Pathophysiology

THE BIOLOGIC BASIS FOR DISEASE IN ADULTS AND CHILDREN

EIGHTH EDITION

KATHRYN L. McCANCE, MS, PhD

*Professor Emeritus
College of Nursing
University of Utah
Salt Lake City, Utah*

SUE E. HUETHER, MS, PhD

*Professor Emeritus
College of Nursing
University of Utah
Salt Lake City, Utah*
SECTION EDITORS

VALENTINA L. BRASHERS, MD, FACP, FNAP

*Professor of Nursing and Woodard Clinical Scholar
Attending Physician in Internal Medicine
University of Virginia Health System
Charlottesville, Virginia*

NEAL S. ROTE, PhD

*Academic Vice-Chair and Director of Research, Department of Obstetrics
and Gynecology
University Hospitals Case Medical Center
William H. Weir, MD Professor of Reproductive Biology and Pathology
Case Western Reserve University, School of Medicine
Cleveland, Ohio
with more than 1200 illustrations*

Introduction to Pathophysiology

References

Part One Central Concepts of Pathophysiology: Cells and Tissues

Unit I The Cell

Chapter 1 Cellular Biology

Prokaryotes and Eukaryotes

Cellular Functions

Structure and Function of Cellular Components

Cell-to-Cell Adhesions

Cellular Communication and Signal Transduction

Cellular Metabolism

Membrane Transport: Cellular Intake and Output

Cellular Reproduction: the Cell Cycle

Tissues

Summary Review

Key Terms

References

Chapter 2 Altered Cellular and Tissue Biology

Cellular Adaptation

Cellular Injury

Manifestations of Cellular Injury

Cellular Death

Aging and Altered Cellular and Tissue Biology

Somatic Death

Summary Review

Key Terms

References

Chapter 3 The Cellular Environment

Distribution of Body Fluids

Aging and Distribution of Body Fluids

Alterations in Water Movement

Sodium, Chloride, and Water Balance

Alterations in Sodium, Water, and Chloride Balance

Alterations in Potassium, Calcium, Phosphate, and Magnesium Balance

Acid-Base Balance

Summary Review

Key Terms

References

Unit II Genes, Gene-Environment Interaction, and Epigenetics

Chapter 4 Genes and Genetic Diseases

DNA, RNA, and Proteins: Heredity at the Molecular Level

Chromosomes

Elements of Formal Genetics

Transmission of Genetic Diseases

Linkage Analysis and Gene Identification

Summary Review

Key Terms

References

Chapter 5 Genes, Environment-Lifestyle, and Common Diseases

Factors Influencing Incidence of Disease in Populations

Principles of Multifactorial Inheritance

Nature and Nurture: Disentangling the Effects of Genes and Environment

Genetics of Common Diseases

Summary Review

Key Terms

References

Chapter 6 Epigenetics and Disease

Overview of Epigenetic Mechanisms

Epigenetics and Human Development

Genomic Imprinting

Epigenetics in Cognitive Development and Mental Health

Exploring the Possible Multigenerational Persistence of Epigenetic States That Arise in Response to Environmental Factors

Epigenetic Change Over the Life Span

Molecular and Computational Tools for Exploring Epigenetic States

Epigenetics and Cancer

Emerging Strategies for the Treatment of Epigenetic Disease

Future Directions

Summary Review

Key Terms

References

Unit III Mechanisms of Self-Defense

Chapter 7 Innate Immunity

Human Defense Mechanisms

First Line of Defense: Physical, Mechanical, and Biochemical Barriers and Normal Microbiome

Second Line of Defense: Inflammation

Local Manifestations of Inflammation

Systemic Manifestations of Acute Inflammation

Chronic Inflammation

Wound Healing

Pediatrics: Innate Immunity in the Newborn Child

Aging: Innate Immunity in the Older Adult Population

Summary Review

Key Terms

References

Chapter 8 Adaptive Immunity

General Characteristics of Adaptive Immunity

Recognition and Response

Generation of Clonal Diversity

Induction of an Immune Response: Clonal Selection

Effector Mechanisms

Fetal and Neonatal Immune Function

Aging and Immune Function

Summary Review

Key Terms

References

Chapter 9 Alterations in Immunity and Inflammation

Hypersensitivity: Allergy, Autoimmunity, and Alloimmunity

References:

Deficiencies in Immunity

Summary Review

Key Terms

References

Chapter 10 Infection

Emerging Infections

References

Microorganisms and Humans: a Dynamic Relationship

Microorganisms and Infections

References

References

References

References

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Countermeasures Against Pathogens

References

Summary Review

Key Terms

References

Chapter 11 Stress and Disease

Historical Background and General Concepts

Concepts of Stress, Homeostasis, and Allostasis

Stress Response

Stress, Illness, and Coping

Aging and Stress: Stress-Age Syndrome

Summary Review

Key Terms

References

Unit IV Cellular Proliferation: Cancer

Chapter 12 Cancer Biology

Cancer Characteristics and Terminology

The Biology of Cancer Cells

Clinical Manifestations of Cancer

Diagnosis and Staging of Cancer

Treatment of Cancer

Targeted Disruption of Cancer

Summary Review

Key Terms

References

Chapter 13 Cancer Epidemiology

Genetics, Epigenetics, and Tissue

Incidence and Mortality Trends

In Utero and Early Life Conditions

Environmental-Lifestyle Factors

Chemicals and Occupational Hazards as Carcinogens

Summary Review

Key Terms

References

Chapter 14 Cancer in Children

Incidence and Types of Cancer

Etiology

Prognosis

Summary Review

Key Terms

References

Part Two Pathophysiologic Alterations: Organs and Systems

Unit V Pathophysiologic Alterations: Organs and Systems

Chapter 15 Structure and Function of the Neurologic System

Overview and Organization of the Nervous System

Cells of the Nervous System

Nerve Impulse

Central Nervous System

Peripheral Nervous System

Autonomic Nervous System

Aging and the Nervous System

Tests of Nervous System Structure and Function

Summary Review

Key Terms

References

Chapter 16 Pain, Temperature Regulation, Sleep, and Sensory Function

Pain

Pediatrics and Perception of Pain

Aging and Perception of Pain

Temperature Regulation

Pediatrics and Temperature Regulation

Aging and Temperature Regulation

Sleep

Pediatrics and Sleep Patterns

Aging and Sleep Patterns

Somatosensory Function and the Special Senses

Aging and Vision

Aging and Hearing

Aging and Olfaction and Taste

Summary Review

Key Terms

References

Chapter 17 Alterations in Cognitive Systems, Cerebral Hemodynamics, and Motor Function

Alterations in Cognitive Systems

Alterations in Cerebral Hemodynamics

Alterations in Neuromotor Function

Summary Review

Key Terms

References

Chapter 18 Disorders of the Central and Peripheral Nervous Systems and the Neuromuscular Junction

Central Nervous System Disorders

Peripheral Nervous System and Neuromuscular Junction Disorders

Tumors of the Central Nervous System

Summary Review

Key Terms

References

Chapter 19 Neurobiology of Schizophrenia, Mood Disorders, Anxiety Disorders, and Obsessive-Compulsive Disorder

Schizophrenia

Mood Disorders: Depression and Bipolar Disorder

Anxiety Disorders

Obsessive-Compulsive Disorder

Summary Review

Key Terms

References

Chapter 20 Alterations of Neurologic Function in Children

Development of the Nervous System in Children

Structural Malformations

Alterations in Function: Encephalopathies

Cerebrovascular Disease in Children

Epilepsy and Seizure Disorders in Children

Childhood Tumors

Summary Review

Key Terms

References

Unit VI The Endocrine System

Chapter 21 Mechanisms of Hormonal Regulation

Mechanisms of Hormonal Regulation

Structure and Function of the Endocrine Glands

Aging and the Endocrine System

Summary Review

Key Terms

References

Chapter 22 Alterations of Hormonal Regulation

Mechanisms of Hormonal Alterations

Alterations of the Hypothalamic-Pituitary System

Alterations of Thyroid Function

Alterations of Parathyroid Function

Dysfunction of the Endocrine Pancreas: Diabetes Mellitus

Alterations of Adrenal Function

Summary Review

Key Terms

References

Chapter 23 Obesity and Disorders of Nutrition

Adipose Tissue

Obesity

Anorexia Nervosa, Bulimia Nervosa, and Binge Eating Disorder

Starvation

Anorexia of Aging

Summary Review

Key Terms

References

Unit VII The Reproductive Systems

Chapter 24 Structure and Function of the Reproductive Systems

Development of the Reproductive Systems

The Female Reproductive System

Structure and Function of the Breast

The Male Reproductive System
Tests of Reproductive Function
Aging and Reproductive Function
Summary Review
Key Terms
References

Chapter 25 Alterations of the Female Reproductive System

Abnormalities of Reproductive Tract Development
Alterations of Sexual Maturation
Disorders of the Female Reproductive System
Disorders of the Female Breast
Summary Review
Key Terms

Chapter 26 Alterations of the Male Reproductive System

Alterations of Sexual Maturation
Disorders of the Male Reproductive System
Disorders of the Male Breast
Summary Review
Key Terms
References

Chapter 27 Sexually Transmitted Infections

Sexually Transmitted Urogenital Infections

Sexually Transmitted Infections of Other Body Systems

Summary Review

Key Terms

References

Unit VIII The Hematologic System

Chapter 28 Structure and Function of the Hematologic System

Components of the Hematologic System

Development of Blood Cells

References

Mechanisms of Hemostasis

Clinical Evaluation of the Hematologic System

Pediatrics and the Hematologic System

Aging and the Hematologic System

Summary Review

Key Terms

References

Chapter 29 Alterations of Erythrocyte, Platelet, and Hemostatic Function

Anemia

Myeloproliferative Red Blood Cell Disorders

Alterations of Platelets and Coagulation

Summary Review

Key Terms

References

Chapter 30 Alterations of Leukocyte and Lymphoid Function

Alterations of Leukocyte Function

Alterations of Lymphoid Function

Alterations of Splenic Function

Summary Review

Key Terms

References

Chapter 31 Alterations of Hematologic Function in Children

Fetal and Neonatal Hematopoiesis

Postnatal Changes in the Blood

Disorders of Erythrocytes

Disorders of Coagulation and Platelets

Neoplastic Disorders

Summary Review

Key Terms

References

Unit XI The Renal and Urologic Systems

Chapter 38 Structure and Function of the Renal and Urologic Systems

Structures of the Renal System

Renal Blood Flow

Kidney Function

Tests of Renal Function

Aging and Renal Function

Summary Review

Key Terms

References

Chapter 39 Alterations of Renal and Urinary Tract Function

Urinary Tract Obstruction

Urinary Tract Infection

Glomerular Disorders

Acute Kidney Injury

Chronic Kidney Disease

Summary Review

Key Terms

References

Chapter 40 Alterations of Renal and Urinary Tract Function in Children

Structure and Function of the Urinary System in Children

Alterations in Renal and Bladder Function in Children

Summary Review

Key Terms

References

Unit XII The Digestive System

Chapter 41 Structure and Function of the Digestive System

The Gastrointestinal Tract

Accessory Organs of Digestion

Tests of Digestive Function

Aging and the Gastrointestinal System

Summary Review

Key Terms

References

Chapter 42 Alterations of Digestive Function

Disorders of the Gastrointestinal Tract

Disorders of the Accessory Organs of Digestion

Cancer of the Digestive System

Summary Review

Key Terms

References

Chapter 43 Alterations of Digestive Function in Children

Disorders of the Gastrointestinal Tract

Disorders of the Liver

Summary Review

Key Terms

References

Unit XIII The Musculoskeletal System

Chapter 44 Structure and Function of the Musculoskeletal System

Structure and Function of Bones

Structure and Function of Joints

Structure and Function of Skeletal Muscles

Tests of Musculoskeletal Function

Aging and the Musculoskeletal System

Summary Review

Key Terms

References

Chapter 45 Alterations of Musculoskeletal Function

Musculoskeletal Injuries

Disorders of Bones

Disorders of Joints

References

Disorders of Skeletal Muscle

Summary Review

Key Terms

References

Chapter 46 Alterations of Musculoskeletal Function in Children

Musculoskeletal Development in Children

Musculoskeletal Alterations in Children

Nonaccidental Trauma

Summary Review

Key Terms

References

Unit XIV The Integumentary System

Chapter 47 Structure, Function, and Disorders of the Integument

Structure and Function of the Skin

Aging and Skin Integrity

Disorders of the Skin

Disorders of the Hair

Disorders of the Nail

Summary Review

Key Terms

References

Chapter 48 Alterations of the Integument in Children

Acne Vulgaris

Dermatitis

Infections of the Skin

Insect Bites and Parasites

Cutaneous Hemangiomas and Vascular Malformations

Other Skin Disorders

Summary Review

Key Terms

About the Cover Image

The bean shaped image is bacteria, *Neisseria gonorrhoeae*, which causes gonorrhea. Gonorrhea is a very common sexually transmitted infection and is sometimes called the *clap* or the *drip*. It is especially prevalent for teens and young adults. Gonorrhea is spread through vaginal, anal, and oral sex. It can infect the vagina, penis, cervix, anus, urethra, throat, and rarely, eyes. If a mother has gonorrhea it can spread to a baby during birth. People often have no symptoms and do not know they are infected until they get tested. It can lead to serious health problems and even infertility if untreated. Gonorrhea can be cured with the right treatment. Treatment is by antibiotics, and all sexual partners need testing and treatment. Some strains of gonorrhea resist antibiotics and have become more challenging to treat.

Preface

Pathophysiology incorporates basic, translational, and clinical research to advance understandings of disease and dysfunction. The study of pathophysiology involves many biomedical sciences and a wide range of research activities. Multiple aspects of cellular physiology are progressing rapidly, generating vast amounts of data to understand. The information expansion involves a greater understanding of the behavior of individual cells, their neighboring microenvironment, and the molecules that not only make up those cells but also communicate with their surroundings. Importantly, the forward movement of biomedical sciences occurs within the context of social, economic, and political processes that determine how disease is defined, experienced, and treated.

Interdisciplinary research has led to significant advancements in genetics, epigenetics, cell signaling and communication, control of cell behavior, metabolism, and cell fate. Knowledge about normal cell structures, function, and signaling pathways is at the forefront of translational science and foundational to the understanding of pathophysiology. Cells are nimble and respond to changes in their environment. Advancements in tools to observe cells are providing new understanding of cellular processes, including how cells function and prioritize their activities, monitor their environment, move, differentiate, and regenerate. For disease, conditions of cells under stress—for example, when stem cells become corrupted—help to define restorative activities that are lost. An important emerging goal is to learn what biologic *switches* restore function and reprogram the cell for normal function. Advances in the molecular mechanisms of disease, particularly cell signaling, genetic directives, and immune and metabolic modulators are providing an understanding of

individual differences in disease risk, biologic markers, diagnostic strategies, and personally tailored treatment.

Although these advancements have created an ever-increasing state of excitement, they have also created the problem of how students, teachers, and clinicians can cope with the expanding new information. Translating and compressing these data into simplified discussions for students and clinicians is challenging. Our approach in this book has been to present an organized, logical sequence of content based on current literature and research reports with understandable explanations and accompanied by illustrations and summary tables. The primary focus is on pathophysiology, and there is less emphasis on the evaluation and treatment that is found in clinical management textbooks. As in previous editions, the following is a list of our specific goals for the textbook:

- Draw attention to differences in etiology, epidemiology, pathophysiology, clinical manifestations, and treatment according to sex and age.
- Pay careful attention to presentations of emerging new data on controversial topics.
- Integrate health promotion and disease prevention by updating risk factors, explaining certain relationships between nutrition and disease, and referencing screening recommendations and other therapeutic approaches.

Organization and Content: What's New in the Eighth Edition

The book is organized into two parts. Part One presents the cellular and tissue responses common to disease. Normal organ system structure and function and the pathophysiology of disease, organized by body systems, are presented in Part Two. All content has been reviewed and updated with extensive new references, revised figures, and one new chapter.

Part One: Central Concepts of Pathophysiology: Cells and Tissues

Part One begins with an in-depth study of the cell and progresses to cover the underlying processes of disease. Concepts covered include cell signaling and cell communication processes; genes and common genetic diseases; epigenetics and disease; fluid, electrolyte, and acid-base balance; inflammation, cytokines and their biologic functions, and normal and altered immunity; infection, stress, coping, and immunity; and tumor biology, epidemiology of cancer, and cancer in children. Particularly important revisions and updated additions to Part One include the following:

- Content on cellular organelles, the plasma membrane, cell signaling, and communication ([Chapter 1](#))
- Content on agents of cell injury, oxidative stress, apoptosis, autophagy, and aging ([Chapter 2](#))
- Chapter on epigenetics and disease ([Chapter 6](#))
- Content on normal innate and adaptive immunity ([Chapters 7 and 8](#))
- Content on alterations of immunity and inflammation ([Chapter 9](#))
- Content on infection ([Chapter 10](#))
- Reorganization of content on stress and disease

(Chapter 11)

- Extensive revisions and reorganization of tumor biology and invasion and metastases (Chapter 12)
- Extensive revisions and reorganization of epidemiology of cancer (Chapter 13)

Part Two: Pathophysiologic Alterations: Organs and Systems

Part Two is a systematic survey of diseases within body systems. Each unit focuses on a specific body system and begins with an anatomy and physiology chapter to provide a basis of comparison for understanding the alterations created by disease. A brief summary of normal aging is included at the end of the section on anatomy and physiology. The discussion of each disease in the alterations chapters is developed in a logical manner that begins with an introductory paragraph on etiology and epidemiology, followed by pathophysiology, clinical manifestations, and evaluation and treatment, which are set off with icons. Separate chapters are dedicated to pediatric pathophysiology, and sensitivity is paid to sex and age. Chapter 23 is a new chapter on Obesity and Disorders of Nutrition. Especially significant revisions and updated additions to Part Two include the following:

- Information on pain syndromes and sleep disorders (Chapter 16)
- Content on concepts of alterations in consciousness, memory, and delirium syndromes; new information related to Parkinson disease; amyotrophic lateral sclerosis; Huntington disease; and the dementias, including Alzheimer disease (Chapter 17)

- Molecular mechanisms of traumatic brain and spinal cord injury, stroke and headache syndromes, and multiple sclerosis ([Chapter 18](#))
- Updated content on schizophrenia, mood disorders, and anxiety ([Chapter 19](#))
- Cerebral palsy, seizure disorders, and pediatric brain tumors ([Chapter 20](#))
- Extensive updates on diabetes mellitus, insulin resistance, and thyroid and adrenal gland disorders ([Chapter 22](#))
- A new chapter on obesity and disorders of nutrition with summaries of the eating disorders and starvation ([Chapter 23](#))
- Extensively rewritten material on female reproductive disorders including cancers, benign breast diseases, and breast cancer ([Chapter 25](#))
- A separate chapter on male reproductive disorders and cancer with extensive updating and reorganization ([Chapter 26](#))
- Reorganization and extensive updating of sexually transmitted infections ([Chapter 27](#))
- Bone marrow, blood cell formation, and hemostasis ([Chapter 28](#))
- Revised content on alterations of leukocyte, lymphoid, and hemostatic function ([Chapter 29](#))
- Extensively rewritten chapter on the anatomy and physiology of the cardiovascular and

lymphatic systems ([Chapter 32](#))

- Extensively updated coverage of atherosclerosis, endothelial injury and dysfunction, coronary artery disease, myocardial infarction, and heart failure ([Chapter 33](#))

- Immune mechanisms of asthma; chronic lung disease; and updates for respiratory tract infection, pulmonary hypertension, pulmonary embolism, and lung cancers ([Chapters 36](#))

- Major updates for childhood asthma, respiratory distress syndrome, cystic fibrosis, lung infections, and sudden infant death syndrome ([Chapter 37](#))

- Kidney stones, urinary tract infection, glomerulopathies, acute and chronic renal failure, and bladder and kidney tumors ([Chapter 39](#))

- Urinary tract infection and renal failure in children ([Chapter 40](#))

- Gastroesophageal reflux disease, peptic ulcer disease, irritable bowel syndrome, inflammatory bowel disease, colon cancer, and hepatitis ([Chapter 42](#))

- New information on gluten-sensitive enteropathy, necrotizing enterocolitis, infections of the intestine, and liver disease in children ([Chapter 43](#))

- Updated content on alterations of the musculoskeletal system ([Chapter 44](#))

- Pressure ulcers, dermatitis and psoriasis, scleroderma, and melanoma ([Chapter 47](#))
- Childhood atopic dermatitis, skin infections, and immune drug reactions ([Chapter 48](#))
- Extensive updating and reorganization of content on septic shock, multiple organ dysfunction syndrome, and burns for adults and children ([Chapters 49](#) and [50](#))

Features to Promote Learning

Ease of learning has been enhanced by designing a number of features that guide and support understanding, including:

- *Chapter Outlines* for each chapter
- *Consistent Headings with Icons* to underscore the consistent treatment of each disease—
Pathophysiology, Clinical Manifestations, and Evaluation and Treatment
- More than 70 *What's New?* boxes that review the most current research and clinical developments; a list of these is included on the inside front cover
- *Nutrition & Disease* boxes to emphasize nutrition as a health promotion strategy that may alter disease risk or pathogenesis
- End-of-chapter *Summary Review* sections that summarize the content in each chapter and serve as built-in content review guides

- Boldface *Key Terms* with end-of-chapter term lists and page numbers for rapid access
- A comprehensive *Glossary* with approximately 1000 terms to help students with the often-difficult terminology related to pathophysiology

Art Program

The art program is extensive and has received as much attention and revision as the narrative. Nearly 100 new or revised full-color illustrations were created and strategically placed throughout the textbook. Also included are many new high-quality, full-color photographs of clinical manifestations, pathologic specimens, and clinical imaging techniques. The combination of illustrations, algorithms, and photographs and the use of color for tables and boxes allow clarification for complex concepts and the emergence of easily recognized essential information.

Ancillaries

For Students

On **Evolve**, at <http://evolve.elsevier.com/McCance/>, students can access Evolve-only figures, tables, and boxes, 570 review questions, 100 animations to help students master the text content, 26 case studies with questions and answers, and downloadable chapter summaries documents for each chapter.

The **Study Guide** includes a variety of question styles, aiming to help the diverse way students learn. Question types include the following:

- Choose the Correct Words
- Complete These Sentences

- Categorize These Clinical Examples
- Explain the Pictures
- Teach These People about Pathophysiology
- Plus many more...

Answers are found in the back of the Study Guide for easy reference for students.

For Instructors

The **Evolve Instructor Resources** for this textbook provide the following teaching aids:

- Image Collection with all of the approximately 1200 figures from the text
- PowerPoint lecture slides for each chapter (approximately 3300 slides and 440 images total), including integrated Audience Response Questions in each chapter (218 total), and integrated case studies at the end of each unit (15 total)
- Teach for Nurses Instructor's Manual, broken down by chapter, detailing the resources available to instructors for their lesson planning, and including unique case studies and class activities they can share with students
- Test Bank in ExamView with 1560 questions (in multiple choice and multiple response formats) with answers, rationales, and textbook page

references

Evolve is an Internet-based learning environment that works in coordination with the text. This resource enables you to publish your class syllabus, outline, and lecture notes; set up “virtual office hours” and e-mail communication; share important dates and information through the online class calendar; and encourage student participation through chat rooms and discussion boards. Free with qualified adoption. Contact your sales representative or visit <http://evolve.elsevier.com> for more information about integrating **Evolve** into your curriculum.

Acknowledgments

The enormous task of keeping this book current and readable greatly depends on our contributors; new writers have joined our team for this edition. We thank them for their knowledge and tremendous labor of reviewing relevant literature, synthesizing it, and writing and revising chapters to make them highly readable for others. Our section editors are Neal Rote and Tina Brashers, and we thank them for their tireless editing, writing, and development of new art. Neal managed the immunity, infection, and cancer biology chapters. Tina managed the endocrine, pulmonary, and cardiovascular alterations chapters. Both Neal and Tina are exceptional teachers and have a special ability to integrate, simplify, and illustrate the complex content of pathophysiology. Always motivated to *really* help students and clinicians, we are grateful to you both. In addition, Tina Brashers, Linda Turchin, and Amber Ballard developed modules for the Online Review Course. There were also many faculty and clinicians who provided critiques of content revision, and we appreciate their insight and recommendations.

We extend gratitude to those who contributed to the book supplements. Linda Felver has thoroughly updated the resourceful Study Guide. Thank you Linda for very astute edits. For the Evolve website, Joanna Cain updated the review questions and PowerPoints. Meg Blair updated and revised the Test Bank. Melanie Cole revised the Teach for Nurses Instructor's Manual. Also thank you to Joanna Cain who aided in the update of the glossary. Thank you all for your help.

Sue Meeks is the leader of our manuscript management team. Her “behind the scenes” work is extensive and complex and completed

with tireless effort, insight, and humor. Every edition is monumental work—and she retypes and recounts endlessly—and unruffled. She coordinates transfer of the manuscript between editors, contributors, and reviewers. For more than 32 years she has provided unwavering dedication to excellence and detail, keeping us sane and on track. As always, you have our deepest appreciation for your continuing skill and patience.

Our production team and editorial staff at Elsevier deserve special recognition. Karen Turner and Jennifer Wade are our Content Development Specialists. This job is key. Karen monitored and suggested edits with an eagle eye and was especially helpful with illustrations. Her questions were thoughtful and critically timed. Jennifer Wade helped keep things moving along so we didn't lose sight of our goals. Beth Welch and Kristin Landon, our copyeditors, were thorough, consistent, and vital for getting the manuscript ready for publication. Thank you all for the top-notch quality of work. Executive Content Strategist Kellie White helped with the overall planning and production of the book and all the business needed for contributors, designers, artists, and other editors. This is a big job, and Kellie made sure that we had all resources necessary to complete this book. Thank you, Kellie.

The production manager for a book of this size and complexity of content has an enormous responsibility. The Senior Project Manager was Mary Pohlman. From copy edit to final page proofs with unremitting attention, Mary was masterful. Her persistent diligence was noteworthy and kept us on schedule. Thank you, Mary. The design of the interior portion of the book was in the capable hands of Ashely Miner and we are especially pleased with the layout, dynamic colors, and presentation of pedagogy. She also coordinated the work that went into creating the striking cover design. Thank you, Ashley.

The newly drawn and revised artwork for this edition was completed by Graphic World. The art is key and challenging, and our initial drawings are often pathetic. Graphic World assisted with the conceptual arrangements, labels, and beautiful colors.

We also thank the Department of Dermatology at the University of Utah School of Medicine, which provided numerous photos of skin lesions. Thanks to Dr. John Hoffman for the PET scan images of non-small cell lung cancer.

We are grateful to the many colleagues and friends at the University of Utah Health Sciences Center for their assistance with references and consultation on content. Special thanks are given to students, particularly nursing and other health science students, for the e-mails and phone calls we receive. Your questions are vital to guide us in our efforts to prepare a clear and up-to-date manuscript with much visual impact.

Sincerely and with great affection we thank our families, especially John, Mae, and Dorothy. Although disentangling certain data is inconvenient at times, we thank those committed to increasing patient-centered quality care, safety, and satisfaction.

Kathryn L. McCance

Sue E. Huether

Introduction to Pathophysiology

The word root “patho” is derived from the Greek word *pathos*, which means suffering. The Greek word root “logos” means discourse or, more commonly, system of formal study, and “physio” pertains to functions of organisms. Generally, pathophysiology is the systematic study of the functional changes in cells, tissues, and organs altered by disease and/or injury. Important, however, is the inextricable component of suffering.

Knowledge of cellular biology as well as anatomy and physiology and the various organ systems of the body is an essential foundation for the study of pathophysiology. To understand pathophysiology the student must also use principles, concepts, and basic knowledge from other fields of study, including biology, genetics, immunology, pathology, and epidemiology. A number of terms are used to focus the discussion of pathophysiology; they may be used interchangeably at times, but that does not necessarily indicate that they have the same meaning. These terms are reviewed in [Table I-1](#).

TABLE I-1

TERMS AND DEFINITIONS RELATED TO PATHOPHYSIOLOGY

Pathology	Study of structural alterations in cells, tissues, and organs that help to identify the cause of disease
Pathogenesis	Pattern of tissue changes associated with the development of disease
Etiology	Study of the cause(s) of disease and/or injury
Idiopathic	Diseases with no identifiable cause
Iatrogenic	Diseases and/or injury as a result of medical intervention
Clinical manifestations	Signs and symptoms

Nosocomial	Diseases acquired as a consequence of being in a hospital environment
Diagnosis	Naming or identification of a disease
Prognosis	Expected outcome of a disease
Acute disease	Sudden appearance of signs and symptoms lasting a short time
Chronic disease	Develops more slowly, lasting a long time or a lifetime
Remissions	Periods when clinical manifestations disappear or diminish significantly
Exacerbations	Periods when clinical manifestations become worse or more severe
Sequelae	Any abnormal conditions that follow and are the result of a disease, treatment, or injury

Pathophysiology is one of the most important bridging sciences between preclinical and clinical courses for students in the health sciences, and it requires in-depth study at an early stage in the curriculum. The definitions or conceptual models of pathophysiology that we carry in our minds influence what we do with our observations and the rationale that we provide for our actions. Therefore, the clinician must understand that although pathophysiology is a science, it also designates suffering in people; the clinician should never lose sight of this aspect of its definition.

As students study clinically-related sciences, they learn to recognize and categorize disease. From the formulation of a differential diagnosis one understands the different *clinical manifestations*, the signs, and the symptoms of certain pathologies. These understandings structure further investigations, treatment plans, and evaluation. The interaction of these activities determines clinical outcomes and treatment success. Still, the concept of disease can be inherently ambiguous and elusive; many pathologies remain hidden and resist easy classification. One should appreciate that the naming and diagnosing of diseases involve evaluative judgments as well as scientific fact, and that the process is as much a social endeavor as it is a scientific one. Some diseases, such as tuberculosis, identify a highly specific causative or etiologic agent or process. Others, such as Alzheimer disease or arthritis, indicate pathologic changes of unclear cause. There is considerable need for more research to validate mental health diagnoses. In addition, syndromes and functional disorders simply describe multiple symptoms and signs that frequently occur

together. Does commonality exist in all of these labels? The answer is “yes” and “no” and depends on our conception of health and disease. In the strictest sense, objective scientific facts help us know if an individual is healthy or suffering from disease and disability. A critical question remains: “Are we living longer, healthy lives as well as longer lives?” The fraction of the United States population aged 65 and over has increased. Older Americans are living longer, and the proportion of life spent with disability is changing. A recent finding for people 65 years and older was that the proportion of life spent with disability decreased, but this finding was not shared among the younger, aging population. In the young, researchers speculate that the increase in disability with aging may have resulted from change in emphasis on mental health, the rise in autism and attention deficit hyperactivity disorder, and the changing patterns of drug use overtime.¹ More studies related to these questions need to be done.

An individual's conception of disease is based on personal beliefs and histories, professional and lay healers who interact with that individual, and society at large. Each idea or construct has the power to influence other ideas and constructs, and each relationship has the ability to shape the way disease is understood and experienced.² Although a discerning mind is key, education for collaboration and tolerance of uncertainty or ambiguity is necessary for the changing science and understanding of disease.

Pathophysiology has had great success in explaining the mechanisms and clinical manifestations associated with infectious diseases. Syndromes of unclear etiology, such as chronic fatigue syndrome or fibromyalgia, have proven to be troublesome. Even more difficult are multifactorial conditions, such as atherosclerosis or type 2 diabetes mellitus, where several interacting factors contribute to the etiology. Learning how interacting factors relate to one another to increase morbidity or actually cause disease contributes to an appreciation of how emerging concepts revolutionize current understandings. One revolution in thought that has driven intensive research is that low levels of chronic inflammation cause or contribute to many diseases.

