, cortisol, thyroid hormone, and growth hormone. Excessive intakes of caffeine, alcohol, and nicotine along with low body fat have been considered risk factors. In addition, significant differences in the levels of trace elements (zinc, copper, manganese) were noted in the bones and hair of unaffected individuals compared with those with osteoporosis. The development of selective estrogen receptor modulators (SERMs) for the treatment of postmenopausal osteoporosis increases bone formation and builds more muscle mass. In theory, selectively affecting bone, muscle mass, and other desired sites, while not affecting lipid or estrogen levels or blood pressure, side effects can be controlled but since the direct effects of SERMs on bone are not yet known, this remains a clinical challenge.³¹

Secondary osteoporosis sometimes develops temporarily in individuals receiving large doses of heparin, perhaps because heparin promotes bone resorption by decreasing collagen synthesis or by increasing collagen breakdown. Osteoporosis caused by heparin therapy usually resolves when therapy ceases. Treatment with other medications may lead to the development of osteoporosis, such as the use of glucocorticoid treatment for many chronic disease processes. Other medications that increase the risk of osteoporosis include lithium, methotrexate, anticonvulsants, cyclophosphamide, and cyclosporine.

One secondary cause, transient osteoporosis of the hip, is associated with the third trimester of pregnancy or the immediate postpartum period. However, most transient osteoporosis is a typically self-limiting syndrome affecting the lower extremity joints of middle-aged men. The etiology is unknown, and although most cases spontaneously resolve, some occurrences of bone demineralization may be related to osteonecrosis.³²

Regional osteoporosis—osteoporosis confined to a region or segment of the appendicular skeleton—usually has a known cause.

Transient regional osteoporosis has no known etiology, is characterized by bone marrow edema, and can cause severe pain. The lower extremity is most often affected, but other areas also may be involved.³³ Fortunately, it is usually self-limited. It tends to occur in middle-aged men and women in their late second or third trimester of pregnancy.³³ It is characterized by bone marrow edema, seen on magnetic resonance imaging (MRI), and areas of localized bone demineralization are seen on plain radiographs. Treatment is primarily symptomatic and the condition usually resolves spontaneously over 3 to 6 months, with no long-term adverse effects.

Classic regional osteoporosis is associated with disuse or immobilization of a limb because of fractures, motor paralysis, or bone or joint inflammation (see [Fig. 45.14](#)). A negative calcium balance develops early and continues throughout the period of immobilization. After 8 weeks of immobilization, significant osteoporosis is present, although it may develop earlier in persons younger than 20 years or older than 50 years. A uniform distribution of osteoporosis also has been observed in astronauts and in individuals treated with air suspension therapy as a result of weightlessness and lack of mechanical strain.

◆Pathophysiology.

Whatever the cause, osteoporosis develops when the remodeling cycle—the process of bone resorption and bone formation—is disrupted, leading to an imbalance in the coupling process. The explosion of new information in the field of bone biology has led to new understanding of the roles of hormones, growth and signaling factors, and cellular biology in osteoporosis. Although hormonal influences remain important in maintaining bone health, genetic factors and the role of oxidative stress are receiving increased attention as critical determinants of bone homeostasis.^{25,28} Reactive oxygen species (ROSs) are normal byproducts of aerobic metabolism, and although they can cause cell damage, at levels below which they cause oxidative stress (OS), ROSs serve as signaling molecules for many cell types, including osteocytes, osteoblasts, and osteoclasts. When excess ROSs

accumulate, OS occurs and can result in loss of bone mass and bone strength.²⁸

The osteoclast differentiation pathway is directed by a series of processes that include proliferation, differentiation, fusion, and activation. These processes are controlled by hormones, cytokines, and paracrine stromal-cell microenvironment interactions. Thus the intercellular communication in bone and the key molecular regulators are necessary for bone homeostasis. Certain transcription factors, known as *Forkhead box (FoxO)*, help protect against the effects of OS by preventing excess accumulation of ROS and regulating certain genes that affect DNA repair and cell life span. FoxOs help remove damaged and abnormal cells by inducing apoptosis.²⁸

Interleukins (IL-1, IL-4, IL-6, IL-7, IL-11, IL-17), tumor necrosis factor-alpha (TNF- α), transforming growth factor-beta (TGF- β), prostaglandin E₂, and hormones interact to control osteoclasts³⁴ (Fig. 45.11). Normal bone homeostasis is dependent on the balance between the cytokine **receptor activator of nuclear factor $\kappa\beta$ ligand (RANKL)**, its receptor **RANK**, and its decoy receptor **osteoprotegerin (OPG)**; understanding this has led to a tremendously increased knowledge of osteoclast biology and pathogenesis of bone loss.³⁵

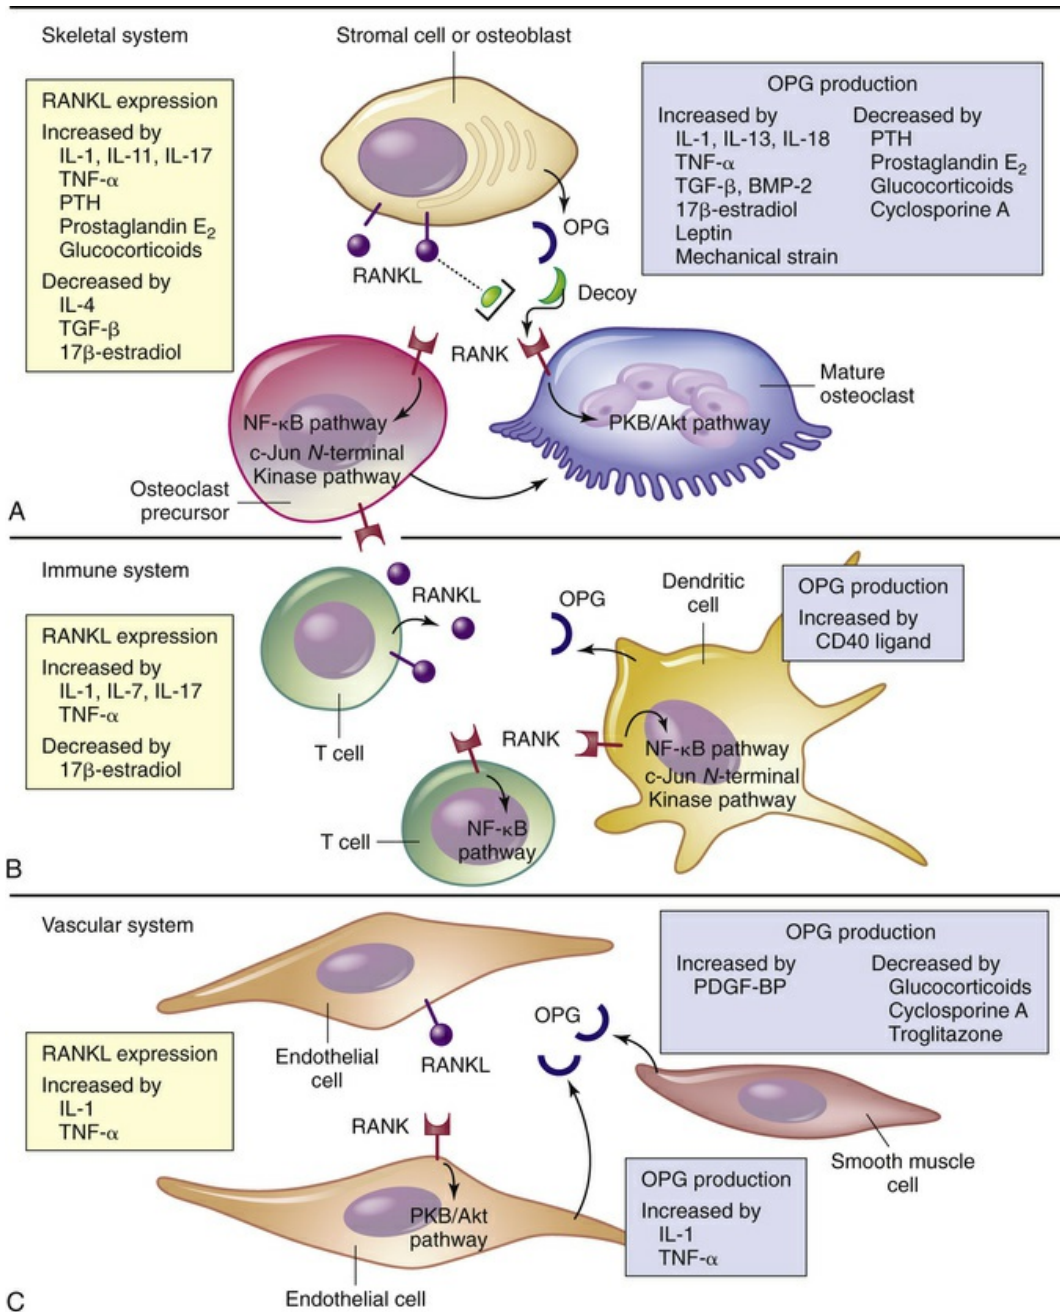

FIGURE 45.11 OPG/RANKL/RANK System. Receptor activator of nuclear factor κ β ligand (*RANKL*, which is a cytokine and part of the tumor necrosis factor [*TNF*] family) and osteoprotegerin (*OPG*, which is a glycoprotein receptor antagonist) are modulated by various cytokines, hormones, drugs, and mechanical strains (see *inserts*). **A**, In bone, *RANKL* is expressed by both stromal cells and osteoblasts. *RANKL* stimulates the receptor *RANK* on osteoclast precursor cells and mature osteoclasts, and activates intracellular signaling pathways to promote osteoclast differentiation and activation and cytoskeletal reorganization and survival (*PKB/Akt pathway*) that increase resorption and bone loss. *OPG*, secreted by stromal cells and osteoblasts, acts as a “decoy” receptor and blocks *RANKL* binding to and activation of *RANK*. **B**, In the immune system, *RANKL* is expressed and secreted by T cells. T-cell-derived *RANKL* also can activate *RANK* on

osteoclasts, T cells, and dendritic cells (antigen-presenting cells), which enhances bone loss that occurs in inflammatory bone diseases such as rheumatoid arthritis. Dendritic cells may regulate these processes by secreting OPG. C, In the vascular system, endothelial cells express RANKL and the RANK receptor. RANKL/RANK interactions contribute to endothelial and smooth muscle cells and can block RANKL binding. The physiologic significance of the OPG/RANKL/RANK system in endothelial and smooth muscle cells is being studied. *BMP-2*, Bone morphogenic protein 2; *IL*, interleukin; *PDGF-BP*, platelet-derived growth factor-beta polypeptide; *PTH*, parathyroid hormone; *TGF- α* , tumor necrosis factor-alpha; *TGF- β* , transforming growth factor-beta. (Adapted from Hofbauer LC, Schoppet M: *JAMA* 292[4]:490–495, 2004.)

RANKL, a member of the TNF family, is expressed by osteoblasts and their immature precursors and is necessary for osteoclast development. RANKL activates the receptor RANK, which is expressed on osteoclasts and their precursors and suppresses apoptosis, which leads to activation and prolongation of osteoclast survival.³⁶ The effects of RANKL are blocked by OPG, a glycoprotein that acts as a decoy receptor for RANKL that prevents it from binding and activating RANK (see Fig. 45.11). Cytokines and hormones regulate the balance between RANKL and OPG. Alterations of the RANKL/RANK/OPG system can lead to dysregulation and pathologic conditions including osteoporosis, immune-mediated bone diseases, malignant bone disorders, and inherited skeletal diseases (see Fig. 45.11).

Postmenopausal osteoporosis is characterized by increased bone resorption relative to the rate of bone formation, leading to sustained bone loss resulting from estrogen deficiency. Bone loss resulting from estrogen deficiency also contributes to osteoporosis in men.^{37,38}

Increased bone resorption results from enhanced development of osteoclasts and decreased osteoclast apoptosis (see Fig. 45.11). Estrogen stimulates OPG secretion and down-regulates RANKL; drugs known as *selective estrogen response modifiers (SERMs)* also stimulate OPG production. In estrogen deficiency, the exact role of OPG is less clear.³⁴ Postmenopausal women express higher levels of RANKL on bone marrow stromal cells, T cells, and B cells than premenopausal women. Importantly, RANKL expression is increased when estrogen levels are decreased, leading to increased formation of osteoclasts while reducing osteoclast apoptosis.²¹ Other factors, such

as sclerostin (SOST), a glycoprotein secreted by osteocytes, are powerful inhibitors of osteoblast formation by binding to low-density lipoprotein (LDL) receptor-related protein 5 (LRP5) and prevent binding with frizzled protein and Wnt signaling, important factors in osteoblast and bone formation.³⁴

Sex steroids (e.g., estrogens) exert antiapoptotic effects on osteoblasts but exert proapoptotic effects on osteoclasts; in both scenarios this is accomplished by activating the **extracellular signal regulated kinases (ERKs)**. Estrogen activates ERKs outside the nucleus; ERKs then accumulate in the nucleus and activate downstream transcription factors.³⁹ This confusing and complicated information eventually revealed that the important determinant of whether proapoptosis or antiapoptosis was exhibited was the *length of time* that the phosphorylated ERKs remained in the nucleus. Prolonged nuclear accumulation of activated ERKs converted the antiapoptotic effect of estradiol to proapoptotic. In addition to ERKs, RANKL promotes the antiapoptotic effects on osteoclasts, thus increasing their life span.⁴⁰ Wnt signaling induces a biochemical series of events that increases osteoblast and bone formation. Alterations in Wnt signaling account for critical pathophysiologic changes in most acquired metabolic bone diseases including postmenopausal osteoporosis, aging effects, and glucocorticoid (i.e., cortisone) excess. Agents such as parathyroid hormone and bisphosphonates, used for treatment of bone loss, exert their positive effects by altering the formation of osteoblasts or osteoclasts or by inducing osteoclast apoptosis.

Glucocorticoid- (e.g., cortisone-) induced osteoporosis is characterized by increased bone resorption and decreased bone formation. Glucocorticoids increase RANKL expression and inhibit OPG production by osteoblasts (see [Fig. 45.11](#)). The use of immunosuppressive drugs (e.g., cyclosporine A) to reduce rejection of transplanted organs also alters the OPG/RANKL/RANK system and can lead to posttransplantation osteoporosis. Other conditions affected by OPG/RANKL/RANK include rheumatoid arthritis, myeloma, vascular diseases, and skeletal metastases from neoplastic disorders.

Age-related bone loss begins in the third to fourth decade. The cause remains unclear, but it is known that decreased serum growth hormone (GH) and IGF levels along with increased binding of RANKL and decreased OPG affect osteoblast and osteoclast function. Loss of trabecular bone in men proceeds in a linear fashion, with thinning of trabecular bone rather than complete loss as is noted in women (Fig. 45.12). Men have approximately 30% more bone mass than women, which may be a factor in their later involvement with osteoporosis (Fig. 45.13). Androgens promote osteoprotegerin production, thus inhibiting the osteoclastic effect of RANKL.⁴¹ Reduction in physical activity in older persons also may be a major factor in the degree of bone loss because preservation of bone mass depends on skeletal stress (mechanical) through muscle contraction and weightbearing.³⁴

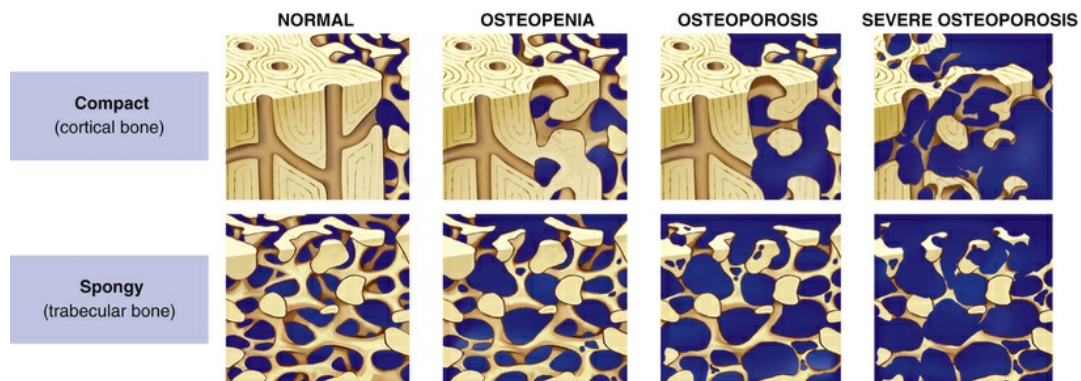

FIGURE 45.12 Osteoporosis in Cortical and Trabecular Bone.

FIGURE 45.13 Mechanism of Loss of Trabecular Bone in Women and Trabecular Thinning in Men. Bone thinning predominates in men because of reduced bone formation. Loss of connectivity and complete trabecular loss predominate in women.

◀Clinical Manifestations.

The specific clinical manifestations of osteoporosis depend on the bones involved. The most common manifestation, however, is bone deformity. Pain tends to occur only when there is a fragility fracture. Fractures are likely to occur because the trabeculae of spongy bone become thin and sparse and compact bone becomes porous. As the bones lose volume, they become brittle and weak and may collapse or become misshapen. Vertebral collapse causes kyphosis (hunchback) and diminished height (Fig. 45.14). Fractures of the long bones (particularly the femur and humerus), distal radius, ribs, and vertebrae are most common. The most serious fractures associated with osteoporosis are hip fractures because of their resultant chronic pain, disability, diminished quality of life, and premature death. Fracture of the neck of the femur (intertrochanteric fracture) tends to occur in older adult women with osteoporosis.⁴² Fatal complications of fractures include fat or pulmonary embolism, hemorrhage, and shock. Approximately 20% of persons with a hip fracture die as a result of surgical complications.

FIGURE 45.14 Kyphosis. This older adult woman's condition was caused by a combination of spinal osteoporotic vertebral collapse and chronic degenerative changes in the vertebral column. (From Kamal A, Brocklehurst JC: *Color atlas of geriatric medicine*, ed 2, St Louis, 1992, Mosby.)

◆Evaluation and Treatment.

Generally, osteoporosis is detected radiographically as increased radiolucency of bone. By the time abnormalities are detected by x-ray examination, as much as 25% to 30% of bone tissue may have been lost.

Types of radiologic examinations include single- or dual-photon absorptiometry (SXA, DXA) and computed tomography (CT) scans. Because osteoporosis is asymptomatic unless a fracture occurs, diagnosis is often delayed. At present, DXA is the current examination of choice for diagnosis. Unfortunately, DXA does not provide information about bone strength or fracture risk.

Bone density is based on the number of standard deviations that differ from the mean bone mineral density of a young-adult reference population (a T-score) ([Table 45.5](#)). Osteopenia is categorized as a

bone density score between 1.5 and 2.5 standard deviations below normal. A T-score of 2.5 or more standard deviations below normal bone density is considered osteoporosis. Severe or established osteoporosis is identified when there has been a fragility fracture associated with low bone density. The disease can be generalized as involving major portions of the axial skeleton or regional loss that involves one segment of the appendicular skeleton.⁴³

TABLE 45.5

T-SCORE CLASSIFICATION*

T-SCORE	CLASSIFICATION
$T \geq -1.0$	Normal bone density
T between -1.0 and -2.5	Osteopenia or low bone density
$T \leq -2.5$	Osteoporosis

*The World Health Organization's T-score classification scale for the diagnosis of osteoporosis. *T*, T-score.

Data from National Osteoporosis Foundation: *Clinician's guide to prevention and treatment of osteoporosis*, Washington, DC, 2017, Author.

Because fractures are the primary complication of osteoporosis, the World Health Organization (WHO) has developed an assessment tool to estimate an individual's 10-year risk of fracture. The WHO's Fracture Risk Assessment (FRAX) is a downloadable computer-drive questionnaire that has been developed for use in Europe, North America, Asia, and Australia. Once completed, the imbedded algorithms predict the 10-year probability of hip, spine, forearm, or shoulder fractures. This tool can be downloaded from <http://www.shef.ac.uk/FRAX> (see Fig. 45.10). Other evaluation procedures include tests for levels of serum calcium, phosphorus, and alkaline phosphatase as well as protein electrophoresis. Body calcium levels also can be measured by neutron activation analysis, a procedure involving use of radioactive calcium-49, whose gamma activity can be measured with a whole-body counter.

Though prevention of osteoporosis is paramount, treatment is more

common and is focused on preventing fractures and maintaining optimal bone function. The role of calcium intake to prevent and treat osteoporosis is controversial. It is well accepted that oral calcium intake sufficient to maintain normal calcium balance is necessary during adolescence to ensure development of peak bone mass, and that calcium-deficient diets can aggravate bone loss associated with menopause and aging. Although recommendations have been established for young women of 1000 mg of calcium daily (particularly from dietary sources) and for postmenopausal women of 1500 mg daily (with vitamin D), it has been difficult to translate these recommendations into clear-cut clinical outcomes (see [Nutrition & Disease: Postmenopausal Women Should Not Take Calcium and Vitamin D to Prevent Fractures](#)). A significant relationship has been observed between an individual's lifetime history of calcium intake and peak bone mineral density. Diets with higher fruit and vegetable intake seem to correlate with higher BMD.⁴⁴ Other nutrients that appear to have a positive impact on bone health include magnesium, vitamin K₂, and docosahexaenoic acid or DHA (from purified fish oil).⁴⁵

Nutrition & Disease

Postmenopausal Women Should Not Take Calcium and Vitamin D to Prevent Fractures

The beneficial effects of vitamin D on fracture risk are attributed to two explanations: (1) the decrease in bone loss in older adults, and (2) the increase in muscle strength and balance mediated through vitamin D receptors in muscle tissue. Vitamin D alone, however, does not appear to reduce fracture risk. In fact, the U.S. Preventive Services Task Force (USPSTF) has made the recommendation that postmenopausal women should not take supplementary calcium (1000 mg or less) and vitamin D (400 international units or less) because, at these doses, it appears that they do not prevent primary fracture risk and pose a small increased risk for renal stones. The

USPSTF also concluded there is not enough evidence either supporting or opposing the use of higher doses of calcium and vitamin D for men or premenopausal women.

Data from Moyer V: *Ann Intern Med* Feb 2013 (online).

Magnesium (Mg^{++}), another mineral important for skeletal development, is an essential mineral in many biochemical and physiologic functions, including activation of enzymes, involvement in adenosine triphosphate (ATP) synthesis and protein synthesis, regulation of membrane channels, and contraction of muscle. Mg^{++} is important to bone quality because it helps control hydroxyapatite crystal growth and thereby prevents formation of brittle bones. It seems reasonable that Mg^{++} is required for normal calcium (Ca^{++}) absorption because severe Mg^{++} deficiency results in hypocalcemia.

Regular, moderate weightbearing exercise can slow the rate of bone loss and, in some cases, reverse demineralization because the mechanical stress of exercise stimulates bone formation. It is important to reduce the risk of falls and enhance bone quality. Therefore an exercise program to enhance muscle strength is advised. Important new findings suggest that estrogen may prevent excessive bone loss before and after menopause by limiting osteoclast life span through promotion of apoptosis.

SERMs are being used to provide the positive effects of estrogen on bone but minimize estrogen's negative effect on breast and endometrial tissues. As a result, in addition to reducing vertebral fractures, SERMs reduce risk of estrogen receptor breast cancer and improve lipid profiles.⁴⁶ Raloxifene and tamoxifen are examples of SERMs.

Bisphosphonates are a class of inorganic pyrophosphate derivatives that bind bone mineral and improve osteoblast and osteocyte survival while promoting osteoclast apoptosis, thus slowing the bone remodeling process.⁴⁷ Nitrogen-containing bisphosphonates are highly effective in reducing both vertebral and nonvertebral osteoporotic fractures; because of this, bisphosphonates are the

mainstay of osteoporosis treatment. Side effects include alterations in TGF- β signaling that may cause osteonecrosis of the jaw.⁴⁷ There also is a small risk of atypical femoral fractures, atrial fibrillation, and possibly esophageal cancer associated with bisphosphonates.⁴⁸⁻⁵¹ The optimal length of treatment with bisphosphonates has not yet been determined.⁵²

One of the most promising treatments for osteoporosis is denosumab, a monoclonal antibody that binds the cytokine receptor activator of nuclear factor- $\kappa\beta$ ligand (RANKL). RANKL inhibition blocks the maturation, function, and survival of osteoclasts, thus reducing bone resorption.⁵³

Teriparatide, also called *PTH 1-34*, is a biosynthetic form of parathormone and contains the first 34 amino acids of parathyroid hormone; PTH 1-84 is a recombinant PTH that contains all 84 amino acids of naturally occurring PTH. Both work by stimulating osteoblasts when administered intermittently.⁵⁴ Given by subcutaneous injection, PTH reduces vertebral fractures but use is limited to a period of 24 months because of the risk of developing osteosarcoma. A recent large meta-analysis of osteoporosis treatment found improved BMD and reduced fractures with bisphosphonates, SERMs, and denosumab, though each regimen has potential adverse effects.⁵⁵ Restoration of a balanced RANKL/OPG ratio (see [Chapter 44](#)) or inhibition of RANK responsiveness is known to prevent osteoclast activation and bone resorption. Anti-RANKL therapy significantly reduces bone resorption. Other biologic agents under investigation include cathepsin K inhibitors, antisclerostin, and anti-dickkopf antibodies that affect the Wnt/ β -catenin signaling pathway in osteoblasts.⁵⁶

Osteomalacia

Osteomalacia is a metabolic disease characterized by inadequate and delayed mineralization of osteoid in mature compact and spongy bone. In osteomalacia the remodeling cycle proceeds normally through osteoid formation, but mineral calcification (hydroxyapatite formation) does not occur. Bone volume remains unchanged, but the

replaced bone consists of soft osteoid instead of rigid bone. The result is abnormal bone matrix mineralization. Rickets is similar to osteomalacia in pathogenesis, but it occurs in the growing bones of children, whereas osteomalacia occurs in adult bone. Chronically low serum phosphate levels can be caused by tumors resulting in osteomalacia.⁵⁷ Fibroblast growth factor-23 (FGF-23) plays a significant role in maintaining normal serum phosphate levels. Primarily produced by osteocytes, FGF-23 functions to inhibit reabsorption of phosphate in the renal proximal tubule.⁵⁸ (Rickets is described in [Chapter 46](#).)

Osteomalacia and rickets are rare in the United States and parts of Europe but are significant health problems in Great Britain, Ethiopia, Pakistan, Iran, and India. In the United States these diseases occur in older adults, in premature infants of very low birth weight, and in individuals adhering to rigid macrobiotic vegetarian diets. Breast-fed black infants who do not receive vitamin D supplementation have been shown to be at risk for developing nutritional rickets.^{59,60}

Many factors contribute to the development of osteomalacia, but the most important is a deficiency of vitamin D. The major causes of vitamin D deficiency are diets deficient in vitamin D, decreased endogenous production of vitamin D, intestinal malabsorption of vitamin D, renal tubular diseases, and anticonvulsant therapy. Classic vitamin D deficiency is rare in the United States because of the addition of synthetic vitamin D to dairy products and bread. Still, disorders of the small bowel, kidneys, hepatobiliary system, and pancreas do cause vitamin D deficiency in the United States. In malabsorptive disease of the small bowel, vitamin D and calcium absorption are decreased, so vitamin D is lost in feces. Liver disease interferes with the metabolism of vitamin D to its more active form, and diseases of the pancreas and biliary system cause a deficiency of bile salts, which are necessary for normal intestinal absorption of vitamin D.

The mechanism by which anticonvulsant drug therapy results in decreased bone mineral density is not completely understood, but appears to be from direct impact on bone or effects on other regulators

of bone metabolism such as calcium, vitamin D, and parathyroid hormone.⁶¹ The anticonvulsants phenobarbital and phenytoin interfere with calcium absorption and increase degradation of vitamin D metabolism in the liver through activation of the cytochrome P-450 pathway.⁶²

◆Pathophysiology.