The language that clinicians use to discuss diseases and their manifestations is powerful. Lives are altered by a few words uttered by a clinician in a white coat or uniform. “AIDS,” “cancer,” and “heart attack” have become culturally ingrained symbols that portend an individual's future. Although some futures are determined by scientific evidence, others are determined by subjective experience.³ For example, a person diagnosed with a familial disease may ask, “Will I suffer like my mother did?” This questioning influences individuals' suffering.

In conclusion, pathophysiology—the understanding of disease—requires descriptive evidence as well as an evaluative component regarding suffering and the language we use to describe it. Combining objective and subjective perspectives requires new conceptual models that take into account the complex interactions among the body, mind, environment, and spirit.

All body functions depend on the integrity of cells. Therefore, an understanding of cellular biology is intrinsically necessary for an understanding of disease. An overwhelming amount of information is revealing how cells behave as a multicellular “social” organism. At the heart of cellular biology is cellular communication (“cellular crosstalk”)—how messages originate and are transmitted, received, interpreted, and used by the cell. This streamlined conversation between, among, and within cells maintains cellular function and specialization. Intercellular signals allow each cell to determine its position and specialized role. Cells must demonstrate a “chemical fondness” for other cells and their surrounding environment to maintain the integrity of the entire organism. When they no longer tolerate this fondness, the conversation breaks down and cells either adapt (sometimes altering function) or become vulnerable to isolation, injury, disease, or even death.

Prokaryotes and Eukaryotes

Living cells generally are divided into two major classes—eukaryotes and prokaryotes. The cells of higher animals and plants are eukaryotes, as are the single-celled organisms fungi, protozoa, and most algae. Prokaryotes include cyanobacteria (blue-green algae), bacteria, and rickettsiae. Prokaryotes traditionally were studied as core subjects of molecular biology. Current emphasis is on the eukaryotic cell; much of its structure and function has no counterpart in bacterial cells.

Eukaryotes (*eu* = good; *karyon* = nucleus; also spelled “eucaryotes”) are larger and have more extensive intracellular anatomy and organization than do prokaryotes. Eukaryotic cells have a characteristic set of membrane-bound intracellular compartments, called *organelles*, that includes a well-defined nucleus. **Prokaryotes** contain no organelles, and their nuclear material is not encased by a nuclear membrane. Prokaryotic cells are characterized by lack of a distinct nucleus.

Besides having structural differences, prokaryotic and eukaryotic cells differ in chemical composition and biochemical activity. The *nuclei* of prokaryotic cells carry genetic information in a single circular chromosome, and they lack a class of proteins called *histones*, which in eukaryotic cells bind with deoxyribonucleic acid (DNA) and are involved in the supercoiling of DNA (see [Fig. 1.2](#)). We now understand that the loops and coiling of DNA are important for many diseases. Eukaryotic cells have several chromosomes. Protein production, or synthesis, in the two classes of cells also differs because of major structural differences in ribonucleic acid (RNA)–protein complexes. Other distinctions include differences in mechanisms of transport across the outer cellular membrane and differences in enzyme content.

Cellular Functions

Cells become specialized through the process of **differentiation**, or

maturation, so that some cells eventually perform one kind of function and other cells perform other functions. Cells with a highly developed function, such as movement, often lack some other property, such as hormone production, which is more highly developed in some other type of specialized cell.

The eight chief cellular functions follow:

- *Movement.* Muscle cells can generate forces that produce motion. Muscles that are attached to bones produce limb movements, whereas those that enclose hollow tubes or cavities move or empty contents when they contract. For example, the contraction of smooth muscle cells surrounding blood vessels changes the diameter of the vessels; the contraction of muscles in walls of the urinary bladder expels urine.
- *Conductivity.* Conduction as a response to a stimulus is manifested by a wave of excitation, an electrical potential that passes along the surface of the cell to reach its other parts. Conductivity is the chief function of nerve cells.
- *Metabolic absorption.* All cells take in and use nutrients and other substances from their surroundings. Cells of the intestine and the kidney are specialized to carry out absorption. Cells of the kidney tubules reabsorb fluids and synthesize proteins. Intestinal epithelial cells reabsorb fluids and synthesize protein enzymes.
- *Secretion.* Certain cells, such as mucous gland

cells, can synthesize new substances from substances they absorb and then secrete the new substances to serve as needed elsewhere. Cells of the adrenal gland, testis, and ovary can secrete hormonal steroids.

- *Excretion.* All cells can rid themselves of waste products resulting from the metabolic breakdown of nutrients. Membrane-bound sacs (lysosomes) within cells contain enzymes that break down, or digest, large molecules, turning them into waste products that are released from the cell.

- *Respiration.* Cells absorb oxygen, which is used to transform nutrients into energy in the form of adenosine triphosphate (ATP). Cellular respiration, or oxidation, occurs in organelles called *mitochondria*.

- *Reproduction.* Tissue growth occurs as cells enlarge and reproduce themselves. Even without growth, tissue maintenance requires that new cells be produced to replace cells that are lost normally through cellular death. Not all cells are capable of continuous division.

- *Communication.* Communication is vital for cells to survive as a society of cells. Pancreatic cells, for instance, secrete and release insulin necessary to signal muscle cells to absorb sugar from the blood for energy. Constant communication allows the

maintenance of a dynamic steady state.

Structure and Function of Cellular Components

Fig. 1.1 shows a “typical” eukaryotic cell. It consists of three components: an outer membrane called the *plasma membrane*, or *plasmalemma*; a fluid filling called **cytoplasm**; and the intracellular “organs,” or *organelles*, which are membrane bound and include the nucleus. Researchers are astounded by the advances in microscopy and computer software that allow resolution to the nanoscale—cells seem to come “alive” with the molecular world more visible. Understanding structure and function will reveal, for example, how the cell responds to mechanical forces or emerges from different gene expression patterns. The overall impact on biology is huge.¹

FIGURE 1.1 Typical or Composite Cell. **A**, Artist's interpretation of cell structure. **B**, Color-enhanced electron micrograph of a cell. Both show the many mitochondria known as the "power plants of the cell." Note, too, the innumerable dots bordering the endoplasmic reticulum. These are ribosomes, the cell's "protein factories." (B courtesy A. Arlan Hinchee. From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

Nucleus

The **nucleus**, which is surrounded by the cytoplasm and generally is located in the center of the cell, is the largest membrane-bound

organelle. Two pliable membranes comprise the **nuclear envelope** (Fig. 1.2, A). The nuclear envelope is pockmarked with pits, called **nuclear pores**, in which **nuclear pore complexes (NPCs)** are positioned that allow molecules to move between the nucleus and the cytosol (see Fig. 1.2, A, B, and D). The outer membrane is continuous with membranes of the endoplasmic reticulum (see Fig. 1.1). The inner membrane encloses the nucleus. The nucleus contains the **nucleolus**, a small, dense structure composed largely of RNA; most of the cellular DNA; and the DNA-binding proteins, the histones, that regulate its activity. The DNA chain in eukaryotic cells is so extensive that the risk of breakage is high. Therefore, the histones binding to DNA cause DNA to fold into chromosomes (Fig. 1.2, C). The wrapping of DNA into tight packages of chromosomes is essential for cell division in eukaryotes.

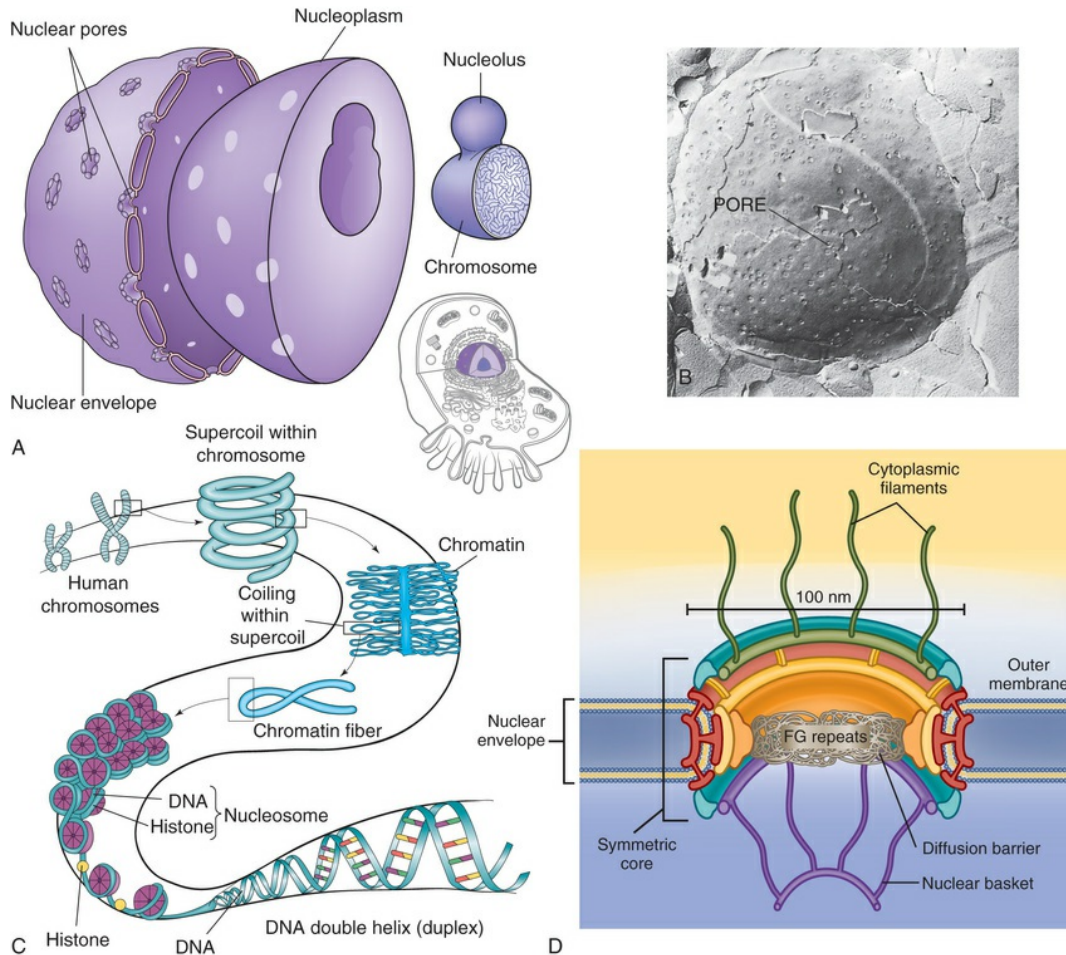

FIGURE 1.2 The Nucleus. The nucleus is composed of a double membrane, called a nuclear envelope, that encloses the fluid-filled interior, called nucleoplasm. The chromosomes are suspended in the nucleoplasm (illustrated here much larger than actual size to show the tightly packed DNA strands). Swelling at one or more points of the chromosome, shown in A, occurs at a nucleolus where genes are being copied into RNA. The nuclear envelope is studded with pores. B, The pores are visible as dimples in this freeze etch of a nuclear envelope. C, Histone-folding DNA in chromosomes. D, Nuclear pore complex. (B from Raven PH, Johnson GB: *Biology*, St Louis, 1992, Mosby. D adapted from *The scientist: infographic: the nuclear pore complex*. Available at <http://www.the-scientist.com/?articles.view/articleNo/47560/title/Infographic-The-Nuclear-Pore-Complex/>.)

The primary functions of the nucleus are cell division and control of genetic information. Other functions include the replication and repair of DNA and the transcription of the information stored in DNA. Genetic information is transcribed into RNA, which can be processed into messenger, transport, and ribosomal RNA and introduced into the cytoplasm, where it directs cellular activities. Most of the processing of RNA occurs in the nucleolus.

Cytoplasmic Organelles

Cytoplasm is an aqueous solution (**cytosol**) that fills the **cytoplasmic matrix**—the space between the nuclear envelope and the plasma membrane. The cytosol represents about half the volume of a eukaryotic cell. It contains thousands of enzymes involved in intermediate metabolism and is crowded with ribosomes that make proteins. The cytosol is the main site for protein synthesis and degradation. Newly synthesized proteins remain in the cytosol if they lack a sorting signal for transport to a cell organelle.² The organelles suspended in the cytoplasm are enclosed in biologic membranes, which enables them to simultaneously carry out functions that require different biochemical environments. These functions, many of which are directed by coded messages carried from the nucleus by RNA, include synthesis of proteins and hormones and their transport out of the cell, isolation and elimination of waste products from the cell, metabolic processes, breakdown and disposal of cellular debris and foreign proteins (antigens), and maintenance of cellular structure and motility. Also, the cytosol functions as a storage unit for fat, carbohydrate, and secretory vesicles.

Ribosomes

Ribosomes are RNA-protein complexes (nucleoproteins) that are synthesized in the nucleolus and secreted into the cytoplasm through pores in the nuclear envelope called nuclear pore complexes (NPCs). These tiny ribosomes may float free in the cytoplasm or attach themselves to the outer membranes of the endoplasmic reticulum (see [Fig. 1.1, A](#)). Their chief function is to provide sites for cellular protein synthesis. Newly formed ribosomes synthesize a “recognition sequence,” or signal, like an address on a letter. Signal recognition particles (SRPs) in the cytosol bind to the ribosome after recognizing the SRP. *Ribophorins*, receiver proteins found on the rough sections of the endoplasmic reticulum (ER), act as the “address” site or binding site. The developing protein threads its way through the ER membrane into the lumen. The SRP is removed and the new protein

chain is folded into its final conformation.

Endoplasmic Reticulum

The **endoplasmic reticulum (ER)** (*endo* = within; *plasma* = cytoplasm; *reticulum* = network) is a membrane factory that specializes in the synthesis and transport of the protein and lipid components of most of the cell's organelles. It consists of a network of tubular or saclike channels (cisternae) that extend throughout the cytoplasm and are continuous with the outer nuclear membrane (Fig. 1.3). The folded membranes that comprise the cisternae of the endoplasmic reticulum may be *rough* (granular) or *smooth* (agranular). The **rough endoplasmic reticulum (rER)** is rough because ribosomes and ribonucleoprotein particles are attached to it (see Fig. 1.3). Some of the proteins synthesized by these ribosomes remain in the ER, and others are used to construct membranes of other organelles (the Golgi complex, lysosomes, peroxisomes, and the nucleus) and of the cell itself. Importantly, the ER is responsible for much of a cell's protein synthesis and folding, and a new role for the ER is sensing cellular stress (see [What's New? Endoplasmic Reticulum, Protein Folding, and ER Stress](#)). Understanding mechanisms of cellular stress will aid diagnosis and treatment of disease.

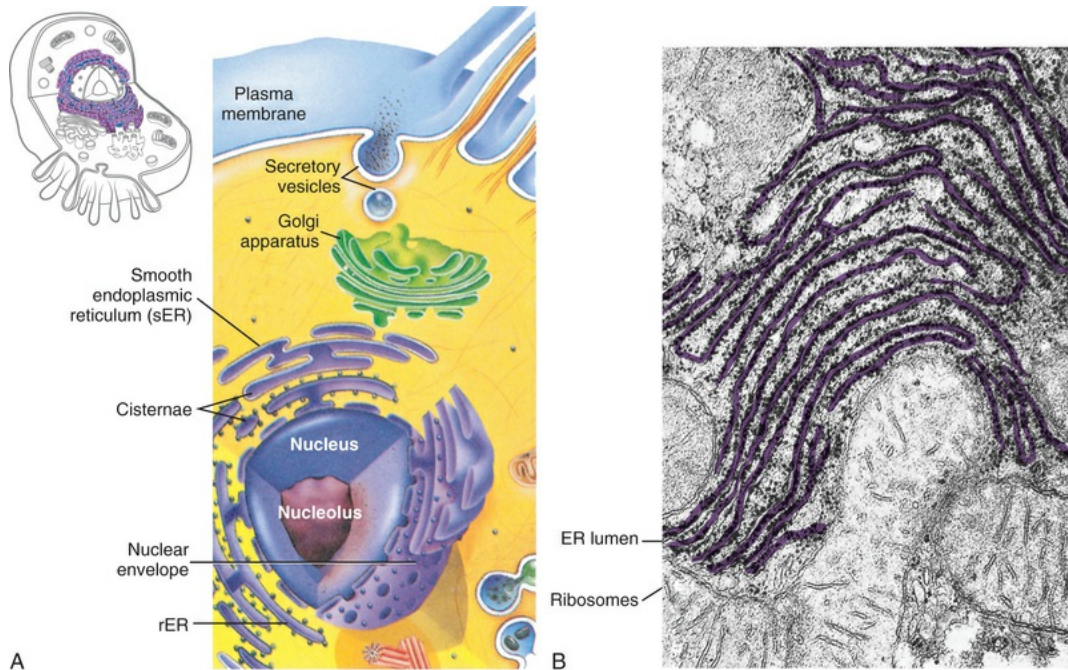

FIGURE 1.3 Endoplasmic Reticulum (ER). A, The ER consists of rough endoplasmic reticulum (*rER*) arranged into ribosome-coated cisternae and vesicles of smooth endoplasmic reticulum (*sER*). What's New?

Endoplasmic Reticulum, Protein Folding, and ER Stress

Protein folding in the endoplasmic reticulum (ER) is critical for us. As the biologic workhorses, proteins perform vital functions in every cell. To do these tasks, proteins must fold into complex three-dimensional structures (see figure). Most secreted proteins *fold* and are modified in an error-free manner, but ER or cell stress, mutations, or random (stochastic) errors during protein synthesis can decrease the folding amount or the rate of folding. Pathophysiologic processes, such as viral infections, environmental toxins, and mutant protein expression, can perturb the sensitive ER environment. Natural processes also can perturb the environment,

such as the large protein-synthesizing load placed on the ER. These perturbations cause the accumulation of immature and abnormal proteins in cells, leading to **ER stress**. Fortunately, the ER is loaded with protective ways to help folding, for example, protein so-called *chaperones* that facilitate folding and prevent the formation of off-pathway types. Because specialized cells produce large amounts of secreted proteins, the movement or flux through the ER is tremendous. Therefore, misfolded proteins not repaired in the ER are observed in some diseases and can initiate apoptosis or cell death. It has recently been shown that the endoplasmic reticulum mediates intracellular signaling pathways in response to the accumulation of unfolded or misfolded proteins; collectively, the adaptive pathways are known as the **unfolded-protein response (UPR)**. Investigators are studying UPR-associated inflammation and how the UPR is coupled to inflammation in health and disease. Specific diseases include Alzheimer disease, Parkinson disease, prion disease, amyotrophic lateral sclerosis, diabetes mellitus, and sepsis. Additionally being studied is ER stress and how it may accelerate age-related dysfunction. Overall, the ER is a major organelle for protein quality control.

Protein Folding

Each protein exists as an unfolded polypeptide (*left*) or a random coil after the process of translation from a sequence of mRNA to a

linear string of amino acids. From amino acids interacting with each other they produce a three-dimensional structure called the folded protein (*right*) that is its native state.

Data from Alberts B et al: *Molecular biology of the cell*, ed 6, New York, 2015, Garland Science; Brodsky J, Skach WR: *Curr Opin Cell Biol* 23:464–475, 2011; Jäger R et al: *Biol Cell* 104(5):259–270, 2012; Khan MM, Yang VVL, Wang P: *Shock* 44(4):294–304, 2015; Shah SZ et al: *J Mol Neurosci* 57(4):529–537, 2015.

Smooth endoplasmic reticulum (sER) does not contain ribosomes or ribonucleoprotein particles (see [Fig. 1.1](#)). Rather, membranous surfaces of the smooth endoplasmic reticulum contain enzymes involved in the synthesis of steroid hormones and are responsible for a variety of reactions required to remove toxic substances from the cell. The endoplasmic reticulum communicates with the Golgi complex and interacts with other organelles, particularly lysosomes and peroxisomes.

Golgi Complex

The **Golgi complex** (or **Golgi apparatus**) is a network of flattened, smooth membranes and vesicles frequently located near the nucleus of the cell ([Fig. 1.4](#)). Proteins from the endoplasmic reticulum are processed and packaged into small membrane-bound sacs or vesicles called **secretory vesicles**, which collect at the end of the membranous folds of the Golgi bodies—called **cisternae** (like a stack of pita breads). The secretory vesicles then break off from the Golgi complex and migrate to a variety of intracellular and extracellular destinations, including the plasma membrane. The vesicles fuse with the plasma membrane, and their contents are released from the cell. The best-known vesicles are those that have coats made largely of the protein **clathrin** and are called *clathrin-coated vesicles*. They bud from the Golgi complex on the outward secretory pathway and from the plasma membrane on the inward endocytic pathway. Newly synthesized ER proteins are carried from the Golgi network to *endosomes* by clathrin-coated transport vesicles before progressing to lysosomes. Many

molecules, including lipids, proteins, glycoproteins, and enzymes of lysosomes, pass through the Golgi complex at some stage in their maturation. The Golgi complex is a refining plant and directs traffic (e.g., protein, polynucleotide, polysaccharide molecules) in the cell² (Fig. 1.5).

FIGURE 1.4 Golgi Complex. A, Schematic representation of the Golgi complex showing a stack of flattened sacs, or cisternae, and numerous small membranous bubbles, or secretory vesicles. B, Transmission

electron micrograph showing the Golgi complex highlighted with color. (B Courtesy Charles Flickinger, University of Virginia.)

FIGURE 1.5 How the Internal Membrane System of a Cell Packages a Protein for Export. The instructions for making a protein that is destined for export from a cell, such as a digestive enzyme made by a pancreas cell, are first transcribed from DNA by RNA in the nucleus. The RNA then leaves the

nucleus through a nuclear pore and proceeds to a ribosome located on the rough endoplasmic reticulum (rER). There, it provides instructions for the correct sequence of amino acids for synthesizing that particular digestive enzyme. When enzyme synthesis is complete, the enzyme travels through the ER and is then encapsulated in a transport vesicle. The transport vesicle fuses with a Golgi body, releasing the enzyme. In the Golgi complex the enzyme is further modified and is then shunted to the flattened stacks, or cisternae. There, the enzyme waits for a secretory vesicle, which will carry it to the perimeter of the cell, the cell membrane. The secretory vesicle membrane then fuses with the cell membrane, and the enzyme is released outside the cell. (From Raven PH, Johnson GB: *Understanding biology*, ed 3, Dubuque, IA, 1995, Brown.)

Lysosomes

Lysosomes (*lyso* = dissolution; *soma* = body) are membrane-enclosed organelles (saclike) filled with enzymes that digest macromolecules and defunct intracellular organelles and particles engulfed from outside the cell by endocytosis (see Fig. 1.1, A). They contain more than 60 digestive enzymes called **hydrolases**, which catalyze bonds in proteins, lipids, nucleic acids, and carbohydrates. Hydrolases function optimally at an acidic pH. Lysosomes function as the intracellular digestive system (Fig. 1.6, A). Lysosomal enzymes are capable of digesting most cellular constituents completely to their basic components, such as amino acids, nucleotides, and carbohydrates. Transport proteins in the lysosome membrane carry these final components to the cytosol where the cell can reuse or excrete them. Recent data have radically shifted the view that lysosomes are not just trash cans and recycling agents but have established a *central role* of the lysosome in nutrient-dependent signal transduction for cellular adaptation.³ The newly discovered signaling function cooperates with the known degradative role of the lysosome to mediate basic cellular functions, such as nutrient-sensing metabolic adaptation, and quality control of proteins and organelles.³ Complex transcriptional programs control the synthesis, composition, and quantity of lysosomes and regulate their activity to match the evolving needs of the cell. Alterations in these essential functions are central to the pathophysiology of an expanding range of conditions and include storage diseases, neurodegenerative diseases, and cancer.³ Lysosomes

maintain cellular health because of efficient removal of toxic cellular components, removal of useless organelles, termination of signal transduction, and maintenance of metabolic homeostasis. Aging can lead to progressive loss of lysosomal efficiency and decline of the regenerative capacity of organs and tissues.⁴ Lysosomes are key signaling hubs of a sophisticated network for cellular adaptation, and the network includes ion and nutrient transporters, protein kinases and phosphatases, and transcription factors and transcriptional regulators.³ Altogether these components integrate functions, such as nutrient abundance, energy levels, and cell stressors, and translate them into instructions that regulate cellular metabolism toward either proliferation or inactivity.³ The signaling functions have far-reaching implications for metabolic regulation in health and in disease.

FIGURE 1.6 Endolysosomal System and Four Pathways to Degradation in Lysosomes. **A**, Endolysosomal system. **B**, Four pathways to degradation in lysosomes and in all pathways the final step is fusion with lysosomes. *ALR*, Autophagic lysosomal reformation; *CMA*, chaperone-mediated autophagy; *MVB*, multivesicular body; *TGN*, *trans*-Golgi network; *rER*, rough endoplasmic reticulum. (A adapted from Perera RM, Zoncu R: *Annu Rev Cell Dev Biol* 2016 Aug 2 [Epub]; B from Damjanov L: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders.)

The lysosomal membrane acts as a protective shield between the powerful digestive enzymes within the lysosome and the cytoplasm, preventing their leakage into the cytoplasmic matrix. Disruption of the membrane by various treatments or cellular injury leads to a release of the lysosomal enzymes, which can then react with their specific substrates, causing *cellular self-digestion*. Lysosomal abnormalities are involved in a number of conditions that involve cellular injury and death.

Lysosomal storage diseases (LSDs) may be the result of a genetic defect or lack of one or more lysosomal enzymes. For example, the lack of lysosomal α -1,4-glucosidase leads to an accumulation of glycogen in lysosomes known as *Pompe disease*. Tay-Sachs disease is characterized by an accumulation of GM2 ganglioside (a lipid) in

lysosomes as a result of the deficiency or absence of lysosomal hexosaminidase A. In gout, undigested uric acid accumulates within lysosomes, damaging the lysosomal membrane. Subsequent enzyme leakage results in cell death and tissue injury. Four pathways of degradation in lysosomes include (1) endocytosis, (2) phagocytosis, (3) macropinocytosis, and (4) autophagy (Fig. 1.6, A).

Endocytosis is the uptake of macromolecules from extracellular fluid; phagocytosis is engulfment of large particles or microorganisms in phagocytic cells, like macrophages and neutrophils; macropinocytosis is the nonspecific uptake of fluids, membrane, and particles attached to the plasma membrane; and autophagy (self-eating) begins in the cytosol and is used to digest cytosol and ineffectual organelles² (see Chapter 2). Extracellular substances are taken into the cell and encapsulated in a membrane-bound vesicle (see discussion on endocytosis). Lysosomes merge with the vesicle to form a digestive vacuole. Lysosomes remain fully active by maintaining a low internal pH. They do this by pumping hydrogen ions into their interiors. The hydrolytic enzymes are only maximally active at acidic pH values. Lysosomes that are not active do not maintain such an acidic internal pH. Lysosomes in this “holding pattern” are called **primary lysosomes**. When a primary lysosome fuses with a vacuole or other organelle, its pH decreases and the hydrolytic enzymes become activated. When it becomes active, it is called a **secondary lysosome**, or **heterophagosome** (Fig. 1.6, B).

As cells complete their life span and die, lysosomes digest the resultant debris or obsolete parts by **autophagy**. Lysosomes involved in this process, which is called **autodigestion**, are called **autolysosomes**, or **autophagosomes** (Fig. 1.6, A and B). In living cells, cellular debris is encapsulated within a vesicle that reacts with a lysosome to complete its degradation. Autophagy promotes homeostasis because it involves continuous biosynthesis and cell turnover. Therefore, autophagy plays a crucial role in health. Defects in autophagy may challenge disposal mechanisms from removing microbes, unnecessary protein aggregates, and abnormal proteins, resulting in contributions to disease ranging from infectious disorders

to neurodegeneration and cancer.

Products of autophagy (and of phagocytosis) pass out of the lysosome and are reused by the cell. Indigestible material is stored in vesicles called **residual bodies**, whose contents are actively expelled from the cell (see [Fig. 1.6](#)). High concentrations of lipids may accumulate within the residual bodies and remain there for a long time. The lipids are eventually oxidized, and a pigmented substance containing polyunsaturated fatty acids and proteins accumulates in the cell. This pigmented substance, termed *lipofuscin*, is often called “age pigment” or “age spots,” and is noted in older individuals.

Peroxisomes

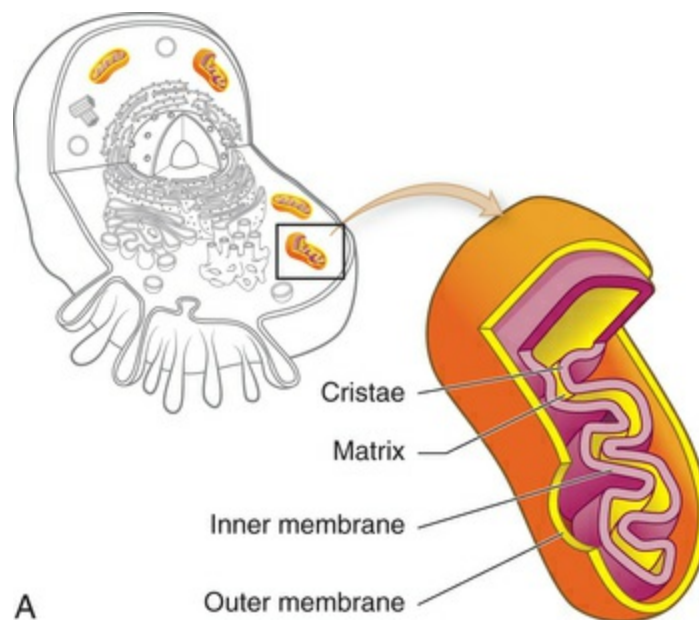

Peroxisomes (microbodies) are membrane-bound organelles that contain several oxidative enzymes such as *catalase* and *urate oxidase*. These oxidative enzymes can detoxify compounds and fatty acids. Similar to lysosomes in microscopic appearance, peroxisomes are larger and oval or irregular in shape. Like mitochondria, peroxisomes are major sites of oxygen utilization. Peroxisomes are so named because they usually contain enzymes that use oxygen to remove hydrogen atoms from specific substrates in an oxidative reaction that produces hydrogen peroxide (H_2O_2). Hydrogen peroxide is a powerful oxidant, potentially destructive if it accumulates or escapes from peroxisomes. Catalase, an antioxidant enzyme, uses the H_2O_2 to oxidize a variety of other substrates—phenols, formic acid, formaldehyde, and alcohol—by the peroxidative reaction:

Thus the breakdown of H_2O_2 yields H_2O and O_2 (see discussion of free radicals in [Chapter 2](#)). Peroxisomes also have an important role in the synthesis of specialized phospholipids necessary for nerve cell myelination. Such reactions are important in detoxifying various wastes within the cell or foreign components that enter the cell, such as ethanol. Impairment of peroxisomes can lead to disease.

Mitochondria

Mitochondria (*mito* = thread; *chondros* = granule), organelles found in large numbers in most cells, are responsible for cellular respiration and energy production. These cytoplasmic organelles appear as spheres, rods, or filamentous bodies that are bound by a double membrane (Fig. 1.7). The **outer membrane** is smooth and surrounds the mitochondrion itself; the inner membrane is convoluted in the mitochondrial matrix to form partitions called **cristae**. The **inner membrane** contains the enzymes of the **respiratory chain**—the name given to the electron-transport chain. These enzymes are essential to the process of oxidative phosphorylation that generates most of the cell's ATP. Metabolic pathways involved in the metabolism of carbohydrates, lipids, and amino acids and special pathways involving urea and heme synthesis are located in the mitochondrial matrix.