Crystallization of minerals in osteoid requires adequate concentrations of calcium and phosphate. When the concentrations are too low, crystallization, and hence ossification, does not proceed normally.

Vitamin D deficiency disrupts mineralization because vitamin D normally regulates and enhances the absorption of calcium ions from the intestine. A lack of vitamin D causes the plasma calcium concentrations to fall. Low plasma calcium levels stimulate increased synthesis and secretion of parathyroid hormone (PTH). Although the increase in the level of circulating PTH raises the plasma calcium concentration, it also stimulates increased renal clearance of phosphate. When the concentration of phosphate in the bone decreases below a critical level, mineralization cannot proceed normally.

Abnormalities occur in spongy as well as compact bone. Trabeculae in spongy bone become thinner and fewer, whereas haversian systems in compact bone develop large channels and become irregular. Because osteoid continues to be produced but not mineralized, abnormal quantities of osteoid accumulate, coating the trabeculae and the linings of the haversian canals. Excessive osteoid also can accumulate in areas beneath the periosteum. The excess of osteoid leads to gross deformities of the long bones, spine, pelvis, and skull.

◆Clinical Manifestations.

Osteomalacia causes varying degrees of diffuse skeletal pain and tenderness. Bone pain is typically between joints, rather than within them.⁵⁹ Pain is noted particularly in the hips, and the individual may be hesitant to walk. Muscular weakness, particularly of the proximal

muscles, is common and may contribute to a waddling gait. Facial deformities and bowed knees, or “knock-knees,” may be present. Bone fractures and vertebral collapse occur with minimal trauma. Low back pain may be an early complaint, but pain also may involve ribs, feet, other areas of the vertebral column, and other sites. Uremia may be present in renal osteodystrophy.

◆Evaluation and Treatment.

Laboratory data may include elevated blood urea nitrogen (BUN) and creatinine levels, normal or low serum calcium levels, and a serum inorganic phosphate level that is usually higher than 5.5 mg. Alkaline phosphatase and PTH levels are usually elevated. Radiographic findings show pseudofractures and radiolucent bands perpendicular to the surface of involved bones. Bone biopsy is useful in determining bone structure and remodeling.⁶³ Diagnosis of certain types of osteomalacia is becoming easier because of the ability to measure an individual's serum FGF-23 level. Elevated FGF-23 levels are common in X-linked hypophosphatemic and tumor-induced osteomalacia.⁶⁴

Treatment of osteomalacia includes the following:

1. Adjusting serum calcium and phosphorous levels to normal
2. Suppressing secondary hyperthyroidism
3. Chelating bone aluminum if needed
4. Administering calcium carbonate to decrease hyperphosphatemia

Paget Disease

Paget disease of bone (PDB or osteitis deformans) is a state of increased metabolic activity in bone characterized by abnormal and excessive bone resorption and formation (remodeling). Genetic manipulations involving the RANK–NF- κ β signaling pathways are significant in the development of Paget disease, resulting in increased

osteoclast activity.⁶⁵ Chronic accelerated remodeling eventually enlarges and softens the affected bones. Classic PDB arises as a consequence of disorderly bone resorption and formation.

PDB most often affects the axial skeleton, especially the vertebrae, skull, sacrum, sternum, pelvis, and femur. The disease process may occur in one or more bones without causing significant clinical manifestations.

The disease is seldom found before age 40 years, but its incidence almost doubles each decade from age 50. It affects men more than women in a proportion of 1.8 : 1. Because it is often symptomless and can be diagnosed only by invasive procedures, few epidemiologic data are available. Autopsy data from England and Germany indicate that approximately 3% to 4% of persons older than 40 years have Paget disease. It is most prevalent in Australia, Great Britain, New Zealand, and the United States.

The cause of PDB is unknown; however, studies have implicated both genetic and environmental factors. About 10% to 30% of individuals with PDB have mutations of a specific gene, sequestosome-1. Even viral etiologies have been proposed.⁶⁵

◆Pathophysiology.

Paget disease begins with excessive resorption of spongy bone and deposition of disorganized bone. The trabeculae diminish, and bone marrow is replaced by extremely vascular fibrous tissue. The resorption phase of Paget disease is followed by the formation of abnormal new bone at an accelerated rate. The collagen fibers are disorganized, and glycoprotein levels in the matrix decrease. Mineralization may extend into the bone marrow. Bone formation is excessive around partially resorbed trabeculae, causing them to thicken and enlarge. Eventually, Paget disease progresses to an inactive phase, in which abnormal remodeling is minimal or absent. Osteoclasts of individuals with Paget disease have increased responses to RANKL.⁶⁵

◆Clinical Manifestations.

In the skull, abnormal remodeling is first evident in the frontal or occipital regions, and then encroaches on the outer and inner surfaces of the entire skull. The skull thickens and assumes an asymmetrical shape (Fig. 45.15). Thickened segments of the skull may compress areas of the brain, producing altered mentality and dementia. Impingement of new bone on cranial nerves causes sensory abnormalities, impaired motor function, deafness, atrophy of the optic nerve, and obstruction of the lacrimal duct. Headache is commonly noted.

FIGURE 45.15 Paget disease of the skull. A, Active Paget disease of the skull, with marked cortical thickening and an area of osteoporosis circumscripta (arrows). B, The same individual several years later (after bisphosphonate treatment), with the lytic lesion largely replaced by sclerotic bone. (From Walsh JP: *Med J Aust* 181[5]:263, 2004.)

Extensive alterations of the facial bones are rare except in the jaw,

where sclerosis and thickening of the maxilla and mandible displace teeth and produce malocclusion. In long bones, resorption begins in the subchondral regions of the epiphysis and extends into the metaphysis and diaphysis. Warmth over the affected area, bone and joint pain, and bone deformity may occur. Occasionally, Paget disease affects both ends of a long bone. In the femur, PDB produces an exaggerated lateral curvature. In the tibia, anterior curvature is also exaggerated. Stress fractures are common in the lower extremities.

Clinical manifestations of PDB in the vertebral column depend on the level of involvement and are caused by compression of adjacent structures. In the cervical spine, cord compression can lead to spastic quadriplegia. Approximately 1% of persons with PDB develop osteogenic sarcoma. Paget-related sarcoma has a poor prognosis.

◆Evaluation and Treatment.

Evaluation of PDB is made on the basis of radiographic findings of irregular bone trabeculae with a thickened and disorganized pattern. A typical V-shaped lesion in long bones and rounded areas of thinning bone in the skull are often seen on plain x-ray. Bone scanning can more readily detect early disease as well as extent of PDB through increased uptake of bone radionuclides. Serum total alkaline phosphatase and urinary hydroxyproline levels are elevated.⁶⁶

Most individuals require no treatment because the disease is localized and does not cause symptoms. Treatment during active disease is for pain relief, prevention of deformity, or fracture. Bisphosphonates (alendronate, risedronate, and pamidronate) and calcitonin (salmon and human) are the mainstays of treatment. Surgery is indicated if there are neurologic complications or severe bony deformities.

Infectious Bone Disease: Osteomyelitis

Osteomyelitis is a bone infection most often caused by bacteria; however, fungi, mycobacteria, parasites, and viruses also can infect bone (Fig. 45.16). Exogenous osteomyelitis is an infection that enters from outside the body, for example, through open fractures,

penetrating wounds, or surgical procedures. In exogenous osteomyelitis, infection spreads from soft tissues into adjacent bone. Endogenous osteomyelitis is caused by pathogens carried in the blood from sites of infection elsewhere in the body. In hematogenous osteomyelitis, infection spreads from bone to adjacent soft tissues. Hematogenous osteomyelitis is commonly found in infants, children, and older adults. (Osteomyelitis in children is discussed in [Chapter 46](#).) In infants, incidence rates among males and females are approximately equal. In children and older adults, however, males are most commonly affected. Osteomyelitis is a common complication of sickle cell anemia and low oxygen tension.

FIGURE 45.16 Osteomyelitis Showing Sequestration and Involucrum.

Staphylococcus aureus (including methicillin-resistant *Staphylococcus aureus* [MRSA]) is the primary cause of hematogenous osteomyelitis.⁶⁷ Other microorganisms include group B streptococci, *Haemophilus influenzae*, *Salmonella*, and gram-negative bacteria. Group B streptococci and *H. influenzae* tend to infect young children; *Salmonella* infection is associated with sickle cell anemia; and gram-negative infections are most common in older adults and individuals with impaired immunity. Mycobacterial and fungal infections occur in immunocompromised individuals.

Cutaneous, sinus, ear, and dental infections are the primary sources of bacteria in hematogenous bone infections. Soft tissue infections, disorders of the gastrointestinal tract, infections of the genitourinary

system, and respiratory tract infections are also sources of bacterial contamination. In addition, infections contracted after total joint replacement surgeries can be causes of osteomyelitis. The vulnerability of a specific bone depends on the anatomy of its vascular supply. In adults, hematogenous osteomyelitis is more common in the spine, pelvis, and small bones.

Microorganisms reach the vertebrae through arteries, veins, or lymphatic vessels. The spread of infection from pelvic organs to the vertebrae is well documented. Vaginal, uterine, ovarian, bladder, and intestinal infections can lead to iliac or sacral osteomyelitis.

Exogenous osteomyelitis can be caused by human bites or fist blows to the mouth. Superficial animal or human bites inoculate local soft tissue with bacteria that later spread to underlying bone. Deep bites can introduce microorganisms directly onto bone. The most common infecting organism in human bites is *S. aureus*. In animal bites the most common infecting organism is *Pasteurella multocida*, which is part of the normal mouth flora of cats and dogs.

Direct contamination of bones with bacteria also can occur in open fractures or dislocations with an overlying skin wound. Intervertebral disk surgery and operative procedures involving implantation of large foreign objects, such as metallic plates or artificial joints, are associated with exogenous osteomyelitis. Local injections and venous punctures are significant causes of exogenous osteomyelitis. Exogenous osteomyelitis of the arm and hand bones tends to occur in drug abusers. *S. aureus* is the most common pathogen. In general, persons who are chronically ill, have diabetes or alcoholism, or are receiving large doses of corticosteroids or immunosuppressive drugs are particularly susceptible to exogenous osteomyelitis or recurring episodes of this disease.

◆Pathophysiology.

Regardless of the source of the pathogen, the pathologic features of bone infection are similar to those in any other body tissue (see [Chapter 10](#)). First, the invading pathogen provokes an intense inflammatory response. Inflammation in bone is characterized by

vascular engorgement, edema, leukocyte activity, small blood vessel thrombosis, and abscess formation.⁶⁸ Once inflammation is initiated, the small terminal vessels thrombose and exudate seals the bone's canaliculi. Inflammatory exudate extends into the metaphysis and the marrow cavity and through small metaphyseal openings into the cortex. In children, exudate that reaches the outer surface of the cortex forms abscesses that lift the periosteum off underlying bone. Lifting of the periosteum disrupts blood vessels that enter bone through the periosteum, which deprives underlying bone of its blood supply; this leads to necrosis and death of the area of bone infected, producing **sequestrum**, an area of devitalized bone (see [Fig. 45.16](#)). Lifting of the periosteum also stimulates an intense osteoblastic response. Osteoblasts lay down new bone that can partially or completely surround the infected bone. This layer of new bone surrounding the infected bone is called an **involucrum**. Openings in the involucrum allow the exudate to escape into surrounding soft tissue and ultimately through the skin by way of sinus tracts. Involucrum in adults is rare because the periosteum is firmly attached to the cortex and resists displacement. Instead, infection disrupts and weakens the cortex, which predisposes the bone to pathologic fracture.

◆Clinical Manifestations.

Clinical manifestations of osteomyelitis vary with the age of the individual, site of involvement, initiating event, infecting organism, and whether the infection is acute, subacute, or chronic. Acute osteomyelitis causes an abrupt onset of inflammation. If an acute infection is not completely eliminated, the disease may become subacute or chronic. In subacute osteomyelitis, signs and symptoms are usually vague. In the chronic stage, infection is indolent or silent between exacerbations. The microorganisms persist in small abscesses or fragments of necrotic bone and produce occasional flare-ups of acute osteomyelitis. The progression from acute to subacute osteomyelitis may be the result of inadequate or inappropriate therapy or the development of drug-resistant microorganisms.

In the adult, hematogenous osteomyelitis has an insidious onset.

The symptoms are usually vague and include fever, malaise, anorexia, and weight loss. Recent infection (urinary, respiratory, skin) or instrumentation (catheterization, cystoscopy, myelography, diskography) usually precedes onset of symptoms.

Back pain is the primary symptom in vertebral osteomyelitis. Pain may be intermittent or constant, aggravated by motion, and throbbing at rest. It may radiate in a radicular distribution and is commonly accompanied by spinal tenderness and rigidity. Hip contracture can occur in the presence of soft tissue inflammation as a result of irritation of the psoas muscle.⁶⁹

Signs and symptoms of sacroiliac osteomyelitis are generally severe and include local pain, tenderness, and a limp. The pain may radiate to the buttock or the abdomen.

Single or multiple abscesses (Brodie abscesses) characterize subacute or chronic osteomyelitis. Brodie abscesses are painless, circumscribed lesions 1 to 4 cm in diameter, usually in the ends of long bones, and surrounded by dense ossified bone matrix. The abscesses are thought to develop when the infectious microorganism has become less virulent or the individual's immune system is resisting the infection somewhat successfully.

In exogenous osteomyelitis, signs and symptoms of soft tissue infection predominate. Inflammatory exudate in the soft tissues disrupts muscles and supporting structures and forms abscesses. Low-grade fever, lymphadenopathy, local pain, and swelling usually occur within days of contamination by a puncture wound. Osteomyelitis in the hand causes exquisite tenderness over the course of tendon sheaths. The fingers are usually in a semiflexed position, and extension usually causes severe pain. Palmar swelling or symmetrical swelling of the fingers may be present.

◆Evaluation and Treatment.

Laboratory data show an elevated white cell count. Radiographic studies include radionuclide bone scanning, CT, and MRI. MRI is especially useful in detecting early bone changes associated with infection.⁷⁰

Infectious bone disease is expensive and difficult to treat and often culminates in extensive physical disability. The following factors contribute to the difficulty in treating bone infection:

1. Bone contains multiple microscopic channels that are impermeable to the cells and biochemicals of the body's natural defenses. Once bacteria gain access to these channels, they are able to proliferate unimpeded.
2. The microcirculation of bone is highly vulnerable to damage and destruction by bacterial toxins. Vessel damage causes local thrombosis (blockage) of the small vessels, which leads to ischemic necrosis (death) of bone.
3. Bone cells have a limited capacity to replace bone destroyed by infections. Initially, osteoclasts are stimulated by infection to resorb bone, which opens up isolated bone channels so that cells of the inflammatory and immune system can gain access to the infected bone. At the same time, however, resorption weakens the structural integrity of the bone. New bone formation usually lags behind resorption, and the haversian systems in the new bone are incomplete.

Treatment of osteomyelitis includes surgical débridement with bone biopsy and culture before or as soon after initiating antibiotics as possible. Initial antibiotic therapy should be intravenous. Chronic conditions may require surgical removal of the inflammatory exudate followed by continuous wound irrigation with antibiotic solutions in addition to systemic treatment with antibiotics. **Hyperbaric oxygen therapy** of 100% oxygen, given at 2 atmospheres of pressure for 2 hours' duration per day for 30 treatments, is also beneficial for chronic refractory osteomyelitis. Implanted hardware may require removal to more thoroughly treat an infected joint.

Bone Tumors

Primary bone cancer is a rare but metastatic disease that commonly affects bone. Many different types of tumors involve the skeleton.

Based on the tissue of origin, bone tumors are classified as osteogenic, chondrogenic, collagenic, or myelogenic. Each of the four types arises from one of the four stem cells that are ultimately derived from the primitive mesoderm (Fig. 45.17). In addition, bone tumors may be classified as being of histiocytic, notochordal, lipogenic, and neurogenic origins (Box 45.3).

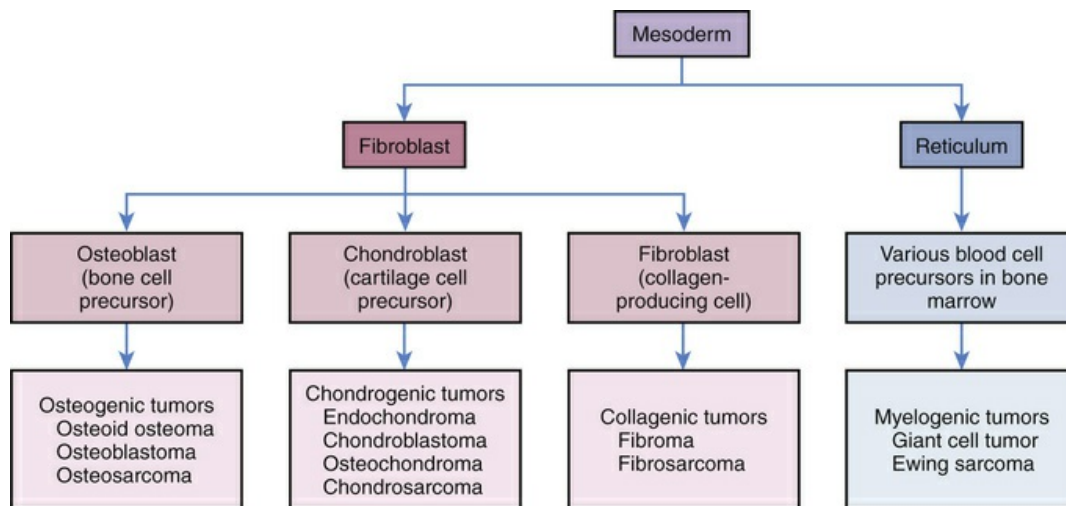

FIGURE 45.17 Derivation of Bone Tumors.

Box 45.3

World Health Organization Classification of Bone Tumors

Cartilage Tumors

- Chondrosarcoma (M)
- Chondroma (B)
- Osteochondroma (B; but may become malignant)
- Chondroblastoma (B)

Osteogenic Tumors

Osteblastoma (B)
Osteoid osteoma (B)
Osteosarcoma (M)

Fibrogenic Tumors (Often Produce Collagen; Do Not Have a Mineralizing Matrix)

Fibrosarcoma (M)

Fibrohistiocytic Tumors (Comprised of Fibroblasts)

Benign fibrous histiocytoma (B)
Malignant fibrous histiocytoma (M)

Ewing Sarcoma

Ewing sarcoma (M)

Hematopoietic Tumors

Plasma cell myeloma (M)
Malignant lymphoma (M)

Giant Cell Tumor

Giant cell tumor (B, but can grow aggressively)
Malignancy in giant cell tumor (M; very rare tumor)

Smooth Muscle Tumors

Leiomyoma (B)

Leiomyosarcoma (M)

Miscellaneous Tumors

Adamantinoma (M; almost exclusively found in tibia)

Metastatic malignancy (M; most common skeletal malignancy)

Miscellaneous Lesions

Aneurysmal bone cyst (B)

Simple cyst (B)

Fibrous dysplasia (B; rarely can become malignant)

Osteofibrous dysplasia (B)

Langerhans cell histiocytosis (B, but can aggressively grow)

Chest wall hamartoma (B; is excessive growth of mesenchymal tissue [mostly cartilage])

Joint Lesions

Synovial chondromatosis (B; rarely becomes M)

B, Benign lesion; *M*, malignant lesion.

Data from Dorfman HD et al: WHO classification of tumours of the bone: introduction. In Christopher EM et al, editors: *World Health Organization classification of tumors, International Agency for Research on Cancer (IARC) pathology and genetics of tumours of soft tissue and bone*, Lyon, France, 2002, IARC Press, p 226.

The mesoderm contributes the primitive fibroblast and reticulum cells. The fibroblast is the progenitor of the osteoblast and the chondroblast. Each cell synthesizes a specific type of intercellular ground substance, and the type of ground substance produced by the cell generally characterizes the tumor derived from the cell. For example, osteogenic tumors usually contain cells that have the

appearance of osteoblasts and produce an intercellular substance that can be recognized as osteoid. Chondrogenic tumors contain chondroblasts and produce an intercellular substance similar to chondroid (cartilage). Collagenic tumors contain fibrous tissue cells and produce an intercellular substance similar to the type of collagen found in fibrous connective tissue.

Tumors also are classified as benign or malignant. The criteria used to identify tumor cells as malignant are (1) an increased nuclear/cytoplasmic ratio, (2) an irregular nuclear border, (3) an excess of chromatin, (4) a prominent nucleolus, and (5) an increase in the number of cells undergoing mitosis. However, many young, rapidly growing, normal cells and cells subjected to inflammation and change in their blood supply also exhibit many of these same characteristics. (Tumor biology is described in [Chapter 12](#).)

Epidemiology

The incidence of bone tumors varies with age. Osteosarcoma is the most common primary malignant bone tumor in children and young adults.⁷¹ Adolescents have the highest incidence of bone tumors, and adults between 30 and 35 years of age have the lowest incidence. After age 35, the incidence slowly increases until, at age 60, it equals the incidence in adolescents, primarily related to metastatic tumors.

Patterns of Bone Destruction

The general pathologic features of bone tumors include bone destruction, erosion or expansion of the cortex, and periosteal response to changes in underlying bone. The least amount of pathologic damage occurs with benign bone tumors that push against neighboring tissue. Because they usually have a symmetrical, controlled growth pattern, benign bone tumors tend to compress and displace neighboring normal bone tissue, which weakens the bone's structure until it is incapable of withstanding the stress of ordinary use, leading to pathologic fracture. Other tumors invade and destroy adjacent normal bone tissue by producing substances that promote

resorption by increasing osteoclast activity or by interfering with a bone's blood supply. Three patterns of bone destruction by bone tumors have been identified: (1) the geographic pattern, (2) the moth-eaten pattern, and (3) the permeative pattern (Table 45.6).

TABLE 45.6

PATTERNS OF BONE DESTRUCTION BY BONE TUMORS

TYPE OF DESTRUCTION	PATTERN SEEN
Geographic	Well-defined margins separated from surrounding normal bone; well-defined lytic area in affected bone
Moth-eaten	Less-defined margin not easily separated from normal bone; areas of partially destroyed bone adjacent to completely lytic areas
Permeative	Poorly demarcated margins; abnormal lytic bone merges imperceptibly with surrounding normal bone

Tumors that erode the cortex of the bone usually stimulate a periosteal response, that is, new bone formation at the interface between the surface of the bone and the periosteum. Slow erosion of the cortex usually stimulates a uniform periosteal response. Additional layers of bone are added to the exterior surface of the bone to buttress the cortex. Eventually the additional layers expand the bone's contour. Aggressive penetration of the cortex usually elevates the periosteum and stimulates erratic patterns of new bone formation. Examples of erratic patterns include concentric layers of new bone; a sunburst pattern, in which delicate rays of new bone radiate toward the periosteum from a single focus on the underlying surface; and rays of new bone that grow perpendicularly, creating a brush or bristle pattern.

Diagnosis

Malignant bone tumors account for less than 0.2% of all cancers.⁷¹ A tumor must be identified early to allow survival of the individual and the preservation of the affected limb. However, individuals often have only vague symptoms that may be attributed to minor trauma,

degenerative changes, or inflammatory conditions. In addition, other conditions may obscure the diagnosis.

Thorough diagnostic studies are needed to determine the exact type and extent of bone tumor present, which also helps determine the optimal treatment regimen. Staging of any bone tumor is critical to determine future treatment and results. The American Joint Committee on Cancer (AJCC) staging system (also known as the *Enneking* or *TNM staging system*) is the most commonly used arrangement (Table 45.7). This system classifies tumors according to grade (G), tumor site (T), and metastasis (M). Benign tumors are given a numeric value of zero, whereas malignant tumors are low grade (G₁) or high grade (G₂).

TABLE 45.7

THE ENNEKING SURGICAL STAGING SYSTEM FOR MALIGNANT BONE TUMORS

STAGE	GRADE	SITE (T)	METASTASIS (M)
IA	Low (G ₁)	Intracompartmental (T ₁)	None (M ₀)
IB	Low (G ₁)	Extracompartmental (T ₂)	None (M ₀)
IIA	High (G ₂)	Intracompartmental (T ₁)	None (M ₀)
IIB	High (G ₂)	Extracompartmental (T ₂)	None (M ₀)
IIIA	Low (G ₁)	Intracompartmental or extracompartmental (T ₁ or T ₂)	Regional or distant (M ₁)
IIIB	High (G ₂)	Intracompartmental or extracompartmental (T ₁ or T ₂)	Regional or distant (M ₁)

Data from National Comprehensive Cancer Network: *Recent updates to NCCN clinical practice guidelines in oncology: bone cancer, Version 1*, Fort Washington, PA, 2013, Author.

Serum alkaline phosphatase levels are elevated in bone lytic tumors, and they are significantly elevated in osteosarcoma and Ewing sarcoma. Radiologic studies include plain radiologic film, technetium-99 bone scan, CT scan, and MRI, which has become the examination of choice for the local staging of bone tumors, especially the staging of peripheral osteosarcomas (see Table 45.6). MRI is also used to monitor the response of osteosarcomas to radiation or chemotherapy and to detect recurrent disease. A CT scan can evaluate involvement of

osteosarcoma in flat bones when the tumor is not well-defined on a plain film, can assist in differentiating the tumor, and can locate pulmonary metastases. Radionuclide bone scans show an increased uptake at the tumor site. Before any surgical procedure, placement of bone biopsy is critical.⁷²

Additional diagnostic studies performed for specific bone tumors include a complete blood count and erythrocyte sedimentation rate (to rule out infection, myeloma, or Ewing sarcoma) and measurement of serum levels of calcium and phosphorus to detect hypercalcemia. Serum glucose levels may be elevated in chondrosarcoma. Acid phosphatase level may be moderately elevated in bone metastases, multiple myeloma, and advanced Paget disease. Serum protein electrophoresis and immunoelectrophoresis are done to rule out multiple myeloma. Fine-needle biopsy is done, usually at the time of surgery, to determine the exact tumor type.

Types

A very large number of lesions are classified as bone tumors. The bone tumors most representative of the four derivative types (see [Fig. 45.17](#))—osteogenic, chondrogenic, collagenic, and myelogenic tumors—are described here.

Osteogenic Tumors: Osteosarcoma.

Osteogenic (bone-forming) tumors are characterized by the formation of bone or osteoid tissue with a sarcomatous tissue. The tissue can have the appearance of compact or spongy bone. The most common malignant primary bone tumor is osteosarcoma. **Osteosarcomas** account for 38% of bone tumors. The male/female ratio is 3:2, and osteosarcoma occurs predominantly in adolescents and young adults; 60% of osteosarcomas occur in persons younger than 20 years. A secondary peak incidence for osteosarcoma occurs in the 60 and older age group, primarily in individuals with a history of radiation therapy several years previously for pelvic or other malignancies ([Fig. 45.18](#)).

FIGURE 45.18 Osteosarcoma. A, Common locations of Ewing sarcoma and osteosarcoma. *Blue*, osteosarcoma; *red*, Ewing sarcoma. B, Comparison of plain radiograph, MRI, and nuclear bone scan appearances of osteosarcoma of the distal femur. Note destruction of the bone cortex and soft tissue component. (A adapted from Bontrager KL, Lampignano JP, editors: *Textbook of radiographic positioning and related anatomy*, St Louis, 2013, Elsevier. B from HaDuong JH et al: *Pediatr Clin N Am* 62:179–200, 2015.)

An osteosarcoma is a malignant bone-forming tumor. It is aggressive and most often found in bone marrow; it has a moth-eaten pattern of bone destruction. The borders of the tumor are indistinct and merge into adjacent normal bone. Osteosarcomas always contain osteoid and callus (osteoblastic sarcoma) produced by anaplastic stromal cells, which are atypical, abnormal cells not seen in normal developing bone; they are neither normal nor embryonal. The osteosarcoma also may contain chondroid (cartilage) (chondroblastic sarcoma) and fibrinoid tissue (fibroblastic sarcoma) that may form the bulk of the tumor. The osteoid is deposited in thick masses or “streamers” between the trabeculae of callus, which infiltrate the normal compact bone, destroy it, and replace it with dense callus and masses of osteoid. Demonstrating the presence of osteoid aids in the diagnosis of osteosarcoma. Bone tissue produced by osteosarcomas never matures to compact bone.

Ninety percent of osteosarcomas are located in the metaphyses of long bones, especially the distal femur and proximal tibia, with 50% around the knee area. The tumor typically breaks through the cortex, lifts the periosteum, and forms a soft tissue mass that is *not* covered by a smooth shell of new bone. Lifting of the periosteum stimulates

bizarre patterns of new bone formation called a *periosteal reaction*. Distinct osteosarcomas occur on the surface of long bones, called *parosteal*, *periosteal*, or *high-grade surface osteosarcomas*; dedifferentiated parosteal and central osteosarcomas also occur.

The most common initial symptoms are pain and swelling. Initially the pain is slight and intermittent, but within a short time it increases in severity and duration. Pain is usually worse at night and gradually requires medication. Systemic symptoms are uncommon. Usually a coincidental history of trauma is noted. Occasionally the individual may have a pathologic fracture.

Systemic chemotherapy and surgery are the treatments of choice, with the location of the tumor and its size, malignancy grade, and evidence of metastasis dictating the type and extent of surgery. Preoperative chemotherapy has greatly increased the number of individuals qualifying for limb salvage surgery. Limb salvaging procedures have been made possible by advances in reconstructive techniques and endoprosthetics. Limb salvage ultimately may be successful in as many as 80% of persons. Individuals must have achieved most of their bone growth to be candidates for limb salvage procedures, which are preferred to amputation. Skeletally immature individuals may have a limb salvage operation, referred to as a *rotationplasty*, in which the major portions of the thigh, the tumor, and contaminated knee are resected while preserving the nerve supply (sciatic) to the leg and foot. The proximal tibia is internally fixed to the stump of the proximal femur after it has been rotated 180 degrees. The foot is positioned at a desired spot or direction, allowing the ankle joint to function as a knee joint with the foot supplying the traditional role of the tibial stump in a below-knee amputation.

If an amputation is done, individuals are monitored closely with chest roentgenograms and CT. Pulmonary metastases are surgically resected, and chemotherapy is now a common therapy given both before and after surgery, using combinations of chemotherapeutic agents. Promising agents under investigation include monoclonal antibodies, hormone antagonists, gene therapy, and other biologic agents that may dramatically improve survival.^{73,74}

Chondrogenic Tumors: Chondrosarcoma.

Chondrogenic (cartilage-forming) tumors produce cartilage or **chondroid**, a primitive cartilage or cartilage-like substance. The most common chondrogenic tumor is chondrosarcoma, accounting for 20% of bone tumors.

Chondrosarcoma, the second most common primary malignant bone tumor, is a tumor of middle-age and older adults; incidence peaks in the sixth decade of life.⁷⁵ The tumor is found more commonly in men than in women. Preexisting chondral lesions, such as osteochondromas, can give rise to secondary chondrosarcoma, which, generally, has a fairly good prognosis.⁷⁶

A chondrosarcoma is a large ill-defined malignant tumor that infiltrates trabeculae in spongy bone. It produces cartilage-forming cells but there is no ossification, as in normal endochondral bone formation.⁷⁷ It occurs most often in the metaphysis or diaphysis of long bones, especially the femur, and in the bones of the pelvis (Fig. 45.19). The tumor contains large lobules of hyaline cartilage that are separated by bands of fibrous tissue and anaplastic cells. Chondrosarcomas typically implant in surrounding tissue (“seeding”).

FIGURE 45.19 Chondrosarcoma. A, Common locations of chondrosarcoma. B, Chondrosarcoma of humerus. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Symptoms associated with chondrosarcoma have an insidious onset. Local swelling and pain are the usual symptoms that cause a person to seek treatment. At first the pain is dull and intermittent, and then gradually intensifies and becomes constant. It may awaken the person at night.

Diagnostic studies include radiographs, which must be reviewed carefully for an accurate diagnosis. Biopsy is done at the time of surgery. (If biopsy is done before scheduled surgical incision, seeding of tumor cells could occur.) Sufficient tumor material must be obtained to facilitate an accurate diagnosis.

Wide surgical excision is generally regarded as the treatment of choice because chemotherapy and radiation seem to have little effect.⁷⁷ Many surgically treated individuals demonstrate recurrences, however, so amputation is becoming one treatment of choice. Therefore individuals with tumors located in the limbs have a better prognosis than those with pelvic lesions.

Collagenic Tumors: Fibrosarcoma.

Collagenic (collagen-forming) tumors produce fibrous connective tissue. The most typical collagenic tumor is the fibrosarcoma.

Fibrosarcomas come from fibroblasts that originate from mesenchymal stem cells and represent 4% of primary malignant bone tumors, with a broad age distribution. They may occur at any age but are most common in adults between 30 and 50 years of age. Fibrosarcoma also may be a secondary complication of radiation therapy, Paget disease, and long-standing osteomyelitis; secondary fibrosarcoma tends to be more aggressive, with poorer outcome.

Fibrosarcoma is a solitary tumor that most often affects the metaphyseal region of the femur or tibia. The tumor is composed of a firm fibrous mass of tissue that contains collagen, malignant fibroblasts, and occasional osteoclast-like giant cells.

The tumor begins in the marrow cavity of the bone and infiltrates the trabeculae. It demonstrates a permeative growth pattern, destroys the cortex, and extends into the soft tissue. Metastasis to the lung is common.

Symptoms associated with the tumor have an insidious onset, which delays diagnosis. Pain and swelling, the usual symptoms that cause the individual to seek treatment, usually indicate that the tumor has broken through the cortex. Local tenderness, the presence of a palpable mass, and limitation of motion also may be present. A pathologic fracture in the affected bone is often the reason for seeking medical help. Diagnostic studies include radiographs and MRI.

Radical surgery and amputation are the treatments of choice for fibrosarcoma. Radiation therapy is generally considered ineffective treatment for this tumor.

Myelogenic Tumors.

Myelogenic tumors originate from various bone marrow cells. Two types of myelogenic tumors are giant cell tumor and myeloma. Myeloma is discussed in [Chapter 30](#).

Giant Cell Tumor.

Giant cell tumor is the sixth most common of the primary bone tumors, accounting for 4% to 5% of bone tumors. Giant cell tumors have a wide age distribution; however, they are rare in persons younger than 10 years or older than 70 years. Most giant cell tumors are found in persons between 20 and 40 years of age. Unlike most other bone tumors, giant cell tumors affect females more often than males.⁷⁸

Giant cell tumors are generally benign, solitary, circumscribed tumors that cause extensive bone resorption because of their osteoclastic origin (Fig. 45.20). There is a high rate of recurrence but metastasis is rare. The tumor is rich in osteoclast-like giant cells and anaplastic stromal cells. It also may contain osteoid, callus, and collagen. Overexpression of several genes, including osteoprotegerin ligand (OPGL), occurs in giant cell tumors. The giant cell tumor is typically located in the center of the epiphysis in the femur, tibia, radius, or humerus. The tumor has a slow, relentless growth rate and is usually contained within the original contour of the affected bone. Tumors are often associated with pathologic fractures because of aggressive bone resorption.⁷⁹ It may, however, extend into the articular cartilage. When the tumor extends, it is usually covered by periosteum or periosteal bone growth.

FIGURE 45.20 Giant Cell Tumor of Bone. A, Common skeletal locations. B, Gross picture of cell tumor of bone (epimetaphysis). (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

The most common symptoms associated with giant cell tumor are pain, local swelling, and limitation of movement. Diagnostic studies include radiographs, CT, and MRI. Cryosurgery and resection of the tumor with the use of adjuvant polymethylmethacrylate (PMMA) for bone grafts decrease recurrence and are more successful treatments than curettage and radiation.⁸⁰ Amputation may be necessary but is not common.

Disorders of Joints

The American College of Rheumatology (ACR) recognizes a growing body of evidence identifying and classifying joint diseases called **arthropathies**. The two major categories of these disorders include noninflammatory joint disease and inflammatory joint disease. Current detection methods, through diagnostic imaging and serum and synovial fluid analysis, allow for a clearer delineation between the inflammatory and noninflammatory pathways once poorly understood.

Osteoarthritis

Osteoarthritis (OA) is the most common form of joint disease and leading cause of disability in middle-aged and older populations.⁸¹ In the United States, OA affects about 27 million people.⁸² OA is characterized by local areas of loss and damage of articular cartilage, new bone formation of joint margins (osteophytosis), subchondral bone changes, variable degrees of mild synovitis, and thickening of the joint capsule (Fig. 45.21). Currently, there is no single specific cause of OA; historically it has been viewed as a mechanical problem and emerging is the evidence of molecular events interacting with mechanical issues.⁸¹ OA has been commonly classified as **noninflammatory joint disease**. However, more recent discoveries have identified the presence of numerous cytokines, chemokines, prostaglandins, and apoptotic molecules within the disease process.⁸³⁻⁸⁵ The ensuing low-grade inflammation, calcification of articular cartilage, and interaction between transcription factors, cytokines, growth factors, matrix molecules, and enzymes affect development and progression of OA. This chemical cascade outlines how the process of cartilaginous destruction begins long before osteoarthritic changes can be detected through the use of MRI, arthroscopy, or traditional x-ray films.

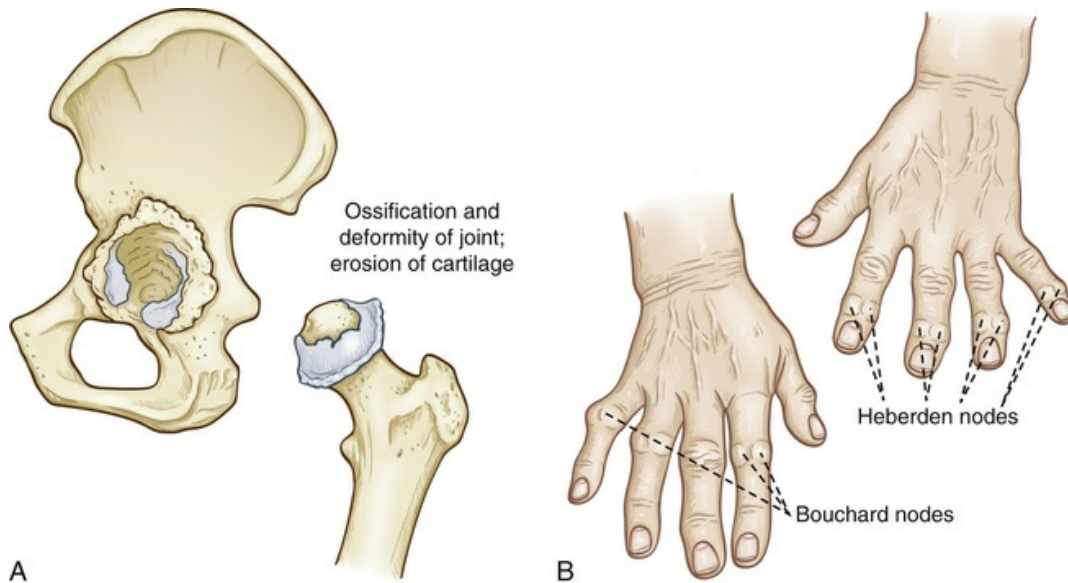

FIGURE 45.21 Osteoarthritis (OA). A, Cartilage and degeneration of the hip joint resulting from osteoarthritis. B, Heberden nodes and Bouchard nodes. C, Severe osteoarthritis with small islands of residual articular cartilage next to exposed subchondral bone. (C from Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

OA often occurs without a known precipitating cause (insidious) with aging, known as *idiopathic* or **primary osteoarthritis**. This progression is usually noted in a few joints but can be generalized.⁸⁶ OA is not a common outcome in younger people with predisposing events, such as injury (e.g., trauma, strains, dislocations, fractures), long-term mechanical stress (e.g., athletics, ballet dancing, repetitive physical tasks, and obesity), or chronic disease (e.g., diabetes, ochronosis, and hemochromatosis). Certain medications can stimulate

collagen-digesting enzyme activity in the synovial membrane (e.g., colchicine, indomethacin, and steroids). With these conditions, the disease is noted as **secondary osteoarthritis**.⁸⁶ The incidence of OA increases with age and is more common in women than in men older than age 50. The prevalence in individuals younger than age 45 is uncommon and generally does not exceed 20% in the elderly.⁸⁷ OA is generally distributed throughout the peripheral and central joints of the body (hips, hands, knees, and spine). The most commonly affected joints include the hips, knees, lower lumbar and cervical vertebrae, proximal and distal interphalangeal joints of the fingers, first carpometacarpal joints, and first tarsometatarsal joints. The distribution of OA seems affected by gender; the hands and knees are more commonly affected in women whereas the hips are more affected in men.⁸⁶ Advancing disease reveals narrowing of the joint space because of cartilage loss, bone spurs (**osteophytes**), and often changes in the subchondral bone.

◆Pathophysiology.

Genome-wide studies show that OA is genetically heterogeneous, and recent advances in epigenetic studies also have indicated the importance of gene expression in the development of OA.⁸¹ The primary pathogenesis in OA is degeneration and then eventual loss and disordered repair of articular cartilage. The chondrocytes of the articular cartilage become damaged early in the disease process because of atypical load bearing as well as both genetic/epigenetic and biochemical factors (Fig. 45.22). These changes lead to increased remodeling of the articular cartilage and a loss of the smooth, frictionless joint.^{88,89} Visually, the articular cartilage loses its glistening appearance, becoming yellow-gray or brownish gray. As the disease progresses, surface areas of the articular cartilage flake off and deeper layers develop longitudinal fissures (fibrillation). The cartilage becomes thin and may be absent over some areas, leaving the underlying subchondral bone unprotected. Consequently, the unprotected subchondral bone becomes sclerotic. Cysts sometimes develop within the subchondral bone and communicate with the

longitudinal fissures in the cartilage. Pressure builds in the cysts until the cystic contents are forced into the synovial cavity, breaking through the articular cartilage on the way. As the articular cartilage erodes, cartilage-coated osteophytes may grow outward from the underlying bone and alter the bone contours and joint anatomy. These spurlike bony projections enlarge until small pieces, called *joint mice*, break off into the synovial cavity. If osteophyte fragments irritate the synovial membrane, synovitis and joint effusion result. The joint capsule also becomes thickened and at times adheres to the deformed underlying bone, which may contribute to the limitation of movement (see [Fig. 45.21](#)).

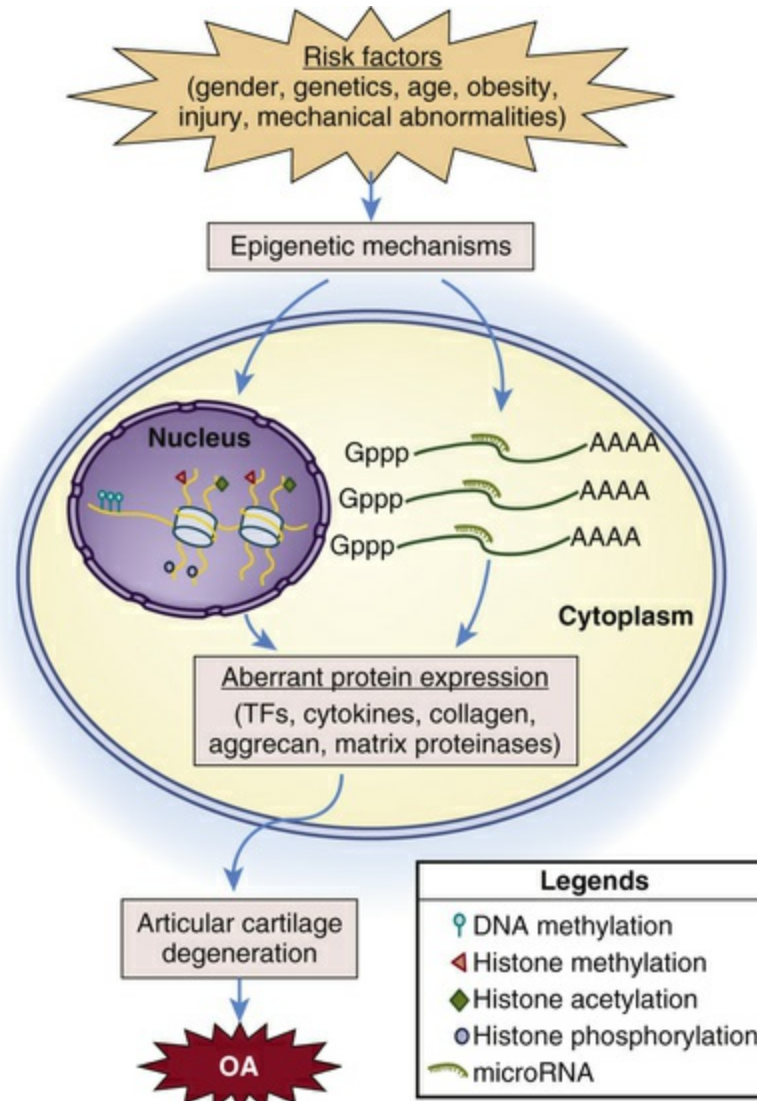

FIGURE 45.22 Working Model Epigenetic Changes in the Pathophysiology of OA. From the proposed effects of risk factors, chondrocytes experience epigenetic events of DNA methylation and histone modifications that occur in the nucleus and miRNAs, which function in the cytoplasm. Overall, these factors result in aberrant expression of transcription factors (TFs), cytokines, collagen, aggrecan, and matrix proteinases. Altered expression of these factors may disrupt the fine balance of anabolic and catabolic activity and affect cartilage homeostasis, resulting in articular cartilage degradation and the development of OA. (Adapted from Zhang M, Wang J: *Genes Dis* 2[1]:69–75, 2015.)

Articular cartilage is lost through a cascade of cytokine, biochemical, and growth factor pathways.⁹⁰ Enzymatic processes, particularly those involving collagenase, break down the macromolecules of proteoglycans, glycosaminoglycans, and collagen into large, diffusible fragments. The fragments are then taken up by

the chondrocytes and digested by the cell's own lysosomal enzymes. (Processes of cellular uptake and lysosomal digestion are described in [Chapter 1](#).) The loss of proteoglycans from articular cartilage is a hallmark of the osteoarthritic process.

Enzymatic destruction of articular cartilage begins in the matrix, with destruction of proteoglycans and collagen fibers. Stromelysin and collagenase enzymes affect proteoglycans by interfering with assembly of the proteoglycan subunit or the proteoglycan aggregate (see [Chapter 44](#)); levels of these enzymes are markedly elevated in OA. Changes in the conformation of proteoglycans disrupt the regulation of water and synovial fluid movement into and out of the cartilage. It is the distribution and active redistribution of this water and synovial fluid that evenly disperse the joint load across the cartilage.⁸⁸ Without the regulatory action of the proteoglycan pump, cartilage absorbs too much fluid and becomes less able to withstand the stresses of weightbearing.

With aging, the proteoglycan content is decreased and the water content in cartilage can be increased by as much as 8%, affecting the strength of the cartilage. Persons with OA, even those with fairly extensive cartilage destruction, have elevated levels of proteoglycans or fragments of proteoglycans in their synovial fluid, perhaps indicative of a more pronounced reparative phase. Inflammatory cytokines (IL-1 β , IL-6, and TNF- α), apoptotic molecules (COX-2, nitric oxide [NO], prostaglandin E₂ [PGE₂]), and prostaglandins play a major role in cartilage degradation in part through induction of nitric oxide synthase (iNOS) and increased nitric oxide (NO) generation.⁸³ ([Chapter 8](#) contains a discussion of cytokines.) These chemical mediators release and activate proteolytic and collagenolytic enzymes (e.g., chemokines and metalloproteinases), causing an imbalance of cell responses to growth factor activity. Chondrocyte apoptosis is increased in OA cartilage, along with increased deposition of calcium phosphate crystals. These deposits are attributed to the disequilibrium between inorganic phosphates and mineralization inhibitors.⁹¹ Nitric oxide stimulates apoptosis in chondrocytes. The resultant cartilage destruction initiates the IL-1 β and TNF- α pathways of inflammation.

Genetic deficiencies of inhibitors of calcification also may contribute to a proliferative calcification cascade of the articular cartilage (Fig. 45.23). Recent epigenetic discoveries continue to outline the role of microRNAs in cartilage development and homeostasis. MicroRNAs provide an inhibitor effect on other cartilage-degrading enzymes, such as MMP13 and ADAMTS4.⁹² When deficits of these microRNA exist, destruction of the fibrils that give articular cartilage its tensile strength accelerates and exposes the chondrocytes to continued mechanical stress and enzymatic attack.

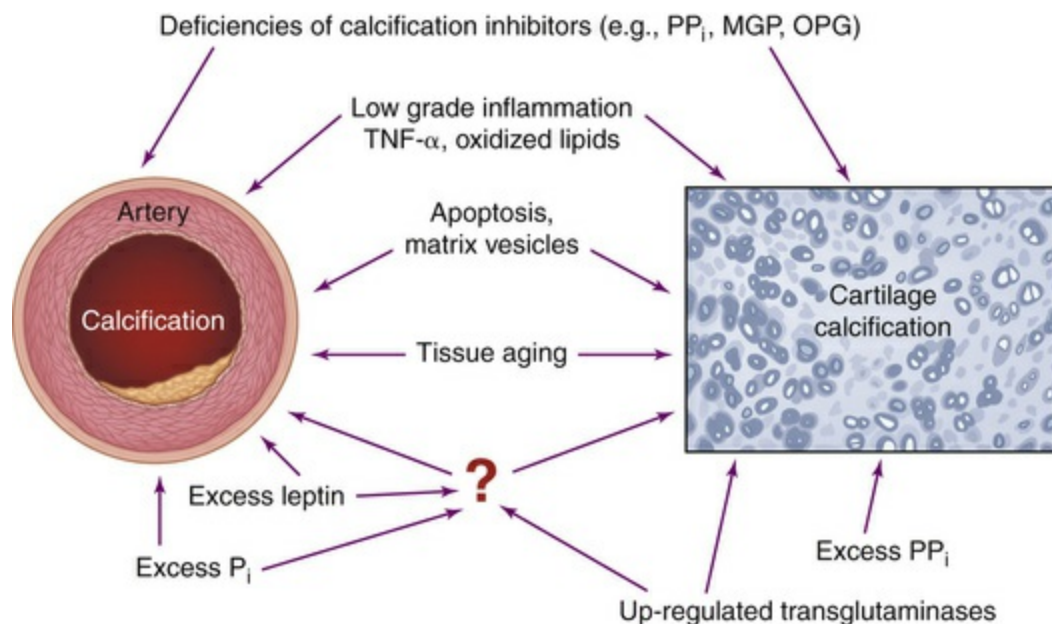

FIGURE 45.23 Possible Mechanisms Driving Artery and Cartilage Calcification. All specified factors have been demonstrated to promote calcification in either arteries and/or cartilage (see text). *MGP*, Matrix GLA-protein; *OPG*, osteoprotegerin; *Pi*, inorganic phosphate; *PPi*, inorganic pyrophosphate. (From Rutsch F, Terkeltaub R: *Joint Bone Spine* 72:110–118, 2005.)

◆Clinical Manifestations.

Asymptomatic articular surface changes are common after age 40, although clinical manifestations of OA typically appear during the fifth or sixth decade of life. Pain and stiffness in one or more weightbearing or load-bearing joints are often the first symptoms of

the disease. Examination typically reveals involvement of peripheral and central joints (see earlier discussion). Joint pain related to overuse is typically relieved by rest.

Pain and stiffness are the predominant symptoms of OA; other symptoms include swelling, tenderness, or enlargement/deformity of joints⁹³ (Box 45.4). Symptoms are usually aggravated by weightbearing or use of the joint and relieved through resting, supporting, bracing, or splinting the joint. Referred pain also may be experienced. Osteoarthritis of the lumbosacral spine, for example, may mimic sciatica, causing severe pain in the back of the thigh along the course of the sciatic nerve. OA in the lower cervical spine may cause brachial neuralgia aggravated by movement of the neck. Additionally, osteoarthritic conditions in the hip cause pain that may be referred to the lower thigh and knee area.

Box 45.4

Signs and Symptoms of Osteoarthritis

Hand

- Pain on range of motion
- Hypertrophic changes at distal and proximal interphalangeal joints (Heberden nodes and Bouchard nodes)
- Tenderness over carpometacarpal joint of thumb

Shoulder

- Pain on range of motion
- Limitation of range of motion, especially external rotation
- Crepitus on range of motion

Knee

Pain on range of motion
Joint effusion
Crepitus on range of motion
Presence of popliteal cyst (Baker cyst)
Lateral instability
Valgus or varus deformity

Hip

Pain on range of motion
Pain in buttock
Limitation of range of motion, especially internal rotation

Foot

Pain on ambulation, especially at first metatarsophalangeal joint
Limited range of motion of first metatarsophalangeal joint, hallux rigidus
Hallux valgus deformity

Spine

Pain on range of motion
Limitation of range of motion
Lower extremity sensory loss, reflex loss, motor weakness caused by nerve root impingement
Pseudoclaudication caused by spinal stenosis

Data from Sinusas K: *Am Fam Physician* 85(1):49–56, 2012.

The mechanism of joint pain perception is complex. Cartilage lacks innervation; therefore the sensation of pain is not experienced from

cartilaginous damage alone. There is little correlation between the radiologic appearance of OA and the perception of pain.^{88,94} Subchondral bone injury, ligamentous injury, weightbearing stress, and inflammation contribute to the sources of joint pain in OA. Articular distention and stretching of the fibrous joint capsule, which has an abundant nerve supply, significantly contribute to the sensation of pain. Finally, inflammation of the joint capsule leads to remodeling and a fibrous contraction of the capsule, causing the joint to become stiff and painful with movement^{95,96} (Fig. 45.24).

FIGURE 45.24 Possible Causes of Pain in Osteoarthritis.

Joint stiffness is generally defined as difficulty in initiating joint movement, immobility, or a loss of range of motion. The extent of cartilage degeneration, along with joint capsule remodeling and fibrous contraction, also contributes to a limitation in range of motion. Stiffness is typically worse in the morning as joint movement begins but dissipates within 30 minutes of continued movement. Enlargement and bulging of joint contour, commonly described as swelling, are actually attributed to thickening of the subchondral bone

from the proliferation of osteophytes around the margins of the joint and hypertrophy of the joint capsule.⁹⁶ These types of joint deformities in the fingers are termed **Heberden** and **Bouchard nodes**.

Swelling may also occur in response to tissue injury. Such injuries initiate the inflammatory cascade of cytokines and chemokines, resulting in capillary permeability and interstitial fluid collection.⁹⁶ If inflammatory exudate or blood enters the joint cavity, the total volume of synovial fluid will be increased. This condition, termed **joint effusion**, is attributed to (1) the presence of osteophyte fragments in the synovial cavity, (2) drainage of cysts from diseased subchondral bone, or (3) acute trauma to joint structures, resulting in hemorrhage and inflammatory exudation into the synovial cavity.

Abnormal knee alignment also has been shown to increase the incidence and progression of OA.⁹⁷ Both varus or valgus disorders of the knee of more than 5 degrees have been associated with increased risk of development and progression of OA. Although the use of biomechanical devices, such as foot wedges or alignment braces, has been shown to decrease pain, the reduction of disease progression has yet to be supported.⁹⁸

◆Evaluation and Treatment.