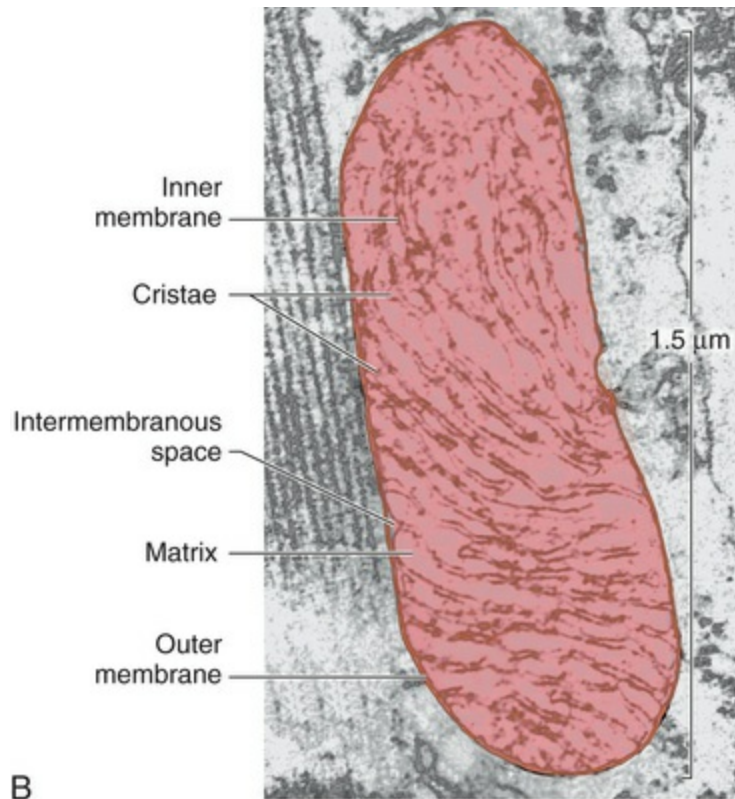

FIGURE 1.7 Mitochondrion. A, Cutaway sketch showing outer and inner membranes. Note the many folds (cristae) of the inner membrane. B, Transmission electron micrograph of a mitochondrion. Although some mitochondria have the capsule shape shown here, many are round or oval. (B Courtesy Brenda Russell.)

The outer membrane is permeable (passable) to many substances, but the inner membrane is highly selective and contains many transmembranous transport systems. The inner membrane contains a transporter to move electrically charged calcium (calcium ions). Mitochondria contain their own DNA that codes for enzymes needed for oxidative phosphorylation.

Cytosol

Cytosol is the gelatinous, semiliquid portion of the cytoplasm accounting for about 55% of the total cell volume. Functions of the cytosol include intermediary metabolism involving enzymatic biochemical reactions; ribosomal protein synthesis; and storage of carbohydrates, fat, and secretory vesicles.

Intermediary metabolism refers to the intracellular chemical

reactions that include synthesis, degradation, and transformation of small organic molecules (e.g., simple sugars, fatty acids, and amino acids). All intermediary metabolism occurs in the cytoplasm or that portion of the cell interior not occupied by the nucleus—with most of the metabolism being accomplished in the cytosol. These reactions enable energy to be used for managing cellular activities and for providing substrates to maintain cell integrity.

Ribosomal protein synthesis takes place in free ribosomes in the cytosol. Cytosolic ribosomes that synthesize identical proteins are collected in “factories” known as **polyribosomes**.

Excess stored nutrients not immediately used for ATP production are converted in the cytosol into storage forms; for example, excess glucose is stored as glycogen. These temporary masses are known as *inclusions* (see [Chapter 2](#)). Secretory vesicles that have been processed and packaged by the endoplasmic reticulum and Golgi complex also remain in the cytosol. By means of signaling, the vesicles transport and empty their contents outside the cell.

Cytoskeleton

All eukaryotic cells contain elaborate and specialized internal structures in the cytosol that provide the “bones and muscles” of the cell—the **cytoskeleton**. The cytoskeleton maintains the cell's shape and internal organization, and it permits movement of substances within the cell and movement of external projections (cilia or microvilli; flagella in sperm) outside the plasma membrane. The internal skeleton is composed of a network of protein filaments; the three main types of filaments include actin filaments, microtubules, and intermediate filaments. These filaments collectively promote cell strength, shape, and movement.

By translating mechanical forces and deformations into biochemical signals, cells sense their physical environment including the extracellular matrix, neighboring cells, and physical stress. The cytoskeleton is involved with the extracellular matrix and nuclear interior in force transmission (mechanical forces) called mechanotransduction. **Mechanotransduction** describes the cellular

processes that translate mechanical stimuli into biochemical signals, allowing cells to adapt to their surroundings. Cell stresses, however, that involve adaptations of mechanotransduction are associated with several alterations and diseases including loss of hearing, cardiovascular disease, muscular dystrophy, and cancer.

Microtubules are small, hollow, cylindrical, unbranched tubules made of protein. When found together, microtubules exhibit rigidity, unlike the rest of the cytoplasm. Microtubules thus add strength to the cell's structure (Fig. 1.8, A, B). Within the cell, microtubules support and move organelles from one part of the cytoplasm to another, facilitate transport of impulses along nerve cells, and have roles in the inflammatory and immune responses and hormone secretion (Fig. 1.8, C). Microtubules are also involved in the external movement, or motility, of some cells.

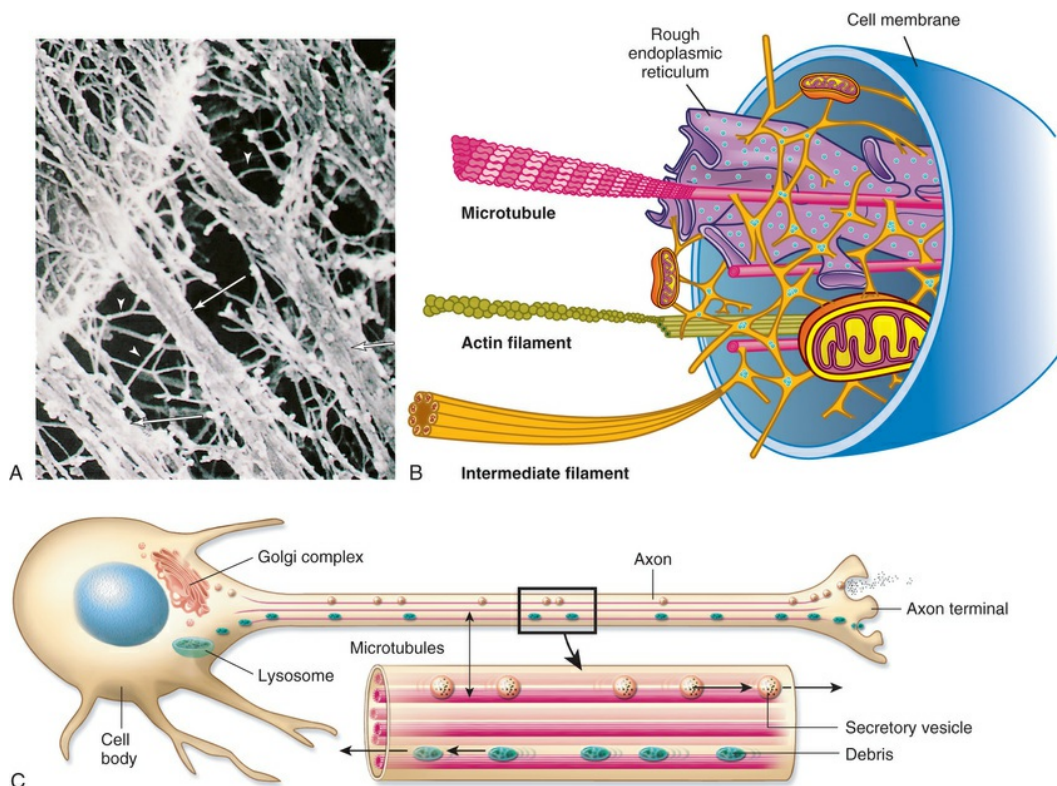

FIGURE 1.8 Cytoskeleton. A, Electron micrograph of a portion of the cell's internal framework. Arrowheads mark the intermediate filaments, and the complete arrows mark the microtubules. B, Artist's interpretation of the cell's internal framework. Note that the "free" ribosomes and other organelles are not really free at all. C, Microtubules are necessary for

maintaining an asymmetrical cell shape, such as that of a nerve cell. In addition, specific chemicals are released from the terminal end of the axon to influence neural transmission. (A and B from Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 6, St Louis, 2007, Mosby.)

Microtubules are arranged in the thickened base, or basal body, of a protrusion from the cell's plasma membrane. This arrangement occurs in the basal bodies of sperm flagella and the cilia of certain other cells. The long, whiplike flagella enable the movement of sperm cells. Cilia usually move substances past the cell, which remains stationary. For example, cilia on cells lining the respiratory tract move together to “beat” mucus toward the throat so it can be removed by coughing.

While the cell is not in the process of division, only a few microtubules are assembled; cellular division (mitosis) or defense (phagocytosis) does, however, induce a cycle of rapid assembly and disassembly. Microtubules involved in cellular division are arranged in a **centriole**. Centrioles always consist of nine bundles containing three microtubules each. During division, the pairs of centrioles split and migrate to opposite poles of the cell.

Actin filaments (microfilaments) are smaller fibrils that generally occur in bundles rather than as single entities (Fig. 1.8, B). They are concentrated in the cell *cortex*, just beneath the plasma membrane.² The cortical actin network is a major driver for many cell functions including cell movement, endocytosis, and maintenance of cell and tissue shape. Actin filaments link the interior of the cell to adjacent cells through cell junctions.

In addition, microfilaments are necessary for regulating cell growth and drive the pinching of one cell into two.² Cellular locomotion depends on contractile properties that involve both microtubules and actin filaments. The actin cytoskeleton in motile cells has recently been described as a “wave of excitation” that may account for the spontaneous migration of cells.⁵

Intermediate filaments are braided, ropelike fibers made of several filament proteins. The different filaments form a mesh called the nuclear lamina beneath the inner nuclear membrane, creating a protective chamber for the cell's DNA.² Other types crisscross the cytoplasm, promoting mechanical strength. In epithelial tissue these

filaments bridge the cytoplasm from one cell junction to another, supporting and strengthening the sheet of epithelium.²

Plasma Membranes

Membranes define the cell's boundaries. Whether they surround the cell or enclose an intracellular organelle, membranes are crucial to normal physiologic function because they control the composition of the space, or compartment, they enclose. They can allow or exclude various molecules, and because of selective transport systems, they can move molecules in or out of the space (Fig. 1.9). By controlling the movement of substances from one compartment to another, membranes exert a powerful influence on metabolic pathways. Directional transport is facilitated by polarized domains, distinct apical and basolateral domains. The direction of cells—**cell polarity**—maintains normal cell and tissue structure for numerous functions, most importantly transport of nutrients in and out of the cell, and becomes altered with diseases such as cancer (Fig. 1.10). In addition to these functions, the plasma membrane has an important role in cell-to-cell recognition. For example, protein receptors for hormones and for other chemical signals are associated with the membrane and act as markers that identify a cell to its neighbors. Other functions of the plasma membrane include assistance with cellular mobility and maintenance of cellular shape (Table 1.1).

FIGURE 1.9 Functions of Plasma Membrane Proteins. The plasma membrane proteins illustrated here show a variety of functions performed by the different types of plasma membranes. (From Raven PH, Johnson GB: *Understanding biology*, ed 3, Dubuque, IA, 1995, Brown.)

FIGURE 1.10 Cell Polarity of Epithelial Cells. A schematic of cell polarity (cell direction) of epithelial cells. Shown are the directions of the basal side and the apical side. The organelles and cytoskeleton are also arranged directionally to enable, for example, cell secretion and absorption in an

intestinal cell. The red circles represent cellular content. (Adapted from Life Science web textbook, The University of Tokyo.)

TABLE 1.1

PLASMA MEMBRANE FUNCTIONS

CELLULAR MECHANISM	MEMBRANE FUNCTIONS
Structure	Usually thicker than the membranes of intracellular organelles Containment of cellular organelles Maintenance of relationship with cytoskeleton, endoplasmic reticulum, and other organelles Outer surfaces in many cells are not smooth but are studded with cilia or even smaller cylindrical projections called microvilli; both are capable of movement; caveolae are also outer indentations Maintenance of fluid and electrolyte balance
Protection	Barrier to toxic molecules and macromolecules (proteins, nucleic acid, and polysaccharides) Barrier to foreign organisms and cells
Activation of cell	Hormones (regulation of cellular activity) Mitogens (cellular division) Antigens (antibody synthesis) Growth factors (proliferation and differentiation)
Transport	Diffusion and exchange diffusion Endocytosis (pinocytosis and phagocytosis); receptor-mediated endocytosis Exocytosis (secretion) Active transport
Cell-to-cell interaction	Communication and attachment at junctional complexes Symbiotic nutritive relationships Release of enzymes and antibodies to extracellular environment Relationships with extracellular matrix

Modified from King DW, Fenoglio CM, Lefkowitz JH: *General pathology: principles and dynamics*, Philadelphia, 1983, Lea & Febiger.

Membrane Composition

The main components of cell membranes are lipids and proteins. The basic structure of cell membranes is the **lipid bilayer**, composed of two continuous opposing leaflets and proteins that span the bilayer or

interact with the lipids on either side of the two leaflets ([Fig. 1.11](#)). The lipid bilayer provides the basic fluid structure of the membrane and is mostly an impermeable barrier to water-soluble molecules. Individual lipid molecules can diffuse readily throughout their own monolayer. Most membrane proteins span the lipid bilayer and mediate most of the functions of the membrane including transport of molecules across the membrane and ATP synthesis² (see [Fig. 1.9](#)).

FIGURE 1.11 Lipid Bilayer Membranes. A, Concepts of biologic membranes have markedly changed in the last two decades, from the classic fluid mosaic model to the current model that lipids and proteins are not evenly distributed but can isolate into microdomains, differing in their protein and lipid composition. An example of a microdomain is lipid rafts (colored yellow). Rafts are dynamic domain structures composed of cholesterol, sphingolipids, and membrane proteins important in different cellular processes. Various models exist to clarify the functions of

domains. The three major phases of lipid bilayer organization include a solid gel phase (e.g., with low temperatures), a liquid-ordered phase (high temperatures), and a fluid liquid-crystalline (or liquid-disordered) phase. B, Some membrane-associated proteins are integrated into the lipid bilayer; other proteins are loosely attached to the outer and inner surfaces of the membrane. Transmembrane proteins protrude through the entire outer and inner surfaces of the membrane, and they can be attracted to microdomains through specific interactions with lipids. Interaction of the membrane proteins with distinct lipids depends on the hydrophobic thickness of the membrane, the lateral pressures of the membrane (mechanical force may shift protein channels from an open to a closed state), the polarity or electrical charges at the lipid-protein interface, and the presence on the protein side of amino acid side chains. Important for pathophysiology is the proposal that protein-lipid interactions can be critical for correct insertion, folding, and orientation of membrane proteins. For example, diseases related to lipids that interfere with protein folding are becoming more prevalent. C, Investigators are studying the cooperative behavior of lipids, membrane fluctuations, and domains that influence protein organization and consequently protein function. Here a perturbed region develops around an integral protein. D, Two proteins are attracted because of the sharing of a perturbed region of the lipid bilayer. *GPI*, glycosylphosphatidylinositol. (Adapted from Bagatolli LA et al: *Prog Lipid Res* 49[4]:378–389, 2010; Contreras F-X et al: *Cold Spring Harb Perspect Biol* 3[6]:pii:a004705, 2011; Cooper GM: *The cell—a molecular approach*, ed 2, Washington, DC, 2000, Sinauer Associates; Defamie N, Mesnil M: *Biochim Biophys Acta* 1818[8]:1866–1869, 2012.)

Historically, the plasma membrane was described as a fluid lipid bilayer composed of a *uniform* lipid distribution with inserted moving proteins. Whether lipid molecules in the plasma membrane in *living* cell membranes segregate into domains called **lipid rafts** is a controversial topic. It is known that many lipids and proteins are not distributed uniformly but are seen to concentrate in a *temporary*, dynamic way assisted by protein-protein interactions that enable transient formation of domains or lipid rafts.² Organization of lipid rafts in living cells may be important for cell communication where protein assemblies convert extracellular signals into intracellular signals.² Larger assemblies of clusters are *caveolae*, flask-shaped invaginations thought to form from lipid rafts and to be important for endocytosis. Carbohydrates are mainly associated with plasma membranes, where they are chemically combined with lipids to form **glycolipids** and with proteins to form **glycoproteins**.

Lipids.

Cell membranes may contain many different lipid classes, but in

animals the main ones are phospholipids, cholesterol, and glycolipids. The most abundant lipids are phospholipids. Phospholipids are key for repairing the membrane—they tend to spontaneously rearrange themselves to avoid a tear (free edge with water) by folding on themselves and forming a sealed compartment.² Inositol phospholipids are a subclass of phospholipids important for cell signaling because in the cytosolic lipid leaflet of the bilayer they respond to extracellular signals. Lipids along with protein assemblies act as “molecular glue” for the structural integrity of the membrane. Each lipid molecule is said to be polar, or amphipathic. An **amphipathic molecule** is one in which one part is **hydrophobic** (uncharged, or “water fearing”) and another part is **hydrophilic** (charged, or “water loving”) (Fig. 1.12). The membrane spontaneously organizes itself into a bilayer because of these two incompatible solubilities. The hydrophobic region (hydrophobic tail) of each lipid molecule is protected from water, whereas the hydrophilic region (hydrophilic head) is immersed in it. The bilayer's structure accounts for one of the essential functions of the plasma membrane: it is impermeable to most water-soluble molecules (molecules that dissolve in water) because they are insoluble in the oily core region. The bilayer serves as a barrier to the diffusion of water and hydrophilic substances while allowing lipid-soluble molecules, such as oxygen (O₂) and carbon dioxide (CO₂), to diffuse through it readily. Because the bilayer is fluid at temperatures greater than freezing, components of the cellular environment move slowly and selectively across the membrane all the time.

FIGURE 1.12 Structure of a Phospholipid Molecule. **A**, Each phospholipid molecule consists of a phosphate functional group and two fatty acid chains attached to a glycerol molecule. **B**, The fatty acid chains and glycerol form nonpolar, hydrophobic “tails,” and the phosphate functional group forms the polar, hydrophilic “head” of the phospholipid molecule. When placed in water, the hydrophobic tails of the molecule face inward, away from the water, and the hydrophilic head faces outward, toward the water. (From Raven PH, Johnson GB: *Understanding biology*, ed 3, Dubuque, IA, 1995, Brown.)

Proteins.

Proteins perform most of the plasma membrane's specific tasks. The amounts and types of proteins in a membrane vary. A **protein** is made from a chain of amino acids, known as **polypeptides**. There are 20 types of amino acids in proteins, and each type of protein has a unique sequence of amino acids. Proteins are the major workhorses of the cell.

Membrane proteins associate with the lipid bilayer in different ways (Fig. 1.13) including (1) **transmembrane proteins** extending across the bilayer and exposed to an aqueous environment on both sides of it (see Fig. 1.13, A); (2) proteins located almost entirely in the cytosol and associated with the cytosolic half of the lipid bilayer by an α helix exposed on the surface of the protein (see Fig. 1.13, B); (3) proteins existing outside the bilayer, on one side or the other, and attached to the membrane by one or more covalently attached lipid groups (see Fig. 1.13, C); and (4) proteins bound indirectly to one or the other bilayer membrane face and held in place by their interactions with other proteins (see Fig. 1.13, D).² Membrane proteins are amphiphilic, with both hydrophobic and hydrophilic regions.

FIGURE 1.13 Proteins Attach to the Plasma Membrane in Different Ways. **A**, Transmembrane proteins extend through the membrane as a single α helix, as multiple α helices, or as a rolled-up barrel-like sheet called a β barrel. **B**, Some membrane proteins are anchored to the cytosolic side of the lipid bilayer by an amphipathic α helix. **C**, Some proteins are linked on either side of the membrane by a covalently attached lipid molecule. **D**, Proteins are attached by weak noncovalent interactions with other membrane proteins. (D adapted from Alberts B: *Essential cell biology*, ed 4, New York, 2014, Garland.)

Proteins exist in densely folded molecular configurations rather than straight chains; so an excess of hydrophilic units is at the surface of the molecule and an excess of hydrophobic units is inside. Membrane proteins, like other proteins, are synthesized mainly by ribosomes in the cytosol and then travel, called *trafficking*. Their fate depends on their amino acid sequence, which contains **sorting signals** that direct their delivery to locations outside the cytosol or to organelle surfaces.² A simplified illustration of protein traffic within a cell is presented in [Fig. 1.14](#).

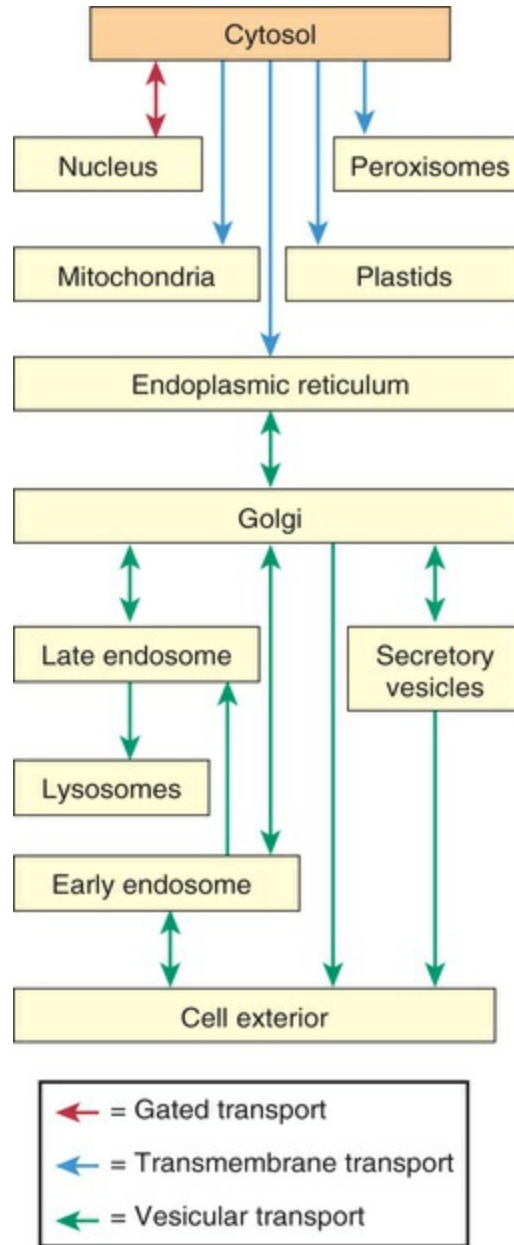

FIGURE 1.14 Simplified “Roadmap” of Protein Traffic. Proteins can move from one compartment to another by gated transport (*red*), transmembrane transport (*blue*), or vesicular transport (*green*). Sorting signals direct a protein's movement through the cell and determine its final destination. The trip begins with synthesis of a protein on a ribosome in the cytosol and ends when the protein reaches the final destination. A sorting signal is required either for retention at an intermediate station (*boxes*) or for exit from the station or compartment. (Adapted from Alberts B: *Essential cell biology*, ed 4, New York, 2014, Garland.)

Proteins move from one compartment to another by (1) gated transport, (2) protein translocation, or (3) vesicular transport. In **gated transport** selective gates direct the movement of proteins and RNA

molecules between the cytosol and the nucleus through nuclear pore complexes in the nuclear envelope². In **protein translocation** *transmembrane protein translocators* directly transport proteins across a membrane from the cytosol to a different distinct location. To snake through the translocator, the protein molecule usually unfolds. In **vesicular transport**, the bubble-like vesicle is a membrane-enclosed intermediate of either a small transport vesicle or a large organelle fragment. These vesicles discharge their cargo into a different compartment by fusing with that compartment's membrane.² Movement of soluble proteins from the ER to the Golgi apparatus occurs by vesicular transport. Those proteins that lack a sorting signal remain in the cytosol permanently. Trafficking places unique demands on membrane proteins for folding, translocation, and stability. Thus, much research is now being done to understand misfolded proteins, for example, as a cause of disease (see [What's New? Endoplasmic Reticulum, Protein Folding, and ER Stress](#)).

Proteins facilitate transport across membranes by serving as receptors, enzymes, or transporters. Proteins act as (1) recognition and binding units (receptors) for substances moving in and out of the cell; (2) pores or transport channels for various electrically charged particles called *ions* or *electrolytes* and specific carriers for amino acids and monosaccharides; (3) specific enzymes that drive active pumps that promote concentration of certain ions, particularly potassium (K^+), within the cell while keeping concentrations of other ions, for example, sodium (Na^+), below concentrations found in the extracellular environment; (4) cell surface markers, such as glycoproteins (proteins attached to carbohydrates), that identify a cell to its neighbor; (5) **cell adhesion molecules (CAMs)**, or proteins that allow cells to hook together and form attachments to the cytoskeleton for maintaining cellular shape; and (6) catalysts of chemical reactions, for example, conversion of lactose to glucose. Membrane proteins are key components of energy transduction, converting chemical energy into electrical energy, or electrical energy into either mechanical energy or synthesis of ATP.⁶

The interaction of plasma membrane proteins with lipids is complex

and is the subject of much research. The role of proteins in the onset and progression of disease is important because they govern communication between cells through enzymatic, transport, and recognition-receptor functions in cellular physiology.

Protein regulation in a cell: Proteostasis.

Proteostasis (or **proteome** [complete collection of cell proteins] homeostasis) is a state of cell balance of the processes of protein synthesis, folding, and degradation. Proteostasis is vital to cellular health. The cellular protein pool is in constant change or flux. The number of copies of a protein in a cell depends on how quickly it is made and how long it survives or is broken down. The system of protein homeostasis is adaptable and defined by the “proteostasis” network comprised of ribosomes (makers); chaperones (helpers); and two protein breakdown systems or **proteolytic** systems, lysosomes and the ubiquitin-proteasome system (UPS). The molecular chaperones called *heat-shock proteins (hsp)* are important and are so named because they increase after cells are exposed to elevated temperature (proteotoxic stress). The increase in hsp is part of a feedback system that responds to an increase in misfolded proteins and helps these proteins refold. These chaperones also facilitate transportation and **ubiquitination** or tagging the protein with a small molecule, *ubiquitin*, that signals the protein to the proteasome for degradation.⁷ Together, all of these systems regulate protein homeostasis under a large variety of conditions including nutrient supply variation, oxidative stress, cellular differentiation, temperature changes, heavy metal ion presence, and other stresses.⁸ Malfunction or failure of the proteostasis network is associated with human disease (Fig. 1.15).

FIGURE 1.15 Protein Homeostasis System and Outcomes. A main role of the protein homeostasis network (*proteostasis*) is to minimize protein misfolding and protein aggregation. The network includes ribosome-mediated protein synthesis, chaperone (folding helpers in the ER) and enzyme-mediated folding, breakdown systems of lysosome and proteasome-mediated protein degradation, and vesicular trafficking. The network integrates biologic pathways that balance folding, trafficking, and protein degradation depicted by arrows *b*, *d*, *e*, *f*, *g*, *h*, and *i*. (Adapted from Lindquist SL, Kelly JW: *Cold Spring Harb Perspect Biol* 3[12]:pii:a004507, 2011.)

Proteases are enzymes that cause the breakdown of proteins. Certain proteases can be tethered to cell membranes. Proteases are involved in the physiologic regulation of essential processes by participating in a tightly orchestrated sequence of events termed a **proteolytic cascade**. Four major proteolytic cascades with disease relevance are candidates for treatment modalities, including (1) cell death or caspase-mediated apoptosis, (2) the blood coagulation cascade, (3) degrading membrane enzymes or matrix metalloproteinase cascade, and (4) the complement cascade. Some proteases within a proteolytic cascade act as initiators; others are involved in amplification and propagation and execution. Understanding the various steps involved is crucial for designing drug interventions. Dysregulation of proteases features prominently in many human diseases, including cancer, autoimmunity, and neurodegenerative disorders.

The short chains of sugars or carbohydrates (*oligosaccharides*)

contained within the plasma membrane are generally bound to membrane proteins (glycoproteins) and lipids (glycolipids). Long polysaccharide chains attached to membrane proteins are called *proteoglycans*. All of the carbohydrate on the glycoproteins, proteoglycans, and glycolipids is located on the outside of the plasma membrane, and the carbohydrate coating is called the *glycocalyx* (or cell coat). The glycocalyx helps protect the cell from mechanical damage.² Additionally, the layer of carbohydrate gives the cell a slimy surface that assists the mobility of other cells, like leukocytes, to squeeze through the narrow spaces.² The functions of carbohydrates are more than protection and lubrication and include specific cell-cell recognition and adhesion. Intercellular recognition is a function of membrane oligosaccharides; for example, the transmembrane proteins, called *lectins* that bind to a particular oligosaccharide, recognize neutrophils at the site of bacterial infection. This recognition allows the neutrophil to adhere to the blood vessel wall and migrate from the blood into the infected tissue to help eliminate the invading bacteria.²

Cellular Receptors

Cellular receptors are protein molecules on the plasma membrane, in the cytoplasm, or in the nucleus that are capable of recognizing and binding with specific smaller molecules called **ligands** (Latin *ligare*, “to bind”) (Fig. 1.16). The region of a protein that associates with a ligand is called its **binding site**. Hormones, for example, are ligands. Recognition and binding depend on the chemical configuration of the receptor and its smaller ligand, which must fit together somewhat like pieces of a jigsaw puzzle. Binding selectively to a protein receptor with high affinity to a ligand depends on formation of weak, noncovalent interactions—hydrogen bonds, electrostatic attractions, and van der Waals attractions—and favorable hydrophobic forces.² Numerous receptors are found in most cells, and ligand binding to receptors activates or inhibits the receptor's associated signaling or biochemical pathway.

B **FIGURE 1.16 Cellular Receptors.** (A) 1, Plasma membrane receptor for a ligand (here, a hormone molecule) on the surface of an integral protein. A neurotransmitter can exert its effect on a postsynaptic cell by means of two fundamentally different types of receptor proteins; 2, channel-linked receptors, and 3, non-channel-linked receptors. Channel-linked receptors are also known as ligand-gated channels. (B) Example of ligand-receptor interaction. Insulin-like growth factor 1 (IGF-1) is a ligand and binds to the insulin-like growth factor 1 receptor (IGF-1R). With binding at the cell membrane the intracellular signaling pathway is activated, causing translation of new proteins to act as intracellular communicators. This pathway is important for cancer growth. Researchers are developing pharmacologic strategies to reduce signaling at and downstream of the IGF-1R, hoping this will lead to compounds useful in cancer treatment. *P*, phosphate group from ATP.

Although the chemical nature of both ligands and the receptors to which they bind differs, receptors are classified on the basis of their location and function (see [Cellular Communication and Signal Transduction](#)). Cellular type determines overall cellular function, but plasma membrane receptors determine which ligands a cell will bind with and how the cell will respond to binding with each. For example, the ability of a hormone or a neurotransmitter to stimulate a cell is regulated by the specificity and number of receptors present on the plasma membrane. Specific processes also control intracellular mechanisms. Hormone binding, for example, depends on special messenger molecules that regulate protein synthesis within the cell (see [Chapter 21](#)). Neurotransmitters also operate by causing special messengers to react with specific receptors.

Receptors for different drugs are found on the plasma membrane, in the cytoplasm, and in the nucleus. Membrane receptors have been found for certain anesthetics, opiates, endorphins, enkephalins, antibiotics, cancer chemotherapeutic agents, digitalis, and other drugs. Membrane receptors for endorphins, which are opiate-like peptides isolated from the pituitary gland, are found in large quantities in pain pathways of the nervous system (see [Chapters 15](#) and [16](#)). With binding, the endorphins (or drugs like morphine) change the cell's permeability to ions, increase the concentration of molecules that regulate intracellular protein synthesis, and initiate molecular events that modulate pain perception.