Evaluation consists of individual subjective reports, clinical assessment, and radiologic studies, which may include CT scan, arthroscopy, and MRI. Treatment is often determined by the severity of symptoms of pain and immobility. Possible treatment regimens span conservative to surgical, as well as nonpharmacologic to pharmacologic. Complementary and alternative therapies also may be considered.

Lifestyle modification, particularly exercise and weight reduction, is a core management approach. Use of supportive devices is recommended, such as a cane, walker, braces, or other devices to decrease weightbearing.⁹⁸⁻¹⁰¹ Physical therapy is an important management strategy for OA. Losing weight reduces pain-associated inflammation, and weight loss combined with physical activity has a greater benefit.¹⁰² Dietary recommendations include increasing intake

of long-chain *n*-3 fatty acids, preferably by eating oily fish twice a week; aiming for a safe level of sun exposure; eating rich vitamin D dietary sources or taking vitamin D supplements ($\leq 25 \mu\text{g}/\text{day}$); and increasing vitamin K intake by eating green, leafy vegetables.¹⁰² Pharmacologic therapy may include the use of analgesic and antiinflammatory drug therapies. The combination of glucosamine and chondroitin may be effective. Other alternative and complementary therapies include the use of magnetic bracelets, therapeutic ultrasound,¹⁰³ balneotherapy, and acupuncture.^{93,104}

Surgical intervention may be used to improve joint movement. However, emerging evidence, based on systematic reviews¹⁰⁵ (see [What's New? Evidence Against the Use of Arthroscopy for Nearly All Patients with Degenerative Knee Disease](#)), cautions against the use of arthroscopy in nearly all persons with degenerative knee disease. This recommendation was triggered by a randomized trial that found, among persons with a degenerative medial meniscus tear, knee arthroscopy was no better than exercise.¹⁰⁶ More aggressive surgical procedures involve creating a new joint with artificial implants.¹⁰⁷

What's New?

Evidence Against the Use of Arthroscopy for Nearly All Patients with Degenerative Knee Disease

An international expert panel provided recommendations on the role of arthroscopic surgery in degenerative disease. These recommendations were based on a recent randomized trial of patients with a degenerative medial meniscus tear; the panel found that knee arthroscopy was no better than exercise therapy alone for these patients.¹ This study adds to the growing evidence that the benefits of arthroscopy may not outweigh the burdens and risks.^{2,3} The panel made a strong recommendation against arthroscopy for degenerative knee disease.⁴ This recommendation applies to patients with or without imaging evidence of osteoarthritis,

mechanical symptoms, or sudden symptom onset. Here, the term degenerative knee disease included patients with knee pain, particularly if they are >35 years old, with or without imaging evidence of osteoarthritis, meniscal tears, locking, clicking, or other mechanical symptoms. However, degenerative knee disease did not include patients with persistent locked knee, patients with acute or subacute onset of symptoms, or patients with major knee trauma and acute onset of joint swelling (such as hemarthrosis).⁴ The international panel included orthopedic surgeons, a rheumatologist, physiotherapists, a general practitioner, general internists, epidemiologists, methodologists, and patients who had experienced degenerative knee disease. Characteristics of patients and trials included in this systemic review were as follows: 13 trials were examined; 12 of 13 trials were free of industry funding; 1668 patients were followed (median age 54.8 years); symptom duration was 3 months (12 months median, 52 months maximum); percent of women studied was 49.2; mean BMI was 27; no patients were involved in designing or conducting trials. In addition, 12 observational studies for complications (>1.8 million patients) were reviewed. In general, it takes 2 to 6 weeks to recover from arthroscopy. Patients may experience pain, swelling, and limited function. Most patients cannot bear full weight on the leg (i.e., they may need crutches) in the first week after surgery, and physical activity and driving are limited during the recovery period. Degenerative knee disease is a chronic condition and symptoms fluctuate. Pain, on average, tends to improve with time after seeing a physician^{5,6} and delaying knee replacement is encouraged when possible.⁷

Classic Inflammatory Joint Disease

Inflammatory joint disease, commonly referred to as *arthritis*, is characterized by damage or destruction in the synovial membrane or articular cartilage and by systemic signs of inflammation (fever, leukocytosis, malaise, anorexia, hyperfibrinogenemia).

Inflammatory joint disease can be infectious or noninfectious. In infectious inflammatory joint disease, inflammation is caused by invasion of the joint by bacteria, mycoplasmas, viruses, fungi, or protozoa. These microorganisms can invade the joint through a number of ports of entry, such as a traumatic wound, surgical incision, or contaminated needle. Additionally, these pathogens can be delivered by the bloodstream from sites of entry through the

body's mucous membranes, as well as infections elsewhere in the body, such as in bones, heart valves, or blood vessels.¹⁰⁸ In noninfectious inflammatory joint diseases such as gout, inflammation is caused by an immune response to the deposition of crystals of monosodium urate in and around the joint. Immune and hypersensitivity reactions occur in conditions such as rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic, systemic inflammatory autoimmune disease that may involve many tissues and organs but particularly affects the joints. RA involves synovial inflammation, joint swelling, and ankylosis and destruction of articular cartilage. The first joint tissue to be affected is the synovial membrane, which lines the joint cavity (see [Chapter 44](#) and [Fig. 44.9](#)). Multiple immunoregulatory cytokines and inflammatory enzymes, such as interleukins, B cells, and collagenase, contribute to the development of an exaggerated immune response resulting in leukocyte infiltration into the synovium.¹⁰⁹ This leads to the development of synovitis and eventual joint damage. Inflammation may spread to the articular cartilage, fibrous joint capsule, and surrounding ligaments and tendons, causing pain, joint deformity, and loss of function ([Fig. 45.25](#)). The joints most commonly affected are in the fingers, feet, wrists, elbows, ankles, and knees. Other joints, such as shoulders, hips, and cervical spine, also may be involved as well as the tissues of the lungs, heart, kidneys, and skin. In addition to joint inflammation and tissue damage, RA can cause fever, malaise, rash, lymph node or spleen enlargement, and Raynaud phenomenon (transient lack of circulation to the fingertips and toes).

FIGURE 45.25 Rheumatoid Arthritis of the Hand. Note swelling from chronic synovitis of metacarpophalangeal joints, marked ulnar drift, subcutaneous nodules, and subluxation of metacarpophalangeal joints with extension of proximal interphalangeal joints and flexion of distal joints. Note also deformed position of thumb. (From Walker BR et al: *Davidson's principles and practice of medicine*, ed 22, London, 2014, Churchill Livingstone.)

Internationally, the prevalence of rheumatoid arthritis ranges from 0.4% to 1.3%. The incidence of RA increases with age and peaks at ages 65 to 74 years, with women having a greater lifetime risk than men (4% vs. 3%).¹¹⁰ However, over the past five decades the incidence and prevalence of RA have decreased in developed countries to approximately 1% of the adult population.^{111,112}

Rheumatoid arthritis is thought to result from a combination of genetic and environmental factors, many of which are unknown.¹¹³ Many genes have been studied as risk factors for RA and most of these genes are involved in immune function.¹¹³ The most significant genetic risk factors for RA are variations in HLA genes, particularly the HLA-DRB1 gene.¹¹³ The proteins produced from HLA genes assist the immune system with distinguishing self proteins from proteins made by invaders such as bacteria and viruses. Investigation of epigenetic factors, such as histone deacetylases, can confer the effects of environmental triggers, such as smoking or diet (e.g., *n*-3 fatty acids, or in combination with γ -linolenic acid [GLA]), or treatment on expression levels of target genes.¹¹⁴ Environmental risk factors for developing RA include age (highest among adults in their sixties), gender (two to three times higher in women), nulliparity, early life

exposures (children whose mothers smoked have double the risk), smoking, low socioeconomic status, and obesity.¹¹⁵ Women who have breast-fed their infants have a decreased risk of developing RA. Additionally, individuals who have a genetic predisposition to the development of rheumatoid arthritis have an increased risk when they smoke or subject themselves to other forms of repeated bronchial stress or infectious agents, such as Epstein-Barr virus, cytomegalovirus, *Proteus* species, and *Escherichia coli*.¹¹⁶

◆Pathophysiology.

The pathologic events are mediated by antibodies against self antigens and inflammatory cytokines, especially CD4+ T cells that promote inflammation. Acting together, T cells produce cytokines that stimulate other inflammatory cells and promote tissue injury.⁸⁶ The most significant cytokines include interferon-gamma (IFN- γ) (activates macrophages and synovial cells), IL-17 (stimulates neutrophils and monocytes), TNF and IL-1 (stimulate synovial cells to secrete proteases that damage hyaline cartilage), and RANKL (activates bone resorption and erosion).⁸⁶

During inflammation, arginine (an α -amino acid) can be enzymatically modified into another α -amino acid, citrulline. This process (citrullination) changes the structure and function of the protein. Other proteins, like fibrin and vimentin, can become citrullinated during cell death and tissue inflammation.¹¹⁷ In turn, the citrullinated proteins may act as antigens.^{118,119}

The inflammatory cytokines convert the synovium into a thick, abnormal layer of granulation tissue known as **pannus** (see [Figs. 45.27](#) and [45.28, A](#)). The pannus acts *like* a locally invasive tumor.^{116,120,121} Macrophages, components of pannus ([Fig. 45.26](#)), stimulate the release of IL-1, platelet-derived growth factor (PDGF), and fibronectin. The pathogenesis of rheumatoid arthritis is summarized in [Fig. 45.26](#).

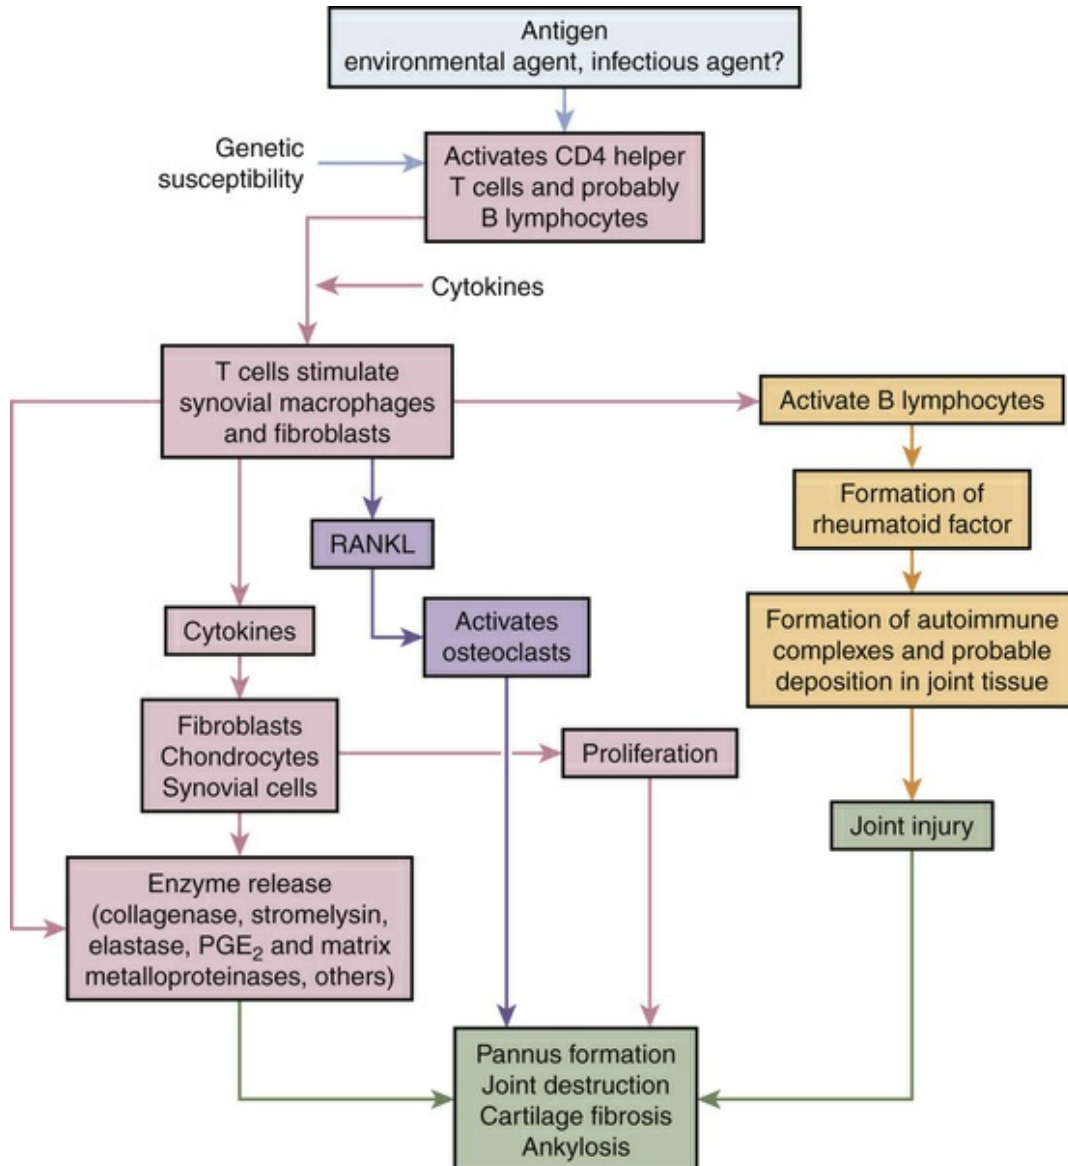

FIGURE 45.26 Emerging Model of Pathogenesis of Rheumatoid Arthritis. Rheumatoid arthritis is an autoimmune disease of a genetically susceptible host triggered by an unknown antigenic agent. Chronic autoimmune reaction with activation of CD4⁺ helper T cells and possibly other lymphocytes and the local release of inflammatory cytokines and mediators eventually destroy the joint. T cells stimulate cells in the joint to produce cytokines that are key mediators of synovial damage. Apparently immune complex deposition also plays a role. Tumor necrosis factor (*TNF*) and interleukin-1 (*IL-1*), as well as some other cytokines, stimulate synovial cells to proliferate and produce other mediators of inflammation, such as prostaglandin E₂ (*PGE*₂), matrix metalloproteinases, and enzymes, which all contribute to destruction of cartilage. Activated T cells and synovial fibroblasts also produce receptor activator of nuclear factor κ B ligand (*RANKL*), which activates the osteoclasts and promotes bone destruction. Pannus is a mass of synovium and synovial stroma with inflammatory cells, granulation tissue, and fibroblasts that grows over the articular surface and causes its destruction.

The ensuing inflammatory and immune process instigates the migration of several types of leukocytes out of the circulation and into the synovial membrane, resulting in a damaging effect on the synovial membrane. The phagocytes of inflammation (neutrophils and macrophages) ingest the immune complexes and, in the process of doing so, release powerful enzymes that degrade synovial tissue and articular cartilage (Fig. 45.27). The immune system's B and T lymphocytes also are activated.¹¹⁶ With long-term or intensive exposure to the antigen, normal antibodies (immunoglobulins [Igs]) become autoantibodies and attack host tissues (self antigens). Because they are usually present in individuals with rheumatoid arthritis, the altered antibodies are termed **rheumatoid factors (RFs)**. RFs usually consist of two classes of immunoglobulin antibodies (antibodies for IgM and IgG) but occasionally involve antibodies for IgA. Their main antigenic targets are portions of the immunoglobulin molecules. RFs bind with their target self antigens in blood and synovial membrane, forming immune complexes (antigen-antibody complexes) (see Chapter 8).

FIGURE 45.27 Synovitis. Inflamed synovium showing typical arrangements of macrophages and fibroblastic cells.

The B lymphocytes are stimulated to produce more RFs, and the T lymphocytes eventually cause release of enzymes that amplify and perpetuate the inflammatory response. Cartilage destruction is mediated by collagenase, which activates the synoviocytes to invade the synovium and cartilaginous matrix.^{118,122} In addition, RANKL is expressed by various cells in the synovium and induces osteoclast maturation and activation, thus producing increased bone resorption (also see [Chapter 44](#)).

Along with the swelling and damage to the synovial membrane caused by leukocyte infiltration, the synovial membrane undergoes hyperplastic thickening as its cells proliferate and become abnormally large. As synovial inflammation progresses to involve its blood vessels, small venules become occluded by the hypertrophied endothelial cells, fibrin, platelets, and inflammatory cells, which

decrease vascular flow to the synovial tissue. Compromised circulation, coupled with increased metabolic needs because of hypertrophy and hyperplasia, causes hypoxia and metabolic acidosis. Acidosis stimulates the release of hydrolytic enzymes from synovial cells into the surrounding tissue, initiating erosion of the articular cartilage and inflammation in the supporting ligaments and tendons. Inflammation causes hemorrhage, coagulation, and fibrin deposition on the synovial membrane, in the intracellular matrix, and in the synovial fluid^{116,118} (Fig. 45.28).

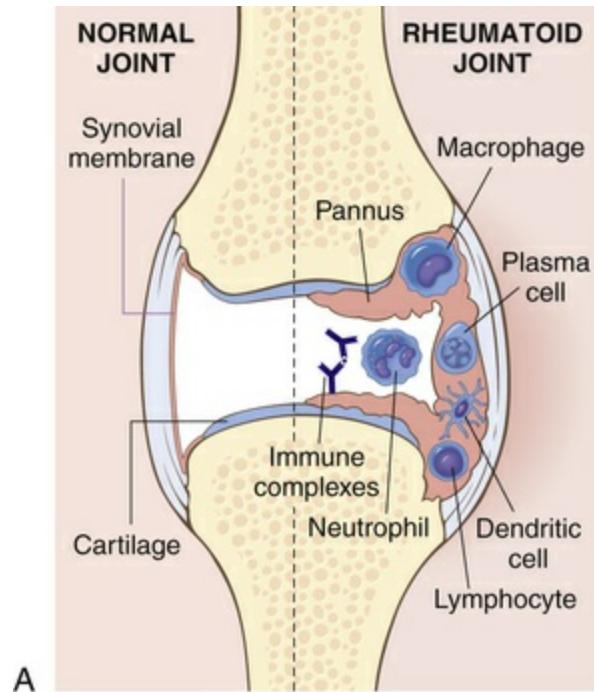

FIGURE 45.28 Rheumatoid Arthritis. A, Schematic view of the joint lesion. B, Advanced rheumatoid arthritis involving femur. There is prominent proliferation of synovium and almost complete destruction of overlying articular cartilage. (A modified from Feldmann M: *Nat Rev Immunol* 2:364, 2002; B from Rosai J: *Ackerman's surgical pathology*, ed 10, Philadelphia, 2011, Mosby.)

🔗 Clinical Manifestations.

The onset of RA is usually insidious, although as many as 15% of cases have an acute onset. RA begins with general systemic manifestations of inflammation, including fever, fatigue, weakness, anorexia, weight loss, and generalized aching and stiffness. Local manifestations appear gradually over weeks or months. The joints typically become painful, tender, and stiff. Pain early in the disease is caused by pressure from swelling; later it is caused by sclerosis of subchondral bone and new bone formation. Stiffness usually lasts for about 1 hour after arising in the morning and may be caused by synovitis. Initially the most commonly involved joints are the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and wrists, with later involvement of larger weightbearing joints.

Widespread and symmetrical joint swelling is caused by increasing amounts of inflammatory exudate (leukocytes, plasma, plasma proteins) in the synovial membrane, hyperplasia of inflamed tissues, and formation of new bone. On palpation, the swollen joint feels warm and the synovial membrane feels "boggy." The skin over the joint may have a ruddy or cyanotic hue and may look thin and shiny.

An inflamed joint may lose some of its mobility; even mild synovitis can lead to loss of range of motion. Extension becomes limited and is eventually lost if flexion contractures form. Chronic synovitis weakens ligamentous structures, leading to deformities of the fingers, toes, and limbs, including ulnar deviation of the hands, boutonnière and swan-neck deformities of the finger joints, plantar subluxation of the metatarsal heads of the foot, and hallux valgus (angulation of the great toe toward the other toes). Flexion contractures of the knees and hips are also common.¹²³

Joint deformities cause the physical limitations experienced by persons with RA. Loss of joint motion is quickly followed by secondary atrophy of the surrounding muscles. With secondary muscle atrophy the joint becomes unstable, which further aggravates joint pathology.

Two complications of chronic RA are caused by an excessive amount of inflammatory exudate in the synovial cavity. One complication is the formation of cysts in the articular cartilage or

subchondral bone. Occasionally these cysts communicate with the skin surface (usually the sole of the foot) and begin to drain, causing a fistula. The second complication is rupture of a cyst or of the synovial joint itself, usually caused by strenuous physical activity that places excessive pressure on the joint. Both of these complications contribute to the formation of bone erosion and worsened outcomes for the individual with RA.¹²⁴

Extrasynovial **rheumatoid nodules**, or swellings, are observed in areas of pressure or trauma in up to 30% of individuals with RA. Each nodule is an aggregate of inflammatory cells surrounding a central core of fibrinoid and cellular debris. T lymphocytes are the predominant leukocytes in the nodule; B lymphocytes, plasma cells, and phagocytes are found around the periphery. Nodules are found most often in subcutaneous tissue over the extensor surfaces of elbows and fingers. Less common sites are the scalp, back, feet, hands, buttocks, and knees.

Rheumatoid nodules also may invade the skin, cardiac valves, pericardium, pleura, lung parenchyma, and spleen.¹²⁵ These nodules are identical to those encountered in some individuals with rheumatic fever and are characterized by central tissue necrosis surrounded by proliferating connective tissue. Also noted are large numbers of lymphocytes and occasional plasma cells. Acute glaucoma may result, with nodules forming on the sclera. Pulmonary involvement may result in diffuse pleuritis or multiple intraparenchymal nodules. Together, the occurrence of pulmonary nodules and pneumoconiosis (chronic inflammation of the lungs from inhalation of dust) creates **Caplan syndrome**.¹²⁶ Diffuse pulmonary fibrosis may occur because of immunologically mediated immune complex deposition.

Rheumatoid nodules within the heart may cause valvular deformities, particularly of the aortic valve leaflets. Pericardial effusion or other pericardial problems occur in almost 50% of individuals with RA.¹²⁷ Lymphadenopathy of the nodes close to the affected joints may develop. Rheumatoid nodules within the spleen result in splenomegaly. Involvement of any blood vessel can result in the development of necrotizing vasculitis.¹²⁸ Thromboses of such

involved vessels may give rise to myocardial infarctions, cerebrovascular occlusions, mesenteric infarction, kidney damage, and vascular insufficiency in the hands and fingers (Raynaud phenomenon). Vascular changes are noted primarily in individuals receiving corticosteroid therapy; thus there is some concern that the therapy may play a role in initiating these lesions. Changes in skeletal muscle are often noted in the form of nonspecific atrophy secondary to joint dysfunction.

◆ Evaluation and Treatment.

In 2010 the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) revised their classification criteria to better identify early stages of RA.¹²⁹ [Box 45.5](#) summarizes the criteria for diagnosing RA. These criteria are dependent upon a combination of physical examination and serologic evaluation of rheumatoid factor (RF) or the much more specific serum marker anti-citrullinated protein antibody (ACPA). These serum markers can be present for years to decades before synovial or radiographic changes become apparent.^{117,129-131} Early, aggressive treatment of RA can decrease the systemic impact of RA, leading to a decreased development of disability and joint destruction.

Box 45.5

The 2010 American College of Rheumatology/European League Against Rheumatism Classification Criteria for Rheumatoid Arthritis

Target population (Who should be tested?) includes individuals:

1. who have at least one joint with definite clinical synovitis (swelling)*
2. who have synovitis not better explained by another disease[†]

Classification criteria for RA (score-based algorithm: add scores of categories A–D; a score $\geq 6/10$ is needed for definite classification of RA)

CLINICAL FINDING	SCORE
A. Joint Involvement[‡]	
1 large joint [§]	0
2–10 large joints	1
1–3 small joints (with or without involvement of large joints) [¶]	2
4–10 small joints (with or without involvement of large joints)	3
>10 joints (at least 1 small joint) [#]	5

≥ 6 weeks	1

*The criteria are aimed at classification of newly presenting patients. In addition, patients with erosive disease typical of rheumatoid arthritis (RA) and with a history compatible with prior fulfillment of the 2010 criteria should be classified as having RA. Patients with longstanding disease, including those whose disease is inactive (with or without treatment) and who (based on retrospectively available data) have previously fulfilled the 2010 criteria, should be classified as having RA.

[†]Differential diagnoses vary among patients with different presentations, but may include conditions such as systemic lupus erythematosus, psoriatic arthritis, and gout. If it is unclear about the relevant differential diagnoses to consider, an expert rheumatologist should be consulted.

[‡]Joint involvement refers to any swollen or tender joint in examination, which may be confirmed by imaging evidence of synovitis. Distal interphalangeal joints, first metacarpophalangeal joints, and first metatarsophalangeal joints are excluded from assessment. Categories of joint distribution are classified

according to the location and number of involved joints, with placement into the highest category possible based on the pattern of joint involvement.

§“Large joints” refer to shoulders, elbows, hips, knees, and ankles.

¶“Small joints” refer to the metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists.

#In this category, at least one of the involved joints must be a small joint; the others can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g., temporomandibular, acromioclavicular, sternoclavicular).

** Negative refers to international unit values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; low-positive refers to international unit values that are >3 times the ULN for the laboratory and assay. Where rheumatoid factor (RF) information is only available as positive or negative, a positive result should be scored as low-positive for RA. *ACPA*, Anti-citrullinated protein antibody.

†† Normal/abnormal is determined by local laboratory standards.

‡‡ Duration of symptoms refers to patient self-report of the duration of signs and symptoms of synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at the time of assessment, regardless of treatment status.

CRP, C-Reactive protein; *ESR*, erythrocyte sedimentation rate.

Data from Aletaha D: *Arthritis Rheum* 62(9):2574, 2010.

Early treatment of RA begins with disease-modifying antirheumatic drugs (DMARDs) such as methotrexate (MTX), azathioprine, sulfasalazine, hydroxychloroquine, leflunomide, and cyclosporine. MTX remains the first line of treatment. More recently, targeted treatment of RA has involved use of agents aimed at interrupting the pathogenesis of the disease. Known as *biological DMARDs* (*bDMARDs*), these medications affect specific processes in the development of RA and include tumor necrosis factor (TNF) inhibitors, such as etanercept, adalimumab, and infliximab, golimumab, and certolizumab. Other agents interfere with cytokine function (anakinra inhibits IL-1 function; tocilizumab targets IL-6), inhibit T-cell activation (abatacept), or deplete B cells (rituximab).

Other treatments and therapies include nonsteroidal antiinflammatory drugs (NSAIDs), glucocorticoids, intraarticular steroid injections, physical and occupational therapy with therapeutic exercise, and use of assistive devices. Surgery is used to treat deformities or mechanical deficiencies of joints and can include synovectomy or joint replacement.

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is the most common of a group of inflammatory arthropathies known as *spondyloarthropathies*. It is a chronic inflammatory joint disease characterized by stiffening and fusion (ankylosis) of the spine and sacroiliac joints.

◆Pathophysiology.

The exact cause of AS continues to be unknown; however, a high association with the histocompatibility antigen human leukocyte antigen (HLA-B27) has been known for decades. A misfolding of HLA-B27 occurs in the endoplasmic reticulum (ER) and, as a result, the misfolded proteins accumulate. This results in a stress response of the ER and increased production of interleukin-23 (IL-23), a potent cytokine that may also act on T-helper 17 cells, promoting their survival.^{132,133}

The prevalence of AS globally is predicted to be between 0.1% and 1.4% with greater incidence in North American and European countries.¹³⁴ Worldwide, the disease also has shown a greater prevalence in men, three times as often as women. In women, AS may affect the peripheral joints of the appendicular skeleton rather than the axial skeleton, progress less rapidly, and cause less dramatic spinal changes. Many individuals with AS remain undiagnosed. Primary AS usually develops in late adolescence or young adulthood, with peak incidence at about 20 years of age. Secondary AS affects older age groups and is often associated with other inflammatory diseases (e.g., psoriatic arthropathy, inflammatory bowel disease, Reiter syndrome).