Receptors for infectious microorganisms, or antigen receptors, bind bacteria, viruses, and parasites. Antigen receptors on white blood cells (lymphocytes, monocytes, macrophages, granulocytes) recognize and bind with antigenic microorganisms and activate the immune and inflammatory responses (see [Chapters 7](#) and [8](#)).

Cell-to-Cell Adhesions

Cells are small and squishy, *not* like bricks. They are enclosed only by a flimsy membrane, yet the cell depends on the integrity of this

membrane for its survival. How can cells be combined together strongly, with their membranes intact, to form a muscle that can lift this textbook? Plasma membranes not only serve as the outer boundaries of all cells but also allow groups of cells to be held together robustly, in **cell-to-cell adhesions**, to form tissues and organs. Once arranged, cells are held together by three different means: (1) the extracellular matrix, (2) cell adhesion molecules in the cell's plasma membrane, and (3) specialized cell junctions.

Extracellular Matrix and Basement Membrane

Cells can be bound together by attachment to one another or through the **extracellular matrix** (ECM; also including the basement membrane), which the cells secrete around themselves. The ECM is an intricate meshwork of interstitial fibrous proteins embedded in a watery, gel-like substance composed of complex carbohydrates (Fig. 1.17). A specialized type of extracellular matrix is called the **basement membrane** (also known as the **basal lamina**). This sheet of matrix molecules is very thin, tough, and flexible; lies beneath epithelial cells; and surrounds individual muscle cells, fat cells, and Schwann cells (which wrap around peripheral nerve cell axons) (Fig. 1.18). The extracellular matrix is like glue; however, it does provide a pathway for diffusion of nutrients, wastes, and other water-soluble traffic between the blood and tissue cells. Overall, the matrix helps regulate cell growth, movement, and differentiation. Specifically, the major functions of the ECM include (1) mechanical support, (2) control of cell proliferation, (3) formation of a scaffold for tissue regeneration, and (4) establishment of tissue microenvironments (Box 1.1). Interwoven within the matrix are three groups of **macromolecules**: (1) fibrous structural proteins, including collagen and elastin; (2) a diverse group of adhesive glycoproteins, such as fibronectin; and (3) proteoglycans and hyaluronic acid.

FIGURE 1.17 Extracellular Matrix. Tissues are not just cells but also extracellular space. The extracellular space is an intricate network of macromolecules called the *extracellular matrix (ECM)*. The macromolecules that constitute the ECM are secreted locally (by mostly fibroblasts) and assembled into a meshwork in close association with the surface of the cell that produced them. Two main classes of macromolecules include proteoglycans, which are bound to polysaccharide chains called glycosaminoglycans; and fibrous proteins (e.g., collagen, elastin, fibronectin, and laminin), which have structural and adhesive properties. Together the proteoglycan molecules form a gel-like ground substance in which the fibrous proteins are embedded. The gel permits rapid diffusion of nutrients, metabolites, and hormones between the blood and the tissue cells. Matrix proteins modulate cell-matrix interactions including normal tissue remodeling (which can become abnormal, for example, with chronic inflammation), embryogenesis, wound healing, and angiogenesis. Disruption of this balance results in serious diseases such as arthritis, tumor growth, and others. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

FIGURE 1.18 Three Ways Basement Membranes (Basal Laminae) Are Organized. Basal laminae (yellow) surround certain cells like skeletal muscle cells, underlie epithelia, and occur between two cell sheets (kidney glomerulus). (Adapted from Alberts B: *Essential cell biology*, ed 4, New

Box 1.1

Functions of the Extracellular Matrix

Mechanical Support—Provides cell anchorage, cell migration, and maintenance of cell polarity.

Control of Cell Proliferation—Provides a warehouse for growth factors and cell signaling through receptors of the integrin family (see Fig. 1.17). Latent growth factors can be activated from injury and inflammation.

Scaffold for Tissue Regeneration—Ongoing maintenance of normal tissue structure requires a basement membrane (stromal scaffold); the integrity of the basement membrane is critical for the organized regeneration of tissue. It provides a guide for the migration of regenerating cells. It is modified after injury, promoting cell migration for wound healing.

Establishment of Tissue Microenvironments—Structurally, the basement membrane acts as a boundary between the epithelium and the underlying connective tissue, but also it is functional. For example, at the neuromuscular synapse, the synaptic basal laminae (or basement membrane) are critical for reconstruction of the synapse after nerve or muscle damage.

Collagen forms cable-like fibers or sheets that provide tensile strength or resistance to longitudinal stress. Collagen breakdown, such as occurs in osteoarthritis, destroys the fibrils that give cartilage its tensile strength.

Elastin is a rubber-like protein fiber most abundant in tissue that must be capable of stretching and recoiling, such as the lungs.

Fibronectin, a large glycoprotein, promotes cell adhesion and cell

anchorage. Reduced amounts have been found in certain types of cancerous cells; this allows cancer cells to travel or metastasize to other parts of the body.

The extracellular matrix is secreted by **fibroblasts** (“fiber formers”), local cells that are present in the matrix. The matrix and the cells within it are known collectively as *connective tissue* because they connect cells together to form tissues and organs. Human connective tissues are enormously varied. They can be hard and dense, like bone; flexible, like tendons or the dermis of the skin; resilient and shock-absorbing, like cartilage; or soft and transparent, like the jelly-like substance that fills the eye. In all these examples, the majority of the tissue is composed of extracellular matrix, and the cells that produce the matrix are scattered within it like raisins in a pudding⁹ (see [Fig. 1.17](#)).

The matrix is not just passive scaffolding for cellular attachment; it also helps regulate the functions of the cells within which it interacts. The matrix helps regulate cell growth, movement, and differentiation.

Cell Adhesion Molecules (CAMs)

Cell adhesion molecules (CAMs) are cell surface proteins that bind the cell to an adjacent cell and to components of the extracellular matrix (ECM). CAMs include four protein families: the integrins, the cadherins, the selectins, and immunoglobulin (Ig) superfamily. **Integrins** are a major class of receptors within the ECM and regulate cell-ECM interactions with collagen, fibronectin, vitronectin, and fibrinogen. **Cadherins** are Ca⁺⁺-dependent glycoproteins and have a unique pattern of tissue distribution, for example, epithelial (E-cadherin). **Selectins** are a family of proteins that bind certain carbohydrates, for example, mucins. The **immunoglobulin superfamily CAMs (IgSF CAMs)** bind integrins or other IgSF CAMs.

Specialized Cell Junctions

Cells in direct physical contact with neighboring cells are often linked together at specialized regions of their plasma membranes called **cell**

junctions. Cell junctions are classified by their function: (1) to hold cells together, forming a tight seal (tight junctions); (2) to provide strong mechanical attachments (adherens junctions, desmosomes, hemidesmosomes); (3) to provide a special type of chemical communication, for example, inorganic ions and small water-soluble molecules to move from the cytosol of one cell to the cytosol of another cell, such as those causing an electrical wave (gap junctions); and (4) to maintain apico-basal polarity of individual epithelial cells (tight junctions) (Fig. 1.19). Overall, cell junctions make the epithelium leak-proof (mediating mechanical attachment of one cell to another), allow communicating tunnels, and maintain cell polarity.

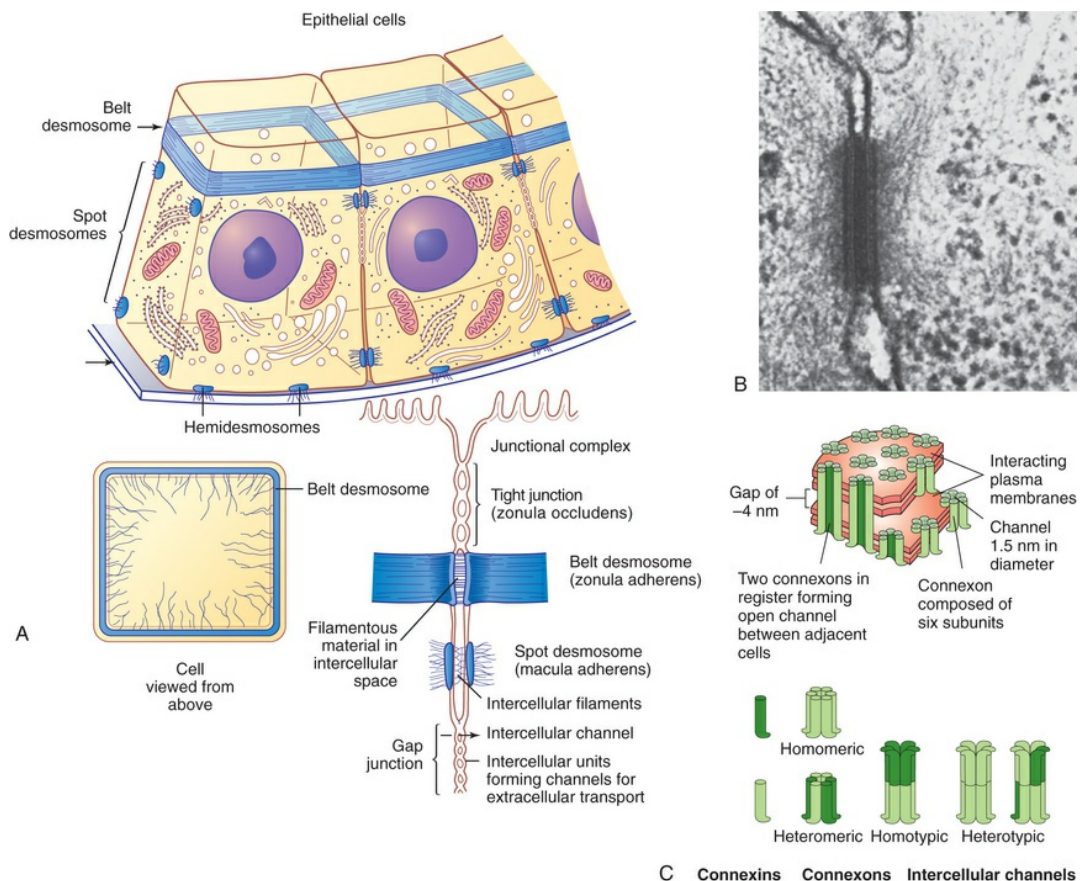

FIGURE 1.19 Types of Cell Connections. **A**, Schematic drawing of a belt desmosome between epithelial cells. This junction, also called *zonula adherens*, encircles each interacting cell. The spot desmosomes and hemidesmosomes, like the belt desmosomes, are adhering junctions. This tight junction is an impermeable junction that holds cells together but seals them in such a way that molecules cannot leak between them. The gap

junction, as a communicating junction, mediates the passage of small molecules from one interacting cell to the other. B, Electron micrograph of desmosomes. C, Connexons. (A and B from Raven PH, Johnson GB: *Biology*, St Louis, 1992, Mosby. C from Alberts B et al: *Molecular biology of the cell*, ed 5, New York, 2008, Garland.)

Cell junctions can be classified as symmetrical and asymmetrical. Symmetrical junctions include tight junctions (zonula occludens), the belt desmosome (zonula adherens), desmosomes (macula adherens), and gap junctions also called intercellular channel or communicating junctions.¹⁰ An asymmetrical junction is the hemidesmosome (see Fig. 1.19). Together the zones between epithelial cells—typically consisting of the zonula occludens, the zonula adherens, and the macula adherens—form the **junctional complex**. **Desmosomes** unite cells either by forming continuous bands or belts of epithelial sheets or by developing button-like points of contact. Desmosomes also act as a system of braces to maintain structural stability. **Tight junctions** are barriers to diffusion, prevent the movement of substances through transport proteins in the plasma membrane, and prevent the leakage of small molecules between the plasma membranes of adjacent cells. **Gap junctions** are clusters of communicating tunnels or connexons that allow small ions and molecules to pass directly from the inside of one cell to the inside of another. **Connexons** are hemichannels that extend outward from each of the adjacent plasma membranes (see Fig. 1.19, C).

The junctional complex is a highly permeable part of the plasma membrane. Its permeability is controlled by a process called **gating**, which depends on concentrations of calcium ions in the cytoplasm. Increased cytoplasmic calcium concentration causes decreased permeability at the junctional complex. Gating is an important cellular defense mechanism because it enables uninjured cells to seal themselves off from injured neighbors. Damaged cells release calcium, which travels through the junctional complex and increases calcium levels in neighboring cells, causing damaging effects. The increased calcium concentration decreases the permeability of the junctional complexes of the neighboring cells, which form a relatively impermeable wall around the injured area (see Chapter 2).

Cellular Communication and Signal Transduction

Cells need to communicate with each other to maintain a stable internal environment, or **homeostasis**; to regulate their growth and division and their development and organization into tissues; and to coordinate their functions. Cells communicate by using hundreds of kinds of signal molecules; however, cells communicate in three main ways: (1) they display plasma membrane-bound signaling molecules (receptors) that affect the cell itself and other cells in direct physical contact (Fig. 1.20, A); (2) they affect receptor proteins *inside* the target cell and the signal molecule has to enter the cell to bind with them (Fig. 1.20, B); and (3) they form protein channels (gap junctions) that directly coordinate the activities of adjacent cells (Fig. 1.20, C). Alterations in cellular communication affect disease onset and progression. In fact, if a cell is unable to perform gap junctional intercellular communication, it is hypothesized that normal growth control and cell differentiation are compromised, favoring cancerous tumor development. Secreted chemical signals involve communication at a distance. Primary modes of intercellular signaling are contact-dependent, paracrine, hormonal, neurohormonal, and neurotransmitter (Fig. 1.21).

FIGURE 1.20 Cellular Communication. Three ways in which cells communicate with one another. (B adapted from Alberts B et al: *Molecular biology of the cell*, ed 5, New York, 2008, Garland.)

FIGURE 1.21 Primary Modes of Chemical Signaling. Five forms of signaling mediated by secreted molecules. Hormones, paracrines, neurotransmitters, and neurohormones are all intercellular messengers that accomplish communication between cells. Autocrines bind to receptors on the same cell. Not all neurotransmitters act in the strictly synaptic mode shown; some act in a contact-dependent mode as local chemical mediators that influence multiple target cells in the area.

Contact-dependent signaling requires cells to be in close membrane-membrane contact. In **paracrine signaling**, cells secrete local chemical mediators that are quickly absorbed, destroyed, or immobilized. Paracrine signaling usually involves different cell types; however, cells also may produce signals that they, themselves, respond to, which is called **autocrine signaling** (see Fig. 1.21). For example, cancer cells use this form of signaling to stimulate their survival and proliferation. **Hormonal signaling** involves specialized endocrine cells that secrete chemicals called hormones (e.g., thyroid-stimulating hormone); hormones are released by one set of cells and travel through the tissue and through the bloodstream to produce a response in other sets of cells. In **neurohormonal signaling**, hormones (e.g., angiotensin II) are released into the blood by neurosecretory neurons. Like endocrine cells, neurosecretory neurons release blood-borne chemical messengers, whereas ordinary neurons secrete short-range neurotransmitters into a small, discrete space (i.e., synapse). Neurons communicate directly with the cells they innervate by

releasing chemicals or **neurotransmitters** at specialized junctions called **chemical synapses**; the neurotransmitter diffuses across the synaptic cleft and acts on the postsynaptic target cell (see [Fig. 1.21](#)). Many of these same signaling molecules are receptors used in hormonal, neurohormonal, and paracrine signaling. The important differences lie in the speed and selectivity with which the signals are delivered to their targets.²

Plasma membrane receptors belong to one of three classes that are defined by the signaling (transduction) mechanism used. [Table 1.2](#) summarizes these classes of receptors.

TABLE 1.2

CLASSES OF PLASMA MEMBRANE RECEPTORS

TYPE OF RECEPTOR	DESCRIPTION
Channel linked	Also called ligand-gated channels; involves rapid synaptic signaling between electrically excitable cells. Channels open and close briefly in response to neurotransmitters, changing ion permeability of plasma membrane of postsynaptic cell.
Catalytic	Once activated by ligands, function directly as enzymes. Composed of transmembrane proteins that function intracellularly as tyrosine-specific protein kinases.
G-protein linked	Indirectly activate or inactivate plasma membrane enzyme or ion channel; interaction mediated by guanosine triphosphate (GTP)-binding regulatory protein (G protein). When activated, a chain of reactions occurs that alters the concentration of intracellular messengers, such as cyclic adenosine monophosphate (cAMP) and calcium, or signaling molecules. Behaviors of other target proteins are also altered. May also interact with inositol phospholipids, which are significant in cell signaling, and molecules involved in the inositol-phospholipid transduction pathway. A G-protein-linked receptor activates the enzyme phosphoinositide-specific phospholipase, which in turn generates two intracellular messengers: (1) inositol triphosphate (IP ₃) releases Ca ⁺⁺ , and (2) diacylglycerol remains in the plasma membrane and activates protein kinase C. Protein kinase C further activates various cell proteins. Several different plasma membrane receptors are known to use the inositol-phospholipid transduction pathway.

Data from Alberts B et al: *Molecular biology of the cell*, ed 5, New York, 2008, Garland.

Signal Transduction

Signal transduction involves incoming signals or instructions from extracellular chemical messengers (ligands) that are conveyed to the cell's interior for execution. Cells respond to external stimuli by activating a variety of **signal transduction pathways**, which are communication pathways, or signaling cascades (Fig. 1.22). Signals are passed between cells when a particular type of molecule is produced by one cell—the **signaling cell**—and received by another—the **target cell**—by means of a **receptor protein** that recognizes and responds specifically to the signal molecule (Fig. 1.22, A and B). In turn, the signaling molecules activate a path of intracellular protein kinases that results in responses, such as grow and divide, survive, or differentiate (Fig. 1.22, C and D). If deprived of appropriate signals, most cells undergo a form of cell suicide known as *programmed cell death*, or *apoptosis*.

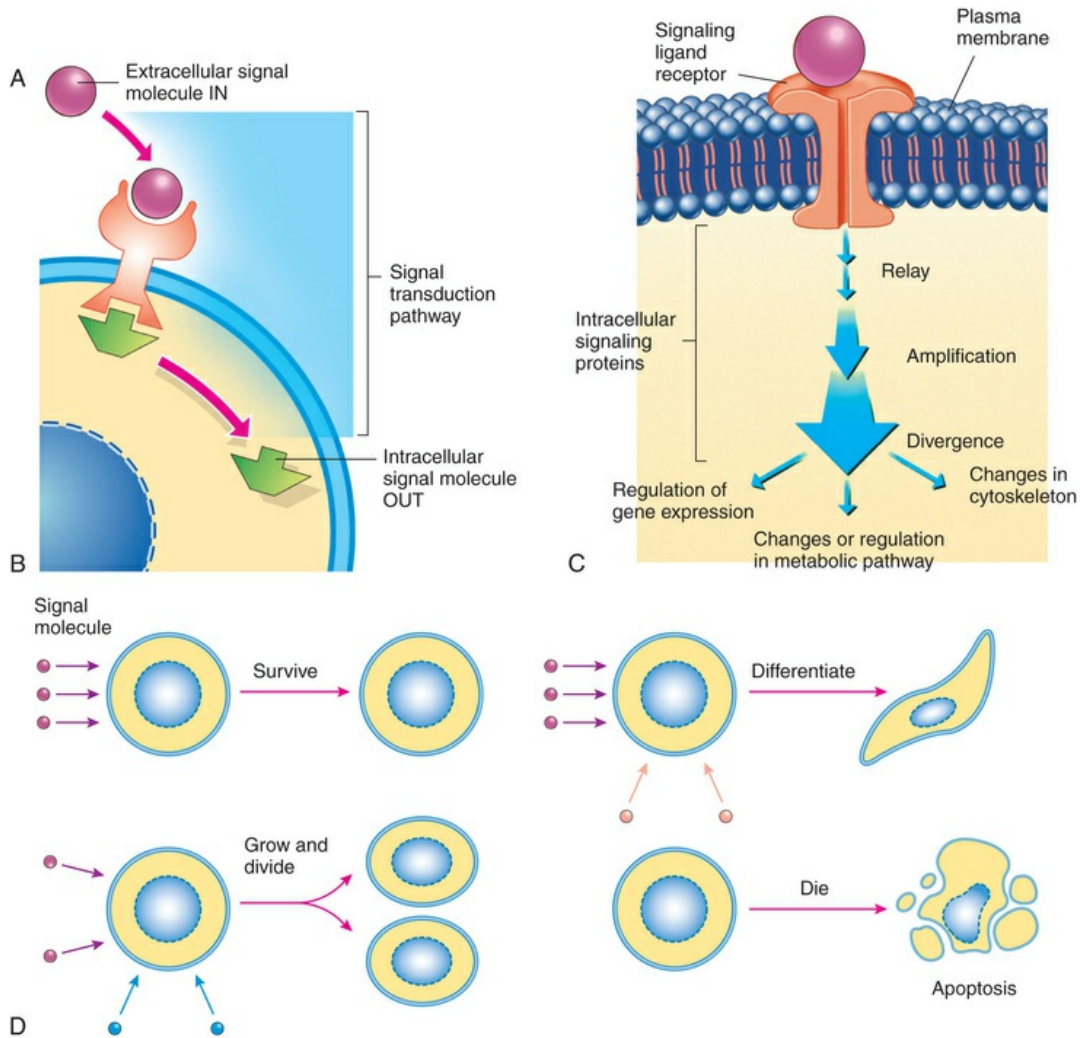

FIGURE 1.22 Schematic of a Signal Transduction Pathway. Like a telephone receiver that converts an electrical signal into a sound signal, a cell converts an extracellular signal (A) into an intracellular signal. B and C, An extracellular signal molecule (ligand) binds to a receptor protein located on the plasma membrane, where it is transduced into an intracellular signal. This process initiates a signaling cascade that relays the signal into the cell interior, amplifying and distributing it en route. Amplification is often achieved by stimulating enzymes. Steps in the cascade can be modulated by other events in the cell. D, Different cell behaviors rely on multiple extracellular signals.

Signal transduction pathways, or relay chains, of intercellular signaling molecules have several important functions (see Fig. 1.22):

1. They physically *transfer* the signal from the place at which it is received to some other part of the cell where the response is expected.

2. They *amplify* the signal received, making it stronger; this is caused by a multiplying effect in the pathways; for example, binding of one ligand molecule to a receptor activates a number of adenylyl cyclase molecules.
3. They *distribute* the signal so that it influences several processes in parallel; at any step in the pathway, the signal can *diverge* and be relayed to several different intracellular targets, creating branches in the flow and causing a complex response (see [Fig. 1.22](#)).
4. Last, the signal can be *modulated* by other interfering factors prevailing inside or outside the cell.

Two general responses from binding of the extracellular signaling messenger (i.e., ligand), or **first messenger**, to the membrane receptors occur: (1) opening or closing specific channels in the membrane to regulate the movement of ions into or out of the cell, and (2) transferring the signal to an intracellular messenger, or **second messenger**, which in turn triggers a cascade of biochemical events within the cell.

Extracellular Messengers and Channel Regulation

Membrane channels, or “gates,” can open and close depending on the circumstances of the first messenger. Opening and closing occur because of conformational changes (shaping) of the proteins that form the channels—blocking the channel (closing) or permitting passage through it (opening). Channel opening and closing can be initiated in one of three ways: (1) by binding of a ligand to a specific membrane receptor that is closely associated with the channel (for example, G proteins); (2) by making changes in the electrical current in the plasma membrane, altering the flow of Na^+ and K^+ ; and (3) by stretching or other mechanical deformation of the channel. [Fig. 1.23](#) summarizes ways by which extracellular messengers regulate channel function for the other two methods of controlling channels.

FIGURE 1.23 How Extracellular Messengers Regulate Channel Function. Binding of an extracellular messenger to a dual receptor/channel brings about a quick opening or closing of ion channels, such as Na^+ or K^+ channels, which generate electrical impulses (1). A transient opening of membrane Ca^{++} channels occurs when binding of an extracellular messenger to a receptor activates a G-protein intermediary, which alters a nearby ion channel, such as a Ca^{++} channel (2). A transient opening of Ca^{++} channels also occurs indirectly in response to electrical impulses produced by extracellular messenger-induced changes in Na^+ and K^+ channels (3). Release of Ca^{++} from intracellular stores results when Ca^{++} channels in organelles open in response to electrical impulses (4). An increase in cytosolic Ca^{++} concentration arising from pathways 2, 3, or 4 causes a change in the shape and function of specific intracellular proteins to produce the desired cellular response. *ECF*, Extracellular fluid; *GTP*, guanosine triphosphate; *ICF*, intracellular fluid. (Redrawn with permission from Sherwood L: *Human physiology*, ed 3, ©1997 Brooks/Cole, a part of Cengage Learning, Inc. Reproduced by permission from www.cengage.com/permissions.)

Second Messengers

Many ligands cannot enter their target cells to cause the desired intracellular response. Instead, the first messengers, or ligands, issue orders by binding with receptors on the surface membrane, triggering a “pass it on” signal. Second messengers are generated in large numbers when the membrane-bound enzyme is activated, and they then rapidly diffuse away from their source, broadcasting the signal throughout the cell (Fig. 1.24). Remember, most cell surface receptor proteins belong to one of three large classes: ion channel–linked receptors, G-protein–linked receptors, or enzyme-linked receptors.

FIGURE 1.24 Extracellular Messenger and Activation of the cAMP Second-Messenger System. The first messenger, or binding of an extracellular chemical messenger to a surface membrane receptor, activates the membrane-bound enzyme adenylyl cyclase by means of a G-protein intermediary (1), which in turn converts intracellular ATP into cAMP (2). cAMP is an intracellular second messenger, triggering the cellular response by activating the cAMP-dependent protein kinase (3), which in turn phosphorylates (4), and therefore modifies (5) a specific intracellular protein. The altered protein then directs the cellular response dictated by

the extracellular messenger. *ADP*, Adenosine diphosphate; *AMP*, adenosine monophosphate; *ATP*, adenosine triphosphate; *ECF*, extracellular fluid; *ICF*, intracellular fluid. (Redrawn with permission from Sherwood L: *Human physiology*, ed 3, 1997, Brooks/Cole, a part of Cengage Learning, Inc. Reproduced by permission from www.cengage.com/permissions.)

The two major second-messenger pathways are **cyclic adenosine monophosphate (cyclic AMP, cAMP)** and Ca^{++} . In the cAMP pathway, binding of the ligand to its surface receptor eventually activates the enzyme adenylyl cyclase on the inner surface of the membrane. A membrane-bound “middleman,” a **G protein**, acts as an intermediary between the receptor and adenylyl cyclase. G proteins are named because they are bound to guanine nucleotides — **guanosine triphosphate (GTP)** or **guanosine diphosphate (GDP)**. An unactivated G protein consists of a complex of alpha (α), beta (β), and gamma (γ) subunits, with a GDP molecule bound to the α subunit. The cAMP pathway with G proteins is summarized in [Fig. 1.24](#).

Instead of cAMP, some cells use Ca^{++} as a second messenger. In this pathway, binding of the first messenger to the surface receptor eventually leads, by means of G proteins, to activation of the enzyme phospholipase C, an enzyme protein effector (an ion channel for an enzyme) that is bound to the inner side of the membrane. [Fig. 1.25](#) summarizes the Ca^{++} second-messenger pathway. The cAMP and Ca^{++} pathways frequently overlap in triggering a specific cellular response. For example, cAMP and Ca^{++} can influence each other. Calcium-activated calmodulin can regulate adenylyl cyclase and thus influence cAMP; conversely, cAMP-dependent kinase may phosphorylate and thereby change the activity of Ca^{++} channels or carriers. In some instances, both Ca^{++} and cAMP regulate the same intracellular protein. In a few cells, **cyclic guanosine monophosphate (cyclic GMP, cGMP)** serves as a second messenger similar to the cAMP pathway. For example, cGMP is the signal transduction pathway involved in vision. Some cellular responses mediated by cAMP and phospholipase C are summarized in [Table 1.3](#). Major types of receptors and signal transduction pathways are contained in [Table 1.4](#).

FIGURE 1.25 Extracellular Messenger and Activation of the Calcium Second-Messenger System. Binding of an extracellular messenger to a membrane receptor activates the membrane-bound enzyme phospholipase C by means of a G-protein intermediary (1). Phospholipase C converts phosphatidylinositol biphosphate (*PIP₂*) into diacylglycerol (*DAG*) and

inositol triphosphate (IP_3) (2). IP_3 then mobilizes Ca^{++} stored within organelles (3). Ca^{++} , as a second messenger, activates calmodulin (4), causing a change in the shape and function of a specific intracellular protein to produce the cellular response (5). *ECF*, Extracellular fluid; *ICF*, intracellular fluid. (Redrawn with permission from Sherwood L: *Human physiology*, ed 3, 1997, Brooks/Cole, a part of Cengage Learning, Inc. Reproduced by permission from www.cengage.com/permissions.)

TABLE 1.3

HORMONE-INDUCED CELL RESPONSES MEDIATED BY cAMP

SIGNALING LIGANDS	TARGET TISSUE	MAJOR RESPONSE
Epinephrine	Heart	Increase in heart rate and force of contraction
Epinephrine, ACTH	Muscle	Breakdown of glycogen
Glucagon	Fat	Breakdown of fat
ACTH	Adrenal gland	Secretion of cortisol
Antidiuretic hormone (vasopressin)	Kidney	Increase in retention of water; promotion of fluid balance
Acetylcholine	Pancreas; smooth muscle	Secretion of amylase; contraction
Antigen	Mast cells	Secretion of histamine
Thrombin	Blood platelets	Secretion of serotonin and platelet-derived growth factor; aggregation of platelets

ACTH, Adrenocorticotrophic hormone; *cAMP*, cyclic adenosine monophosphate.

TABLE 1.4

MAJOR TYPES OF RECEPTORS AND SIGNALING TRANSDUCTION PATHWAYS

RECEPTOR AND SIGNALING PATHWAY	LIGANDS
Receptors with Intrinsic Tyrosine Kinase Activity	
PI3 kinase pathway, MAP-kinase pathway, IP_3 pathway	Signaling ligands include most growth factors (EGF, TGF- α , HGF, PDGF, VEGF, FGF), stem cell factor, insulin
Receptors Lacking Intrinsic Tyrosine Kinase Activity	
JAK/STAT pathway	Several cytokines including IL-2, IL-3, and others; interferons α , β , and γ ; erythropoietin; G-CSF; growth

	hormone; and prolactin
G-Protein–Coupled Receptors	
cAMP pathway	ADH, serotonin, histamine, epinephrine, norepinephrine, calcitonin, glucagon, parathyroid hormone, corticotropin, rhodopsin, and many drugs
Steroid Hormone Receptors	
Includes steroid hormone receptors as well as a group called peroxisome proliferator–activated receptors (PPARs)	Many steroid hormones, thyroid hormone, vitamin D, and retinoids

ADH, Antidiuretic hormone; *cAMP*, cyclic adenosine monophosphate; *EGF*, epidermal growth factor; *FGF*, fibroblast growth factor; *G-CSF*, granulocyte colony–stimulating factor; *HGF*, hepatocyte growth factor; IL-2, IL-3, interleukin-2 and interleukin-3; IP_3 , inositol triphosphate; *JAK/STAT*, Janus kinase-signal transducers and activators of transcription; *MAP-kinase*, mitogen-activated protein kinase; *PI3*, phosphatidylinositol-4,5-bisphosphate 3-kinase; *PDGF*, platelet-derived growth factor; *TGF- α* , transforming growth factor-alpha; *VEGF*, vascular endothelial growth factor.

A large number of human disorders involve problematic signaling in cells. Cancer, for example, results from genetic mutations leading to the overactivity of proteins in signal relaying pathways that normally induce the cells to divide. Affected proteins cause cells to behave as if other cells were constantly telling them to reproduce, even when no such orders were sent. Signal blockers are already in use against tumors.