◀Clinical Manifestations.

The most common signs and symptoms of early AS are low back pain and stiffness. Typically, the individual with primary disease develops low back pain during the early twenties. The pain is at first insidious but progressively becomes persistent. It is often worse after prolonged rest and is alleviated by physical activity. Early morning stiffness usually accompanies the low back pain, and the individual typically has difficulty sitting up or twisting the spine. Forward flexion, rotation, and lateral flexion of the spine are restricted and painful. Early pain and resultant loss of motion are caused by the underlying inflammation and reflex muscle spasm rather than by soft tissue or bony fusion.

As the disease progresses, the normal convex curve of the lower spine (lumbar lordosis) diminishes and concavity of the upper spine (kyphosis) increases. The individual becomes increasingly stooped. The thoracic spine becomes rounded, the head and neck are held forward on the shoulders, and the hips are flexed (Fig. 45.29).

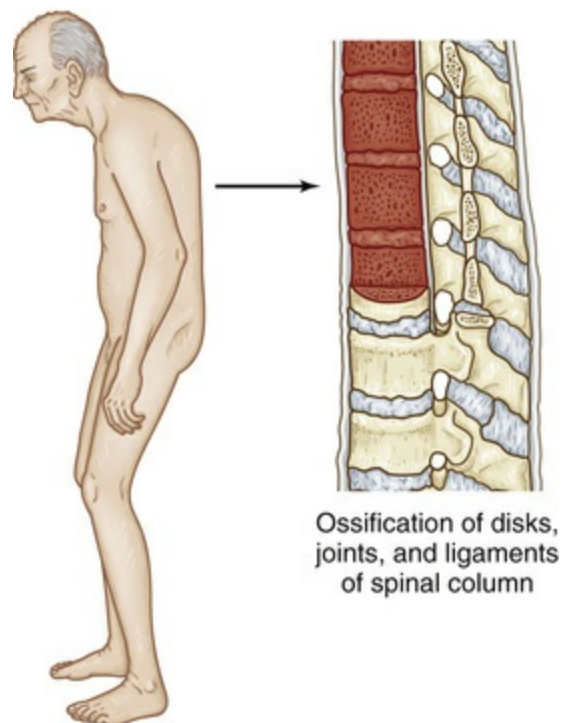

FIGURE 45.29 Ankylosing Spondylitis. Characteristic posture and primary pathologic sites of inflammation and resulting damage.

Inflammation in the tendon insertions of the many costosternal and costovertebral muscles can cause pleuritic chest pain and restricted chest movement. The pain is usually worse on inspiration. Movement in the diaphragm is normal and full. Pressure on the anterior chest wall over the sternum, ribs, and costal cartilages may cause tenderness. Tenderness over the pelvic brim may cause discomfort at night and interfere with sleep because turning onto the iliac crests causes pain. Tenderness over the ischial tuberosities may make sitting on hard seats unbearable. Tenderness in the heels may contribute to a limp or the cautious placement of the feet during walking.

Pain in the sacroiliac joint in men is often the first clinical manifestation, while initial symptoms typically present as knee pain in women.^{133,135} Along with low back pain, many individuals have peripheral joint involvement, uveitis, fibrotic changes in the lungs, cardiomegaly, aortic incompetence, amyloidosis, and Achilles tendinitis. Symptoms may include fatigue, weight loss, low-grade fever, hypochromic anemia, and an increased erythrocyte sedimentation rate.

◆ Evaluation and Treatment.

Diagnosis of AS is made on the basis of both clinical and radiologic findings. Low back pain and stiffness lasting more than 3 months that improves with exercise but is not relieved by rest, limited spine range of motion (ROM) in both frontal and sagittal planes, and limited chest expansion relative to normal values for age and gender are the classic clinical criteria. Radiologic changes at the sacroiliac joint are graded according to severity of abnormality; abnormalities include sclerosis, widening, narrowing, or ankylosis.¹³⁶ With traditional radiographic imaging, a delay exists between the onset of joint damage and radiographic identification. Laboratory tests, including serum analysis for the presence of the histocompatibility antigen HLA-B27, elevated erythrocyte sedimentation rate (ESR) (normal is 0 to 9 mm/hour in males, 0 to 2 mm/hour in females), and elevated alkaline phosphatase levels, can be used to help monitor the course of the disease.

Treatment of individuals with AS consists of a multidisciplinary

approach: physical therapy to maintain skeletal mobility and prevent the natural progression of contractures, support groups to help individuals cope with the disease process, nonsteroidal antiinflammatory drugs (NSAIDs) to suppress some of the pain and stiffness and to facilitate exercise, and corticosteroid injections to help reduce inflammation in joints.¹³⁷ Surgical interventions also have been shown to help in decreasing severe disabling deformity.

Gout

Gout is an inflammatory response to excessive quantities of uric acid in the blood (hyperuricemia) and in other body fluids, including synovial fluid. These elevated levels lead to the formation of monosodium urate (MSU) crystals in and around joints.¹³⁸ When the uric acid concentration is >6.8 mg/dL in fluids, it crystallizes and forms insoluble precipitates of MSU that are deposited in connective tissues throughout the body. Crystallization in synovial fluid triggers TNF- α , causing the release of chemokines and interleukins. The result of crystallization in synovial fluid is acute, painful inflammation of the joint. This inflammatory response triggers macrophages. When macrophages phagocytize MSU crystals, they form a protein scaffold known as an *inflammasome*. Inflammasomes then convert inactive interleukins of IL-1 β and IL-18 into their active forms.^{139,140} Prolonged accumulation results in joint damage, a condition known as **gouty arthritis**. With time, crystal deposition in subcutaneous tissues causes the formation of small, white nodules, or **tophi**, that are visible through the skin. Hyperuricemia and tophi deposits are significantly associated with joint damage; however, associations also exist with hypertension, heart disease, diabetes mellitus type 2, kidney disease, and metabolic syndrome and increased death rates.¹⁴¹⁻¹⁴³

Although hyperuricemia is essential for the development of gout, it is not the only factor. Other factors include age (rare before 30 years), genetic predisposition (X-linked alteration of the enzyme hypoxanthine-guanine phosphoribosyltransferase [HGPRT]), excessive alcohol consumption, obesity, certain drugs (especially thiazides), and lead toxicity. Dietary intake of purine-rich foods, such

as organ meats, pork, some fish, and beer, also has been shown to contribute to the incidence of gout. Additionally, evidence exists identifying the contributory nature of foods high in fructose and sugar-sweetened soft drinks. Conversely, dairy products, coffee, and vitamin C have been shown to have a protective effect against gout.¹³⁸

In classic gouty arthritis, monosodium urate crystals form and cause joint inflammation. **Pseudogout** mimics gout; however, it is caused by the formation and deposition of calcium pyrophosphate dihydrate (CPPD) crystals. Calcium pyrophosphate dihydrate crystals predominantly deposit in joint cartilage and intervertebral disks.¹⁴⁴ The effect of either crystal is the same—the onset of a cytokine-mediated acute inflammatory response (see [Chapter 7](#)).

Gout is rare in children and premenopausal women and is uncommon in males younger than 30 years. Gout is more common in men and is thought to occur at a 3 : 1 ratio compared to women. Onset in men often peaks between the ages of 40 and 50 years. Onset of gout in females tends to occur at a later age since it is rarely seen in premenopausal women.^{144,145} Additionally, a greater correlation exists in women with coexisting diseases, such as hypertension and renal insufficiency.¹⁴⁵ The plasma urate concentration is an important determinant of the risk of developing gout ([Table 45.8](#)). The risk of developing gouty arthritis is similar in males and females for particular urate concentrations.

TABLE 45.8

MEAN URATE CONCENTRATIONS BY AGE AND GENDER

CHARACTERISTIC	MEAN URATE LEVELS (mg/dL)
Prepuberty	3.5
Males (at puberty)	Steep rise to 5.2
Females (puberty to premenopause)	Slow rise to \cong 4
Females (after menopause)	4.7
Hyperuricemia	
Men	7
Women	6

Uric acid (UA) is a byproduct of protein metabolism that normally assists with removal of nitrogen waste from the body. At lower levels, UA is an important antioxidant but at higher levels it acts as a pro-oxidant where it increases levels of free radicals and causes other inflammatory changes.¹⁴⁶ When ionized, uric acid can form salts with various cations but 98% of extracellular uric acid is in the form of monosodium urate (uric acid salt). At any time, the proportion of uric acid or urate is pH dependent, so the ratio of these two forms varies considerably in urine (Fig. 45.30).

FIGURE 45.30 Effect of pH on Uric Acid and Urate Equilibrium. At pH 5.7, equal amounts of uric acid and urate are present in the solution. (Redrawn from Klippel JH, Dieppe PA, editors: *Rheumatology*, ed 2, London, 1998, Mosby-Wolfe.)

The solubility of urate and uric acid is critical to the development of crystals. Urate is more soluble in plasma, synovial fluid, and urine than in aqueous solutions; the solubility in urine rises dramatically as the pH increases to more than 4. There is little change, however, in the

solubility of urate within the normal pH range that exists in the plasma, synovial fluid, and other tissues. Decreasing temperatures cause both urate and uric acid solubility to fall. The pathways of production of uric acid are shown in Fig. 45.31.

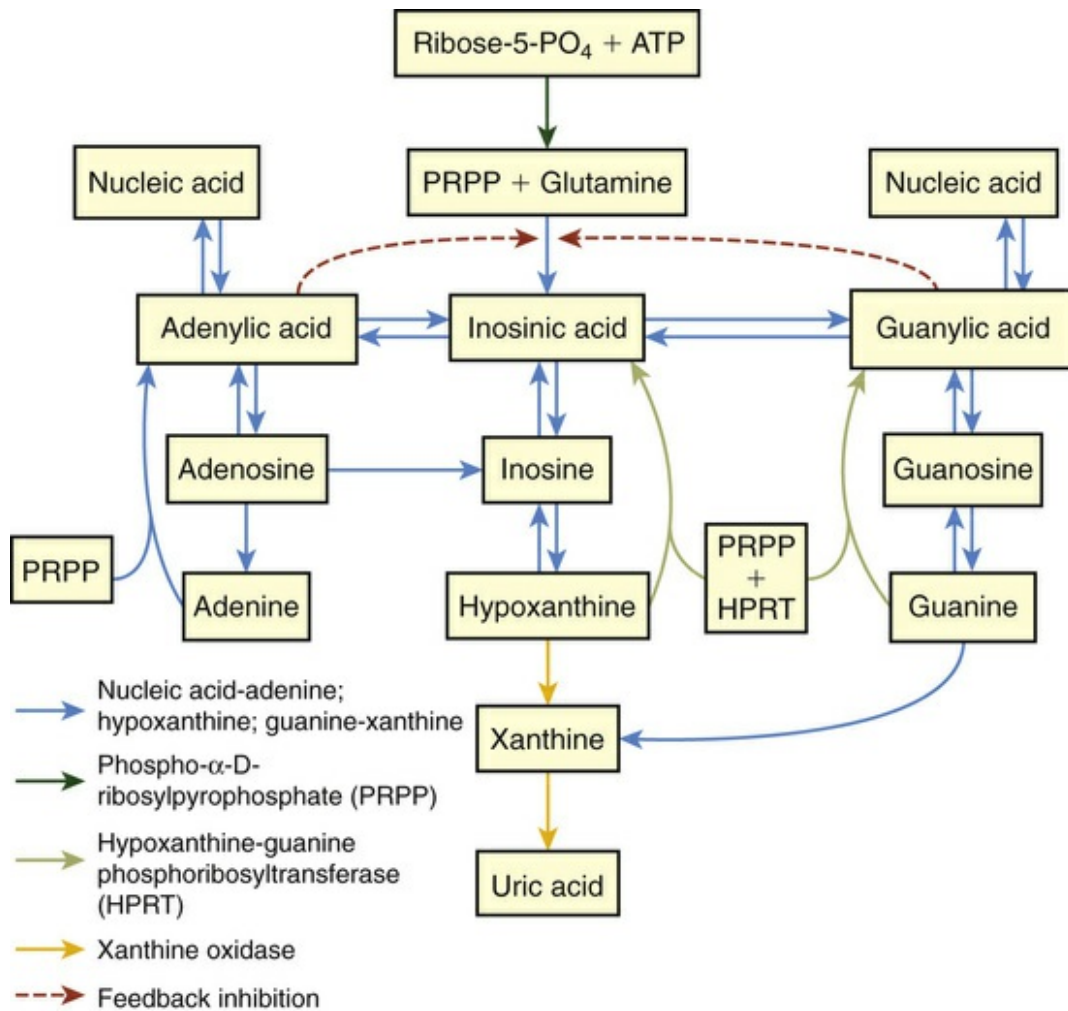

FIGURE 45.31 Production of Uric Acid. The major pathways involved in purine nucleotide synthesis. (Redrawn from Klippel JH, Dieppe PA, editors: *Rheumatology*, ed 2, London, 1998, Mosby-Wolfe.)

◆ Pathophysiology.

The pathophysiology of gout is closely linked to purine metabolism and kidney function. At the cellular level, purines are synthesized to purine nucleotides, which are used in the synthesis of nucleic acids,

adenosine triphosphate, cyclic adenosine monophosphate (cAMP), and cyclic guanosine monophosphate (cGMP). Uric acid is a breakdown product of purine nucleotides (uric acid synthesis and elimination are illustrated in Fig. 45.32).¹⁴¹ Individuals with gout may have an accelerated rate of purine synthesis accompanied by an overproduction of uric acid. Other individuals break down purine nucleotides at an accelerated rate, also resulting in an overproduction of uric acid. A deficiency of the enzyme HGPRT (see earlier) can lead to an increased production of uric acid. A complete absence of HGPRT is uncommon but can occur in the X-linked Lesch-Nyhan syndrome, with males at risk for hyperuricemia, neurologic alterations, and sometimes gouty arthritis. The majority of individuals with gout, however, have an unknown metabolic defect, which is referred to as **primary gout**. When the etiology is known, it is referred to as **secondary gout**.

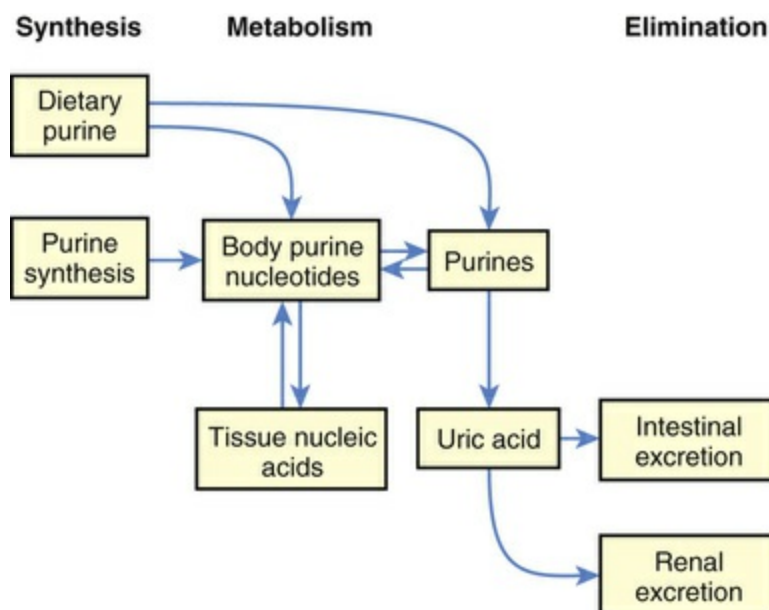

FIGURE 45.32 Uric Acid Synthesis and Elimination. Uric acid is derived from ingested purines or synthesized from ingested foods, as well as recycled following cell breakdown. Uric acid is then eliminated through the kidneys and gastrointestinal tract. (Redrawn from Klippel JH, Dieppe PA, editors: *Rheumatology*, ed 2, London, 1998, Mosby-Wolfe.)

Most uric acid is eliminated from the body through the kidneys.

Urate is filtered at the glomerulus and undergoes reabsorption and excretion within the proximal renal tubules. In primary gout, urate excretion by the kidneys is sluggish; this may be the result of a decrease in glomerular filtration of urate or acceleration in urate reabsorption. In addition, MSU crystals deposited in renal tubules can cause acute nephropathy.¹⁴¹ (Kidney function is described in [Chapter 38](#).)

Monosodium urate crystals can stimulate and perpetuate the inflammatory response ([Fig. 45.33](#)). The presence of MSU crystals triggers the acute inflammatory response. Initiation of the complement system activates cytokines and interleukins, which draw neutrophils out of the circulation to begin phagocytizing the crystals.

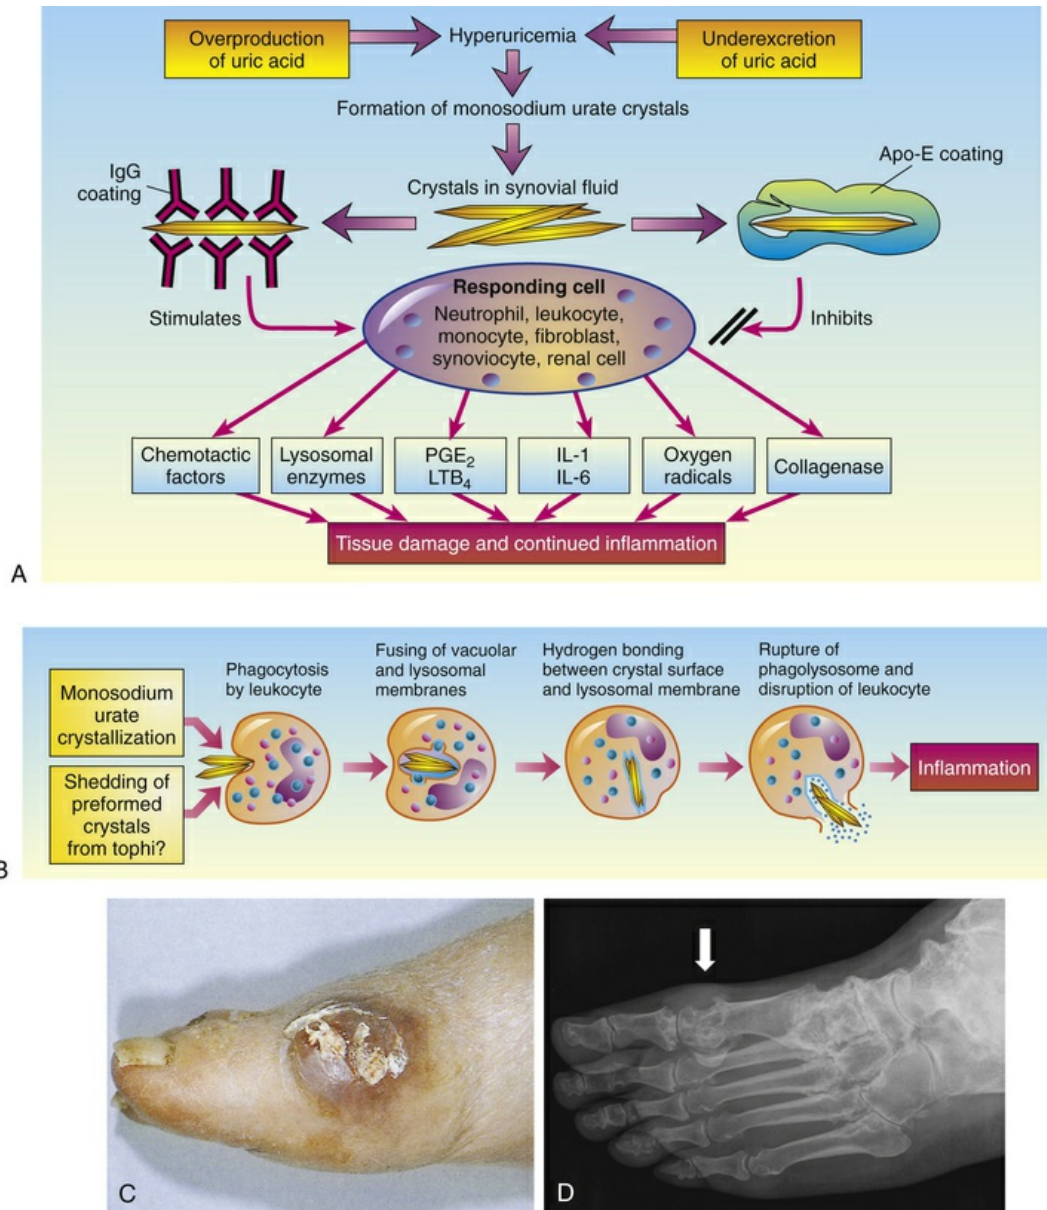

FIGURE 45.33 Pathogenesis of Acute Gouty Arthritis. A, Depending on the urate crystal coating, a variety of cells may be stimulated to produce a wide range of inflammatory mediators. B, Sequence of events in the production of inflammatory response to urate crystals. C, Gouty tophus on right foot. D, Bone destruction of first metatarsal because of gout. *Apo-E*, Apolipoprotein E; *IgG*, immunoglobulin G; *IL*, interleukin; *LTB₄*, leukotriene B₄; *PGE₂*, prostaglandin E. (C from Dieppe P et al: *Arthritis and rheumatism in practice*, London, 1991, Gower. D from Chhana A, Dalbeth N: *Rheum Dis Clin North Am* 40[2]:291–309, 2014.)

A variety of inflammatory mediators are released during the crystal/cell response, of which IL-1 β appears to be of prime importance. Other factors including chemotactic factors, lysosomal

enzymes, eicosanoids, prostaglandin E₂ (PGE₂), reactive oxygen species, and collagenase also are released¹⁴¹ (see Fig. 45.33, A). Some of these mediators stimulate the influx of neutrophils, monocytes, and lymphocytes. (Acute inflammation and phagocytosis are described in Chapter 7.)

Within the joint fluid, urate crystals react particularly with neutrophils and monocytes. Tissue damage begins to occur, principally when the neutrophils release the contents of their phagolysosomes (see Fig. 45.33, B). These contents also perpetuate inflammation. At an early phase of an acute gouty attack, synovial microtophi have been demonstrated. As the process continues, numerous microtophi may be present on the synovial membrane (see Fig. 45.33, C).

◆Clinical Manifestations.

Gout is manifested by (1) an increase in serum urate concentration (hyperuricemia); (2) recurrent attacks of monoarticular arthritis (inflammation of a single joint); (3) deposits of monosodium urate monohydrate (tophi) in and around the joints; (4) renal disease involving glomerular, tubular, and interstitial tissues and blood vessels; and (5) the formation of renal stones. These manifestations appear in three clinical stages:

1. **Asymptomatic hyperuricemia:** The serum urate level is elevated but arthritic symptoms, tophi, and renal stones are not present; may persist throughout life.
2. **Acute gouty arthritis:** Attacks develop with increased serum urate concentrations; tends to occur with sudden or sustained increases of hyperuricemia but also can be triggered by trauma, drugs, and alcohol.
3. **Tophaceous gout:** The third and chronic stage of disease; can begin as early as 3 years or as late as 40 years after the initial attack of gouty arthritis. Progressive inability to excrete uric acid expands the urate pool until urate crystal deposits (tophi) appear in cartilage, synovial membranes, tendons, and soft

tissue.

Attacks of gouty arthritis occur abruptly, usually in a peripheral joint. The primary symptom is severe pain. Approximately 50% of the initial attacks occur in the metatarsophalangeal joint of the great toe. The other 50% involve the heel, ankle, and instep of the foot; knee; wrist; or elbow. The pain is usually noticed at night. Within a few hours the affected joint becomes hot, red, and extremely tender and may be slightly swollen. Lymphangitis and systemic signs of inflammation (leukocytosis, fever, elevated sedimentation rate) occasionally are present. Untreated, mild attacks usually subside in several hours but may persist for 1 or 2 days. Severe attacks may persist for several days or weeks. After recovery, the symptoms resolve completely. Intervals between acute attacks of gouty arthritis are called *intercritical periods*. Some individuals never have a second attack; others experience subsequent attacks within days to as long as 5 to 10 years after the first episode. Tophaceous deposits are the characteristic diagnostic lesions of chronic gout. These deposits produce irregular swellings of the fingers, hands, knees, and feet. Tophi within the soft tissue commonly form lumps along the ulnar surface of the forearm, the tibial surface of the leg, the Achilles tendon, and the olecranon bursa. The helix of the ear is the most common site of tophi. Each tophus consists of a deposit of urate crystals, surrounded by a granuloma made up of mononuclear phagocytes (macrophages) that have developed into epithelial and giant cells. (Granuloma formation is described and illustrated in [Chapter 7](#).) Tophi may produce marked limitation of joint movement and eventually cause grotesque deformities of the hands and feet. Although the tophi themselves are painless, they often cause progressive stiffness and persistent aching of the affected joint. Tophi in the extremities may cause nerve compressions such as carpal tunnel syndrome or tarsal tunnel syndrome. They also may erode and drain through the skin.

Renal stones are 1000 times more prevalent in individuals with primary gout than in the general population. The stones can vary in

size from a grain of sand to the size of gravel. A large accumulation can produce a staghorn calculus. Renal stones may be comprised of pure monosodium urate, but also may consist of calcium oxalate or calcium phosphate. Renal stones can form in the collecting tubules, pelvis, or ureters, causing obstruction, dilation, and atrophy of the more proximal tubules and leading eventually to acute renal failure. Stones deposited directly in renal interstitial tissue initiate an inflammatory reaction that leads to chronic renal disease and progressive renal failure.

◆Evaluation and Treatment.

Diagnosis of gout is from the individual's history and physical examination; also included may be blood tests, possible joint aspiration, and the use of diagnostic imaging.^{147,148} The goals of gout treatment are to terminate the acute gouty attack as promptly as possible; decrease serum uric acid levels; avoid recurring attacks; prevent or reverse complications associated with urate deposits in the joints, soft tissues, and kidneys; and prevent formation of kidney stones.¹⁴⁹ Numerous drugs are used to prevent or abort attacks of arthritis. Nonpharmacologic treatment includes the application of ice to relieve pain and inflammation of the joint. Weightbearing on the involved joint is avoided until the acute attack subsides. Reducing body weight, avoiding alcohol, and changing dietary practices may reduce recurrent gouty episodes.¹⁴⁰

Disorders of Skeletal Muscle

Weakness and fatigue are common symptoms of disorders of the skeletal muscles. In many cases, neural, traumatic, and psychogenic causes provide an adequate explanation for the failure to generate force (weakness) or sustain force (fatigue) seen in myopathies. The pathophysiologic mechanisms in some of the metabolic and inflammatory muscle diseases have been explored, but the cause of many of the myopathies remains obscure. Recognition and improved understanding of ryanodine receptor (RyR1) function have allowed

identification of therapeutic targets in treating central core disease (CCD). The term *CCD* refers to the mitochondrial lack of oxidative enzyme activity in the central cytoplasmic area of the muscle caused by a genetic abnormality on chromosome 19. Complex interactions between muscles and nerves affect muscular function as well. Only inherited and acquired disorders of skeletal muscles are discussed here.

Secondary Muscular Dysfunction

Muscular symptoms arise from a variety of causes unrelated to the muscle itself. Secondary muscular phenomena (contracture, stress-related muscle tension, immobility) are common disorders that influence muscular function.

Contractures

Contractures are the lack of full passive range of motion of a joint because of muscle, connective tissue, or soft tissue limitations.¹⁵⁰ These limitations may be termed either *pathologic* or *physiologic*. A *physiologic muscle contracture* occurs as a result of the absence of a muscle action potential in the sarcolemma. Muscle shortening is caused by failure of calcium pumps in the presence of ATP. A physiologic contracture is seen in McArdle disease (muscle myophosphorylase deficiency) and malignant hyperthermia. The contracture is usually temporary if the underlying pathology is reversed.