Cellular Metabolism

All the chemical tasks of maintaining essential cellular functions are referred to as **cellular metabolism**. The energy-using process of metabolism is called **anabolism** (*ana* = upward), and the energy-releasing process is known as **catabolism** (*cata* = downward). Metabolism provides the cell with the energy it needs to synthesize (produce) cellular structures.

Dietary proteins, fats, and starches are hydrolyzed in the intestinal tract into amino acids, fatty acids, and glucose, respectively. These constituents are then absorbed, circulated, and taken up by the cell,

where they may be used for various vital cellular processes, including the production of ATP. The process by which ATP is produced is one example of a series of reactions called a **metabolic pathway**. A metabolic pathway involves several intermediate steps whose end products are not always detectable. A key feature of cellular metabolism is the directing of biochemical reactions by protein catalysts, or enzymes. Most biochemical reactions in a pathway are catalyzed by a specific enzyme. Each enzyme has a high affinity for a **substrate**—a specific substance that is converted to a product of the reaction.

Role of Adenosine Triphosphate

Best known about ATP is its role as a universal “fuel” *inside* living cells. This fuel or energy drives biologic reactions necessary for cells to function. For a cell to function it must be able to extract and use the chemical energy contained within the structure of organic molecules. When 1 mole (mol) of glucose is metabolically broken down in the presence of oxygen into carbon dioxide (CO₂) and water (H₂O), 686 kilocalories (kcal) of energy are released. In a test tube this energy is released as heat. Because a cell cannot transform heat into work, chemical energy, rather than heat, is created by metabolism. The chemical energy lost by one molecule is transferred to the chemical structure of another molecule by an energy-carrying or energy-transferring molecule, such as ATP. The energy stored in ATP can be used in a variety of energy-requiring reactions and in the process is generally converted to adenosine diphosphate (ADP) and inorganic phosphate (Pi). The energy available as a result of this reaction is about 7 kcal/mol of ATP. In addition to its use in synthesis (anabolism) of organic molecules, ATP is used by the cell for muscle contraction and active transport of molecules across cellular membranes. The function of ATP is not only to *store* energy but also to *transfer* it from one molecule to another. Energy is stored by molecules of carbohydrate, lipid, and protein, which, when catabolized, transfer energy to ATP.

Food and Production of Cellular Energy

The process of catabolism of the proteins, lipids, and polysaccharides found in food can be divided into the following three phases (Fig. 1.26).

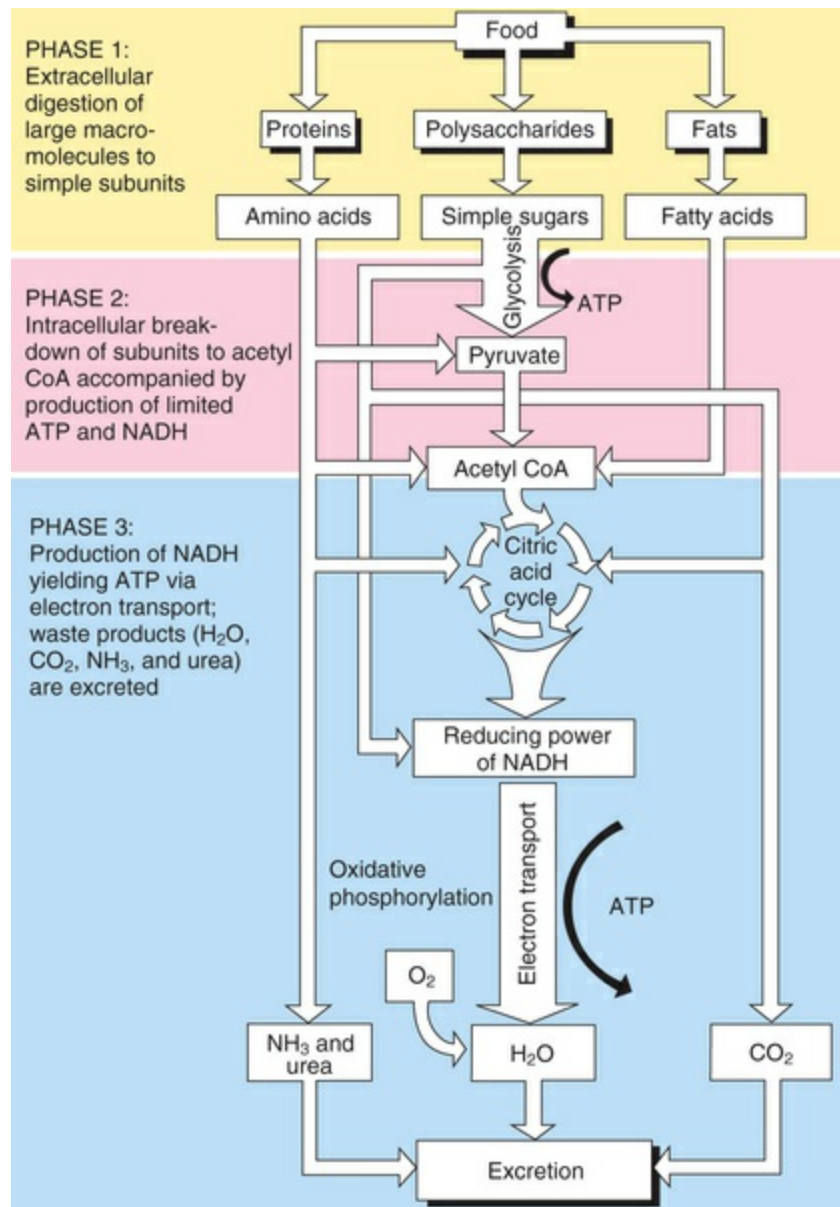

FIGURE 1.26 Three Phases of Catabolism, Which Lead from Food to Waste Products. These reactions produce adenosine triphosphate (ATP), which is used to drive other processes in the cell. CoA, Coenzyme A; NADH, nicotinamide adenine dinucleotide.

*Phase 1: **Digestion.*** Large molecules are broken down into their smaller subunits—proteins into amino acids, polysaccharides into simple sugars, and fats into fatty acids and glycerol. These processes occur outside the cell by the action of secreted enzymes.

*Phase 2: **Glycolysis and oxidation.*** The small molecules enter cells and are further broken down in the cytoplasm. Most of the sugars are converted into pyruvate. Pyruvate then enters mitochondria and is converted to the acetyl groups of acetyl coenzyme A (acetyl CoA). Acetyl CoA, like ATP, releases energy when it is hydrolyzed. The most important part of phase 2 is the lysis (splitting) of glucose, known as glycolysis (Fig. 1.27). Glycolysis produces a net of two molecules of ATP per glucose molecule through the process of oxidation, or the removal and transfer of a pair of electrons. This process, often called **oxidative cellular metabolism**, involves 10 biochemical reactions. In reactions 1 through 5, glucose is converted to two, three-carbon aldehyde compounds (glyceraldehyde-3-phosphate [G3P]), which require energy in the form of ATP. The next five reactions convert G3P molecules into pyruvate molecules and generate four molecules of ATP for each two molecules of G3P. In addition, two molecules of nicotinamide adenine dinucleotide (NAD) are further oxidized to produce four more molecules of ATP. After subtracting two molecules of ATP to drive the reactions, the net yield is six ATP molecules for each molecule of glucose.

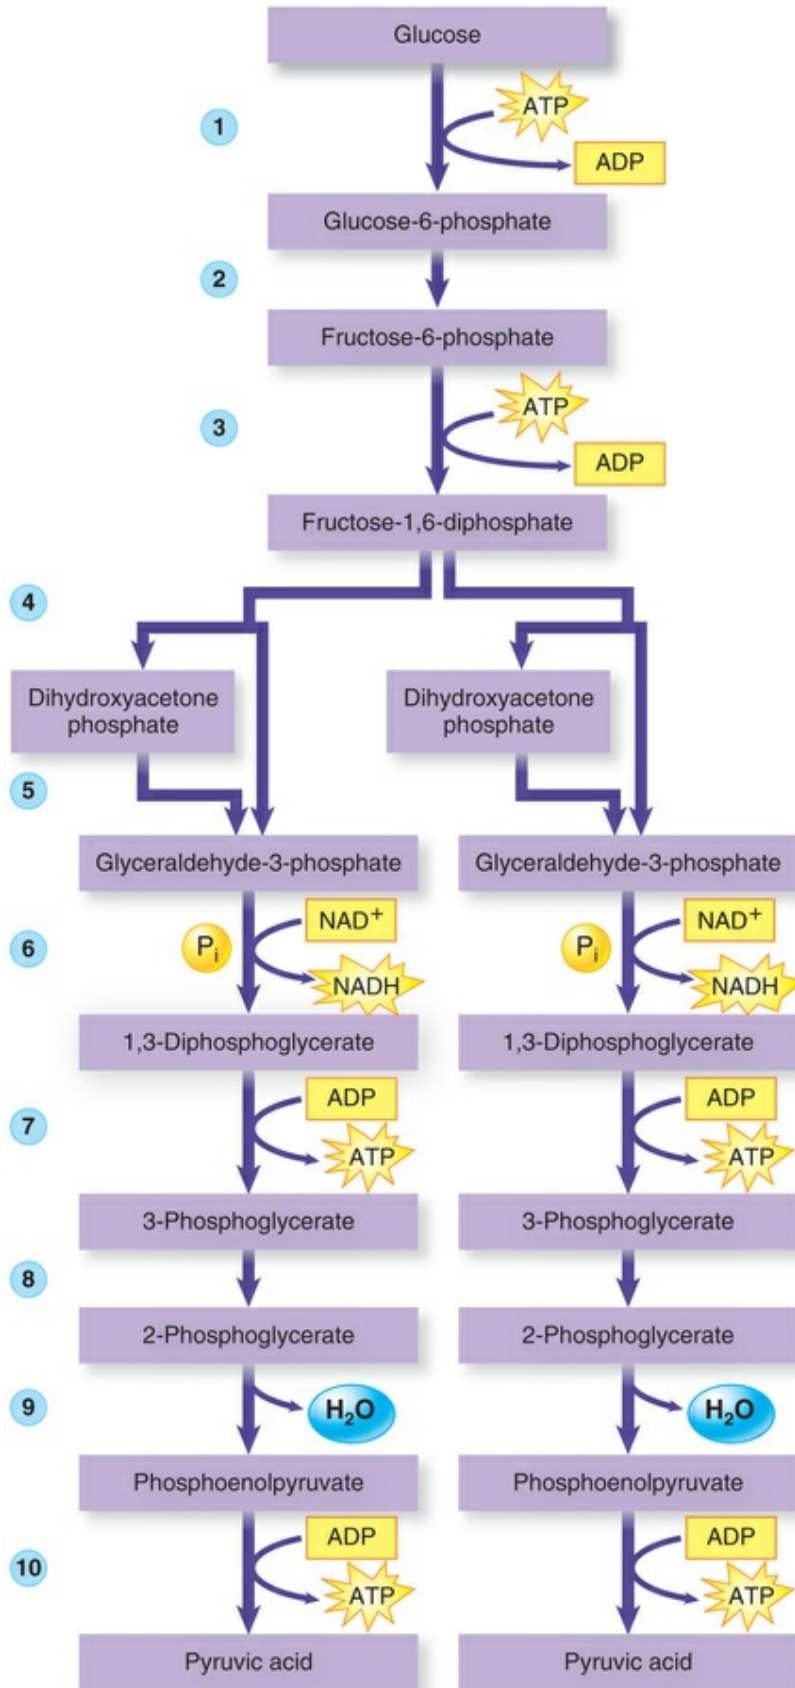

FIGURE 1.27 Glycolysis. Each of the numbered reactions is catalyzed by a different enzyme. At step 4, a six-carbon sugar is broken down to give two, three-carbon sugars, so that the number of molecules at every step after this is doubled. Reactions 5 and 6 are the reactions responsible for the net synthesis of adenosine triphosphate (*ATP*) and reduced nicotinamide adenine dinucleotide (*NADH*) molecules. *ADP*, adenosine diphosphate; *P_i*, three phosphate groups. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

Phase 3: Citric acid cycle (Krebs cycle, tricarboxylic acid cycle).

Most of the ATP is generated during this final phase. It begins with the citric acid cycle and ends with oxidative phosphorylation. About two thirds of the total oxidation of carbon compounds in most cells is accomplished during this phase. The major end products are carbon dioxide (CO_2) and two dinucleotides—reduced nicotinamide adenine dinucleotide (*NADH*) and the reduced form of flavin adenine dinucleotide (*FADH₂*)—which transfer their electrons into the electron-transport chain.

Oxidative Phosphorylation

Oxidative phosphorylation occurs in the mitochondria and is the mechanism by which the energy produced from carbohydrates, fats, and proteins is transferred to ATP. During the breakdown (catabolism) of foods, many of the reactions involve the removal of electrons from various intermediates. These reactions generally require a coenzyme (a nonprotein carrier molecule), such as nicotinamide adenine dinucleotide (*NAD*), to transfer the electrons and thus are called **transfer reactions**.

Molecules of *NAD* and flavin adenine dinucleotide (*FAD*) transfer electrons they have gained from the oxidation of substrates to molecular oxygen, O_2 . The electrons from reduced *NAD* and *FAD*, *NADH* and *FADH₂*, respectively, are transferred to a series of carrier molecules (the **electron-transport chain**) on the inner surfaces of the mitochondria with the release of hydrogen ions. Some carrier molecules are a group of brightly colored iron-containing proteins

known as **cytochromes** that accept a pair of electrons. These electrons eventually combine with molecular oxygen. If oxygen is not available to the electron-transport chain, ATP will not be formed by the mitochondria. Instead, an anaerobic (without oxygen) metabolic pathway synthesizes ATP. This process, called **substrate phosphorylation**, or **anaerobic glycolysis**, is linked to the breakdown (glycolysis) of carbohydrate (Fig. 1.28).

FIGURE 1.28 What Happens to Pyruvate, the Product of Glycolysis? In the presence of oxygen, pyruvate is oxidized to acetyl coenzyme A (*acetyl CoA*) and enters the citric acid cycle. In the absence of oxygen, pyruvate instead is reduced, accepting the electrons extracted during glycolysis and carried by reduced nicotinamide adenine dinucleotide (*NADH*). When pyruvate is reduced directly, as it is in muscle, the product is lactic acid. When CO₂ is first removed from pyruvate and the remainder reduced, as it is in yeasts, the product is ethanol.

Because glycolysis occurs in the cytoplasm of the cell, it provides energy for cells that lack mitochondria. However, as noted, glycolysis also provides energy to the cell when oxygen delivery is insufficient or delayed (e.g., with strenuous exercise). The reactions in anaerobic glycolysis involve the conversion of glucose to pyruvic acid (pyruvate) with the simultaneous production of ATP. With the

glycolysis of one molecule of glucose, two ATP molecules and two molecules of pyruvate are liberated. If oxygen is present, the two molecules of pyruvate move into the mitochondria, where they enter the citric acid cycle.

If oxygen is absent, pyruvate is converted to lactic acid, which is released into the extracellular fluid (see Fig. 1.28). Elevated lactate level is indicative of tissue hypoxia or low oxygen concentration. The conversion of pyruvic acid to lactic acid is reversible; therefore, once oxygen is restored, lactic acid is quickly converted back to either pyruvic acid or glucose. The anaerobic generation of ATP from glucose, through the reactions of glycolysis, is not as efficient as the aerobic generation of ATP. The addition of an oxygen-requiring stage to the catabolic process (stage 3) provides cells with a much more powerful method for extracting energy from food molecules.

Membrane Transport: Cellular Intake and Output

Cell survival and growth depend on the constant exchange of molecules with their environment. Cells continually import nutrients, fluids, and chemical messengers from the extracellular environment and expel metabolites or the products of metabolism and end products of lysosomal digestion. Cells also must regulate ions in their cytosol and organelles. Simple diffusion across the lipid bilayer of the plasma membrane occurs for such important molecules as O_2 and CO_2 . However, the majority of molecule transfer depends on specialized **membrane transport proteins** that span the lipid bilayer and provide private thoroughfares for select molecules.² Membrane transport proteins occur in many forms and are present in all cell membranes.² Transport by membrane transport proteins is sometimes called **mediated transport**. Most of these transport proteins allow selective passage, for example, Na^+ but not K^+ or K^+ but not Na^+ . Each type of cell membrane has its own transport proteins that determine which solute can pass into and out of the cell or organelle.² The two

main classes of membrane transport proteins are *transporters* and *channels*. These transport proteins differ in the type of **solute**—small particles of dissolved substances—they transport. A **transporter** is specific, allowing only those ions that fit the unique binding sites on the protein (Fig. 1.29, A). A transporter undergoes conformational changes to enable membrane transport. A **channel**, when open, forms a pore across the lipid bilayer that allows ions and selective polar organic molecules to diffuse across the membrane (see Fig. 1.29, B). Transport by a channel depends on the size and electrical charge of the molecule. Some channels are controlled by a gate mechanism that determines which solute can move into it. Ion channels are responsible for the electrical excitability of nerve and muscle cells and play a critical role in the membrane potential.

FIGURE 1.29 Inorganic Ions and Small, Polar Organic Molecules Can Cross a Cell Membrane through Either a Transporter or a Channel. (Adapted from Alberts B: *Essential cell biology*, ed 4, New York, 2014, Garland.)

The mechanisms of membrane transport depend on the characteristics of the substance to be transported. In **passive transport**, water and small, electrically uncharged molecules move easily through pores in the plasma membrane's lipid bilayer (see Fig. 1.29). This process occurs naturally through any semipermeable barrier. Molecules will easily flow “downhill” from a region of high concentration to a region of low concentration; this movement is called *passive* because it does not require expenditure of energy or a

driving force. It is driven by osmosis, hydrostatic pressure, and diffusion, all of which depend on the laws of physics and do not require life.

Other molecules are too large to pass through pores or are ligands bound to receptors on the cell's plasma membrane. Some of these molecules are moved into and out of the cell by **active transport**, which requires life, biologic activity, and the cell's expenditure of metabolic energy (see Fig. 1.29). Unlike passive transport, active transport occurs across only living membranes that have to drive the flow “uphill” by coupling it to an energy source. Movement of a solute against its concentration gradient occurs by special types of transporters called *pumps* (see Fig. 1.29). These transporter pumps must harness an energy source to power the transport process. Energy can come from ATP hydrolysis, a transmembrane ion gradient, or sunlight (Fig. 1.30). The best-known is the Na⁺-K⁺-dependent adenosine triphosphatase (ATPase) pump (see Fig. 1.34). It continuously regulates the cell's volume by controlling leaks through pores or protein channels and maintaining the ionic concentration gradients needed for cellular excitation and membrane conductivity. The maintenance of intracellular K⁺ concentrations is required also for enzyme activity, including enzymes involved in protein synthesis. Large molecules (macromolecules), along with fluids, are transported by endocytosis (taking in) and exocytosis (expelling). Receptor-macromolecule complexes enter the cell by means of receptor-mediated endocytosis.

FIGURE 1.30 Pumps Carry Out Active Transport in Three Ways. 1, Coupled pumps link the uphill transport of one solute to the downhill transport of another solute. 2, ATP-driven pumps drive uphill transport from hydrolysis of ATP. 3, Light-driven pumps are mostly found in bacteria and use energy from sunlight to drive uphill transport. (Adapted from Alberts B: *Essential cell biology*, ed 4, New York, 2014, Garland.)

Mediated transport systems can move solute molecules singly or two at a time. Two molecules can be moved simultaneously in one direction (a process called **symport**, for example, sodium-glucose in the digestive tract) or in opposite directions (called **antiport**, for example, the sodium-potassium pump in all cells), or a single molecule can be moved in one direction (called **uniport**, for example, glucose) (Fig. 1.31).

FIGURE 1.31 Mediated Transport. Illustration shows simultaneous movement of a single solute molecule in one direction (*Uniport*), of two different solute molecules in one direction (*Symport*), and of two different solute molecules in opposite directions (*Antiport*).

Electrolytes as Solutes

Body fluids are composed of two types of solutes: **electrolytes**, which are electrically charged and dissociate into constituent **ions** when placed in solution; and nonelectrolytes, such as glucose, urea, and creatinine, which do not dissociate. Electrolytes account for approximately 95% of the solute molecules in body water. Electrolytes exhibit **polarity** by orienting themselves toward the positive or negative pole. Ions with a positive charge are known as **cations** and migrate toward the negative pole, or cathode, if an electrical current is passed through the electrolyte solution. **Anions** carry a negative charge and migrate toward the positive pole, or anode, in the presence of electrical current. Anions and cations are located in both the intracellular fluid (ICF) and the extracellular fluid (ECF) compartments, although the concentration of particular ions varies depending on their location. For example, Na^+ is the predominant extracellular cation, and K^+ is the principal intracellular cation. The difference in ICF and ECF concentrations of these ions is important to the transmission of electrical impulses across the plasma membranes

of nerve and muscle cells (see [Chapter 3](#)).

Electrolytes are measured in milliequivalents per liter (mEq/L) or milligrams per deciliter (mg/dL). Milliequivalents per liter indicate the number of electrical charges per unit volume of fluid. The term *milliequivalent* thus indicates the chemical-combining activity of an ion, which depends on the electrical charge, or valence, of its ions. In abbreviations, valence is indicated by the number of plus or minus signs. Monovalent ions, or ions with one charge, include sodium (Na⁺), chloride (Cl⁻), and potassium (K⁺). Divalent ions, which have two charges, include calcium (Ca⁺⁺) and magnesium (Mg⁺⁺). One milliequivalent of any cation can combine chemically with 1 mEq of any anion; one monovalent anion will combine with one monovalent cation. Divalent ions combine more strongly than monovalent ions. To maintain electrochemical balance, one divalent ion will combine with two monovalent ions (e.g., Ca⁺⁺ + 2 Cl⁻ = CaCl₂).

Passive Transport: Diffusion, Filtration, and Osmosis

Diffusion.

Diffusion is the movement of a solute molecule from an area of greater solute concentration to an area of lesser solute concentration. This difference in concentration is known as a **concentration gradient**. Particles in a solution move randomly in any direction. If the concentration of particles in one part of the solution is greater than that in another part, the particles distribute themselves evenly throughout the solution. According to the same principle, if the concentration of particles is greater on one side of a *permeable membrane* than on the other side, the particles diffuse spontaneously from the area of greater concentration to the area of lesser concentration until equilibrium is reached. The higher the concentration on one side, the greater the diffusion rate. The overall effect of diffusion is the passive movement of particles “down” a concentration gradient, that is, from an area of high concentration to an area of low concentration.

The diffusion rate is influenced by differences of electrical potential across the membrane. Because the pores in the lipid bilayer are often linked with Ca^{++} , other cations (e.g., Na^+ and K^+) diffuse slowly because they are repelled by positive charges in the pores.

The rate of diffusion of a substance depends also on its size (diffusion coefficient) and its lipid solubility (Fig. 1.32). Usually the smaller the molecule and the more soluble it is in oil, the more hydrophobic or nonpolar it is and the more rapidly it will diffuse across the bilayer. Oxygen, carbon dioxide, and the steroid hormones are all examples of nonpolar molecules. Water-soluble substances, such as sugars and inorganic ions, diffuse very slowly, whereas uncharged lipophilic (“lipid-loving”) molecules, such as fatty acids and steroids, diffuse rapidly. Ions and other polar molecules generally diffuse across cellular membranes more slowly than lipid-soluble substances.

FIGURE 1.32 Passive Diffusion of Solute Molecules Across the Plasma Membrane. Oxygen, nitrogen, water, urea, glycerol, and carbon dioxide can diffuse readily down the concentration gradient. Macromolecules are too

large to diffuse through pores in the plasma membrane. Ions may be repelled if the pores contain substances with identical charges. If the pores are lined with cations, for example, other cations will have difficulty diffusing because the positive charges will repel one another; diffusion can still occur, but it occurs more slowly.

Water readily diffuses through biologic membranes because water molecules are small and uncharged. Although the mechanism is not known with certainty, the dipolar structure of water allows it to cross rapidly through the regions of the bilayer containing the lipid head groups. Lipid head groups constitute the two outer regions of the lipid bilayer.

Filtration: Hydrostatic pressure.

Filtration is the movement of water and solutes through a membrane because of a greater pushing pressure (force) on one side of the membrane than on the other side. **Hydrostatic pressure** is the mechanical force of water pushing against cellular membranes (Fig. 1.33, 1). In the vascular system, hydrostatic pressure is the *blood pressure* generated in vessels by the contraction of the heart. Blood reaching the capillary bed has a hydrostatic pressure of 25 to 30 mmHg, which is sufficient force to push water across the thin capillary membranes into the interstitial space. Hydrostatic pressure is partially balanced by osmotic pressure, whereby water moving *out* of the capillaries is partially balanced by osmotic forces that tend to *pull* water *into* the capillaries. Water that is not osmotically attracted back into the capillaries moves into the lymph system.

FIGURE 1.33 Hydrostatic Pressure and Oncotic Pressure in Plasma. 1, Hydrostatic pressure in plasma. 2, Oncotic pressure exerted by proteins in the plasma usually tends to *pull* water into the circulatory system. 3, Individuals with low protein levels (e.g., starvation) are unable to maintain a normal oncotic pressure; therefore, water is not reabsorbed into the circulation and, instead, causes body edema.

Osmosis.

Osmosis is the movement of water “down” a concentration gradient, that is, across a semipermeable membrane from a region of higher water concentration to a region of lower water concentration. For osmosis to occur, the membrane must be more permeable to water than to solutes and the concentration of solutes must be greater so that water moves more easily. Osmosis is directly related to both hydrostatic pressure and solute concentration but *not* to particle size or weight. For example, particles of the plasma protein albumin are small but more concentrated in body fluids than the larger and heavier particles of globulin. Therefore, albumin exerts a greater osmotic force than globulin.

Osmolality controls the distribution and movement of water between body compartments. The terms *osmolality* and *osmolarity* are often used interchangeably in reference to osmotic activity, but they define different measurements. **Osmolality** is a measure of the number of milliosmoles per kilogram (mOsm/kg) of water, or the concentration of molecules per *weight* of water. **Osmolarity** is a measure of the number of milliosmoles per liter (mOsm/L) of solution, or the concentration of molecules per *volume* of solution. When solute is added to water, the volume is expanded and includes the original liter of water plus the volume occupied by the solute particles. In measuring osmolarity, the volume of water is therefore reduced by an amount equal to the volume of added solute (also see [Chapter 3](#)).

In solutions that contain only dissociable substances, such as Na^+ and Cl^- , the difference between the two measurements is negligible. In considering all the different solutes in plasma (e.g., proteins, glucose, lipids), however, the difference between osmolality and osmolarity becomes more significant. In plasma less of the plasma weight is water, and the overall concentration of particles is therefore greater. The osmolality will be greater than the osmolarity because of the smaller proportion of water. Osmolality is thus the preferred measure of osmotic activity in clinical assessment of individuals.

The normal osmolality of body fluids is 280 to 294 mOsm/kg. The osmolality of intracellular and extracellular fluid tends to equalize and therefore provides a measure of body fluid concentration and thus the body's hydration status. Hydration is also affected by hydrostatic pressure because the movement of water by osmosis can be opposed by an equal amount of hydrostatic pressure. The amount of hydrostatic pressure required to oppose the osmotic movement of water is called the **osmotic pressure** of the solution. Factors that determine osmotic pressure are the type and thickness of the plasma membrane, the size of the molecules, the concentration of molecules or the concentration gradient, and the solubility of molecules within the membrane. Examples of movement of water in relation to hydrostatic and osmotic forces occur in the glomerulus of the kidney and in the capillaries of the microcirculation.

Effective osmolality is sustained osmotic activity and depends on the concentration of solutes remaining on one side of a permeable membrane. If the solutes penetrate the membrane and equilibrate with the solution on the other side of the membrane, the osmotic effect will be diminished or lost. For example, urea is a small solute that readily diffuses across cellular membranes. Solutions containing urea rapidly lose their effective osmolality because they rapidly equilibrate. Solutes too large to pass through the membrane thus sustain an effective osmolality, meaning that they enhance osmotic activity. Plasma proteins are examples of molecules that provide effective osmolality because they normally do not cross cellular membranes.

Plasma proteins also influence osmolality because they have a negative charge (see [Fig. 1.33](#)). The principle by which the plasma protein charge influences osmolality is known as *Gibbs-Donnan equilibrium*, and it affects the distribution of ions across cellular membranes. Gibbs-Donnan equilibrium occurs when fluid in one compartment contains small, diffusible ions such as Na^+ and Cl^- , together with large, nondiffusible charged particles, such as plasma proteins. Because the body tends to maintain an electrical equilibrium, the nondiffusible protein molecules cause asymmetry in the distribution of small ions. Anions such as Cl^- are thus driven out of the cell or plasma, and cations such as Na^+ are attracted. The protein-containing compartment will maintain a state of electroneutrality, but the osmolality will be higher. The overall osmotic effect of colloids, such as plasma proteins, is called the **oncotic pressure**, or **colloid osmotic pressure**.

Tonicity describes the effective osmolality of a solution. (The terms *osmolality* and *tonicity* may be used interchangeably.) Solutions, then, have relative degrees of tonicity. An **isotonic solution** (or isosmotic solution) has the same osmolality or concentration of particles (285 mOsm/kg) as the ICF or ECF. Diarrhea, for example, is loss of isosmotic fluid from the gastrointestinal tract. As a result, ECF volume decreases but there is no change in ECF osmolarity. Examples of isotonic solutions include 5% dextrose in water and normal (0.9%) saline solution. A **hypotonic solution** has a lower concentration and is

thus more dilute than body fluids. Water is a hypotonic solution. Consequently, water is osmotically pulled into the cells, causing cells to swell or burst. A **hypertonic solution** has a concentration greater than 285 to 294 mOsm/kg. An example of a hypertonic solution is 3% saline solution. Water can be pulled out of the cells by a hypertonic solution, so the cells shrink. The concept of tonicity is important when correcting water and solute imbalances by administering different types of replacement solutions.

Active transport of Na⁺ and K⁺.

The active transport system for Na⁺ and K⁺ is found in virtually all mammalian cells. The Na⁺-K⁺ antiport system (Na⁺ moving out of and K⁺ moving into the cell) uses the direct energy of ATP to move these cations. The transporter protein is an enzyme, adenosine triphosphatase (ATPase). ATPase has a requirement for Na⁺, K⁺, and Mg⁺⁺ ions. The concentration of ATPase in plasma membranes is directly related to Na⁺-K⁺ transport activity. Approximately 60% to 70% of the ATP synthesized by cells, especially muscle and nerve cells, is used to maintain the Na⁺-K⁺ transport system. Excitable tissues (e.g., muscle and nerve tissues) have a high concentration of Na⁺-K⁺ ATPase, as do other tissues that transport significant amounts of Na⁺, for example, kidneys and salivary glands. For every ATP molecule hydrolyzed, three molecules of Na⁺ are transported out of the cell, whereas only two molecules of K⁺ move into the cell. The process leads to an electrical potential and is called *electrogenic*, with the inside of the cell more negative than the outside. The exact mechanism for transport of Na⁺ and K⁺ across the membrane is uncertain. One proposal is that ATPase induces the transporter protein to undergo several conformational changes, causing Na⁺ and K⁺ to move short distances (Fig. 1.34). The conformational change creates a lowering affinity for Na⁺ and K⁺ to the ATPase transporter, resulting in the release of the cations after transport.

FIGURE 1.34 Active Transport and the Sodium-Potassium Pump. 1, Three Na^+ ions bind to sodium-binding sites on the carrier's inner face. 2, At the same time, an energy-containing adenosine triphosphate (ATP) molecule produced by the cell's mitochondria binds to the carrier. The ATP dissociates, transferring its stored energy to the carrier. 3 and 4, The carrier then changes shape, releases the three Na^+ ions to the outside of the cell, and attracts two potassium (K^+) ions to its potassium-binding sites. 5, The carrier then returns to its original shape, releasing the two K^+ ions and the remnant of the ATP molecule to the inside of the cell. The carrier is now ready for another pumping cycle.