A **pathologic contracture** is a permanent muscle shortening caused by muscle spasm or weakness. Heel cord (Achilles tendon) contractures are examples of pathologic contractures. They are associated with plentiful ATP and occur in spite of a normal action potential. Most occurrences of pathologic contractures are seen in neuromuscular disorders such as Charcot-Marie-Tooth disease, amyotrophic lateral sclerosis (ALS), cerebral palsy (see [Chapter 46](#)), and central nervous system (CNS) injury. Prolonged splinting in a single position, such as an elbow, also may lead to a contracture.¹⁵¹ Contractures also may develop secondary to scar tissue contraction in

the flexor tissues of a joint, for example, contracture of burned tissues in the antecubital area of the forearm or the palmar surface of the hand leading to a flexion contracture.¹⁵²

Stress-Induced Muscle Tension

Abnormally increased muscle tension has been associated with chronic anxiety, as well as a variety of stress-related muscular symptoms, including neck stiffness, back pain, and headache.¹⁵³ Abnormalities in the CNS, reticular activating system, and autonomic nervous system (ANS) have been implicated. The underlying pathophysiology may be related to the fact that as a muscle contracts, the muscle spindle is activated. This gamma-feedback system produces a series of impulses that are transmitted to the brain by the sensitive 1A afferent fibers. Unconscious tension is thought to increase the activity of the reticular activating system as well. This causes increased firing of the efferent loop of the gamma fibers and produces further muscle contraction, which increases muscle tension. ANS function that regulates increased blood flow to the muscle during sympathetic activity may be related to increased muscle contraction tension.

Various forms of treatment have been used to reduce the muscle tension associated with stress. Progressive relaxation training, yoga, meditation, and biofeedback are examples of stress reduction therapies.

Fibromyalgia

Fibromyalgia (FM) is a chronic musculoskeletal syndrome characterized by widespread joint and muscle pain, fatigue, and tender points. The absence of systemic or localized inflammation and the presence of increased sensitivity to touch (i.e., tender points), fatigue/nonrestorative sleep, and anxiety and depression are common. Individuals with FM report diffuse tenderness in all body regions and an increased sensitivity to numerous types of stimuli, including heat, cold, and electrical stimuli. Other research also identifies sensitivity to

light and sound.¹⁵⁴ New research suggests the possible link between an inflammatory process and the development of FM.¹⁵⁵⁻¹⁵⁷ In the past, a common misdiagnosis has been chronic fatigue syndrome and there is overlap of symptoms between these two conditions. From 80% to 90% of individuals affected are women, and the peak age is 30 to 50 years. Although the incidence is unknown, the prevalence is reported to be 2% to almost 6% and increases with age.¹⁵⁸ The American College of Rheumatology has identified new criteria for the diagnosis of FM. A tender point evaluation is no longer required; instead, the use of a widespread pain index (WPI) and symptom severity inventory (SSI) is recommended.¹⁵⁹ For the WPI evaluation, the individual also is asked to identify body regions where pain has been experienced during the last 1-week time period (Fig. 45.34). For the SSI evaluation, the individual is then asked to rank specific symptoms of fatigue, waking unrefreshed, cognitive symptoms, and somatic symptoms on a scale of 0 to 3. A diagnosis of FM is then determined on the basis of both the WPI score and the SSI score.^{158,159} For example, a WPI of at least 7 and SSI of at least 5; or a WPI of 3 to 6 and SSI of at least 9.

FIGURE 45.34 Location of Specific Tender Points for Diagnostic Classification of Fibromyalgia. (Redrawn from Freundlich B, Leventhal L: The fibromyalgia syndrome. In Schumacher HR Jr, Klippel JH, Koopman WJ, editors: *Primer on the rheumatic diseases*, ed 11, Atlanta, 1997, Arthritis Foundation. Copyright ©1997. Reprinted with permission of the Arthritis Foundation.)

Although the etiology of FM is unknown, it is thought to involve both genetic susceptibility and environmental exposure that triggers alterations in gene expression (epigenetics).¹⁶⁰ Current hypotheses for the etiology of FM include numerous interacting factors: psychologic, genetic/epigenetic, neurobiologic, and environmental.¹⁶⁰ Despite much debate on the classification and pathophysiology of FM, it is now recognized as a disorder.¹⁶⁰

◆Pathophysiology.

FM has unclear pathophysiology. Genetic factors are increasingly being suggested as important in developing FM. Aggregation of fibromyalgia within families and other coexisting conditions, such as

irritable bowel syndrome, chronic fatigue, and mood disorders, suggest a major role for neuroendocrine and stress-response alterations (see [Chapter 11](#)). Studies of genetic factors have implicated alterations in genes affecting serotonin, catecholamines, and dopamine—all of these substances are involved in the stress response and sensory processing.^{161,162} In spite of these studies, the role of genetic factors in FM has not yet been fully identified. Studies have suggested a link between stress/stressors (such as infection including Lyme disease, psychosocial stress, sleep abnormalities, immune dysfunction, physical or emotional trauma) and FM.¹⁵⁴ These relationships continue to be researched.

Functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) scans of the brains of persons with FM have shown activity in different areas of the brain than in healthy individuals when exposed to painful stimuli.¹⁶³ Individuals with fibromyalgia have lowered mechanical and thermal pain thresholds, high pain ratings for provoking stimuli, and altered temporal summation of pain stimuli. Functional abnormalities within the CNS are shown in [Fig. 45.34](#). Other pathophysiologic evidence includes hypothalamic-pituitary-adrenal (HPA) axis alterations that demonstrate abnormal response to pain.¹⁶⁴ Recent investigations suggest cytokines are involved in the pathogenesis of FM.¹⁵⁷ Corticotropin-releasing hormone (CRH) and locus ceruleus–norepinephrine (LC/NE), their peripheral effectors, and the hypothalamic-pituitary-adrenal axis are the main components of the stress system. Impaired functioning of the HPA axis and LC/NE system may be associated with fibromyalgia.¹⁵⁴

◆Clinical Manifestations.

The prominent symptom of fibromyalgia is diffuse, chronic pain. As discussed previously, the American College of Rheumatology has identified new criteria for the diagnosis of FM that expand to include other nonpain symptoms.¹⁶⁵ A tender point evaluation is no longer required. Instead, the use of a widespread pain index (WPI) and symptom severity inventory (SSI) is recommended. Pain often begins

in one location, especially the neck and shoulders, but then becomes more generalized. Fatigue is most notable when arising from sleep and during the midafternoon. Headaches, symptoms of irritable bowel syndrome, and excess sensitivity to cold (Raynaud-like) are reported in 50% of individuals.

Almost 25% of individuals seek psychologic support for depression. Anxiety, particularly in regard to their diagnosis and future, is almost universal. Again, the only reliable finding on examination is the presence of multiple tender points.

◆ Evaluation and Treatment.

Because the manifestations of chronic, generalized pain and fatigue are present in many musculoskeletal (e.g., rheumatic) disorders, these disorders should be considered in the diagnosis of fibromyalgia (Tables 45.9 and 45.10). The WPI and SSI are then used for diagnostic and evaluation purposes.

TABLE 45.9

DIFFERENTIAL DIAGNOSIS OF FIBROMYALGIA

DIFFERENTIAL DIAGNOSIS	HELPFUL DIFFERENTIAL FEATURES
Rheumatoid arthritis*	Synovitis, serologic tests, elevated erythrocyte sedimentation rate (ESR)
Systemic lupus erythematosus	Dermatitis, serositis (renal, central erythematosus,* nervous system, etc.)
Polymyalgia rheumatica*	Elevated ESR, older adults, response to corticosteroids
Myositis	Increased muscle enzymes, weakness more than pain
Hypothyroidism*	Abnormal thyroid function tests
Neuropathies	Clinical and electrophysiologic evidence of neuropathy

*Fibromyalgia may also more commonly coexist with these conditions.

Data from Klippel JH, Dieppe PA, editors: *Rheumatology*, ed 2, London, 1998, Mosby-Wolfe.

TABLE 45.10

CONCOMITANT CONDITIONS WITH FIBROMYALGIA

CONCOMITANT CONDITION	RELATIONSHIP TO FIBROMYALGIA
Depression	Present in 25%–60% of fibromyalgia cases
Irritable bowel syndrome	Present in 50%–80% of fibromyalgia cases
Migraine	Present in 50% of fibromyalgia cases
Chronic fatigue syndrome (CFS)	70% of CFS cases meet criteria for fibromyalgia
Myofascial pain	May be a localized form of fibromyalgia

Data from Klippel JH, Dieppe PA, editors: *Rheumatology*, ed 2, London, 1998, Mosby-Wolfe.

No single regimen of medication has proved successful for fibromyalgia. Current recommendations outline a combination of both pharmacologic and nonpharmacologic therapies.¹⁵⁸ Stress reduction, sleep, and exercise remain central lifestyle modifications for individuals living with FM. Medications that improve sleep may be helpful as well as vitamin D supplementation. Antiinflammatories have been used despite the fact there is no evidence of tissue inflammation, but these medications have not been effective. Certain CNS-active medications, most notably pregabalin, were better than placebo in controlled trials.¹⁶⁶ Other medications, designed to augment the activity of neurotransmitters and the endogenous opioid system, also have been shown to provide symptom relief.¹⁵⁸ The most effective approach is a combination of modalities, including education, medication, exercise, and cognitive-behavioral therapy.¹⁶⁷⁻¹⁶⁹ Box 45.6 lists some of these modalities.

Box 45.6

Education and Reassurance for Individuals With Fibromyalgia

- Stress that the illness is real, not imagined.
- Explain that fibromyalgia is not a deforming or deteriorating condition.

- Explain that fibromyalgia is neither life-threatening nor markedly debilitating, although it is an irritating presence.
- Discuss the role of sleep disturbances and the relationship of neurohormones to pain, fatigue, abnormal sleep, and mood.
- Reassure individual that although the cause is unknown, some information is known about the physiologic changes responsible for the symptoms.
- Use muscle “spasms” and perhaps low muscle blood flow to lay the groundwork for exercise recommendations.
- Assist individual to use aerobic exercise to reduce stress and increase rapid eye movement (REM) sleep.

Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS), also known as **myalgic encephalomyelitis (ME)**, is a debilitating and complex disorder characterized by profound fatigue, musculoskeletal pain, cognitive impairment, unrefreshing sleep, impaired neurologic energy production, and immune impairments. Additionally, individuals may experience sore throat, headache, and tender lymph nodes. These symptoms, however, occur without a clear pathophysiologic explanation.¹⁷⁰ Without a clear etiology, diagnosis of CFS is often a diagnosis of exclusion. Current research is investigating the potential impact of the immune and adrenal systems, as well as genetics and biopsychosocial involvement.¹⁷¹ As a result, CFS/ME is believed to be less of a musculoskeletal disorder and more related to hypersensitivity of the central nervous system, a condition also known as *central sensitization*. Although individuals with CFS have widespread pain and fatigue, they do not have the tender points associated with fibromyalgia.¹⁷²

◆Pathophysiology.

The exact etiology and pathophysiology of CFS remain unknown. Therefore recent International Consensus Criteria have recommended

use of the term myalgic encephalomyelitis (ME) rather than chronic fatigue syndrome, because ME indicates an underlying pathophysiology.¹⁷³ Studies are currently investigating the possible involvement of skeletal muscle abnormalities, mitochondrial dysfunction, abnormal cytokine regulation, and dysfunction of the hypothalamic-pituitary-adrenal (HPA) axis.^{174,175} In support of this, functional MRI (fMRI) has shown lower blood perfusion to the brainstem in individuals affected by CFS.¹⁷² Other researchers have shown apparent central nervous system abnormalities, immunologic dysregulation, and higher-than-normal levels of proinflammatory cytokines. Certain points in skeletal muscle may be affected by oxidative stress reactions (see [Chapter 2](#)), accounting for the muscle pain and fatigue associated with CFS; however, other research implicates central sensitization of the CNS.¹⁷⁶

◆Clinical Manifestations.

Unrestful sleep is a hallmark of CFS. Defining symptoms include debilitating fatigue made worse by physical or mental exercise (postexertional fatigue), muscle pain, noninflammatory joint pain, headaches, flulike symptoms, and memory or concentration problems.¹⁷¹ Other common symptoms include bloating, morning joint stiffness, chest or jaw pain, chills and night sweats, visual disturbances, sore throat, and tender axillary or cervical lymph nodes. Symptoms and their consequences can be severe.

◆Evaluation and Treatment.

Diagnosis of CFS is often delayed or missed because there is no biologic marker or specific laboratory test for CFS, many CFS symptoms are shared with other illnesses, individuals with CFS do not necessarily appear sick, and symptoms typically have a variable course. Currently, the CDC recommends considering a diagnosis of CFS if the following two criteria are met¹⁷⁷:

1. Unexplained, persistent fatigue is not due to ongoing exertion, is not substantially relieved by rest, is of new onset (not

lifelong), and results in a significant reduction of previous levels of activity.

2. Four or more of the following symptoms are present for 6 months or more:

Impaired memory or concentration

Postexertional malaise (extreme, prolonged exhaustion and exacerbation of symptoms following physical or mental exertion)

Unrefreshing sleep

Muscle pain

Multijoint pain without swelling or redness (adults)

Headaches of a new type or severity

Sore throat that is frequent or recurring

Tender cervical or axillary lymph nodes

Treatment of CFS should focus on symptom management, especially management of sleep disturbances, depression, and pain.¹⁷¹ Consideration of the person's individual needs also must be made, and involves consideration of psychosocial factors as well as symptomatic and supportive care. Acknowledging the validity of the person's symptoms is important. Collaborative decision making between the individual and healthcare provider with regard to treatment, professional counseling, medication, diet, and activity helps CFS sufferers deal with the limitations imposed by the disease. Alternative therapies such as acupuncture, massage, and therapeutic touch can relieve anxiety.

Disuse Atrophy

Disuse atrophy describes the pathologic reduction in normal size of muscle fibers from an accelerated degradation of myofibrillar proteins. This may be associated with the normal aging process (sarcopenia), as well as following periods of prolonged immobilization and low mechanical load, such as from inactivity during bed rest, trauma (casting), local nerve damage, and space flight.¹⁷⁸ Disease-induced atrophy also is seen in debilitating

conditions, such as cancer, acquired immunodeficiency syndrome (AIDS), renal failure, congestive heart failure, chronic obstructive pulmonary disease, and burns.¹⁷⁹ Studies have shown the effects of muscular deconditioning associated with lack of physical activity have been seen in as few as 5 days after immobility.¹⁸⁰ Oxidative stress from lack of muscle activity causes decreased protein synthesis and increased proteolysis, leading to muscle atrophy.¹⁸¹ The normal individual on bed rest loses muscle strength from baseline levels at a rate of 3% per day. Bed rest also is associated with cardiovascular, skeletal, and other organ system changes.

The most effective restorative measure for disuse atrophy is to reapply mechanical load to the muscle group. Resistance exercise, stretching, and electrical stimulation have been shown to reduce the extent of atrophy in individuals who are immobilized or on bed rest.¹⁷⁹ Measures to prevent atrophy include adequate nutrition, frequent forceful isometric muscle contractions, and passive lengthening exercises. If reuse is not restored within 1 year, regeneration of muscle fibers becomes impaired.

Muscle Membrane Abnormalities

Two defects of the muscle membrane (plasma membrane of the muscle fiber) have been linked to clinical syndromes: the hyperexcitable membrane seen in the myotonic disorders and the intermittently unresponsive membrane seen in periodic paralyses. Although these are infrequent disorders, research into the pathologic processes has led to an improved understanding of the cell membrane channelopathies.

Skeletal Muscle Channelopathies

Skeletal muscle channelopathies can be divided into two primary groups: those presenting with myotonia (nondystrophic myotonias) and those associated with episodes of weakness (periodic paralysis). In **myotonic channelopathies**, muscle relaxation is delayed after voluntary contractions, such as handgrip or eye closure, leading to a

disabling muscle stiffness and/or weakness. Periodic paralysis is an autosomal dominant disorder in which depolarization of the sarcolemma is severe enough that the muscle cannot be “fired” again, resulting in paralysis or even myotonia.¹⁸²

Myotonia can be reproduced by removing extracellular chloride, thus reducing chloride conductance across the plasma membrane. The delicate balance in which sodium diffuses into the intracellular fluid, potassium diffuses out of the intracellular fluid, and chloride is in flux is thus interrupted. Because the normal diffusion processes (described in [Chapter 3](#)) stabilize the membrane, the shift in chloride ions is thought to increase membrane excitability. The chloride abnormality may explain the resting membrane hyperexcitability, but it does not explain the delayed relaxation present in myotonia and has not been detected in human myotonia.

Myotonia is seen in several disorders: myotonia congenita, paramyotonia congenita, myotonic muscular dystrophy, and some forms of periodic paralysis. Most are inherited disorders and are mild in symptomatology, with the exception of myotonic muscular dystrophy (see [Chapter 46](#)). Myotonia is treated by drugs that reduce muscle fiber excitability, such as sodium channel blocking agents (mexiletine, procainamide) and phenytoin.¹⁸³

Central core disease (CCD) is another inherited channelopathy that involves mutations in ryanodine receptors (RyR1) and affects calcium channels. In CCD, RyR1 channels are defective and either too much or too little calcium is released from the cell's sarcoplasmic reticulum, resulting in symmetrical proximal muscle weakness. This weakness, however, is typically not progressive in nature.¹⁸⁴ Classified as a neuromuscular disorder, CCD typically manifests during infancy as decreased muscle tone, delayed motor development, muscle weakness (particularly around the hip girdle), and other skeletal deformities, such as scoliosis.¹⁸⁵ Thought to be the most common congenital myopathy, the pathology of CCD relates to the lack of “cores” within skeletal myofibers that do not contain mitochondria and their oxidative enzymes. Therefore definitive diagnosis is made through muscle biopsy.¹⁸⁴

Periodic Paralysis

Periodic paralysis (PP) encompasses a group of muscle diseases caused by the inheritance of an autosomal dominant mutation of skeletal muscle sodium, calcium, or potassium channels.^{186,187} During an attack of PP the muscle membrane is unresponsive to neural stimuli and the resting membrane potential is reduced from -90 to -45 mV. Periodic paralysis can be either hyper- or hypokalemic. As the name implies, PP is usually transient.

The paralysis, which leaves the individual flaccid and weak, typically only affects the skeletal muscles and not the respiratory muscles. The weakness is accompanied by a change in serum potassium level, although in most individuals the change is negligible unless a secondary underlying condition affecting potassium distribution coexists.¹⁸⁸ For this reason, cardiac dysrhythmias, although not common, have been present during attacks.

Hypokalemic periodic paralysis is most often triggered by thyrotoxicosis caused by alterations in potassium ion channels that are regulated by triiodothyronine (T_3).^{188,189} (The effect of potassium on the resting membrane potential is discussed in [Chapter 3](#).) Glucose and insulin infusions and oral potassium loading are used as provocative tests; oral and intravenous potassium can relieve acute attacks. Treatment includes potassium-sparing diuretics and a high-salt diet. Acetazolamide, dichlorphenamide, and a low-salt diet are useful for long-term therapy. **Hyperkalemic periodic paralysis** is caused by an *SNC4A* genetic mutation affecting sodium channels and can be precipitated by several factors including pregnancy, alcohol, illness, exercise, and increased potassium intake.¹⁹⁰ Attacks are usually less severe than the hypokalemic form. Treatment includes small carbohydrate-rich meals, light exercise, and intravenous calcium gluconate.¹⁹¹

Metabolic Muscle Diseases

Metabolic muscle diseases are a collection of disorders caused by a genetic mutation impacting a muscle's metabolism. Disorders in

muscle metabolism can be caused by endocrine abnormalities or by diseases of energy metabolism, such as glycogen storage disease, enzyme deficiencies, and abnormalities in lipid metabolism and mitochondrial function.

Endocrine Disorders

Often the systemic effects of hormonal imbalance overshadow the individual's muscular symptoms. For example, individuals with thyrotoxicosis may have signs of proximal weakness, paresis of the extraocular muscles (exhibited as exophthalmic ophthalmoplegia), or hypokalemic periodic paralysis, as discussed earlier in the previous section. Hypothyroidism is often associated with a decrease in muscle mass and strength, with weak, flabby skeletal muscles and sluggish movements.

Thyroid hormone is believed to regulate muscle protein synthesis and electrolyte balance. Changes in muscle protein synthesis and electrolyte balance may therefore explain the alterations in muscle mass and contractility seen in endocrine disorders. The muscle symptoms subside with appropriate treatment of the primary hormonal disorder.

Other endocrine disorders affecting the musculoskeletal system include Dent disease (a syndrome that causes bone deformities); rickets or osteomalacia (softening of the bone because of deficiencies in vitamin D and calcium); and osteopetrosis (also known as *Albers-Schönberg disease*) caused by failure of osteoclasts to resorb bone, which thereby results in increased bone mass while causing increased bone fragility, growth abnormalities, and bone marrow failure in infants as bone marrow is replaced by bony masses.¹⁹² Familial hypomagnesemia is an autosomal recessive disease that primarily affects the renal system, causing hypomagnesemia and secondary hypocalcemia, and can result in tetany and convulsions.¹⁹³

Diseases of Energy Metabolism

Muscle relies on carbohydrates, such as glycogen and lipids (free fatty

acids), for energy. When stored glycogen or lipids cannot be used because of a lack of the enzyme necessary to convert energy for contraction, the individual experiences cramps, fatigue, and exercise intolerance. Disorders of muscle metabolism can be self-limiting, such as is seen in McArdle disease and some lipid disorders, or can cause widespread irreparable muscle destruction, as in acid maltase deficiency.

McArdle Disease.

McArdle disease, or glycogen myophosphorylase deficiency, is an autosomal recessive disease and was the first myopathy in which a single enzyme defect was identified (Fig. 45.35). Individuals with McArdle disease lack muscle phosphorylase, which is responsible for the breakdown of glycogen in muscle.¹⁹⁴ Normally after the body uses the short-term ATP and phosphocreatine stores, intramuscular lactic acid accumulates as glycogen is used (see Chapter 44). The individual with McArdle disease is not able to break down muscle glycogen stores or produce lactic acid.¹⁹⁵

FIGURE 45.35 McArdle Disease. A, Normal muscle fibers. B, Muscle fibers of McArdle disease. Note the enlarged (*white*) peripheral vacuoles. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

The altered energy production manifests itself in exercise intolerance, fatigue, and painful muscle cramps. When exercise is carried to an extreme, painful muscle contracture and myoglobinuria develop.¹⁹⁶ Some individuals describe a “second wind” phenomenon,

in which exercise tolerance increases if they slow their pace once the initial sensation of fatigue commences. This is caused by the use of free fatty acids as a secondary source of energy.¹⁹⁵ As the disease progresses, some individuals have pronounced muscle weakness and wasting. Other organs are not involved because the absence of phosphorylase is limited to muscle. Generally, individuals with McArdle disease learn to adapt their daily routine to avoid muscle symptoms. Usually the diagnosis of McArdle disease is made by the histochemical evaluation of myophosphorylase activity in frozen sections. There is no staining of myofibrils in affected individuals.

Acid Maltase Deficiency.

Acid maltase deficiency is an uncommon, autosomal recessive disorder affecting glycogen storage from an accumulation of glycogen in the lysosomes of muscle and other tissue cells.¹⁹⁷ The usual pathways of glycogen degradation are preserved. However, deficiency of α -glucosidase (GAA) enzyme is responsible for the abnormality in glycogen metabolism.

The infantile form, **Pompe disease**, is often recognized shortly after birth because of the presence of hypotonia, respiratory weakness, dysreflexia, and physiologic abnormalities such as cardiomegaly, an enlarged tongue, and hepatomegaly.¹⁹⁸ The adult form tends to be less severe than the infantile form. Hypertrophy of these tissues is thought to be the result of glycogen deposition. Diagnosis of Pompe disease can be made through the evaluation of GAA activity in blood or through muscle biopsy.¹⁹⁹ Previously, children with Pompe disease often died of cardiac or respiratory failure before age 2; now enzyme replacement therapy (ERT) with recombinant human acid α -glucosidase and physical therapy has shown a significant improvement in symptom presentation.^{200,201}

Myoadenylate Deaminase Deficiency.

Myoadenylate deaminase deficiency (MDD), also referred to as *adenosine monophosphate deaminase deficiency*, is a fairly common, autosomal recessive, enzyme deficiency that causes changes in

skeletal muscles and is associated with exercise intolerance accompanied by muscle pain and cramps, although the majority of individuals are asymptomatic.^{202,203} Because these individuals lack myoadenylate deaminase, they have a poor capacity for sustained energy production. Myoadenylate deaminase is the catalytic enzyme that forms phosphocreatine and ATP during exercise through a metabolic pathway that binds the purine and phosphate molecules that constitute ATP. Persons with MDD differ from those with McArdle disease in that during the ischemic exercise test, lactate production is normal when ATP and phosphocreatine are synthesized. Symptoms range from minimal complaints to exercise-induced muscle pain, to rhabdomyolysis.²⁰⁴ Currently, there are limited reports of successful treatments. Avoidance of rigorous exercise is generally recommended.²⁰³

Lipid Deficiencies.

Inherited disorders of lipid metabolism are uncommon but account for severe changes in muscle metabolism. The lipid content of muscle cells consists of free fatty acids, which are oxidized in the mitochondria. These acids require carnitine and the enzyme carnitine palmitoyltransferase (CPT) to transport long-chain fatty acids to the mitochondria. Individuals with CPT deficiency often have mild muscular symptoms but can experience bouts of renal failure caused by rhabdomyolysis. Individuals with a deficiency of carnitine alone have progressive muscle weakness and can experience sudden exacerbations.²⁰⁵

Measuring the CPT and carnitine content in muscle aids in the diagnosis. Cells in the muscle biopsy show vacuoles and lipid deposits. Treatments with riboflavin, medium-chain triglycerides, oral carnitine, prednisone, and propranolol are proposed.²⁰⁶

Inflammatory Muscle Diseases: Myositis

Viral, Bacterial, and Parasitic Myositis

Viral, bacterial, and parasitic infections of varying severity are known

to produce inflammatory changes in skeletal muscle, a group of conditions collectively described by the term **myositis**. In tuberculosis and sarcoidosis, chronic inflammatory changes and granulomas are found in muscle, as well as in other affected tissues. In trichinellosis, *Trichinella* larvae reside in infected muscles of infected animals, such as pigs, horses, and other wildlife, such as cougars and black bears.²⁰⁷ After ingestion, the parasites migrate to the intestinal mucosa and from there to the lymphatic and circulatory systems. Initial symptoms occur 1 to 2 days following consumption of infected meat and present as gastrointestinal distress (nausea, diarrhea, vomiting, abdominal pain). The more traditional trichinellosis symptoms generally occur from 2 to 8 weeks after ingestion and include muscle pain and stiffness, fever, rash, itching, and headaches.²⁰⁷ Treatment includes administration of corticosteroids, such as prednisone, and antiparasitic agents, such as albendazole. Mebendazole also may be used, though it is not available in the United States.²⁰⁸ Toxoplasmosis, a common parasitic infection, is also associated with a generalized polymyositis that responds rapidly to therapy.

In the tropics, more prevalent disorders include bacterial infections with *Staphylococcus aureus* and parasites such as cysticercus, the larva of the tapeworm *Taenia solium*. Viral infections can be associated with an acute myositis. Muscle pain, tenderness, signs of inflammation, and elevation of creatine kinase (CK) level are common manifestations of viral myositis. The self-limiting symptoms of muscle aches and pains during a bout of influenza may actually be a subacute form of viral myopathy.