The sarcoplasmic reticulum of heart muscle and skeletal muscle has an ATP-dependent Ca^{++} active transport system that regulates the Ca^{++} levels in the cell's cytoplasm, which in turn regulates muscle contraction and relaxation cycles. The Ca^{++} transport system depends on ATPase activity and is similar to that of $\text{Na}^+\text{-K}^+$ ATPase.

The transport of sugars and amino acids across the plasma membrane depends on the simultaneous movement (symport) of Na^+ or Na^+ -dependent transport (see Fig. 1.31). Na^+ -dependent symport occurs primarily in the plasma membrane of epithelial cells of the kidney tubules and intestines. The transport of glucose is not directly dependent on the hydrolysis of ATP; however, the Na^+ gradient is ATP dependent, and thus ATP is indirectly involved in glucose transport.

The epithelial cells that line the intestines depend on Na^+ to transport various amino acids. Similarly, the uptake of Cl^- by the small intestine depends on Na^+ symport and antiport mechanisms for the secretion of Ca^{++} from the cell.

Table 1.5 summarizes the major mechanisms of transport through pores and protein transporters in the plasma membranes. Many disease states are caused or manifested by loss of these membrane transport systems.

TABLE 1.5

MAJOR TRANSPORT SYSTEMS IN MAMMALIAN CELLS*

SUBSTANCE TRANSPORTED	MECHANISM OF TRANSPORT	TISSUES
Sugars		
Glucose	Passive: protein channel Active: symport with Na^+	Most tissues Small intestines and renal tubular cells
Fructose	Passive	Intestines and liver
Amino Acids		
Amino acid-specific transporters	Coupled channels	Intestines, kidney, and liver
All amino acids except proline	Active: symport with Na^+	Liver
Specific amino acids	Active: group translocation	Small intestine

	Passive	
Other Organic Molecules		
Cholic acid, deoxycholic acid, and taurocholic acid	Active: symport with Na ⁺	Intestines
Organic anions (e.g., malate, α-ketoglutarate, glutamate)	Antiport with counter-organic anion	Mitochondria of liver cells
ATP-ADP	Antiport transport of nucleotides; can be active	Mitochondria of liver cells
Inorganic Ions		
Na ⁺	Passive	Distal renal tubular cells
Na ⁺ /H ⁺	Active: antiport, proton pump	Proximal renal tubular cells and small intestines
Na ⁺ /K ⁺	Active: ATP driven, protein channel	Plasma membrane of most cells
Ca ⁺⁺	Active: ATP driven, antiport with Na ⁺	All cells, antiporter in red cells
H ⁺ /K ⁺	Active	Parietal cells of gastric cells secreting H ⁺
Cl ⁻ /HCO ₃ ⁻ (perhaps other anions)	Mediated: antiport (anion transporter-band 3 protein)	Erythrocytes and many other cells
Water	Osmosis passive	All tissues

* **NOTE:** The known transport systems are listed here; others have been proposed. Most transport systems have been studied in only a few tissues, and their sites of activity may be more limited than indicated.

ADP, Adenosine diphosphate; *ATP*, adenosine triphosphate.

Data from Alberts B et al: *Molecular biology of the cell*, ed 5, New York, 2008, Garland; Devlin TM, editor: *Textbook of biochemistry: with clinical correlations*, ed 3, New York, 1992, Wiley; Raven PH, Johnson GB: *Understanding biology*, ed 3, Dubuque, IA, 1995, Brown.

Transport by Vesicle Formation

Endocytosis

Endocytosis is a cellular internalizing process where a section of the plasma membrane enfolds substances from outside the cell, invaginates (folds inward), and separates from the plasma membrane, forming an **endocytic vesicle** that moves into the inside of the cell

(Fig. 1.35, A). Endocytosis mediates cellular uptake of receptor-ligand complexes, nutrients and their carriers, extracellular matrix components, bacteria, viruses, cell debris, and sometimes even other cells.² Endocytosis regulates the composition of the plasma membrane in response to changes in the extracellular environment, counterbalances exocytosis, and maintains homeostasis.

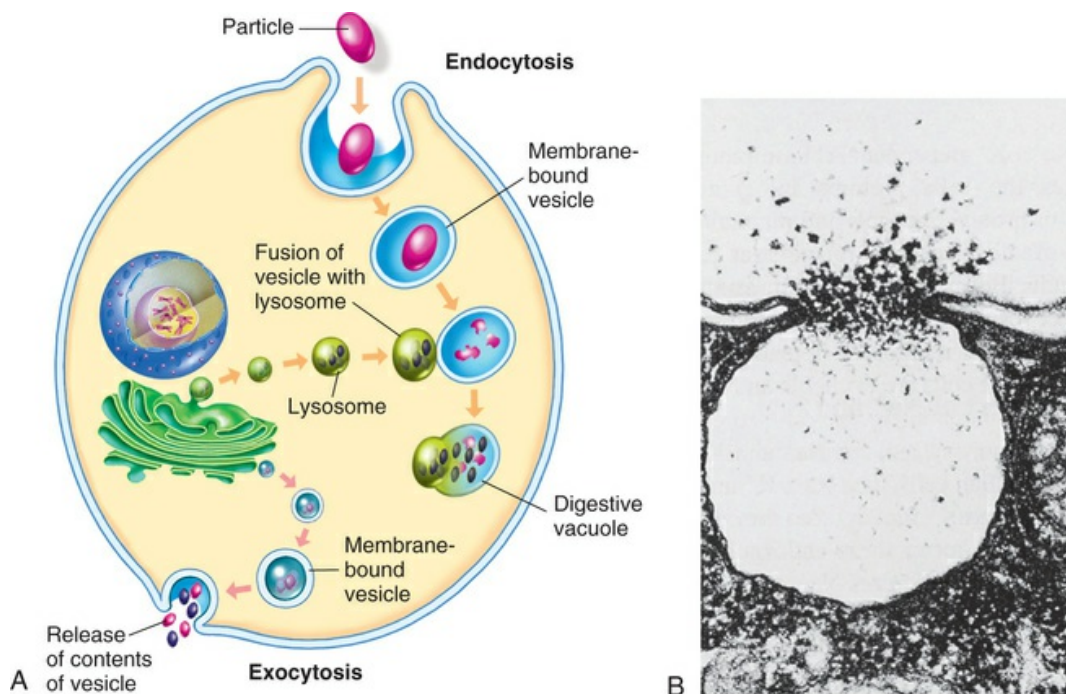

FIGURE 1.35 Endocytosis and Exocytosis. A, Endocytosis and fusion with lysosome and exocytosis. B, Electron micrograph of exocytosis. (B from Raven PH et al: *Biology*, ed 8, New York, 2008, McGraw-Hill.)

Depending on the size of the cargoes and other factors, binding of ligands on the cell surface activates appropriate intracellular mechanisms that then trigger changes in membrane shape to mediate their cell entry (Fig. 1.36). Endocytosis can be subdivided into four different categories: (1) clathrin-mediated endocytosis, (2) caveolae-mediated endocytosis, (3) macropinocytosis, and (4) phagocytosis. Over time, however, these categories may change.

FIGURE 1.36 Multiple Pathways of Endocytosis. The pathways of endocytosis depend on the class of cargo (receptors, ligands, and lipid-associated molecules), the mechanism of vesicle formation (coats, GTPases, and dynamin), and the size of the endocytic vesicle that eventually pinches off into the cytoplasm. **A**, *Clathrin-mediated endocytosis* (CME) uses adaptor proteins that link cargo proteins to the clathrin scaffold, forming the endocytic vesicle. **B**, *Caveolae*, formed by caveolin proteins, are adorned in cholesterol, sphingolipids, and glycolipids that are believed concentrated in membrane microdomains. **C**, During *macropinocytosis* fluid-phase uptake is dependent on actin-driven membrane protrusions that enclose the extracellular fluid and fuse with the plasma membrane. **D**, Some cargoes associate with membrane microdomains that eventually are internalized in a clathrin- and caveolin-independent manner. Different modes of internalization are distinguished by their dependence on dynamin, a membrane-remodeling GTPase. **E**, *Phagocytosis* mediates internalization by membrane protrusions formed around large, ligand-coated molecules. (Adapted from Krauss M, Haucke V: *Rev Physiol Biochem Pharmacol* 161:45–66, 2011.)

Because most cells continually ingest fluid and solutes by **pinocytosis**, the terms *pinocytosis* (cell ingestion of extracellular fluid and its contents and bits of the plasma membrane) and *endocytosis* are often used interchangeably. **Micropinocytosis** is the taking up of specific macromolecules by invagination of the cell membrane, which is then pinched off, forming a small vesicle in the cytoplasm. In micropinocytosis the vesicle containing fluids, solutes, or both, fuses with a lysosome, and lysosomal enzymes digest them for use by the cell. **Macropinocytosis** is when a large fluid-filled vesicle or *macropinosome* is pinched off from the cell membrane and brought into the interior of the cell (gulping rather than sipping). Macropinocytosis

is an important pathway for antigen presentation by specialized antigen presenting cells.¹¹ In **phagocytosis** the large molecular substances are engulfed by the plasma membrane and enter the cell so that they can be isolated and destroyed by lysosomal enzymes. Substances that are not degraded by lysosomes are isolated in residual bodies and released by the cell by exocytosis. Both pinocytosis and phagocytosis require metabolic energy and often involve binding of the substance with plasma membrane receptors before membrane invagination and fusion with lysosomes in the cell.

Clathrin-mediated endocytosis.

Ligand binding to *some* plasma membrane receptors leads to clustering, aggregation, and immobilization of the receptors in specialized areas of the membrane called **coated pits** (Fig. 1.37). The pits, which are coated with a complex of proteins and cytosolic bristle-like structures (or clathrin), deepen and enfold (invaginate), internalizing ligand-receptor complexes and forming clathrin-coated vesicles (CCVs). This internalization process is not completely understood, called **clathrin-mediated endocytosis** (also **receptor-mediated endocytosis**), is rapid and enables the cell to ingest large amounts of specific ligands, for example, low-density lipoprotein, growth factors, and antibodies, without ingesting large volumes of extracellular fluid. After the coated pits pinch off from the plasma membrane, they quickly shed their coat and fuse with an endosome. An **endosome** is a vesicle pinched off from the plasma membrane from which their contents can be recycled to the plasma membrane or sent to lysosomes for digestion (see Fig. 1.37). Additionally, clathrin is required for the internalization of pumps and transporters for ions and small nutrients to maintain homeostasis and synaptic transmission in neurons.¹² The ingested material is processed by lysosomal enzymes inside the cell.

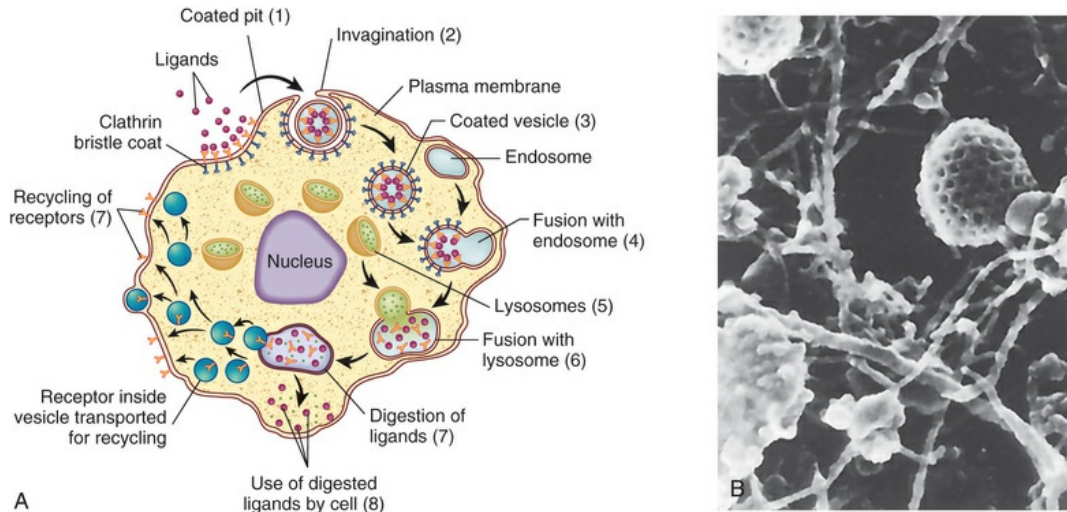

FIGURE 1.37 Ligand Internalization by Means of Receptor-Mediated Endocytosis. A, The ligand attaches to its surface receptor (through the bristle coat or clathrin coat) and, through receptor-mediated endocytosis, enters the cell. The ingested material fuses with a lysosome and is processed by hydrolytic lysosomal enzymes. Processed molecules can then be transferred to other cellular components. B, Electron micrograph of a coated pit showing different sizes of filaments of the cytoskeleton ($\times 82,000$). (B from Erlandsen SL, Magney JE: *Color atlas of histology*, St Louis, 1992, Mosby.)

Caveolae-mediated endocytosis.

The outer surface of the plasma membrane is dimpled with tiny flask-shaped pits (cavelike) called caveolae. Caveolae are also called **microdomains**. Caveolae are cholesterol- and glycosphingolipid-rich microdomains where the protein caveolin is thought to be involved in several processes, including transportation and endothelial cell functions, membrane repair, uptake of various cell surface receptors, protection against lipotoxicity, and mechanotransduction.¹³ Caveolae are present in most mammalian cell types and are abundant in endothelial and smooth muscle cells, adipocytes, and fibroblasts.¹⁴ Caveolae-mediated endocytosis has been implicated in the endocytosis of simian virus 40 (SV40), papillomavirus (wart causing), and cholera. Additionally, evidence is accumulating that these microdomains are important in regulating endothelial cell functions mainly because they compartmentalize various signaling molecules.¹⁴

Clathrin- and caveolin-independent endocytosis.

Some proteins or small molecules enter cells by clathrin- and caveolin-independent pathways (see Fig. 1.36, C and D).¹² These routes are defined and classified by their requirements for dynamin during fission, and the regulatory roles of guanosine triphosphatases (GTPases). The mechanism by which internalization occurs is not known but is thought to be dependent on cargo concentration and membrane curvature.

Much new research in the past decade has shown extracellular vesicles as important mediators of intercellular communication involved in biologic signaling to mediate a diverse number of biologic processes.¹⁴ Extracellular vesicles play a key role in the regulation of normal physiology, such as stem cell number, tissue repair, immune surveillance, and blood coagulation, and in the pathology of many diseases. Extracellular vesicles have been tightly linked to carcinogenesis; the dissemination of viruses such as HIV-1, amyloid- β -derived peptides, and alpha-synuclein (linked to Alzheimer and Parkinson diseases); and the spread of abnormal cell surface prion protein PrP^C.¹⁵

A new advancement in cellular biology is the role of exosomes in understanding the biology of vesicles and their role in disease and therapeutic potential. **Exosomes** are small membrane vesicles of endocytic origin containing lipid, protein, and RNA species in a single biologic unit. Exosomes, secreted by nearly all mammalian cell types, confer messages between cells, proximal and distal, by transporting cargo in the form of proteins, nucleic acids, and lipids¹⁶ (Fig. 1.38). They are present in the intracellular space and in body fluids including plasma, saliva, urine, plural ascites, amniotic fluid, cerebrospinal fluid, colostrum, breast milk, and semen. Importantly, tumor-derived exosomes can prepare a favorable microenvironment at future metastatic sites and mediate nonrandom patterns of metastasis.¹⁷ Investigators have defined a specific group of integrins expressed on tumor-derived exosomes, distinct from tumor cells, which dictate exosome adhesion to specific cell types and ECM molecules in particular organs. Recent data show that the actin cytoskeletal regulatory protein *cortactin* promotes exosome secretion.¹⁸

Thus, exosomes may be important not only to predict metastatic propensity but also to determine organ sites of future metastasis¹⁷ (see Chapter 12).

FIGURE 1.38 Exosomes and Cellular Functions. Exosomes are vesicles of endocytic origin formed from the inward budding of the multivesicular body (MVB) membrane. Exosomes undergo cargo sorting to generate

exosomes of certain biochemical compositions. Exosomes are secreted following the fusion of MVBs with the cell membrane. Extracellular vesicles are regarded as signaling moieties (signalosomes) for many biologic processes. They are involved in antigen presentation and transfer of both major histocompatibility complex (MHC) molecules and antigens and are thereby involved in immune regulation. Extracellular vesicles can directly activate cell surface receptors from protein and lipid ligands, transfer receptors, or deliver effectors, including transcription factors, oncogenes, and infectious particles, into recipient cells. Various RNA species, including mRNAs and small regulatory RNAs (e.g., microRNAs [miRNAs] and noncoding RNAs), are contained in extracellular vesicles and delivered to appropriate recipient cells. The same properties of extracellular vesicles that are important for normal physiology can lead to their involvement in pathologic conditions. For example, extracellular vesicles can support tumor growth and tumor-related pathologies by inducing unwanted immune tolerance, spreading oncogenes, switching on angiogenic programs, and promoting metastases. For autoimmune diseases, vesicles can induce immune responses toward self-antigens. Vesicles can mediate transfer of prion proteins and toxic protein aggregates that modulate the progression of neurodegenerative diseases; vesicle transfer-bound viral material has been implicated in HIV-1 infection. Because of their involvement in disease progression, extracellular vesicles may be targets for therapeutic intervention as well as disease biomarkers. (Adapted from Andaloussi SEL et al: *Nat Rev Drug Discov* 12:347–357, 2013.)

Exocytosis

In eukaryotic cells, secretion of macromolecules almost always occurs by exocytosis (see Fig. 1.35, B). **Exocytosis** is the discharge or secretion of material from the intracellular vesicles at the cell surface. For example, to secrete macromolecules of insulin across plasma membranes, insulin-producing cells store and package insulin molecules in intracellular vesicles, which fuse with the plasma membrane and open to the extracellular space, or matrix, releasing the insulin. Not all secreted substances are secreted into the extracellular matrix. Some adhere to the plasma membrane and are thought to replace segments of the membrane lost through endocytosis or diffuse into the blood to nourish or signal other cells. Research findings suggest membrane lipids may be a regulator of exocytosis.^{19,20} Understanding how the *exocyst complex* is regulated is critical for diverse physiological processes.²¹ The intact phospholipid phosphoinositide PI(4,5)P₂ plays a critical role in most, if not all, cellular events associated with the plasma membrane, including vesicle exocytosis, endocytosis, cell adhesion, phagocytosis, viral

budding, enzyme activation, ion channel regulation, and cytokinesis.²² Exocytosis has two main functions: (1) replacement of portions of the plasma membrane that have been removed by endocytosis, and (2) release of molecules synthesized by the cells into the extracellular matrix.

Movement of Electrical Impulses: Membrane Potentials

All body cells are electrically polarized, with the inside of the cell more negatively charged than the outside. The difference in electrical charge, or voltage, is known as the **resting membrane potential** and is about -70 to -85 millivolts. The difference in voltage across the plasma membrane is a result of the differences in the ionic composition of ICF and ECF. Sodium ions have a greater concentration in the ECF, and potassium ions have a greater concentration in the ICF. The concentration difference is maintained by the active transport of Na^+ and K^+ (the sodium-potassium pump), which transports sodium outward and potassium inward (Fig. 1.39). Because the resting plasma membrane is more permeable to K^+ than to Na^+ , K^+ can diffuse easily from its area of higher concentration in the ICF to its area of lower concentration in the ECF. Because Na^+ and K^+ are both cations, the net result is an excess of anions inside the cell, resulting in the resting membrane potential.

FIGURE 1.39 Sodium-Potassium Pump and Propagation of an Action

Potential. **A**, Concentration difference of sodium (Na^+) and potassium (K^+) intracellularly and extracellularly. The direction of active transport by the sodium-potassium pump is also shown. **B**, The left diagram represents the polarized state of a neuronal membrane when at rest. The middle and right diagrams represent changes in sodium and potassium membrane permeabilities with depolarization and repolarization.

Nerve and muscle cells are excitable and can change their resting membrane potential in response to electrochemical stimuli. Changes in resting membrane potential convey messages from cell to cell. When a nerve or muscle cell receives a stimulus that exceeds the membrane threshold value, there is a rapid change in the resting membrane potential known as the **action potential**. The action potential carries signals along the nerve or muscle cell and conveys information from one cell to another. When a resting cell is stimulated through voltage-regulated channels, the cell membranes become more permeable to sodium. There is a net movement of sodium into the cell, and the membrane potential decreases, or “moves forward,” from a negative value (in millivolts) to zero. This decrease is known as **depolarization**. The depolarized cell is more positively charged, and its polarity is neutralized.

To generate an action potential and the resulting depolarization, a critical value known as the **threshold potential** must be reached. Generally this occurs when the cell has depolarized by 15 to 20

millivolts. When the threshold is reached, the cell will continue to depolarize with no further stimulation. The sodium gates open, and sodium rushes into the cell, causing the membrane potential to reduce to zero and then become positive (depolarization). The rapid reversal in polarity results in the action potential.

During **repolarization** the negative polarity of the resting membrane potential is reestablished. As the voltage-gated sodium channels begin to close, voltage-gated potassium channels open. Membrane permeability to sodium decreases, and potassium permeability increases, with an outward movement of potassium ions. The sodium gates close, and with the outward movement of potassium, the membrane potential becomes more negative. The Na^+ - K^+ pump then returns the membrane to the resting potential by pumping potassium back into the cell and sodium out of the cell.

During most of the action potential, the plasma membrane cannot respond to an additional stimulus. This time is known as the **absolute refractory period** and is related to changes in permeability to sodium. During the latter phase of the action potential, when permeability to potassium increases, a stronger-than-normal stimulus can evoke an action potential, known as the **relative refractory period**.

When the membrane potential is more negative than normal, the cell is in a *hyperpolarized* (less excitable) state. A larger-than-normal stimulus is then required to reach the threshold potential and generate an action potential. When the membrane potential is more positive than normal, the cell is in a *hypopolarized* (more excitable than normal) state, and a smaller-than-normal stimulus is required to reach the threshold potential. Changes in the intracellular and extracellular concentration of ions or a change in membrane permeability can cause these alterations in membrane excitability. Understanding the mechanisms of ion movement and membrane excitability led to the discovery of calcium blocking agents for heart disease and migraine.

Cellular Reproduction: the Cell Cycle

The most fundamental task for the generation of life is cellular

reproduction. “The only way to make a new cell is to duplicate a cell that already exists.”² The continuity of life depends on constant rounds of cell growth and division. The cycle of repeated duplication and division is called the **cell cycle** (Fig. 1.40, A). Humans must make millions of cells every second to just survive.²

FIGURE 1.40 The Cell Cycle. A, Simplified figure of schematic cell with one green chromosome and one yellow chromosome to show how two genetically identical daughter cells are produced in each cycle. B, Cell cycle events: mitosis and cytokinesis. (Adapted from Alberts B et al: *Molecular biology of the cell*, ed 6, New York, 2015, Garland Science.)

Reproduction of gametes (sperm and egg cells) occurs through a process called *meiosis*, described in [Chapter 4](#). The reproduction, or division, of other body cells (somatic cells) involves two sequential phases: **mitosis**, or nuclear division, and **cytokinesis**, or cytoplasmic division ([Fig. 1.40, B](#)). These two phases occur in close succession, with cytokinesis beginning toward the end of mitosis. Before a cell can

divide, however, it must double its mass and duplicate all its contents. Most of the work of preparing for division occurs during the growth phase, called **interphase**. The cell cycle drives the alternation between mitosis and interphase in all tissues with cellular turnover.

Most of the early work on the cell cycle was limited to microscopic observation of mitosis and cytokinesis. Interphase was considered the “resting stage” of the cell. With recent technologic advances a considerable amount has been learned about the interphase part of the cell cycle. During interphase many important processes are taking place as the cell produces DNA, RNA, protein, lipids, and other substances; and each pair of **chromosomes** (paired organelles that carry genetic information) makes exact copies of themselves.

The four designated phases of the cell cycle are (1) the **G₁ phase** (G = gap), which is the period between the M phase and the start of DNA synthesis; (2) the **S phase** (S = synthesis), in which DNA is synthesized in the cell nucleus; (3) the **G₂ phase**, in which RNA and protein synthesis occurs, the period between the completion of DNA synthesis and the next phase (M); and (4) the **M phase** (M = mitosis), which includes both nuclear and cytoplasmic division (Fig. 1.41).

FIGURE 1.41 Four Phases of the Cell Cycle. The four phases of the cell cycle are gap 1 (or G_1 , presynthesis), S (DNA synthesis), G_2 (premitotic), and M (mitotic phase). Not a main phase of the cell cycle but a specialized nondividing state called G_0 refers to cells where the cell cycle control system is disassembled (various cyclin-dependent kinases and cyclins are permanently turned off), and cell division rarely occurs.

Phases of Mitosis and Cytokinesis

Interphase (the G_1 , S, and G_2 phases) is the longest phase of the cell cycle. During interphase the chromatin consists of very long, slender rods that are jumbled together in the nucleus. Late in interphase, strands of **chromatin** (the substance that gives the nucleus its granular appearance) begin to coil, causing them to shorten and thicken.

The M phase of the cell cycle, mitosis and cytokinesis, begins with **prophase**, the first appearance of chromosomes. As the phase proceeds, each chromosome is seen as two identical halves called **chromatids**, which lie together and are attached at some point by a spindle attachment site called a **centromere**. (The two chromatids of each chromosome, which are genetically identical, are sometimes called *sister chromatids*.)

The nuclear membrane, which surrounds the nucleus, disappears. Spindle fibers are microtubules formed in the cytoplasm. **Spindle fibers** radiate from two centrioles located at opposite poles of the cell. The role of the spindle fibers is to pull the chromosomes to opposite sides of the cell.

During **metaphase**, the next phase of mitosis and cytokinesis, the spindle fibers begin to pull the centromeres of the chromosomes. The centromeres become aligned in the middle of the spindle, which is called the **equatorial plate** (or **metaphase plate**) of the cell. In this stage chromosomes are easiest to observe microscopically because they are highly condensed and arranged in a relatively organized fashion in the two-dimensional equatorial plate.

Anaphase begins when the centromeres split and the sister chromatids are pulled apart. The spindle fibers shorten, causing the sister chromatids to be pulled, centromere first, toward opposite sides of the cell. When the sister chromatids are separated, each is

considered to be a chromosome. Thus the cell has 92 chromosomes during this stage. By the end of anaphase, 46 chromosomes are lying at each side of the cell. Barring mitotic errors, each of the 2 groups of 46 chromosomes is identical to the original 46 chromosomes present at the start of the cell cycle.

During **telophase**, the final stage, a new nuclear membrane is formed around each group of 46 chromosomes, the spindle fibers disappear, and the chromosomes begin to uncoil. Cytokinesis causes the cytoplasm to divide into roughly equal parts during this phase. At the end of telophase, two identical diploid cells, called *daughter cells*, have been formed from the original cell.

The Cell Cycle Control System

Various features of the cell cycle differ from one cell type to another including the length of time to complete certain functions. Most of the variability in cell cycle length in the adult body occurs during the time the cell spends in the G_1 or G_0 phase of the cell cycle. This length of time is different than the brief time a cell takes to progress from the beginning of the S phase through mitosis—typically 12 to 24 hours. Cells are capable of disassembly of their cell cycle control system and can withdraw from the cycle to a nondividing state called G_0 . The reversibility of the G_0 state varies in different types of cells. For example, most of the neurons and skeletal muscle cells are in a *terminally differentiated* G_0 state; with their cell cycle control system disassembled, the molecular regulatory switches (Cdks and cyclins, see following text) become permanently turned off and cell division rarely occurs.²

In eukaryotic cells, the basic organization of the cell cycle is mainly the same.² The **cell cycle control system** triggers the essential events of the cell cycle. The system operates like a timer that triggers the constant sequence of events. Although early embryonic divisions are independent of feedback controls, in most cells the control system responds to feedback (information) from the processes it controls. For example, if some malfunction occurs with DNA synthesis, signals are

sent to the control system to delay progression to the M phase.² Such delays allow repair and prevent progression of cellular disasters.

The cell cycle control system works because of a connected series of biochemical switches that either activate or inhibit cell events. Two classes of *switches* or regulatory molecules that determine a cell's progress through the cell cycle are cyclin-dependent kinases (Cdks) and cyclins (Fig. 1.42).

FIGURE 1.42 Cell Cycle Control System. A, Key components or protein kinases of the cell cycle control system are cyclin-dependent kinases (Cdks) and cyclins. Cyclin forms a complex with Cdk. B, Cyclin-Cdk complexes of the cell cycle control system. APC/C, Anaphase promoting complex. (Adapted from Alberts B et al: *Molecular biology of the cell*, ed 6, New York, 2015, Garland Science.)

Cyclin-dependent kinases (Cdks) are protein kinases and their functions rise and fall as the cell moves through the cycle. The rise and fall leads to cyclical changes in phosphorylation of intracellular proteins that start or regulate the events of the cell cycle. Many enzymes and other proteins regulate the different Cdks and the most important are proteins called **cyclins**.² Cdk activity is dependent on binding of cyclins (*cyclin-Cdk complexes*). For example, activation of S-phase cyclin-Cdk complexes (s-Cdk) initiates the S phase. Without cyclin, Cdk is inactive. Binding of *Cdk inhibitor proteins (CKIs)*

inactivates cyclin-Cdk complexes. Two other essential enzyme complexes that regulate the cell cycle control system are the APC/C and SCF ubiquitin ligases, which promote ubiquitylation (process of marking for destruction) and subsequent destruction of various proteins that modulate the cell cycle (see [Fig. 1.42](#)).

Control of Cell Division and Cell Growth: Mitogens, Growth Factors, and Survival Factors

The size of an organ depends on the total number of cells and cell size. Cell number depends on the total quantity of cell division and cell death. Organ size and body size are determined by three main processes: cell growth, cell division, and cell survival.² These processes are tightly regulated by intracellular programs and extracellular signal molecules. The signal molecules that regulate growth, division, and survival are usually soluble proteins, proteins bound to cells, or components of the extracellular matrix. The molecules can be divided into three main classes: (1) mitogens, (2) growth factors, and (3) survival factors.

A **mitogen** is a substance that induces or stimulates mitosis (cell division). For a cell to proliferate it must receive an extracellular signal, or mitogen, from other cells, usually neighboring cells. Mitogens relieve intracellular braking mechanisms that block progress through the cell cycle by triggering a wave of G_1/S -Cdk activity.² One of the first mitogens to be identified was *platelet-derived growth factor* (*PDGF*). Importantly, when blood clots, platelets that exist in the clot are stimulated to release the contents of their secretory vesicles such as PDGF. Liberated PDGF helps stimulate blood clotting at sites of tissue damage to prevent excessive bleeding. PDGF can stimulate many cell types including smooth muscle cells, neuroglial cells, and fibroblasts. In addition to cell division, PDGF and other mitogens can stimulate cell growth, differentiation, migration, and survival.²

Mitogens interact with cell receptors to activate multiple intracellular signaling pathways. A major pathway through the GTPase is **Ras**, which leads to activation of a mitogen-activated

protein kinase (*MAP kinase*) cascade (Fig. 1.43). Eventually, this cascade leads to the production of transcription regulatory proteins including MYC. **Myc** is very important because it activates many genes involved in cell growth and is under investigation as a contributor to cancer cell stemness.²³ Tumors appear to be “addicted” to Myc (proto-oncogene), and the persistence of many human cancers requires sustained Myc activation.²⁴ Activation of Myc leads to increases in expression of many *delayed-response genes* including those that increase G₁-Cdk activity, causing phosphorylation of a molecular ON-OFF switch, the **retinoblastoma (Rb) susceptibility protein**. In its unphosphorylated (or hypophosphorylated) state, RB prevents cells from replicating by forming a tight inactive complex with the transcription factor **E2F** (Fig. 1.44). Phosphorylation of RB eliminates the “brakes” (by reducing binding to E2F proteins) and the liberated E2F proteins then activate other target genes, promoting cell cycle progression and cell replication.