Polymyositis, Dermatomyositis, and Inclusion-Body Myositis

Idiopathic inflammatory myopathies (IIMs) are a group of autoimmune diseases that typically target skeletal muscles, though cutaneous manifestations have been documented in 50% to 60% of individuals.²⁰⁹ IIMs are characterized by symmetrical proximal muscle weakness (hip and neck flexors, and shoulder girdle) and myalgia that

develops over weeks to months. The four principle types are polymyositis (PM), dermatomyositis (DM), necrotizing myopathy (NM), and inclusion-body myositis (IBM).²¹⁰ The incidence of IIM appears to be increasing, but this may simply reflect improved diagnosis. With an incidence of 5 to 22 per 100,000, it is more prevalent in nonwhite women older than age 50.

◆Pathophysiology.

Polymyositis and dermatomyositis are characterized by inflammation of connective tissue and muscle fibers. Polymyositis is mediated by T cells, whereas dermatomyositis is humorally mediated.²¹¹ CD8+ T cells and macrophages are typically found in PM-affected muscles. Fig. 45.36 shows the distribution of CD4+ and CD8+ lymphocytes in myositis. Innate and adaptive immune responses are activated in these myopathies, including myositis-specific antibodies and cytokines.²¹² Inflammatory cells, including T cells, macrophages, and plasma cells, surround, displace, and even invade muscle fibers in PM. Perimysial and perivascular sites are selectively enriched in B cells and helper T cells in those with DM.

FIGURE 45.36 Distribution of CD4+ and CD8+ Lymphocytes in Different Types of Myositis. Dermatomyositis shows perivascular and CD4+ T cells (helper T cells). Polymyositis shows mostly CD8+ T cells (cytotoxic T cells).

◆Clinical Manifestations.

The acute symptoms include many of those seen in any inflammatory process: malaise, fever, muscle swelling, pain and tenderness, lethargy, and listlessness. In adults, weakness of the shoulder and pelvic girdle muscles is a primary manifestation of PM. Both PM and DM often are associated with symmetrical proximal muscle weakness and initially can be confused with other myopathies. A thorough evaluation is required to exclude other disorders. Clinical features common to both are dysphagia, reduced esophageal motility,

vasculitis, Raynaud phenomenon, cardiomyopathy, and interstitial pulmonary fibrosis. Some individuals have other coexisting collagen vascular disorders, such as RA, systemic lupus erythematosus (SLE), and progressive systemic sclerosis (formerly called *scleroderma*).

Although PM and DM have similar histories of onset, DM includes cutaneous manifestations. The two most classic signs of skin involvement are (1) a heliotrope (reddish purple) rash that generally covers the eyelids and periorbital area (Fig. 45.37), and often includes the chest; and (2) erythematous, scaly lesions (Gottron lesions) that cover joints, such as the knees and elbows.²¹² DM is slightly more common in children and older adults, with onset before age 15 or after age 50. The adult with DM occasionally has underlying malignancies.²¹³

FIGURE 45.37 Dermatomyositis. Heliotrope (violaceous) discoloration around the eyes and periorbital edema. (From Habif TP: *Clinical dermatology*, ed 3, St Louis, 1996, Mosby.)

Additional differences between PM and DM exist. Muscle biopsy and histopathologic studies of IBM show degenerative changes of muscle, accumulation of multiple proteins within muscle fibers, and evidence of endoplasmic reticular stress with misfolding of proteins.^{214,215} Clinically, IBM may show weakness of the wrist and finger flexors as well as asymmetrical atrophy and quadriceps weakness. Additionally, IBM does not respond to standard pharmacologic treatment of immunosuppressants and immunomodifying agents.²¹⁶

◆Evaluation and Treatment.

The use of muscle biopsy in the diagnosis of PM or DM provides significant benefit. Most individuals show inflammatory cells grouped around blood vessels and atrophy of cells in muscle fascicles.²¹³ MRI may be used concomitantly not only to identify regions of muscular inflammation and edema suitable for biopsy but also to identify affected muscles not otherwise recognized on clinical examination. Levels of creatine kinase (CK) and other muscle enzymes, including aspartate transaminase (AST), lactate dehydrogenase (LDH), and alanine transaminase (ALT), and the sedimentation rate are often extremely elevated in both disorders. The presence of serum antinuclear antibodies (ANAs) also may be helpful in diagnosing DM. Electromyography (EMG) shows a typical “myopathic” pattern, with short, low-amplitude polyphasic potentials, as well as signs of marked muscle irritability. This is done through the delivery of a large number of low-amplitude action potentials of brief duration in which signs of muscle irritability and myopathic changes are identified.²¹³

Treatment primarily includes pharmacologic immunosuppression, although the evidence surrounding the effectiveness of this treatment is not robust. The use of pulsed intravenous glucocorticoids is followed by a 4-week oral regimen, concluding with a tapering of medication. High-dose intravenous immunoglobulin administration is sometimes used during active disease. Successful treatment with intravenous immunoglobulin (IVIg), azathioprine, methotrexate, mycophenolate mofetil, and cyclosporine has been reported.^{213,217}

Myopathy

Myopathy is the term applied to a primary muscle disorder. Many pathologic processes affect muscles and cause loss of functional muscle cells. Myopathies affect muscle strength, tone, and bulk. Primary muscle disease is invariably associated with marked weakness. The distribution of the weakness in myopathy is usually symmetrical and proximal, although occasionally the weakness is predominantly distal, such as in myotonic dystrophy. The weakness is associated with mild fatigue. Tone is decreased, as are the tendon

reflexes. Atrophy may be present. Some myopathies are associated with muscle hypertrophy as in cretinism and the familial progressive muscular dystrophies of childhood, in which hypertrophied muscles are rubbery and weak. Fasciculations are not present with myopathy because no denervation is present. No sensory changes are found. (Specific neurologic-associated myopathies are discussed in [Chapter 17](#).)

Toxic Myopathies

A number of agents, including corticosteroids, chloroquine, alcohol, phenytoin, azathioprine, organophosphates, and reverse transcriptase inhibitors, have been shown to cause **toxic myopathy**. Other contributing agents may include lipid-lowering agents, and opioids, such as heroin.

Alcohol specifically has been attributed to myopathies since the mid-nineteenth century and is associated with approximately 50% of skeletal muscle myopathies.^{218,219} Alcoholic toxic myopathies may have either an acute or a chronic presentation.²²⁰ The mechanisms by which alcohol affects the muscle include increasing the rate of proteolysis and amino acid oxidation and causing impaired cellular metabolism, gene dysregulation, and premature initiation of apoptosis.²¹⁸

Acute alcoholic myopathy can range from benign cramps and pain resolving in a matter of hours to severe weakness and markedly increased CK level associated with myoglobinuria and renal failure. Individuals are prone to repeated attacks following recovery. The first-line treatment remains abstinence from alcohol and improved nutrition.²¹⁸ An individual with chronic alcoholic myopathy often has a coexisting peripheral neuropathy that complicates the diagnosis.

Repeated intramuscular injections have been associated also with changes in muscle fibers. Local necrosis of muscle fiber and elevated CK concentration have been reported after intramuscular injections of certain cephalosporins, lidocaine, diazepam, and digoxin; these effects were not produced with injections of saline. When drugs are injected over long periods, a chronic focal myopathy develops. Proliferation of connective tissue both in the muscle fiber and in the overlying skin

and subcutaneous tissue has been reported. Over time, segments of the muscles, particularly the deltoid and quadriceps, are converted into fibrotic bands. Pathophysiologic mechanisms for these changes include repeated needle trauma and infection, along with the nonphysiologic acidity and alkalinity of the injected material. [Box 45.7](#) lists some of the causes of toxic myopathy.

Box 45.7

Agents That Can Cause Toxic Myopathy

Drug-Induced

- Alcohol
- Amiodarone (and others that inhibit CYP3A4 when combined with simvastatin)
- Amphotericin B
- Azathioprine
- AZT (zidovudine)
- Chloroquine
- Clofibrate
- Cocaine
- Colchicine
- Ethanol
- Ipecac (withdrawn from U.S. markets)
- 3,4-Methylenedioxymethamphetamine (MDMA, “ecstasy”)
- Pentachlorophenol (PCP)
- Statins
- Steroids (especially with prolonged high doses; doses >25 mg/day; fluorinated steroids)

Endocrine Disorders

- Adrenal disorders (Addison disease, Cushing disease)

Hyperparathyroidism
Hyperthyroidism (creatinine kinase may be normal)
Hypothyroidism (creatinine kinase may be mildly elevated)
Infectious disorders
Coxsackie A and B viruses
Human immunodeficiency virus (HIV)
Influenza
Lyme disease
Staphylococcus aureus muscle infection (frequent cause of pyomyositis)
Toxoplasmosis
Trichinosis

Miscellaneous

Licorice
Certain edible wild mushrooms
Lead poisoning
Organophosphates
Red yeast rice
European migratory quail (quail eat toxic hemlock, hellebore seeds)
Any medication that alters serum concentrations of sodium, potassium, calcium, phosphorus, or magnesium

Data from Kuncel RW: *Curr Opin Neurol* 22(5):506–515, 2009; Valiyil R, Christopher-Stine L: *Curr Rheumatol Rep* 12(3):213–220, 2010.

Muscle Tumors

Rhabdomyoma

Rhabdomyoma is an extremely rare benign tumor of striated muscle that generally occurs in the tongue, neck muscles, larynx, uvula, nasal cavity, axilla, vulva, and heart. These tumors are usually treated by

surgical excision and do not recur. When malignant, these tumors are referred to as *rhabdomyosarcomas*.

Rhabdomyosarcoma

A rare malignant tumor of striated muscle is called **rhabdomyosarcoma**, which is a subgroup of sarcoma. It is the most common soft tissue sarcoma in children and adolescents, constituting 50% of all soft tissue sarcomas and 10% of all malignant tumors in children. These tumors are highly malignant, with rapid metastasis. They are located in the muscle tissue of the head, neck, and genitourinary tract in 75% of cases. The remaining 25% of these tumors are located in the trunk, extremities, and urinary tract.²²¹⁻²²³

Three types of rhabdomyosarcoma are differentiated on pathologic section: pleomorphic, embryonal, and alveolar. The pleomorphic, or spindle cell, type is considered to be one of the most highly malignant tumors of the extremities seen in adulthood, but has a better outcome in children.²²¹ Embryonal tumors are most commonly seen in childhood and appear on biopsy to be shaped like a tadpole or tennis racquet. Alveolar-type tumors, which appear lattice-like, resemble alveolar lung tissue and have the poorest outcome.²²⁴

The diagnosis and staging of rhabdomyosarcoma are made by history, physical examination, serologic testing, CT, and MRI. Diagnosis is confirmed by incisional biopsy with surgical resection and by examination of the specimen by a pathologist.²²¹ On electron microscopy the tissue demonstrates myofilaments and Z-band material; CT scan helps define the tissue borders. Staging is based on the site of origin, residual disease, lymph node involvement, and distant metastases.²²¹ This information allows a diagnosis of rhabdomyosarcoma (RMS) to be classified into one of the following four different groups: group I, completely resected without lymph node involvement; group II, localized disease with or without complete resection, or microscopic residual disease with or without lymph node involvement; group III, localized gross residual disease; and group IV, distant metastases.²²⁵ This staging is then helpful in determining prognosis and treatment.

Treatment consists of a combination of surgical excision, systemic chemotherapy, and adjuvant radiation therapy. Overall survival of childhood rhabdomyosarcoma has improved over the past decades but adult survival remains poor (see [Chapter 46](#)).

Other Tumors

Metastatic muscle tumors are rare in spite of the extensive vascular supply of skeletal muscles. It is suggested that local pH or metabolic changes discourage metastatic involvement from other tumors. When adjacent carcinomas do cause muscle damage, it is usually related to the compression of tissue and resultant muscle atrophy.

Summary Review

Musculoskeletal Injuries

1. The most common skeletal injury is a fracture. A bone can be completely or incompletely fractured. A closed fracture leaves the skin intact. An open fracture has an overlying skin wound. The direction of the fracture line can be linear, oblique, spiral, or transverse. Greenstick, torus, and bowing fractures are examples of incomplete fractures that occur in children. Stress fractures occur in normal or abnormal bone that is subjected to repeated stress. Fatigue fractures occur in normal bone subjected to abnormal stress. Normal weightbearing can cause an insufficiency fracture in abnormal bone.
2. Dislocation is complete loss of contact between the surfaces of two bones. Subluxation is partial loss of contact between two bones. As a bone separates from a joint, it may damage adjacent nerves, blood vessels, ligaments, tendons, and muscle.
3. Tendon tears are called *strains*, and ligament tears are called *sprains*. A complete separation of a tendon or ligament from its attachment is called an *avulsion*.

4. Epicondylopathy is degeneration of a tendon where it attaches to a bone. Bursitis is inflammation of the bursae (small sacs lined with synovial membrane and filled with synovial fluid). Bursitis can be inflammatory, septic, or hemorrhagic.
5. Muscle strain can range from mild injury to severe damage that can result in loss of muscle function.
6. Rhabdomyolysis can be a life-threatening complication of severe muscle trauma wherein muscle cell contents are released into the circulation. It may result in myoglobinuria, the presence of myoglobin in the urine, and is often associated with acute renal failure.

Disorders of Bones

1. Metabolic bone diseases are characterized by abnormal bone structure. In osteoporosis bone tissue is normally mineralized, but the density or mass of bone is reduced because the bone remodeling cycle is disrupted. Osteoporosis is a complex, multifactorial, chronic disease that often progresses silently for decades until fractures occur. It is the most common bone disease. Multiple factors are involved including alteration in the OPG/RANKL/RANK system.
2. Postmenopausal osteoporosis occurs in middle-aged and older women and is caused by increased osteoclast activity (probably caused by changes in osteoprotegerin), decreased IGF levels, a combination of inadequate dietary calcium intake and lack of vitamin D, possibly decreased levels of magnesium, lack of exercise, decreased levels of estrogen, and family history.
3. Glucocorticoids increase RANKL expression and inhibit OPG production by osteoblasts, thus leading to lower bone density.
4. Osteomalacia is a metabolic bone disease characterized by inadequate bone mineralization.
5. Excessive and abnormal bone remodeling occurs in Paget disease. Sporadic Paget disease involves overexpression of

RANKL.

6. Osteomyelitis is a bone infection caused most often by bacteria (e.g., *S. aureus*) that can enter bone from outside the body (exogenous osteomyelitis) or from infection sites within the body (hematogenous osteomyelitis).
7. Bone tumors originate from bone cells, cartilage cells, fibrous tissue cells, or vascular marrow cells. Each cell produces a specific type of ground substance that is used to classify the tumor as osteogenic (bone cell), chondrogenic (cartilage cell), collagenic (fibrous tissue cell), or myelogenic (vascular marrow cell). Malignant bone tumors are large, aggressively destroy surrounding bone, invade surrounding tissue, and initiate independent growth outside the site of origin. Benign bone tumors are less destructive, limit their growth to the anatomic confines of the bone, and have a well-demarcated border.

Disorders of Joints

1. Noninflammatory joint disease is differentiated from inflammatory joint disease by the absence of synovial membrane inflammation, the absence of systemic signs and symptoms, and the presence of normal synovial fluid.
2. OA is an inflammatory joint disease and is characterized by the degeneration and loss of articular cartilage, sclerosis of underlying bone, and formation of bone spurs (osteophytes).
3. RA is an inflammatory joint disease characterized by inflammatory destruction of the synovial membrane, articular cartilage, joint capsule, and surrounding ligaments and tendons. RA involves an aberrant immune response and the transformed antibodies are called *rheumatoid factors*. The OPG/RANKL/RANK system is also involved. Rheumatoid nodules may also invade the skin, lung, and spleen and involve small and large arteries. RA is a systemic disease that affects the heart, lungs, kidneys, and skin, as well as the joints.

4. AS is a chronic inflammatory joint disease characterized by stiffening and fusion of the spine and sacroiliac joints. Recent data show that synovitis and bone marrow inflammation, rather than solely the connective tissue between tendon or ligament and bone (enthesis) involvement, explain the alteration in sacroiliac joints.
5. Gout is a metabolic disorder associated with high levels of uric acid in the blood and body fluids. Uric acid crystallizes in the connective tissue of a joint, where it initiates inflammatory destruction of the joint.

Disorders of Skeletal Muscle

1. A pathologic contracture is permanent muscle shortening caused by muscle spasticity, as seen in CNS injury or severe muscle weakness.
2. Stress-induced muscle tension is presumably caused by increased activity in the reticular activating system and gamma loop in the muscle fiber. Progressive relaxation training and biofeedback have been advocated to reduce muscle tension.
3. Fibromyalgia is a chronic musculoskeletal syndrome characterized by diffuse pain and tender points. Current research indicates that muscle is the end organ responsible for the pain and fatigue of the disease. Comorbidities (e.g., irritable bowel syndrome, mood disorders, and chronic fatigue) suggest a major role for neuroendocrine and stress-response alterations.
4. Chronic fatigue syndrome (CFS) is a debilitating and complex disorder with profound fatigue not improved by bed rest. The cause of CFS is hypothesized to include central nervous system alterations, immunologic disruptions, and chronic proinflammatory cytokines.
5. Atrophy of muscle fibers and overall diminished size of the muscle are seen after prolonged inactivity. Isometric

contractions and passive lengthening exercises decrease atrophy to some degree in immobilized persons.

6. Hyperexcitable membranes cause the physical and electrical phenomenon of myotonia. The disorder is treated with drugs that reduce fiber excitability. Periodic paralysis is caused by an unresponsive muscle membrane and is accompanied by changes in the level of serum potassium. The biochemical defect is possibly related to changes in the muscle membrane and sarcoplasmic reticulum.
7. Metabolic muscle diseases are caused by endocrine disorders, glycogen storage disease, enzyme deficiencies, and abnormal lipid function. The muscle depends on a complex system of carbohydrates and fats converted by enzymes to produce energy for the muscle cell. Abnormalities in these pathways can inhibit function or cause damage to the muscle fiber. These illnesses are rare, yet they account for significant functional abnormalities.
8. Viral, bacterial, and parasitic infections of muscles produce the characteristic clinical and pathologic changes associated with inflammation. These are usually treatable and self-limiting disorders.
9. Polymyositis (generalized muscle inflammation) and dermatomyositis (polymyositis accompanied with skin rash) are characterized by inflammation of connective tissue and muscle fibers, and muscle fiber necrosis. Cell-mediated and humoral immune factors have been implicated. Treatment with immunosuppressive agents is effective in many cases.
10. Primary disorders with weakness and atrophy are known as *myopathies*.
11. The most common toxic myopathy is caused by alcohol abuse. Direct toxic effects of alcohol-producing necrosis of muscle fibers and nutritional deficiency have been identified. The most effective treatment is abstinence and improved nutrition. The toxic effects of many drugs on muscle fibers cause local trauma to the muscle fibers from direct effects of the needle,

secondary infection, and changes caused by nonphysiologic acidity and alkalinity in the fibers.

12. Sarcomas of muscle tissue are rare. Rhabdomyosarcoma has a uniformly poor prognosis because of an aggressive invasion and early, widespread dissemination. The usual treatment includes surgical excision, radiation therapy, and systemic chemotherapy.

Key Terms

Acid maltase deficiency, 1462

- Musculoskeletal Tumors in Children, 1489

Nonaccidental Trauma, 1492

Musculoskeletal alterations in children are very common. They may be congenital, such as clubfoot; hereditary, such as muscular dystrophy; or acquired, such as Legg-Calvé-Perthes disease. Some of these disorders are acute, and the child will recover completely; other disorders are chronic or, in some cases, terminal. An understanding of the pathophysiology of these alterations will aid in providing the best care possible for these children.

Musculoskeletal Development in Children

Bone Formation

Bone formation, which begins at about the sixth week of gestation, involves two phases: (1) the delivery of bone cell precursors to sites of bone formation and (2) the aggregation of these cells at **primary centers of ossification**, where they mature and begin to secrete osteoid (see [Chapter 44](#)). Some of the bone cell precursors are present in fetal connective tissues, whereas others migrate in blood to sites of bone formation after blood vessels have grown into the tissue.

Cellular aggregation and maturation occur in two types of fetal tissue, depending on which bones are being formed. The cranium, facial bones, clavicles, and parts of the jawbone (classically called *flatbones*) arise from a fetal membrane termed the *mesenchyme*. Bones that develop on or within the mesenchyme grow by the process of **intramembranous formation of bone**. As the mesenchyme becomes vascularized, the immature bone cells aggregate and mature into osteoblasts, which form the centers of ossification and create solid bone or osteoid.

Endochondral formation of bone is the development of new bone from cartilage ([Fig. 46.1](#)). First, mesenchymal tissue forms a **cartilage anlage**, which defines the shape of the bone. This is usually found by 6 weeks' gestation. Blood vessel invasion to inside the anlage brings osteoprogenitor cells leading to primary centers of calcification by 8 weeks. Endochondral bone formation begins in the outer layer of the

cartilage model, which consists of a layer of dense connective tissue called **perichondrium**. The perichondrium contains cells that develop into osteoblasts, forming a collar of bone, termed the **periosteal collar**, around the cartilage model. Cartilage enclosed within the periosteal collar degenerates, and capillaries from outside the perichondrium invade the degenerating cartilage cells, carrying with them osteoblast precursors from the inner layer of the perichondrium and osteoclast precursors from the blood itself.

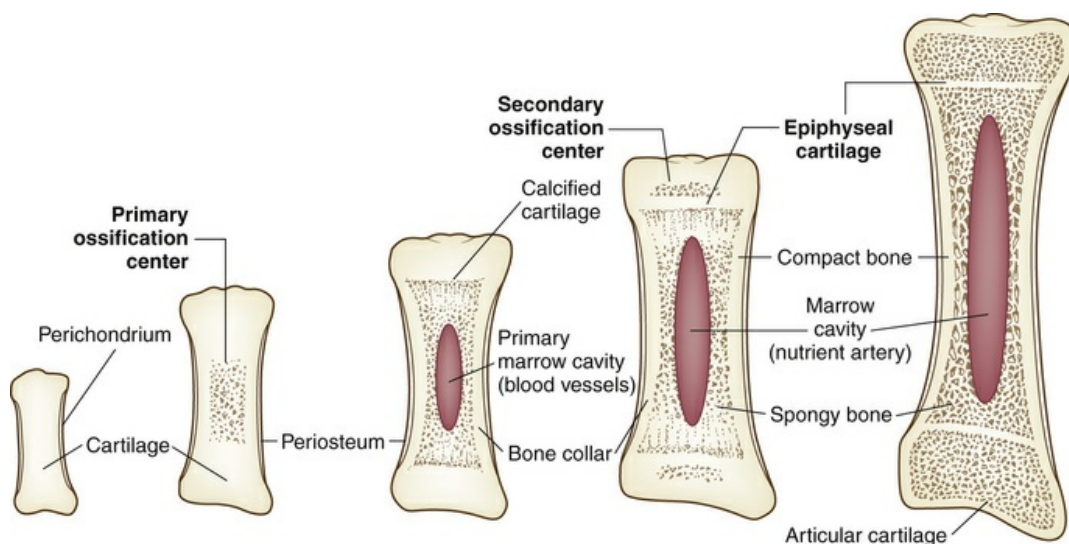

FIGURE 46.1 Stages of Endochondral Bone Formation and Centers of Ossification in Long Bone.

Endochondral bone formation progresses at the primary center of ossification in the middle of the cartilage model and extends toward either end of the developing bone. At the same time, the periosteal collar thickens and becomes wider toward the epiphyses. By the end of gestation **secondary centers of ossification** (i.e., the epiphyseal centers) begin to lay down bone at both ends of the cartilage model. Here, too, cartilage within the periosteal collar degenerates, and blood vessels grow inward, delivering bone cell precursors. Once the osteoblasts begin to secrete osteoid, ossification spreads from the secondary centers in all directions until all the cartilage within the model is replaced by bone.

Two regions of cartilage remain at the ends of long bones: (1)

articular cartilage over the free ends of the bone, and (2) the physal plate, a layer of cartilage between the metaphysis and epiphysis. (These structures are described and illustrated in [Chapter 44](#); see [Fig. 44.3](#)). The physal plate retains the ability to form and calcify new cartilage and deposit bone until the skeleton matures approximately 1 year after sexual maturity (11 to 15 years of age in females, 15 to 18 in males).

Bone Growth

Until adult stature is reached, growth in the length of long bones occurs at the physal plate through endochondral ossification. Cartilage cells at the epiphysal side of the physal plate multiply and enlarge. As rapidly as new cartilage cells form, cartilage cells at the metaphysal side of the plate are destroyed and replaced by bone.

In the shaft of new bone, where growth is relatively slow, the bone produced by accretion is compact and dense. The compact bone is thickest where it has to withstand the maximal stresses, which generally occur in the middle of the shaft.

The two physes of the long bone often have varying activity rates. For example, the distal physis in the femur contributes 80% of the overall length, whereas the proximal physis at the hip contributes only 20%. The more active of the two has more power to remodel deformity but also can be more sensitive to injury. The architecture of the physis also dictates its sensitivity to injury. The distal femur, for example, has an undulating pattern that increases its resistance to shear force; when injured, however, growth disturbance is highly likely. On the other hand, the distal radius, which contributes 80% of overall radial length, is a flat, smooth physis that is far more resistant to traumatic injury.

Growth in the diameter of bone occurs by deposition of new bone on an existing bone surface. Bone matrix is laid down by osteoblasts on the periosteal surface and subsequently becomes calcified. At the same time, bone resorption occurs on the endosteal surface. Endosteal resorption increases the diameter of the medullary cavity, which contains marrow and spongy bone.

Many factors affect the development, physiology, and rate of growth of the epiphyseal plate. Growth hormone must be secreted by the pituitary gland at a constant rate to stimulate the growth plate consistently. Other known factors affecting growth include peptide regulatory factors (e.g., fibroblast growth factor [FGF]); changes in cell-to-cell interactions through cell adhesion molecules (CAMs) and cell junctions; and complex interactions or changes in the extracellular matrix (ECM), nutrition, general health, and other hormones (e.g., thyroid hormone, adrenal and gonadal androgens, estrogens). When these factors are poorly controlled, skeletal dysplasias, such as achondroplasia, can occur.

Even after physeal closure at skeletal maturity, bone is constantly being destroyed and re-formed (see [Chapter 44](#)). This is a rapid process in young children, allowing them to heal bone injury more quickly than adults. By adulthood, however, bone turnover, or remodeling, occurs at a relatively slow rate. Peak bone mass is achieved by the middle to late twenties and slowly decreases throughout life; therefore ensuring appropriate intake of calcium and phosphorus, performing weightbearing exercises, and minimizing caffeine intake are especially important for a young female if she is to avoid osteoporosis in later life. Recently, the importance of vitamin D levels also has been emphasized. In one study, nearly 70% of American children had low levels of vitamin D.¹ The actual percentages of children and adults with low levels of vitamin is debated. Children with vitamin D insufficiency have a higher incidence of fracture² and also may be at greater risk for sustaining more severe fractures.³

Skeletal Development

The axial skeleton changes shape with growth. (The axial skeleton and appendicular skeleton are described and illustrated in [Chapter 44](#); see [Fig. 44.5](#).) In a newborn the entire spine is concave anteriorly, or **kyphosed**. In the first 3 months of life, with the infant's ability to control the head, the upper (cervical) spine begins to arch, or become **lordotic**. The normal lordotic curve of the lower (lumbar) spine begins

to develop with sitting.

The appendicular skeleton (the extremities) grows faster during childhood than does the axial skeleton. The newborn has a relatively large head and long spine with disproportionately shorter limbs than an adult. By 1 year of age, 50% of the total growth of the spine has occurred and is more than 70% complete by age 8.⁴ Therefore failure of the spine to grow (e.g., spinal fusion) does not limit eventual height as much as the premature fusion of the growth plates of the lower extremities. In children with congenital curvature of the spine, growth tends to worsen the deformity rather than to increase the length of the spine.