FIGURE 1.43 Signaling Cascade RAS, MAPK, MYC. Binding of a ligand (growth factor) causes a chain of reactions of proteins in the cell that relays a signal to the DNA in the nucleus and results in transcription of MYC protein. The pathway includes many protein kinases acting as “on/off” switches by adding phosphate groups to neighboring proteins. Mutations in RAS can lead to increased proliferation common in cancers. (From Kumar et al: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

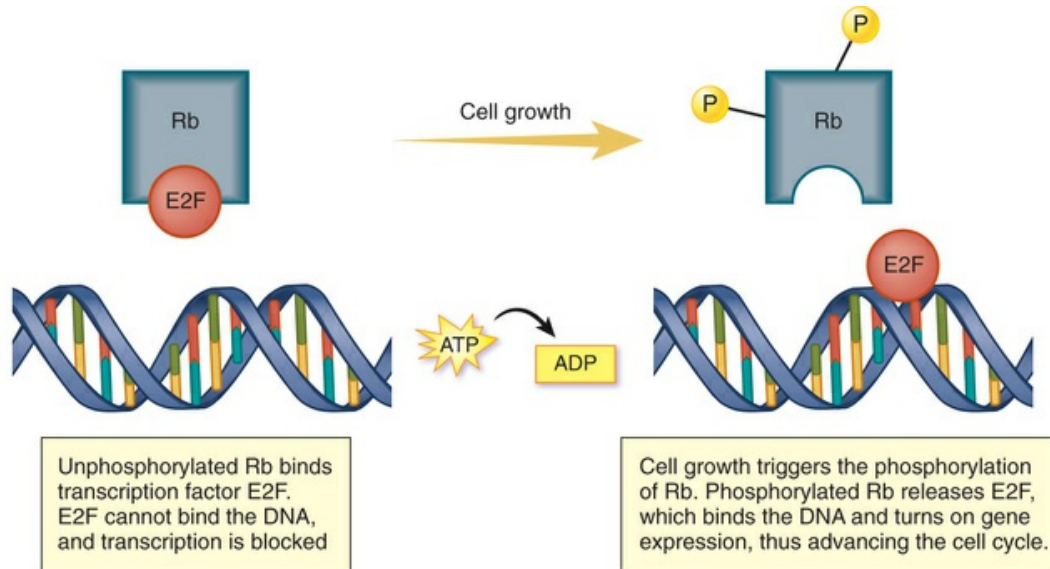

FIGURE 1.44 Rb Master Regulator of Cell Cycle. *P*, Phosphate group from ATP. (Adapted from OpenStax, Control of the Cell Cycle. OpenStax CNX. <http://cnx.org/contents/69b8e2ee-f350-4202-8085-878c433e1cd5@6.>)

Growth factors (also called *cytokines*) stimulate an increase in cell mass or cell growth by promoting the synthesis of proteins and other macromolecules and inhibiting their degradation. Table 1.6 includes examples of mitogens and growth factors. Cells that are starved of growth factors come to a halt after mitosis and enter the arrested, or G_0 , state of the cell cycle. **Survival factors** promote cell survival by suppressing the type of programmed cell death called *apoptosis* (see Chapter 2).

TABLE 1.6

EXAMPLES OF MITOGENS AND GROWTH FACTORS AND THEIR ACTIONS

GROWTH FACTOR	PHYSIOLOGIC ACTIONS
Platelet-derived growth factor (PDGF)	Stimulates proliferation of connective tissue cells and neuroglial cells
Epidermal growth factor (EGF)	Stimulates proliferation of epidermal cells and other cell types
Insulin-like growth factor 1 (IGF-1)	Collaborates with PDGF and EGF; stimulates proliferation of fat cells and connective tissue cells
Insulin-like growth factor 2 (IGF-2)	Collaborates with PDGF and EGF; stimulates proliferation of fat cells and connective tissue cells
Transforming growth factor-beta (TGF- β)	Stimulates or inhibits response of most cells to other growth

β)	factors; regulates differentiation of some cell types (e.g., cartilage)
Fibroblast growth factor (FGF)	Stimulates proliferation of fibroblasts, endothelial cells, myoblasts, and other cell types
Interleukin-2 (IL-2)	Stimulates proliferation of T lymphocytes
Nerve growth factor (NGF)	Promotes axon growth and survival of sympathetic and some sensory and CNS neurons
Hematopoietic cell growth factors (IL-3, GM-CSF, M-CSF, G-CSF, erythropoietin)	Promotes growth of white and red blood cells

CNS, Central nervous system; *CSF*, colony-stimulating factor; *G*, granulocyte; *GM*, granulocyte-macrophage; *M*, macrophage.

DNA Damage Response: Blocks Cell Division

The **DNA damage response** occurs when DNA is damaged and several protein kinases are recruited to the site of damage and start a signaling pathway that stops the progression of the cell cycle, or **cell cycle arrest** (Fig. 1.45). Importantly, the cell cycle control system detects DNA damage and arrests the cycle at two points: (1) at Start, which prevents entry into the S phase; and (2) at the G₂/M transition, stopping entry into mitosis. DNA damage initiates a signaling pathway by activating one of a pair of protein kinases called **ataxia-telangiectasia mutated (ATM)** and **ataxia-telangiectasia and rad-3 (ATR)** (see Fig. 1.45).

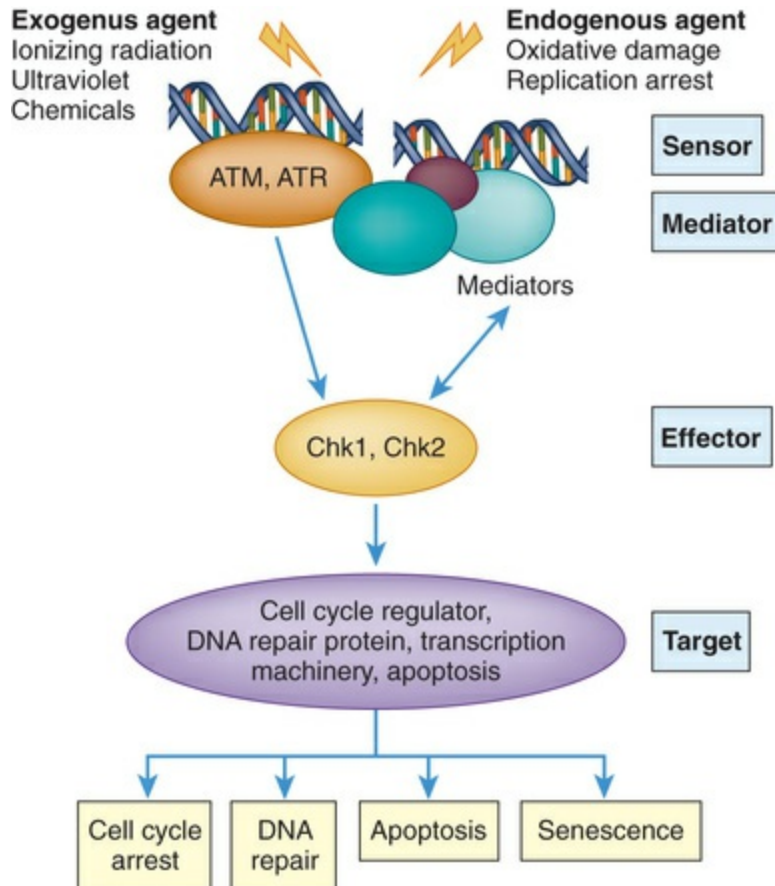

FIGURE 1.45 DNA Damage Response. In response to DNA damage the first kinase at the damaged site is either ATM or ATR, depending on the injurious agent. Protein kinases Chk1 and Chk2 are then recruited and activated. (Although not shown in the figure, these kinases result in phosphorylation of the transcription regulatory protein p53.) Mdm2 is a protein that acts as a ubiquitin ligase (enzyme involved in the ligation [binding] step of ubiquitylation), which targets p53 for destruction by proteasomes.² Phosphorylation of p53 blocks its binding to Mdm2, causing p53 to accumulate to high levels, which stimulates transcription of numerous genes, including the gene that encodes protein 21. p21 binds G₁/S-Cdk and S-Cdk complexes, causing arrest of the cell cycle in G₁. The arrest prevents entry into mitosis. Several cell fates can occur including DNA repair, apoptosis or cell death, and senescence (not capable of dividing). *ATM*, ataxia-telangiectasia mutated; *ATR*, ataxia-telangiectasia and rad-3. (Adapted from Yun J: *Molecular signal transduction laboratory*, Busan, South Korea, 2009, Dong-A University. <http://web.donga.ac.kr/yunj/page01.htm>.)

Tissues

The body is made up of four levels of organization: cells, tissues, organs, and systems. Cells of common structure and function are organized into **tissues**, of which there are four primary types: *muscle*, *neural*, *epithelial*, and *connective* tissue.

Tissue Formation

To form tissues, cells must exhibit intercellular recognition and communication, adhesion, and memory. Specialized cells sense their environment through signals, such as growth factors, from other cells. This type of communication ensures that new cells are produced only when and where they are required. Different cell types have different adhesion molecules in their plasma membranes, sticking selectively to other cells of the same type. They also can adhere to extracellular matrix components. Strength can occur because of the extracellular matrix and the strength of the cytoskeleton with cell-cell adhesions to neighboring cells. Cells have memory because of specialized patterns of gene expression evoked by signals that acted during embryonic development. Memory allows cells to autonomously preserve their distinctive character and pass it on to their progeny.²

Form generation, or *morphogenesis*, that cells undergo to assemble into tissues and organs with different shapes and sizes is less well understood than the processes of gene expression and induced signaling that result in cell-type specialization.² The underlying molecular mechanisms are complex. Fully specialized or terminally differentiated cells that are lost are generated from committed proliferating *precursor cells* or transit amplifying cells; and they, in turn, have been derived from a smaller number of stem cells.² **Stem cells** are cells with the potential to develop into many different cell types during early development and growth. A stem cell itself is not terminally differentiated; it can divide without limit, and when it divides each daughter cell has a choice. The daughter cell either can remain a stem cell or can move on a course that commits it to terminal differentiation.² Two ways a stem cell can produce daughter cells with

different fates are asymmetrical division and independent choice, as shown in Fig. 1.46.

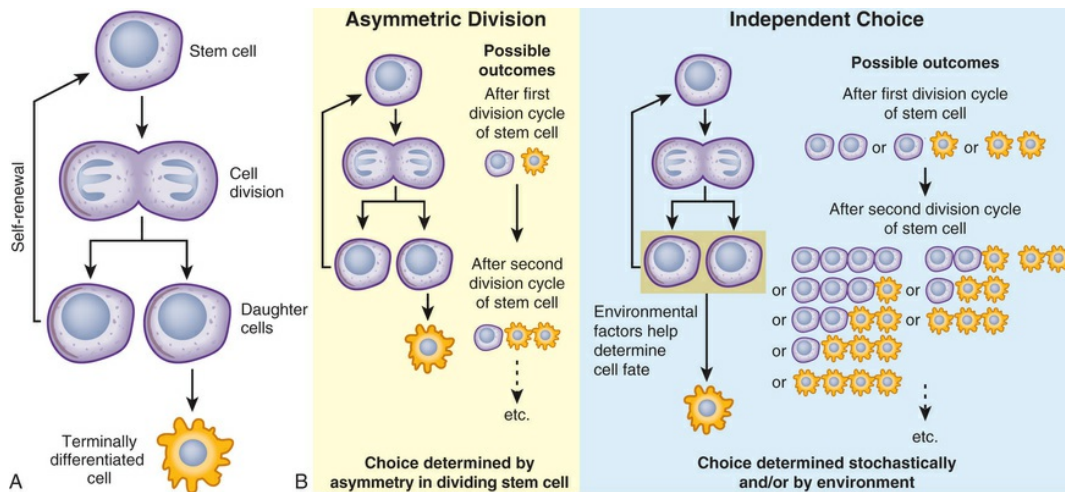

FIGURE 1.46 Stem Cell and Asymmetrical Division and Independent Choice Theory. A, When a stem cell divides, each daughter cell can either remain a stem cell or proceed to become terminally differentiated. Frequently, a daughter cell that becomes terminally differentiated undergoes additional cell divisions before terminal differentiation. B, Emerging understandings have defined two ways a stem cell can produce daughter cells with different fates: (1) asymmetrical division and (2) independent choice. Asymmetrical division gives a clone one stem cell plus an increasing number of differentiating cells proportional to the number of cell divisions. The independent-choice strategy has more variability or possibilities. These possibilities are subject to the cell's environment, sometimes called a stochastic or random occurrence. (Adapted from Alberts B et al: *Molecular biology of the cell*, ed 6, New York, 2015, Garland Science.)

In many tissues, stem cells serve as an internal repair and maintenance system dividing indefinitely. These cells can maintain themselves over very long periods of time, called **self-renewal**, and can generate all the differentiated cell types of the tissue, or **multipotency**. This stem cell-driven tissue renewal is very evident in the epithelial lining of the intestine, stomach, blood cells, and skin, which is continuously exposed to environmental factors. Tissue renewal and repair, however, do not always depend on stem cells.² For example, enlargement and renewal of insulin-producing cells in the pancreas occur by simple duplication of existing insulin-producing cells. In the liver, differentiated hepatocytes can divide

throughout life and significantly increase their division rate when needed. At the extreme opposite end of this spectrum, some tissues, like the ear and the eye, do not undergo any turnover and are not renewable—once lost, forever lost.²

Types of Tissues

Epithelial Tissue

Epithelial tissue covers most internal and external surfaces of the body. Epithelial cells are closely joined and are attached to a basement membrane or lamina (extracellular matrix), which provides a supporting layer and separates the epithelium from underlying connective tissue (see Table E 1.1 on Evolve). Because of its variety of locations, epithelial tissue has several diverse functions, including protection, absorption, secretion, and excretion. For example, the epidermis provides a protective barrier between the host and the outside environment, and the linings of the internal body organs help absorb substances into the body, excrete waste products, and secrete substances into body cavities.

Epithelial cell surfaces differ according to their location and function. Epithelial cells that line body cavities and blood vessels are smooth, whereas other epithelial cells have tiny cytoplasmic projections called **microvilli** on their free surfaces. Microvilli considerably increase a cell's surface area and are found on cells whose main functions are absorption and secretion, such as the epithelial cells lining the digestive tract. **Cilia**, which are hairlike projections that propel mucus, pus, and dust particles out of the body, characterize cells lining the respiratory passages.

Epithelial tissue is classified in two ways: (1) according to the number and arrangement of cell layers and (2) according to cell shape. Epithelium that is formed by a single layer of cells, all of which are in contact with the basement membrane, is called **simple epithelium**. **Stratified epithelium** has two or more layers of cells, and only the deepest layer is in contact with the basement membrane. Tissue that appears to consist of several cellular layers but is actually a single

layer with all cells contacting the basement membrane is called **pseudostratified epithelium**.

Three basic cell shapes are found in epithelium: squamous, cuboidal, and columnar. **Squamous cells** are flat and thin; **cuboidal cells** are as high as they are wide and thus appear square in vertical sections; and **columnar cells** are taller than they are wide and appear rectangular in vertical sections. Overall classifications of epithelial tissue, which take into account both the number of cell layers and the cell shape, are summarized in Table E 1.1 on Evolve.

Connective Tissue

Connective tissue varies considerably in structure and function but is most common as the framework on which epithelial cells cluster to form organs. Other functions include binding various tissues and organs together, supporting them in their locations, and serving as storage sites for excess nutrients.

In contrast to epithelial tissue, connective tissue is characterized by an abundant extracellular matrix that surrounds few cells. The extracellular matrix is composed of ground substance and fibers. **Ground substance** is a homogeneous mass that varies in consistency from fluid to semisolid gel. Fibers are produced by connective tissue cells (fibroblasts) found within the ground substance. The three types of fibers are collagenous (white), elastic (yellow), and reticular. **Collagenous fibers** are formed of bundles of smaller fibers appearing as wavy bands under the microscope. These fibers are composed of the protein collagen and are strong and inelastic. **Elastic fibers** are long, branching fibers composed of a protein called *elastin* that enables the fibers to return to their original length after stretching. Elastin occurs not only as fibers but also as membranes, particularly the membranes of blood vessels. **Reticular fibers** are thin, short, branching fibers that form an inelastic network made from a collagen-like protein called *reticulum*. Reticular fibers form the internal framework (stroma) to which the epithelial cells of glands are attached. They are found in loose connective tissue, generally in bone marrow and in the **parenchyma** (i.e., the essential substance of an

organ rather than its framework) of the liver, spleen, and lymph nodes.

Connective tissues are classified according to the consistency (e.g., loose, dense) of the ground substance and the type and organization of the fibers within it. Table E 1.2 on Evolve summarizes the characteristics of connective tissues.

Muscle Tissue

Muscle tissue is composed of long, thin cells or fibers called *myocytes*. Myocytes are highly contractile. The three types of muscle tissues are skeletal, cardiac, and smooth (see Table E 1.3 on Evolve). (Muscles are discussed in detail in [Chapter 44](#).)

Neural Tissue

Neural tissue is composed of highly specialized cells called *neurons*, which receive and transmit electrical impulses very rapidly across junctions called synapses. **Synapses** are points of functional contact between neurons. At synapses, impulses pass from neuron to neuron or from a neuron to a muscle cell while chemical messengers called *neurotransmitters* are released. The total number of neurons is fixed at birth, and replacement is impossible thereafter.

Different types of neurons have special characteristics that depend on their distribution and function within the nervous system. All neurons, however, are composed of the following parts: (1) a cell body, (2) a single axon, and (3) one or more dendrites (see [Fig. 15.1](#)). The cell body contains special cytoplasmic structures, as well as microtubules, actin filaments, Golgi complex, lysosomes, and lipofuscin. The axons and dendrites can be very long. Generally, the axon conducts nerve impulses away from the cell body, and dendrites conduct nerve impulses toward the cell body.

Summary Review

Cellular Functions

1. Cells become specialized through the process of differentiation, or maturation.
2. The eight specialized cellular functions are movement, conductivity, metabolic absorption, secretion, excretion, respiration, reproduction, and communication.

Structure and Function of Cellular Components

1. The eukaryotic cell consists of three general components: the plasma membrane, the cytoplasm, and the intracellular organelles.
2. The nucleus is the largest membrane-bound organelle and is usually found in the cell's center. The chief functions of the nucleus are cell division and control of genetic information.
3. Cytoplasm, or the cytoplasmic matrix, is an aqueous solution (cytosol) that fills the space between the nucleus and the plasma membrane.
4. The organelles are suspended in the cytoplasm and are enclosed in biologic membranes.
5. The endoplasmic reticulum (ER) is a network of tubular channels (cisternae) that extends throughout the outer nuclear membrane. It specializes in the synthesis and transport of protein and lipid components of most of the organelles. Importantly, the ER is responsible for protein folding and sensing cell stress.
6. The Golgi complex is a network of smooth membranes and vesicles located near the nucleus. The Golgi complex is responsible for processing and packaging proteins into secretory vesicles that break away from the Golgi complex and migrate to a variety of intracellular and extracellular destinations, including the plasma membrane.
7. Lysosomes are sac-like structures that originate from the Golgi complex and contain digestive enzymes. These enzymes are

responsible for digesting most cellular substances completely to their basic components, such as amino acids, fatty acids, and carbohydrates. A newly understood role of lysosomes is nutrient-dependent signal transduction. The signaling function cooperates with the known degradative role to mediate basic cell functions, such as nutrient sensing, metabolic adaptation, and quality control of proteins and organelles.

8. Four pathways of degradation in lysosomes include endocytosis, phagocytosis, macropinocytosis, and autophagy.
9. Peroxisomes are similar to lysosomes but contain several oxidative enzymes, such as catalase and urate oxidase.
10. Mitochondria are found in great numbers in most cells and are responsible for cellular respiration and energy production. The enzymes of the respiratory chain (electron-transport chain), found in the inner membrane of the mitochondria, generate most of the cell's ATP.
11. The cytosol or liquid portion of the cytoplasm has several functions including intermediary metabolism involving enzymatic biochemical reactions; ribosomal protein synthesis; and storage of carbohydrates, fat, and secretory vesicles.
12. The cytoskeleton is the “bone and muscle” of the cell. The internal skeleton is composed of a network of protein filaments including microtubules and actin filaments (microfilaments).
13. The plasma membrane encloses the cell and, by controlling the movement of substances across it, exerts a powerful influence on metabolic pathways.
14. The plasma membrane is a bilayer of lipids and proteins. The basic structure of the cell membrane is the lipid bilayer.
15. Membrane functions are determined largely by proteins. These functions include (a) recognition and binding units (receptors) for substances moving in and out of the cell; (b) pores or transport channels; (c) enzymes that drive active pumps; (d) cell surface markers, such as glycoproteins; (e) cell adhesion molecules; and (f) catalysts of chemical reactions.

16. The information regarding concepts of biologic membranes has changed markedly in the last two decades.
17. A protein is made from a chain of amino acids known as polypeptides. Proteins are the major workhorses of the cell. Proteins move from one compartment to another by gated transport, protein translocation, or vesicular transport.
18. Proteostasis is a state of cell balance of the processes of protein synthesis, folding, and degradation. Proteostasis is vital to cellular health.
19. Cellular receptors are protein molecules on the plasma membrane, in the cytoplasm, or in the nucleus that are capable of recognizing and binding smaller molecules, called *ligands*.
20. The ligand-receptor complex initiates a series of protein interactions, causing adenylyl cyclase to catalyze the transformation of cellular ATP to messenger molecules that stimulate specific responses within the cell.
21. The carbohydrate contained within the plasma membrane is generally bound to membrane proteins.

Cell-to-Cell Adhesions

1. Cell-to-cell adhesions are formed on plasma membranes, thereby allowing the formation of tissues and organs. Cells are held together by three different means: (a) the extracellular matrix, (b) cell adhesion molecules in the cell's plasma membrane, and (c) specialized cell junctions.
2. The extracellular matrix includes three types of protein fibers: collagen, elastin, and fibronectin. The matrix helps regulate cell growth and differentiation.
3. The basement membrane is a thin layer of connective tissue underlying the epithelium of many organs. It is also called the basal lamina.
4. Cell adhesion molecules (CAMs) are cell surface proteins that bind to an adjacent cell and to components of the extracellular matrix. CAMs include four main protein families: the

integrins, the cadherins, the selectins, and the immunoglobulin (Ig) superfamily.

5. The three main types of cell junctions are desmosomes, tight junctions, and gap junctions.

Cellular Communication and Signal Transduction

1. Cells communicate in three main ways: (a) they display plasma membrane-bound signaling molecules (receptors) that affect the cell itself and other cells in direct physical contact; (b) they activate receptor proteins inside the target cell, and the signal molecule has to enter the cell to bind to them; and (c) they form protein channels (gap junctions) that directly coordinate the activities of adjacent cells.
2. Primary modes of intercellular signaling are contact-dependent, paracrine, hormonal, neurohormonal, and neurotransmitter.
3. Signal transduction involves signals or instructions from extracellular chemical messengers that are conveyed to the cell's interior for execution.
4. Signal transduction pathways (signaling cascades, relay chains) have several important functions, including physically transferring the signal around the cell, amplifying the signal, distributing the signal, and modulating the signal.
5. Two important second-messenger pathways are cAMP and Ca^{++} .
6. G protein is an intermediary between the receptor and adenylyl cyclase.
7. Phospholipase C, an enzyme protein effector, is bound to the inner side of the membrane.

Cellular Metabolism

1. The chemical tasks of maintaining essential cellular functions

are referred to as *cellular metabolism*. Anabolism is the energy-using process of metabolism, whereas catabolism is the energy-releasing process.

2. ATP functions as an energy-transferring molecule. Energy is stored by molecules of carbohydrate, lipid, and protein, which, when catabolized, transfer energy to ATP.
3. Oxidative phosphorylation occurs in the mitochondria and is the mechanism by which the energy produced from carbohydrates, fats, and proteins is transferred to ATP.

Membrane Transport: Cellular Intake and Output

1. Cell survival and growth depend on the constant exchange of molecules with their environment. Simple diffusion across the lipid bilayer of the plasma membrane occurs for important moles, such as O_2 and CO_2 .
2. The majority of molecule transfer depends on specialized membrane transport proteins that span the lipid bilayer and provide private thoroughfares for select molecules.
3. The two main classes of membrane transport proteins are transporters and channels.
4. Water and small, electrically uncharged molecules move through pores in the plasma membrane's lipid bilayer in the process called *passive transport*.
5. Passive transport does not require the expenditure of energy; rather, it is driven by the physical effects of osmosis, hydrostatic pressure, and diffusion.
6. Larger molecules and molecular complexes (e.g., ligand-receptor complexes) are moved into the cell by active transport, which requires expenditure of energy (by means of ATP) by the cell.
7. Two types of solutes exist in body fluids: electrolytes and nonelectrolytes. Electrolytes are electrically charged and dissociate into constituent ions when placed in solution. Nonelectrolytes do not dissociate when placed in solution.

8. Diffusion is the passive movement of a solute from an area of higher solute concentration to an area of lower solute concentration.
9. Hydrostatic pressure is the mechanical force of water pushing against cellular membranes.
10. Osmosis is the movement of water across a semipermeable membrane from a region of lower solute concentration to a region of higher solute concentration.
11. The amount of hydrostatic pressure required to oppose the osmotic movement of water is called the *osmotic pressure* of the solution.
12. The overall osmotic effect of colloids, such as plasma proteins, is called the *oncotic pressure* or *colloid osmotic pressure*.
13. Mediated transport can be passive or active. Mediated transport includes the movement of two molecules simultaneously in one direction (symport) or in opposite directions (antiport), or the movement of a single molecule in one direction (uniport).
14. Endocytosis is a cellular internalizing process where a section of the plasma membrane enfolds substances from outside the cell, invaginates, and separates from the plasma membrane forming a vesicle that moves inside the cell.
15. Endocytosis can be subdivided into four categories: (1) clathrin-mediated endocytosis, (2) caveolae-mediated endocytosis, (3) macropinocytosis, and (4) phagocytosis. Over time, however, these categories may change.
16. A new advancement in cellular biology is the role of exosomes in understanding the biology of vesicles and their role in disease. Exosomes are small membrane vesicles of endocytic origin containing lipid, protein, and RNA species in a single biologic unit. They are secreted by nearly all mammalian cell types and confer messages between cells.
17. Exocytosis is the discharge or secretion of material from the intracellular vesicles at the cell surface. Exocytosis has two main functions: replacement of portions of the plasma

membrane that have been removed by endocytosis and release of molecules synthesized by the cells into the extracellular matrix.

18. Pinocytosis is a type of endocytosis in which fluids and solute molecules are ingested through formation of small vesicles.
19. Phagocytosis is a type of endocytosis in which large particles, such as bacteria, are ingested through formation of large vesicles, called *vacuoles*.
20. All body cells are electrically polarized, with the inside of the cell more negatively charged than the outside. The difference in voltage across the plasma membrane is the resting membrane potential.
21. When an excitable (nerve or muscle) cell receives an electrochemical stimulus, cations enter the cell, causing a rapid change in the resting membrane potential known as the *action potential*. The action potential “moves” along the cell's plasma membrane and is transmitted to an adjacent cell. This is how electrochemical signals convey information from cell to cell.

Cellular Reproduction: The Cell Cycle

1. The continuity of life depends on constant rounds of cell growth and division.
2. Cellular reproduction in body tissues involves mitosis (nuclear division) and cytokinesis (cytoplasmic division).
3. Only mature cells are capable of division. Maturation occurs during a stage of cellular life called *interphase* (growth phase).
4. The cell cycle is the reproductive process that begins after interphase in all tissues with cellular turnover. The four phases of the cell cycle are (1) the **G₁ phase** (G = gap), which is the period between the M phase and the start of DNA synthesis; (2) the **S phase** (S = synthesis), in which DNA is synthesized in the cell nucleus; (3) the **G₂ phase**, in which RNA and protein synthesis occurs, the period between the completion of DNA synthesis and the next phase (M); and (4) the **M phase** (M =

mitosis), which includes both nuclear and cytoplasmic division.

5. The M phase (mitosis) involves four stages: prophase, metaphase, anaphase, and telophase.
6. The mechanisms that control cell division depend on the integrity of genetic, epigenetic, and protein growth factors.
7. Two classes of switches or regulatory molecules that determine a cell's progress through the cell cycle are cyclin-dependent kinases (Cdks) and cyclins.
8. Organ size and body size depend on cell growth, cell division, and cell survival.
9. A mitogen is a substance that induces or stimulates mitosis.
10. Growth factors stimulate an increase in cell mass or cell growth by promoting the synthesis of proteins and other macromolecules and inhibiting their degradation.
11. The DNA damage response occurs when DNA is damaged and several protein kinases are recruited to the site of damage and start a signaling pathway that stops the progression of the cell cycle called cell cycle arrest.

Tissues

1. Cells of one or more types are organized into tissues, and different types of tissues compose organs. Organs are organized to function as tracts or systems.
2. To form tissue, cells must exhibit intercellular recognition and communication, adhesion, and memory.
3. The four basic types of tissues are epithelial, muscle, neural, and connective tissues.
4. Stem cells are cells with the potential to develop into many different cell types during early development and growth. Stem cells serve as an internal repair and maintenance system dividing indefinitely. Tissue repair and renewal does not always depend on stem cells.
5. Epithelial tissue covers most internal and external surfaces of

the body. The functions of epithelial tissue include protection, absorption, secretion, and excretion.

6. Connective tissue binds various tissues and organs together, supporting them in their locations and serving as storage sites for excess nutrients.
7. Muscle tissue is composed of long, thin, highly contractile cells or fibers called *myocytes*. Muscle tissue that is attached to bones enables voluntary movement. Muscle tissues in internal organs enable involuntary movement, such as the heartbeat.
8. Neural tissue is composed of highly specialized cells called *neurons* that receive and transmit electrical impulses very rapidly across junctions called *synapses*.

Injury to cells and their surrounding environment, called the *extracellular matrix*, leads to tissue and organ injury. Although the normal cell is restricted by a narrow range of structure and function, it can *adapt* to physiologic demands or stress to maintain a steady state called *homeostasis*. **Adaptation** is a reversible, structural, or functional response to both normal or physiologic conditions and adverse or pathologic conditions. For example, the uterus adapts to pregnancy—a normal physiologic state—by enlarging. Enlargement occurs because of an increase in the size and number of uterine cells. In an adverse condition, such as high blood pressure, myocardial cells are stimulated to enlarge by the increased work of pumping. Like most of the body's adaptive mechanisms, however, cellular adaptations to adverse conditions are usually only temporarily successful. Severe or long-term stressors overwhelm adaptive processes and cellular injury or death ensues. Altered cellular and tissue biology can result from adaptation, injury, neoplasia, accumulations, aging, or death.

Knowledge of the structural and functional reactions of cells and

tissues to injurious agents, including genetic defects, is key to understanding disease processes. Cellular injury can be caused by any factor that disrupts cellular structures or deprives the cell of oxygen and nutrients required for survival. Injury may be reversible (*sublethal*) or irreversible (*lethal*) and is classified broadly as chemical, hypoxic (lack of sufficient oxygen), free radical, unintentional or intentional, and immunologic or inflammatory. Cellular injuries from various causes have different clinical and pathophysiologic manifestations. Stresses from metabolic derangements may be associated with intracellular *accumulations* and include carbohydrates, proteins, and lipids. Sites of cellular death can cause accumulations of calcium resulting in *pathologic calcification*. Cellular death is confirmed by structural changes seen when cells are stained and examined with a microscope. The most important changes are nuclear; clearly, without a healthy nucleus, the cell cannot survive. The two main types of cell death are *necrosis* and *apoptosis*, and nutrient deprivation can initiate *autophagy* that results in cell death.