Besides getting longer, growing bones of the extremities undergo changes in rotation and alignment. In the newborn the proximal femur is rotated forward up to 40 degrees and the tibia is rotated inward. With growth the femur assumes its normal alignment (by 12 years of age) and tibial rotation neutralizes at 8 years of age.⁵ Bowlegs and knock knees can be normal at certain stages of growth. At birth the newborn's legs are bowed because of stresses in utero. **Genu varum (bowleg)** reaches a peak by 30 months of age, whereas **genu valgum (knock knee)** maximizes by 5 to 6 years of age. If genu varum or genu valgum persists past these ages, a pathologic process rather than a physiologic phase may be present. Pathologic causes of genu varum are Blount disease, rickets, skeletal dysplasias (such as achondroplastic dwarfism), traumatic injury, and musculoskeletal infection. Genu valgum also may persist in children with a skeletal dysplasia, benign musculoskeletal tumors (multiple hereditary exostoses), osteogenesis imperfecta, or following a traumatic injury or infection. A genetic predisposition to genu valgum also may be evident.

Muscle Growth

The composition and size of muscles vary with age. In the fetus, muscle tissue contains a large amount of water and much intercellular matrix. After birth, both are reduced considerably as the muscle fibers (cells) enlarge by accumulating cytoplasm. Little information is

available about the numbers of fibers in a given muscle at various ages, but the total mass of muscle in the body can be estimated from the amount of creatinine excreted in the urine, because the conversion of creatine to creatinine takes place only in muscle (see [Chapter 44](#)). Between birth and maturity the number of muscle nuclei in the body increases 14 times in boys and 10 times in girls. Muscle fibers reach their maximal size in girls at approximately 10 years of age and in boys by 14 years. Growth in length occurs at the ends of muscles, and the increase in length is accompanied by an increase in number of nuclei in the fibers. Muscle fibers increase in diameter as the fibrils become more numerous. The fibrils themselves do not increase in diameter. Connective tissue components of muscle grow where the tendon and muscle meet.

A potent stimulus to the growth of a muscle is the separation of its attachments as the skeleton grows. The length of a muscle fiber is the direct consequence of its intended range of movement. The stimulus for the formation of a tendon is probably the pull of the muscle rudiment on undifferentiated connective tissue. If the normal opponents of a muscle are paralyzed, the muscle fails to grow properly and can result in contracture of a joint.

Muscle growth during adolescence is a major factor in weight gain. Gender differences in muscle size and weight are minor in childhood but become considerable with the onset of puberty.

In the infant, muscle accounts for approximately 25% of total body weight, compared with 40% in the adult. In the adult, approximately 55% of muscle weight is in the lower limb muscles, whereas in the infant the majority of the weight is axial musculature. The respiratory and facial muscles are well developed at birth so that the infant can perform the vital functions of breathing and sucking. Other muscle groups, such as the pelvic muscles, take several years to develop fully. Throughout life the weight of the skeletal muscles can be increased by exercise.

Musculoskeletal Alterations in Children

Congenital Defects

Syndactyly

The most common congenital defect of the upper extremity is **syndactyly**, or webbing of the fingers (Fig. 46.2). Simple webbing involves the soft tissue envelope alone and is best released surgically when the child is 6 months to 1 year of age. Complex syndactyly involves fusion of the bones and nails as well as the soft tissues; it may be associated with absence or anomaly of bony or neurovascular units. The primary goal in surgical correction of these defects is to achieve maximal function and appearance. Ideally, corrective surgery is deferred until the child is 1 to 2 years old and completed before the child enters school. **Vestigial tabs**, such as an extra digit, however, are best removed during the immediate neonatal period. Anomalies on the radial aspect of the arm, such as a foreshortened or absent radius, are often associated with abnormalities of blood, heart, or kidneys. Lateral or ulnar-sided defects are less often associated with systemic anomalies and are extremely rare.

FIGURE 46.2 Syndactyly with Polydactyly.

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH), formerly known as *congenital dislocation of the hip*, is an abnormality in the development of the proximal femur, acetabulum, or both (Fig. 46.3). Although most often present at birth, it may occur at any time in the newborn or infant period.

FIGURE 46.3 Hip Dysplasia in Children. Developmental dysplasia of the hip (DDH) with residual acetabular dysplasia (*red arrows*). Radiographs at birth, 3, 10, and 19 years (top to bottom) show persisting dysplasia.

The incidence of true dislocation of the hip or a dislocatable hip is 1 in 1000 live births. Some degree of instability of the hip is present in approximately 10 per 1000 live births. The left hip is affected in 60% of cases, whereas the right hip alone is affected only 20% of the time. Bilateral DDH occurs 20% of the time.

Risk factors for DDH include family history, female gender (6:1),

metatarsus adductus (20%), torticollis (10%), oligohydramnios, first pregnancy, and breech presentation. First pregnancies and oligohydramnios (deficient volume of amniotic fluid) are thought to limit fetal movement, and breech presentation not only limits movement but also places the hips in a position of flexion and adduction, which creates a more shallow socket, or acetabulum. Although only 2% of births have breech history, as many as 40% of infants with DDH had a breech birth. Maternal hormones that reportedly increase joint laxity also have an effect on DDH, although the exact mechanism is unknown. DDH also is more common in whites and those cultures that swaddle infants with the hips in extension and adduction. It is almost unknown in African cultures where infants are carried, with legs abducted, on the back.

◆Pathophysiology.

The hip can be described as subluxated (partial contact only), dislocated (no contact between femoral head and acetabulum), and acetabular dysplasia (the femoral head is located properly but the acetabulum is shallow or underdeveloped) (Fig. 46.4). The **subluxated hip** maintains contact with the acetabulum but is not well seated within the hip joint. The acetabulum is often dysplastic (or shallow) although the femur is often normal. The **dislocatable hip** is sometimes located but can be dislocated easily. The dislocated hip has no contact between the femoral head and the acetabulum. Some degree of **acetabular dysplasia** is present in almost all cases. Typically, the acetabulum is shallow or sloping rather than cup shaped.

FIGURE 46.4 Configuration and Relationship of Structures in Developmental Dysplasia of the Hip. (From Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 10, St Louis, 2015, Mosby.)

By approximately 10 weeks' gestation, the femur, acetabulum, and hip joint capsule are well developed. It appears that most hip dysplasia develops within the second and third trimesters and is often the result of positioning factors (i.e., breech positioning). There also can be a genetic component, although this is still poorly understood. In addition, 2% of DDH cases are teratologic or caused by a systemic syndrome, such as arthrogryposis or spina bifida, in which muscle contracture or imbalance leads to DDH.

If DDH is left untreated in the growing child, secondary changes occur. If the hip remains subluxated or dislocated, the acetabulum becomes increasingly shallow and the soft tissues shorten around the proximal femur. Subluxation leads to early osteoarthritis (OA), and it is now estimated that at least 60% of all OA of the hip is related to DDH. If the hip is dislocated, the bone acetabulum fills with soft tissue and a false acetabulum forms where the femoral head contacts the iliac crest. An apparent limb length inequity and hip muscle weakness occur, leading to a waddling gait. Back pain and hip pain develop in adulthood. Adult reconstruction of a dislocated hip, even with an artificial hip, is very difficult.⁶

◆Clinical Manifestations.

The clinical manifestations of DDH vary with the severity of the condition and the age of the child. Signs and symptoms that should be noted include the following:

1. Asymmetry of gluteal or thigh folds
2. Limb length discrepancy (Galeazzi sign)
3. Limitation of hip abduction
4. Positive Barlow maneuver (hip reduced, but dislocatable) (Fig. 46.5, A)

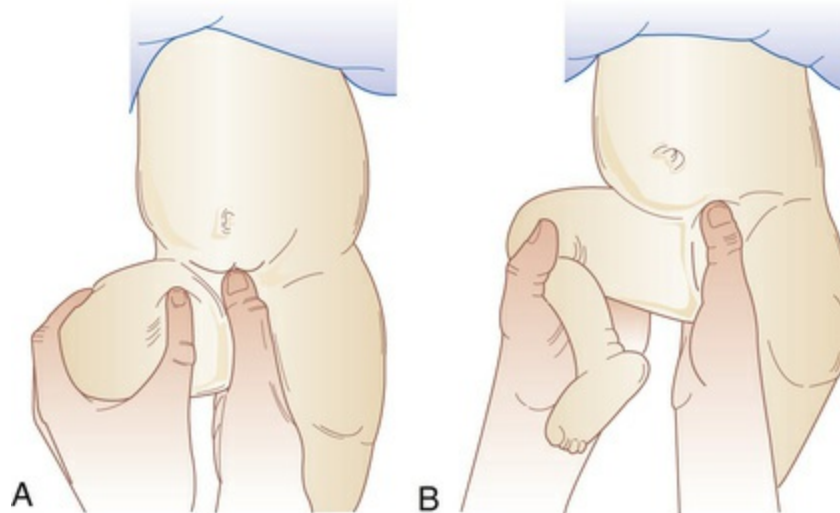

FIGURE 46.5 Congenital Dislocation of the Hip. **A**, Barlow maneuver. With one hand pressing the symphysis in front and the sacral spine in back, lateral pressure is applied to the thigh with the thumb of the other hand while pressure is applied with the palm to the knee on the side being examined. The hip that has been flexed to 90 degrees is then adducted. A positive sign is a sensation of abnormal movement, indicating dislocation of the femoral head from the acetabulum. The hands are reversed for examining the other hip. This sign and Ortolani sign may be found only in the first weeks of life. **B**, Ortolani maneuver. Sign of jerking into correct position. After the Barlow maneuver (**A**), the hip should be abducted to about 80 degrees while the femur is lifted anteriorly with the fingers along the thigh. A positive sign is a sensation of a jerk or snap with reduction into the joint socket. (Adapted from Specht EE: *Am Fam Physician* 9:88–96, 1974.)

5. Positive Ortolani sign (hip dislocated, but reducible) (Fig. 46.5, B)
6. Positive Trendelenburg gait (waddling)
7. Pain (very late)

The child also should be examined for other anomalies, such as torticollis or metatarsus adductus, which can be associated with DDH.

◆Evaluation and Treatment.

In the newborn period clinical examination is the most important diagnostic tool. Real-time ultrasound, in which the hip is examined while the ultrasound is performed, also is extremely valuable in the newborn period, especially in high-risk infants. The use of ultrasound allows visualization of the cartilaginous structures of the hip (the femoral head and the outer lip of the acetabulum), which are not seen on plain roentgenogram. Radiographs are used after age 6 months when the ossific nucleus of the femoral head appears.⁷

Treatment depends on the age of the child, severity of dysplasia, and duration of dysplasia. The earlier that treatment is begun, the better the result. In children less than 4 to 6 months of age, a Pavlik harness can brace the hip in abduction and flexion, and the acetabulum will remodel as the femoral head rests centered in the socket (Fig. 46.6). With this treatment, up to 98% of children will have an excellent result. A “closed” reduction (without opening the joint) followed by spica or body casting for up to 3 months can be done in children up to 12 months of age. After 12 months, surgical intervention—including opening the joint and cutting and realigning the femur and/or acetabulum—may be required. The percentage of good outcomes decreases as the child ages. Up to 70% of children treated surgically for DDH after age 3 develop early osteoarthritis.⁸ Early intervention before age 1 is critical for a good outcome; therefore vigilance for this problem within the first year is essential. Moderate evidence supports performing an imaging study (ultrasound) before 6 months of age in infants with one or more of the following risk factors: breech presentation, family history, or history of clinical instability.⁹

FIGURE 46.6 Pavlik Harness for Bilateral Hip Dislocation. (From Wheaton Brace Co.)

Deformities of the Foot

Congenital Deformity.

Congenital foot deformity is found in approximately 4% of all newborns, and metatarsus adductus accounts for 75% of these deformities (Table 46.1). **Metatarsus adductus** is a forefoot adduction deformity associated with a normal, plantigrade hindfoot and is believed to be secondary to intrauterine positioning. It is associated

with developmental dysplasia of the hip in 20% of cases; consequently, the hips of these infants must be carefully evaluated. Metatarsus adductus is usually classified by two criteria: flexibility (passively correctable vs. rigid) and degree of deformity. The degree of deformity (mild, moderate, severe) is ascertained by the heel bisection line. A mild deformity is one in which the heel bisection line passes medial to the third toe; moderate, through the third or fourth toes; and severe, lateral to the fourth toe. Serial casts during the first 6 months of life are suggested for moderate to severe deformities and those deformities that appear less flexible. By 6 years of age, 87% of children usually correct *spontaneously*, and 95% by 15 years of age. Even in those children with some residual deformity, functional symptoms are rare.

TABLE 46.1

TERMS USED TO DESCRIBE FOOT ABNORMALITIES

TERM	DEFINITION
Position	
Abduction	Lateral deviation away from the midline of the body
Adduction	Lateral deviation toward the midline of the body
Eversion	Twisting of the foot outward along its long axis
Inversion	Twisting of the foot inward along its long axis
Dorsiflexion	Bending the foot upward and backward
Plantar flexion	Bending the foot downward and forward
Abnormality	
Talipes	Congenital abnormality of the foot (clubfoot)
Pes	Acquired deformity of the foot
Varus	Inversion and adduction of the heel and forefoot
Valgus	Eversion and abduction of the heel and forefoot
Equinus	Plantar flexion of the foot in which the heel is lower than the toes
Calcaneus	Dorsiflexion of the foot in which the heel is lower than the toes
Planus	Flattening of the medial longitudinal arch of the foot (flatfoot)
Cavus	Elevation of the medial longitudinal arch of the foot (high arch)
Equinovarus	Coexistent equinus and varus deformities

Calcaneovarus	Coexistent calcaneus and varus deformities
Equinovalgus	Coexistent equinus and valgus deformities
Calcaneovalgus	Coexistent calcaneus and valgus deformities

Clubfoot: Equinovarus Deformity.

Clubfoot describes a range of foot deformities in which the foot turns inward and downward. Technically called **equinovarus**, the heel is positioned varus (inwardly deviated) and equinus (plantar flexed) (Figs. 46.7 and 46.8). The clubfoot deformity can be positional (correctable passively), idiopathic, or teratologic equinovarus (as a result of another syndrome, such as spina bifida). These three types are discussed in the following sections. Overall, the positional equinovarus deformity lends itself to rapid correction by conservative stretching exercises or by application of a few serial casts. The idiopathic variety is treated by weekly cast correction/manipulation, followed by Achilles tenotomy and abduction bracing. Teratologic equinovarus deformities more often require surgical correction or muscle-balancing procedures, or both; however, initial serial casting may achieve correction of the foot deformity albeit with a higher risk of recurrence.

FIGURE 46.7 Bilateral Clubfoot. A, Infant with bilateral congenital talipes equinovarus. B, Ponseti casting. (A courtesy Dr. A.E. Chudley, Section of Genetics and Metabolism, Department of Pediatrics and Child Health, Children's Hospital and University of Manitoba, Winnipeg, Manitoba, Canada. In Moore KL et al: *The developing human*, ed 10, Philadelphia, 2016, Saunders.)

FIGURE 46.8 Idiopathic Clubfoot. Idiopathic clubfoot displaying forefoot adduction (toward midline of body) and supination (upturning) and hindfoot equinus (pointed downward). Note skin creases along arch and back of heel.

Positional Equinovarus.

Positional equinovarus is a deformity in which an infant's foot is in equinovarus position but does not have flexibility without deep creases at the posterior ankle or midfoot. The Achilles tendon is still flexible. The foot can be passively brought to a plantigrade position and is amenable to stretching and casting. In general, conservative therapy corrects this foot without the need for surgical intervention or lengthy bracing.

Idiopathic Congenital Equinovarus.

The etiology of idiopathic equinovarus (clubfoot) is unknown. In one human fetal study, all clubfeet were associated with identifiable anterior horn cell changes in L5 and S1. Muscle biopsies of both the anterior tibialis long flexors and the peroneus brevis muscles in clubfoot reveal that at least 50% of cases show a decreased number of

muscle fibers and/or abnormal fiber histology. The soleus often has an increase in type 1 fibers, whereas the peroneus brevis has a fiber type disproportion. The more abnormal the histopathology, the more severe the deformity, and the greater the chance of recurrent deformity after treatment. The genetic component is unclear and studies are ongoing.

Idiopathic equinovarus occurs in approximately 0.3 to 7.8 per 1000 newborns, with males being affected twice as often as females. Historically, these deformities were treated by posteromedial release, a surgical procedure that lengthened all tight structures and opened the capsule of all tight joints in the foot. However, since 1998 the casting technique developed by Ignacio Ponseti (see [Fig. 46.7, B](#)) has been used; the technique involves six to eight above-knee casts, left on for 5 to 7 days each, followed by a percutaneous tendo achilles lengthening procedure performed with local anesthesia. The child then uses special braces at night until 3 to 4 years of age. Noncompliance with braces leads to increased recurrence and need for additional casting or surgery. Nearly 30% of children may need an anterior tibialis transfer around age 3.¹⁰ Studies comparing operative posteromedial release with Ponseti techniques show better long-term results with the less invasive Ponseti method¹¹ ([Box 46.1](#)).

Box 46.1

Ponseti Casting

Ponseti casting implements toe-to-groin casts changed weekly for 6 weeks. Casting begins as early as possible after birth and culminates in a percutaneous tendo achilles lengthening in the clinic, followed by a final cast worn for 3 weeks. In recalcitrant cases, a full surgical posteromedial release (PMR) still may be required. The need for PMR in idiopathic clubfoot has decreased from 90% to less than 20% of infants when this casting technique is used. Long-term results, presumably because of less scarring and more long-term flexibility, are better with Ponseti casting than with the PMR method.

Teratologic Equinovarus.

The most common cause of **teratologic equinovarus** is either neuromuscular (such as spina bifida) or syndromic (such as arthrogryposis or osteochondrodysplasia [e.g., diastrophic dwarfism]). The teratologic clubfoot, unlike the idiopathic type, more often fails to be corrected with Ponseti casting and may require operative intervention. The surgery is often more extensive than that for an idiopathic clubfoot, and revision surgery is also more common (see [Box 46.1](#)).

Pes Planus (Flatfoot) Deformity.

Pes planus (flatfoot) commonly raises parental concern. Despite medical evidence to the contrary, it can be very difficult to convince families that a flexible flatfoot is often as functional as one with a “normal” arch. The majority of babies are born with flat (or “fat”) feet, with the arch becoming more apparent with age. The relatively benign natural history, however, should not overshadow the importance of accurate diagnosis. Significant ankle valgus, vertical talus, tarsal coalition, and skewfoot must be accurately differentiated from flexible pes planus.

Flexible flatfoot deformity appears to be familial, with occasional association of generalized ligamentous laxity. Careful evaluation of possible occult Achilles contracture is done by holding the hindfoot in varus position and dorsiflexing the ankle. Achilles contracture can signify a more severe flatfoot variant. The flexibility of the hindfoot is evaluated by having the child stand on his or her toes facing away from the examiner. In flexible pes planus, the hindfoot swings into a varus position as the planter fascia tightens in toe raise. In rigid pes planus, the hindfoot stays in valgus and the child has more difficulty going up onto tip-toe.

Surgical or orthotic treatment of *asymptomatic* flexible pes planus is unnecessary. Custom orthotics, Helfet heel cups, and corrective orthopedic shoes have no influence over the natural history (clinically or radiographically) of flat feet. Adult studies on army recruits have

shown that soldiers with flat feet perform just as well as their counterparts without “fallen” arches.

There is a small subset of children with painful, flexible flat feet. For these children careful attention to the possibility of Achilles contracture or tarsal coalition (congenital union of the hindfoot bones) must be made. This group of children is best treated with inexpensive shoe inserts and then expectantly watched. If pain continues into adolescence, requiring more aggressive treatment, calcaneal lengthening will correct the pes planus without decreasing hindfoot motion. In rigid flat feet, a computed tomographic (CT) scan often will reveal a coalition, a bony or cartilaginous connection between the bones—if painful, this can be resected. Heel cord contractures can be surgically lengthened if stretching alone is inadequate. All surgery carries risk; if a foot is flat but nonpainful, treatment is not required. The painless flatfoot should be viewed as a variation of normal feet.

Abnormal Density or Modeling of the Skeleton

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) (brittle bone disease) is a collagen-related bone dysplasia. Collagen is the main component of bone and blood vessels. The disorder was first described in 1840 as a syndrome in newborns that consisted of osteoporosis with fractures and skeletal deformities. The Silience classification is based on both models of inheritance and clinical findings (Table 46.2), and has been useful to describe the most common types of OI. Newer classifications also exist and are based on the mode of inheritance, identifying the defective gene, protein, or mechanism¹² (Table 46.3).

TABLE 46.2

SILIENCE CLASSIFICATION OF OSTEOGENESIS IMPERFECTA SYNDROMES

	MAIN			
TYPE	TRANSMISSION	BIOCHEMICAL DEFECT	ORTHOPEDIC	MISCELLANEOUS

IA	AD	Decreased production of type I collagen	Mild to moderate bone fragility, osteoporosis, normal stature	Blue sclera, hearing loss, easy bruising, dentinogenesis imperfecta absent
IB	AD		Short stature	More severe in IA with dentinogenesis imperfecta
II	AD, AR, and mosaic	Substitutions of glycyl residue in X1 or X2 chains in triple helix	Multiple intrauterine fractures, extreme bone fragility	Usually lethal in perinatal period, delayed ossification of skull, intrauterine growth restriction
IIA			Long bones broad, crumpled; ribs broad with continuous beading	
IIB			Long bones broad, crumpled; ribs discontinuous or beading	
IIC			Long bones thin, fractured; ribs thin, beaded	
IID			Severely osteoporotic with generally well-formed skeleton; normal-shaped vertebrae and pelvis	
III	AD and AR	Abnormal type I collagen	Progressive deforming phenotype, severe bone fragility with fractures	Hearing loss, short stature, blue sclerae becoming less blue with age, shortened life expectancy, dentinogenesis imperfecta, relative macrocephaly with triangular facies
IVA	AD	Shortened pro- α (I) chains	Mild to moderate bone fragility, osteoporosis, bowing of long bones, scoliosis	Light sclerae, normal hearing, normal dentition, dentinogenesis imperfecta absent

IVB	AD			Dentinogenesis imperfecta present
-----	----	--	--	-----------------------------------

AD, Autosomal dominant; AR, autosomal recessive.

TABLE 46.3

OSTEOGENESIS IMPERFECTA (OI) TYPES CAUSED BY DEFECTS IN GENES AND THE COLLAGEN-RELATED PROTEINS THAT THEY ENCODE

	OI TYPE	DEFECTIVE GENE	DEFECTIVE PROTEIN	DEFECTIVE MECHANISM	
Autosomal dominant	I	<i>COL1A1</i>	α 1(I) collagen	Collagen quantity Collagen structure	85%–90% of OI case types I–IV
	II	<i>COL1A1</i> or <i>COL1A2</i>	α 1(I)/ α 2(I) collagen		
	III	<i>COL1A1</i> or <i>COL1A2</i>	α 1(I)/ α 2(I) collagen		
	IV	<i>COL1A1</i> or <i>COL1A2</i>	α 1(I)/ α 2(I) collagen		
	V	<i>IFITM5</i>	BRIL	Matrix mineralization	10%–15% of OI cases
Autosomal recessive	VI	<i>SERPINF1</i>	PEDF	Collagen 3-hydroxylation	10%–15% of OI case types VI to unclassified
	VII	<i>CRTAP</i>	CRTAP		
	VIII	<i>LEPRE1</i>	P3H1		
	IX	<i>PPIB</i>	CyPB		
	X	<i>SERPINH1</i>	HSP47	Collagen chaperoning	
	XI	<i>FKBP10</i>	FKBP65	Telopeptide hydroxylation	
	XII	<i>BMP1</i>	BMP1/mTLD	Collagen processing	
	Unclassified	<i>SP7/OSX</i>	<i>SP7/OSTERIX</i>	Osteoblast development	
		<i>WNT1</i>	<i>WNT1</i>		
<i>TMEM38B</i>		TRIC-B			
<i>CREB3L1</i>		OASIS			

Data from Marini J et al: *Curr Opin Pediatr* 26(4):500–506, 2014.

In the most severe form of this disorder, the child is usually stillborn or dies soon after birth, although some survive into childhood. OI in its more severe forms is evident at birth because fractures and deformity have occurred in utero. The less severe forms may not become evident until the child begins to walk. Some children with this milder form then experience numerous fractures that can be mistaken for nonaccidental trauma until the diagnosis is made. The prevalence rate of the most common form is about 1 in 30,000. Inheritance is usually autosomal dominant but can be autosomal recessive. At least four syndromes have been identified that have various clinical manifestations and prognoses (see [Table 46.2](#)).

◆Pathophysiology.

The major errors in OI lie in the synthesis of collagen, a triple helix with two matching α chains and one β chain. Collagen is present in bone, cartilage, eye tissue, skin, and the vascular system. The severity of the OI phenotype and the related anomalies of the eye, dentition, or vascular system are all dependent on the severity of the genetic anomaly and the part of the triple helix that is affected.¹³ (Genes are discussed in [Chapter 4](#).)

A number of metabolic abnormalities are associated with OI. Some individuals have increased serum thyroxine levels, suggesting hyperthyroidism. This is consistent with the findings of increased sweating, heat intolerance, increased body temperature, a resting tachycardia, and tachypnea. Studies of leukocyte metabolism suggest an uncoupling of oxidative phosphorylation. Reports of alterations of platelet function with defects in adhesion and clot retraction also exist.

◆Clinical Manifestations.

The classic clinical manifestations of OI are osteoporosis and increased rate of fractures, possible bony deformation, triangular facies, possible vascular weakness (i.e., aortic aneurysm), possible blue sclerae, and poor dentition. The Sillence classification designated types I through IV on the basis of severity. The most severe, types II and III, are comparable to *osteogenesis imperfecta congenita*. These two types are

characterized by autosomal recessive inheritance and early onset of manifestations. Both can cause stillbirth or severe neonatal deformity and a short life expectancy. Less severe are types I and IV, which are comparable to *osteogenesis imperfecta tarda*. Type I is slightly more common than types II and III, and type IV is quite rare. Types I and IV are inherited as autosomal dominant traits and vary in age of onset from birth to adulthood. Type IV, especially when the sclerae are white, is the least deforming type and is often confused with nonaccidental trauma (child abuse).

◆Evaluation and Treatment.

Evaluation of OI is based primarily on clinical manifestations. Serum alkaline phosphatase level is elevated in all forms of the disease. OI can be diagnosed prenatally by ultrasound or chorionic villi sampling. Quantitative analysis of cultured skin fibroblast collagen by electrophoresis shows a decreased quantity of collagen in 95% of individuals.

Type II OI is often terminal in the perinatal period, and therefore little is known about appropriate treatment for the few children who survive. For other types of OI, careful positioning and handling of the newborn help prevent fractures. Beyond the neonatal period, various orthopedic measures are applied, such as prompt splinting of fractures and correction of deformities arising from the progressive bowing or bending of the skeleton by intramedullary rodding of the bones (Fig. 46.9). Newer, telescoping rods, which grow with the child, have been shown to reduce the reoperative rate by 30%.¹⁴ Scoliosis is present in up to 50% of Sillence III cases and often requires surgery. A multicenter study of a bisphosphonate therapy showed promising results in type III OI, with marked improvements of bone density (up to 30%). Chronic bone pain and fatigue also are thought to be lessened with routine bisphosphonate therapy. Despite these results, there is concern that the healing of fractures and surgical intervention can be more difficult. More study is needed to address the efficacy and safety of these types of drugs. Genetic counseling for affected families should aim at primary prevention.

FIGURE 46.9 Osteogenesis Imperfecta Treated with Osteotomies and Telescoping Medullary Rods. A, Severe deformity of both femurs. B, Same individual after multiple osteotomies with telescoping medullary rod fixation. C, Same individual 4 years later demonstrating growth of femurs, no recurrence of deformity, and elongation of rods. (Plaster casts are in place for immobilization of tibial osteotomies.)