Cellular aging causes structural and functional changes that eventually lead to cellular death or a decreased capacity to recover from injury. Mechanisms explaining how and why cells age are not known, and distinguishing between pathologic changes and physiologic changes that occur with aging is often difficult. Aging clearly causes alterations in cellular structure and function, yet *senescence*—growing old—is both inevitable and normal.

Cellular Adaptation

Cells adapt to their environment to escape and protect themselves from injury. An adapted cell is neither normal nor injured—its condition lies somewhere between these two states. Adaptations are reversible changes in cell size, number, phenotype, metabolic activity, or functions of cells.¹ However, cellular adaptations are a common and central part of many disease states. In the early stages of a successful adaptive response, cells may have enhanced function; thus, it is hard to differentiate a pathologic response from an extreme

adaptation to an excessive functional demand. The most significant adaptive changes in cells include atrophy (decrease in cell size), hypertrophy (increase in cell size), hyperplasia (increase in cell number), and metaplasia (reversible replacement of one mature cell type by another less mature cell type or a change in the phenotype). Dysplasia (deranged cellular growth) is not considered a true cellular adaptation but rather an atypical hyperplasia. These changes are shown in Fig. 2.1.

FIGURE 2.1 Adaptive Alterations in Simple Cuboidal Epithelial Cells.

Atrophy

Atrophy is a decrease or shrinkage in cellular size. If atrophy occurs in a sufficient number of an organ's cells, the entire organ shrinks or becomes atrophic. Atrophy can affect any organ, but it is most

common in skeletal muscle, the heart, secondary sex organs, and the brain (Fig. 2.2). Atrophy can be classified as *physiologic* or *pathologic*. **Physiologic atrophy** occurs with early development. For example, the thymus gland undergoes physiologic atrophy during childhood. **Pathologic atrophy** occurs as a result of decreases in workload, use, pressure, blood supply, nutrition, hormonal stimulation, and nervous stimulation. Individuals immobilized in bed for a prolonged time exhibit a type of skeletal muscle atrophy called **disuse atrophy**. Aging causes brain cells to become atrophic and endocrine-dependent organs, such as the gonads, to shrink as hormonal stimulation decreases. Whether atrophy is caused by normal physiologic conditions or by pathologic conditions, atrophic cells exhibit the same basic changes.

FIGURE 2.2 Atrophy. A, Normal brain of a young adult. B, Atrophy of the brain in an 82-year-old male with atherosclerotic disease. Atrophy of the brain is a result of aging and reduced blood supply. Note that loss of brain substance narrows the gyri and widens the sulci. The meninges have been stripped from the right half of each specimen to reveal the surface of the brain. (From Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

The atrophic muscle cell contains less endoplasmic reticulum (ER) and fewer mitochondria and myofilaments (part of the muscle fiber that controls contraction) than does the normal cell. In muscular

atrophy caused by nerve loss, oxygen consumption and amino acid uptake are rapidly reduced. The mechanisms of atrophy include decreased protein synthesis or increased protein degradation, or both. The degradation of proteins occurs mainly by the ubiquitin-proteasome pathway (see [Chapter 1](#)).

Atrophy as a result of malnutrition may activate ubiquitin ligases that target the proteins for degradation in proteasomes. The accelerated protein degradation may be a mechanism responsible for catabolic conditions, including cancer cachexia. Atrophy is often accompanied by a “self-eating” process called *autophagy* inducing **autophagic vacuoles**. These vacuoles are membrane-bound vesicles within the cell that contain cellular debris—small fragments of mitochondria and ER—and hydrolytic enzymes. Atrophic change causes a rapid increase in hydrolytic enzymes, which are isolated in autophagic vacuoles to prevent uncontrolled cellular destruction. Thus the vacuoles proliferate as needed to protect the uninjured organelles from the injured organelles and are eventually taken up and destroyed by lysosomes. Certain contents of the autophagic vacuole may resist destruction by lysosomal enzymes and persist in membrane-bound residual bodies. An example of this is granules that contain **lipofuscin**, the yellow-brown age pigment. Lipofuscin accumulates primarily in liver cells, myocardial cells, and atrophic cells.

Hypertrophy

Hypertrophy is an increase in the size of cells that consequently increases the size of the affected organ. Much of the knowledge on hypertrophy is from studies of the heart. The cells of the heart and kidneys are particularly responsive to enlargement. Hypertrophy can be *physiologic* or *pathologic*. **Physiologic hypertrophy** is the result caused by increased demand, stimulation by hormones (e.g., atrial natriuretic peptide hormone), and growth factors (e.g., IGF-1). Physiologic hypertrophy in skeletal muscle occurs in response to heavy work. Muscular hypertrophy tends to diminish if the excessive workload diminishes. Pregnancy is an example of physiologic

hypertrophy and hormone-induced uterine enlargement.

Pathologic hypertrophy results from chronic hemodynamic overload, for example, from hypertension or heart valve dysfunction. A focus of much research is the molecular basis of cardiac hypertrophy because it can progress to maladaptive states, including dysrhythmias, heart failure, and sudden death.

The triggers for cardiac hypertrophy include two types of signals: *mechanical signals*, such as stretch, and *trophic signals*, such as growth factors and vasoactive agents (Fig. 2.3). The stretch mechanical sensors are triggered from increased workload. These sensors, themselves, can increase production of growth factors (e.g., IGF-1) and vasoactive factors (e.g., angiotensin II).¹ The signals from these membrane sensors activate complex signaling pathways, including the phosphoinositide 3-kinase (PI3K)/AKT pathway and G-protein-coupled receptors. Transcription factors are activated from the signaling pathways to increase synthesis of muscle proteins.¹ Initial enlargement of the heart is caused by dilation of the cardiac chambers, is short-lived, and is followed by increased synthesis of cardiac muscle proteins allowing muscle fibers to do more work. The nucleus also is hypertrophic and exhibits increased synthesis of deoxyribonucleic acid (DNA). The increase in cellular size is associated with an increased accumulation of protein in the cellular components (plasma membrane, ER, myofilaments, mitochondria) and *not* with an increase in the amount of cellular fluid. With time cardiac hypertrophy is characterized by extracellular matrix remodeling and increased growth of adult myocytes. Prolonged cardiac hypertrophy progresses to contractile dysfunction, decompensation, and finally heart failure. Heart failure is a leading cause of mortality worldwide. One area of investigation is microRNAs (miRNAs) that regulate target gene expression posttranscriptionally. In mice, the miRNA 212-/132 family regulates cardiac hypertrophy and autophagy in cardiomyocytes.^{2,3} Remodeling of cardiac tissue occurs after cardiac stress and can progress to heart failure and death. Investigators are studying the formation of cardiac fibrosis caused by increased activity of cardiac fibroblasts leading to excessive

extracellular matrix production. Noncoding RNAs (ncRNAs) as gene regulators is one focus of study for cardiac fibrosis and therapeutic targets.⁴

FIGURE 2.3 Mechanisms of Myocardial Hypertrophy. Mechanical sensors appear to be the main stimulators for physiologic hypertrophy. Other stimuli possibly more important for pathologic hypertrophy include agonists (initiators) and growth factors. These factors then signal transcription pathways whereby transcription factors then bind to DNA sequences, activating muscle proteins that are responsible for hypertrophy. These pathways include induction of embryonic/fetal genes, increased synthesis of contractile proteins, and production of growth factors. *ANF*, atrial natriuretic factor; *IGF-1*, insulin-like growth factor-1. (From Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

Hyperplasia

Hyperplasia is an increase in the number of cells in an organ or tissue resulting from an increased rate of cellular division. Hyperplasia occurs as a response to injury that results when the injury has been severe and prolonged. The main mechanism for hyperplasia is the production of growth factors, which stimulate the remaining cells

(after cell loss or injury) to synthesize new cell components and, ultimately, to divide. Another mechanism is increased output of new cells from tissue stem cells. For example, if liver cells are compromised, new cells can regenerate from intrahepatic stem cells.¹ Although hyperplasia and hypertrophy have distinct processes, they can occur together and the specific mechanism is unknown. Hyperplasia can be *physiologic* or *pathologic*.

Two types of normal, or physiologic, hyperplasia are compensatory hyperplasia and hormonal hyperplasia. **Compensatory hyperplasia** is an adaptive mechanism that enables certain organs to regenerate. For example, removal of part of the liver leads to hyperplasia of the remaining liver cells (hepatocytes) to compensate for the loss. Even with removal of 70% of the liver, regeneration is complete in about 2 weeks. The liver can renew itself by simple duplication of fully differentiated cells.⁵ Hepatocytes usually live a year or more; and then, through a very slow rate of cell division, they renew themselves. If large numbers of hepatocytes are lost from surgery or injury, a burst of cell division occurs from the surviving hepatocytes—rapidly replacing the lost tissue.⁵ Much is unknown about stem cell activation and hepatocyte renewal in severe forms of liver injury.

Significant compensatory hyperplasia occurs in epidermal and intestinal epithelia, hepatocytes, bone marrow cells, and fibroblasts. An example of compensatory hyperplasia is a **callus**, or thickening, of the skin as a result of hyperplasia of epidermal cells in response to a mechanical stimulus. Another example is the response to wound healing as part of the inflammation process (see [Chapter 7](#)).

Hormonal hyperplasia occurs chiefly in estrogen-dependent organs, such as the uterus and breast. After ovulation, for example, estrogen stimulates the endometrium to grow and thicken for reception of the fertilized ovum. If pregnancy occurs, hormonal hyperplasia, as well as hypertrophy, enables the uterus to enlarge.

Pathologic hyperplasia is the abnormal proliferation of normal cells and can occur as a response to excessive hormonal stimulation or the effects of growth factors on target cells ([Fig. 2.4](#)). Hyperplastic cells are identified by pronounced enlargement of the nucleus, clumping of

chromatin, and the presence of one or more enlarged nucleoli. The most common example is pathologic hyperplasia of the endometrium, which is caused by an imbalance between estrogen and progesterone levels with relative increases of estrogen. Pathologic endometrial hyperplasia, which causes excessive menstrual bleeding, is under the influence of regular growth-inhibition controls. If these controls fail, hyperplastic endometrial cells can undergo malignant transformation. Benign prostatic hyperplasia is another example of pathologic hyperplasia and results from changes in hormone balance. In both of these examples, if the hormonal imbalance is corrected hyperplasia regresses.¹

FIGURE 2.4 Hyperplasia of Bronchial Epithelium (Bronchial Brush). (From Damjanov I, Linder J: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Dysplasia: Not a True Adaptive Change

Dysplasia refers to abnormal changes in the size, shape, and organization of mature cells. Dysplasia is not considered a true adaptive process but is related to hyperplasia and is often called **atypical hyperplasia**. Dysplastic changes are mostly found in epithelia. The architecture of the dysplastic tissue can be disorderly. Importantly, the term *dysplasia* is *not* cancer and may not progress to cancer. Dysplasias that do not involve the entire thickness of epithelium may be completely reversible.¹ Removal of the inciting

stimulus, for example, certain hormonal stimuli, in mild to moderate dysplasia that does not involve the entire epithelium may be reversed.¹ When dysplastic changes penetrate the basement membrane it is considered a preinvasive neoplasm and is known as *carcinoma in situ*.

Metaplasia

Metaplasia is the reversible replacement of one mature cell type (epithelial or mesenchymal) by another, sometimes less differentiated, cell type. It is found in association with tissue damage, repair, and regeneration.¹ At certain times, the adaptive replacement cell type may be more suitable to the changed conditions in the surrounding environment. For example, gastroesophageal reflux damages squamous epithelium of the esophagus, and the adapted change or replacement by glandular epithelium may better tolerate the acidic environment.¹ Usually, however, the change is not beneficial. In the long-term cigarette smoker, the chronic irritation from the smoke causes the normal ciliated columnar epithelial cells of the trachea and bronchi to become replaced by stratified squamous epithelial cells (Fig. 2.5). The newly formed squamous epithelial cells do not secrete mucus or have cilia, causing loss of a vital protective mechanism. Bronchial metaplasia can be reversed if the inducing stimulus, usually cigarette smoking, is removed. If the inducing stimulus is persistent, it can initiate malignant transformation in the metaplastic epithelium.

FIGURE 2.5 Reversible Changes in Cells Lining the Bronchi. A, Normal ciliated epithelium, metaplasia, and dysplasia. B, Histologic slide with upper left (*black arrow*) normal columnar epithelium and basement membrane, and upper right (*red arrow*) squamous metaplasia. (B from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2007, Saunders.)

Metaplasia develops from a reprogramming of stem cells existing in most epithelia or of undifferentiated **mesenchymal** (tissue from embryonic mesoderm) **cells** present in connective tissue. These precursor cells mature along a new pathway because of signals generated by cytokines and growth factors in the cell's environment. The mechanism of metaplasia is, therefore, *not* the result of a change in the phenotype of an already differentiated cell type.¹

Cellular Injury

Injury to cells and to extracellular matrix (ECM) leads to injury of tissues and organs ultimately determining the structural patterns of disease. Loss of function derives from cell and ECM injury and cell death. Cellular injury occurs if the cell is “stressed” or unable to maintain homeostasis in the face of injurious stimuli or cell stress. Injured cells may recover (**reversible injury**) or die (**irreversible injury**). Injurious stimuli include chemical agents, lack of sufficient oxygen (hypoxia), free radicals, infectious agents, physical and mechanical factors, immunologic reactions, genetic factors, and nutritional imbalances. Types of cellular injury and their responses are summarized in [Table 2.1](#) and [Fig. 2.6](#).

TABLE 2.1

PROGRESSIVE TYPES OF CELL INJURY AND RESPONSES

TYPE	RESPONSES
Adaptation	Atrophy, hypertrophy, hyperplasia, metaplasia
Active cell injury	Immediate response of “entire” cell
Reversible	Loss of adenosine triphosphate (ATP), swelling of cell, detachment of ribosomes, autophagy of lysosomes
Irreversible	“Point of no return” structurally when severe vacuolization of mitochondria occurs and Ca^{++} moves into the cell, including mitochondrial membrane damage
Necrosis	Common type of cell death with severe cell swelling and breakdown of organelles
Apoptosis, a type of programmed cell death	Cellular self-destruction for elimination of unwanted cell populations
Chronic cell injury (subcellular alterations)	Persistent stimuli response may involve only specific organelles or cytoskeleton (e.g., phagocytosis of bacteria)
Accumulations or infiltrations	Water, pigments, lipids, glycogen, proteins
Pathologic calcification	Dystrophic and metastatic calcification

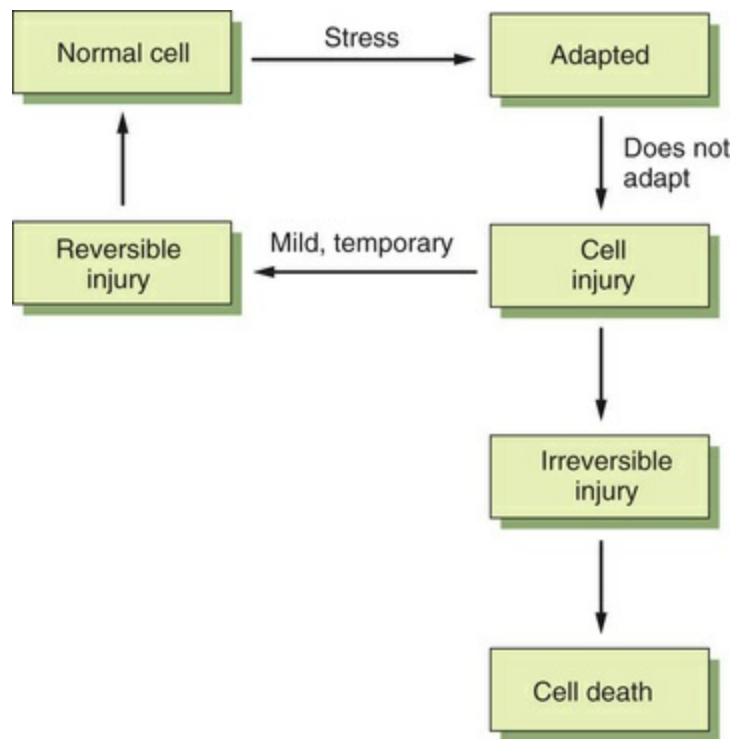

FIGURE 2.6 Stages of Cellular Adaptation, Injury, and Death. The normal cell responds to physiologic and pathologic stresses by adapting (atrophy, hypertrophy, hyperplasia, metaplasia). Cell injury occurs if the adaptive responses are exceeded or compromised by injurious agents, stress, and mutations. The injury is reversible if it is mild or transient, but if the stimulus persists the cell suffers irreversible injury and eventually death.

Cell injury and cell death often result from exposure to toxic chemicals, infections, physical trauma, and hypoxia. The mechanisms causing chemical and hypoxic injury are perhaps the best understood. Both of these mechanisms can lead to disruption of selective permeability (i.e., transport mechanisms) of the plasma membrane; reduction or cessation of cellular metabolism; lack of protein synthesis; damage to lysosomal membranes with leakage of destructive enzymes into the cytoplasm; enzymatic destruction of cellular organelles; cellular death (exhibited by nuclear changes); and phagocytosis of the dead cell by cellular components of the acute inflammatory response. The extent of cellular injury depends on the type, state (including level of cell differentiation and increased susceptibility to fully differentiated cells), and adaptive processes of

the cell, as well as the type, severity, and duration of the injurious stimulus. Two individuals exposed to an identical stimulus may incur varying degrees of cellular injury. Modifying factors, such as nutritional status, can profoundly influence the extent of injury. The precise “point of no return” that leads to cellular death is a biochemical puzzle, and the exact mechanisms responsible for the transition from reversible to irreversible cellular damage are being debated.

General Mechanisms of Cell Injury

Common biochemical mechanisms are important to understanding cell injury and cell death regardless of the injuring agent (Table 2.2). These mechanisms include adenosine triphosphate (ATP) depletion, mitochondrial damage, accumulation of oxygen and oxygen-derived free radicals, membrane damage (depletion of ATP), protein folding defects, DNA damage defects, and calcium level alterations (Fig. 2.7). Examples of cell injury are (1) ischemic and hypoxic injury, (2) ischemia-reperfusion injury, (3) oxidative stress or accumulation of oxygen-derived free radicals–induced injury, and (4) chemical injury.

TABLE 2.2

COMMON MECHANISMS IN CELL INJURY AND CELL DEATH

THEME	COMMENTS
ATP depletion	Loss of mitochondrial adenosine triphosphate (ATP) and decreased ATP synthesis; results include cellular swelling, decreased protein synthesis, decreased membrane transport, and lipogenesis, all changes that contribute to loss of integrity of the plasma membrane (see text)
Oxygen and oxygen-derived free radicals	Lack of oxygen is key in progression of cell injury in ischemia (reduced blood supply); activated oxygen species (free radicals, H_2O_2 , $OH\cdot$, NO) cause destruction of cell membranes and cell structure
Intracellular calcium and loss of calcium steady state	Normally intracellular cytosolic calcium concentrations are very low; ischemia and certain chemicals cause an increase in cytosolic Ca^{++} concentrations; sustained levels of Ca^{++} continue to increase with damage to plasma membrane; Ca^{++} causes intracellular damage by activating a number of enzymes (see text)

Defects in membrane permeability

Early loss of selective membrane permeability found in all forms of cell injury (see text)

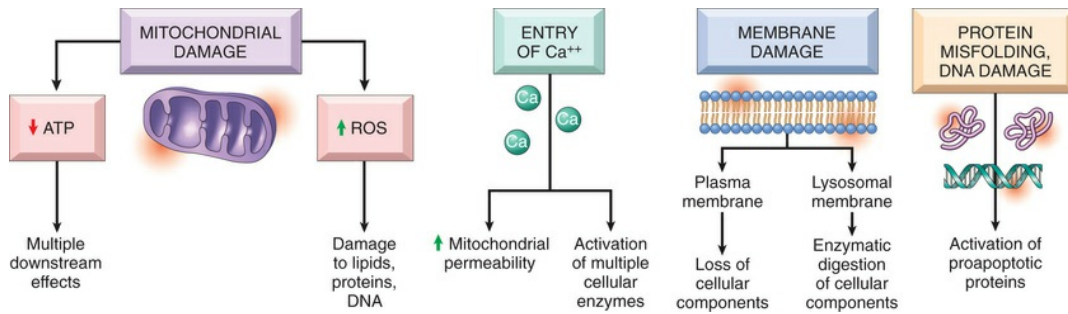

FIGURE 2.7 Example of Biochemical Mechanisms and Damage in Cell Injury. *ATP*, Adenosine triphosphate; *ROS*, reactive oxygen species. (Adapted from Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

Ischemic and Hypoxic Injury

Hypoxia, or lack of sufficient oxygen, is the single most common cause of cellular injury (Fig. 2.8). Hypoxia can result from a reduced amount of oxygen in the air, loss of hemoglobin or hemoglobin function, decreased production of red blood cells, consequences of respiratory and cardiovascular system diseases, and poisoning of the oxidative enzymes (cytochromes) within the cells. The most common cause of hypoxia is **ischemia** (reduced blood supply). Hypoxia can induce inflammation, and inflamed lesions can become hypoxic (Fig. 2.9).

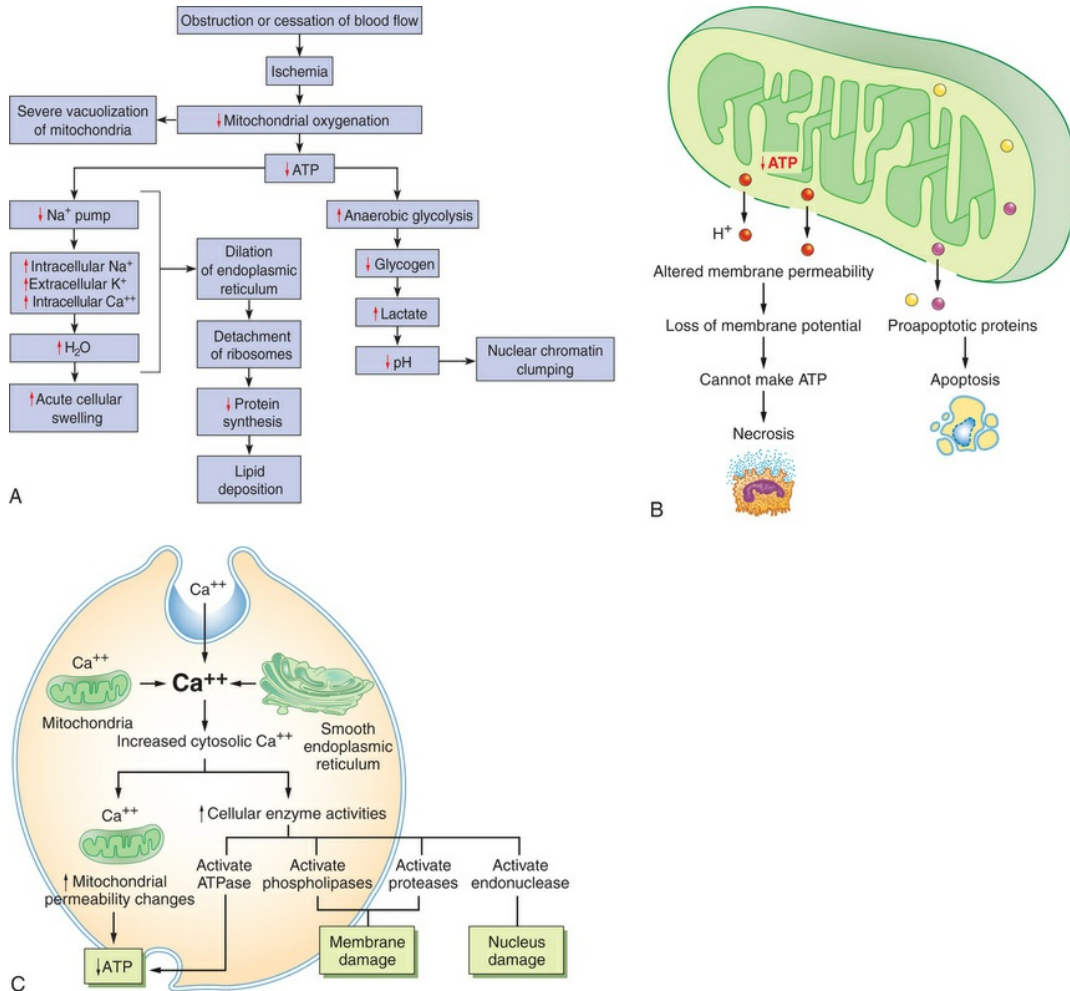

FIGURE 2.8 Hypoxic Injury Induced by Ischemia. **A**, Consequences of decreased oxygen delivery or ischemia with decreased ATP. The structural and physiologic changes are reversible if oxygen is delivered quickly. Significant decreases in ATP concentration result in cell death, mostly by necrosis. **B**, Mitochondrial damage can result in changes in membrane permeability, loss of membrane potential, and a decrease in ATP production. Between the outer and inner membranes of the mitochondria are proteins that can activate the cell's suicide pathways, called *apoptosis*. **C**, Calcium ions are critical mediators of cell injury. Calcium ions are usually maintained at low concentrations in the cell's cytoplasm; thus, ischemia and certain toxins can initially cause an increase in the release of Ca^{++} from intracellular stores and later an increased movement (influx) across the plasma membrane. *ATP*, Adenosine triphosphate; *ATPase*, enzyme.

FIGURE 2.9 Hypoxia and Inflammation. Shown is a simplified drawing of clinical conditions characterized by tissue hypoxia that causes inflammatory changes (*left*) and inflammatory diseases that ultimately lead to hypoxia (*right*). These diseases and conditions are discussed in more detail in their respective chapters. (Adapted from Eltzschig HK, Carmeliet P: *N Engl J Med* 364:656–665, 2011.)

Ischemic injury is often caused by gradual narrowing of arteries (arteriosclerosis) and complete blockage by blood clots (thrombosis). Progressive hypoxia caused by gradual arterial obstruction is better tolerated than the sudden acute **anoxia** (total lack of oxygen) caused by a sudden obstruction, such as can occur with an embolus (a blood clot or other plug in the circulation). An acute obstruction in a coronary artery can cause myocardial cell death (infarction) within

minutes if the blood supply is not restored, whereas the gradual onset of ischemia usually results in myocardial adaptation. Myocardial infarction and stroke, which are common causes of death in the United States, generally result from atherosclerosis (a type of arteriosclerosis) and consequent ischemic injury.

Cellular responses to hypoxic injury in heart muscle have been extensively studied. Within 1 minute after blood supply to the myocardium is interrupted, the heart becomes pale and has difficulty contracting normally. Within 3 to 5 minutes the ischemic portion of the myocardium ceases to contract. The abrupt lack of contraction is caused by a rapid decrease in mitochondrial phosphorylation, which results in insufficient adenosine triphosphate (ATP) production. Lack of ATP leads to an increase in anaerobic metabolism, which generates ATP from glycogen when there is insufficient oxygen. When glycogen stores are depleted, even anaerobic metabolism ceases.

A reduction in ATP levels causes the plasma membrane's sodium-potassium ($\text{Na}^+\text{-K}^+$) pump and sodium-calcium exchange to fail, which leads to an intracellular accumulation of sodium and calcium, resulting in cellular swelling and diffusion of potassium out of the cell. Because all cells are bathed in a fluid rich in calcium ions, cell membrane damage allows rapid movement of calcium intracellularly. The movement of water and ions into the cell causes early dilation of the ER. Dilation causes the ribosomes to detach from the rough ER, resulting in reduced protein synthesis. With continued hypoxia, the entire cell becomes markedly swollen, with increased concentrations of sodium, water, and chloride and decreased concentrations of potassium. These disruptions are reversible if oxygen is restored. If oxygen is not restored, however, there is **vacuolation** (formation of vacuoles or cytoplasmic small cavities) within the cytoplasm, swelling of lysosomes, and marked swelling of the mitochondria resulting from mitochondrial membrane damage. Continued hypoxic injury with accumulation of calcium subsequently activates multiple enzyme systems, including proteases, nitric oxide synthase, phospholipases, and endonuclease. These activations result in cytoskeleton disruption, membrane damage, inflammation, DNA and chromatin degradation,

ATP depletion, and eventual cell death (see [Figs. 2.8](#) and [2.30](#)). Structurally, with plasma membrane damage, extracellular calcium readily moves into the cell and intracellular calcium stores are released.

Intracellular calcium results in the activation of enzymes that can further damage membranes, proteins, ATP, and nucleic acids. The increased permeability of the membrane causes continued loss of proteins, essential coenzymes, and ribonucleic acids. In addition, the substrates necessary to reconstitute ATP are lost. Increased intracellular calcium levels activate cell enzymes (caspases) that promote cell death by apoptosis (see [Fig. 2.36](#)).

Acid hydrolases from leaking lysosomes are activated in the reduced pH of the injured cell and they digest cytoplasmic and nuclear components. Leakage of intracellular enzymes into the peripheral circulation provides a diagnostic tool for detecting tissue-specific cellular injury and death using blood samples; for example, the contractile protein troponin from cardiac muscle is found after myocardial injury and liver transaminases are found after hepatic injury.

Ischemia-Reperfusion Injury

Restoration of oxygen, however, can cause additional injury called **reperfusion (reoxygenation) injury**. Reperfusion injury results from the generation of highly reactive oxygen intermediates (oxidative stress), including hydroxyl radical ($\text{OH}\bullet$), superoxide O_2^- , and hydrogen peroxide (H_2O_2). These radicals can all cause further membrane damage and mitochondrial calcium overload. The white blood cells (neutrophils) are especially affected with reperfusion injury, including neutrophil adhesion to the endothelium.

Reperfusion is a serious complication and an important mechanism of injury in instances of tissue transplantation and in myocardial, hepatic, intestinal, cerebral, renal, and other ischemic syndromes, including stroke.^{6,7} Xanthine dehydrogenase, an enzyme that normally uses oxidized nicotinamide adenine dinucleotide (NAD^+) as an

electron acceptor, is converted during reperfusion with oxygen to xanthine oxidase. During the ischemic period, excessive ATP consumption leads to the accumulation of the purine catabolites hypoxanthine and xanthine, which upon subsequent reperfusion and influx of oxygen are metabolized by xanthine oxidase to make *massive* amounts of superoxide and hydrogen peroxide. These radicals can all cause membrane damage and mitochondrial calcium overload.⁸ Cardiac ischemia and reperfusion injury cause excessive reactive oxygen species (ROS), pH alterations, osmotic changes, gap junction changes, inflammatory signaling, and calcium overload of the mitochondria. These changes, especially rapid restoration of intracellular pH, lead to the opening of a large conductance pore on the mitochondrial membrane called the *mitochondrial permeability transition pore* (MPTP) with massive escape of ATP and solutes leading to cell death activation (apoptosis).^{6,9} These changes also lead to irreversible cardiomyocyte hypercontracture.¹⁰ Cardioprotection from ischemia/reperfusion injury is an important focus of much research. Other potential and current treatments include use of antioxidants, blockage of inflammatory mediators, and inhibition of apoptotic pathways.

Free Radicals and Reactive Oxygen Species

It is now widely accepted that inherent reactive oxygen species (ROS) from aerobic metabolism play a crucial biologic role not just in various diseases but also for normal cellular communication and cell function (Fig. 2.10). ROS reversibly modulates many intracellular signaling pathways.¹¹ ROS are increasingly implicated in various cell fates and signal transduction pathways.¹¹ ROS-dependent signaling involves the reversible oxidation and reduction of specific amino acids; reactive cysteine (Cys) residues are most frequently targeted.¹¹ ROS can affect protein functions through several mechanisms, including regulation of protein expression, posttranslational modifications, and alteration of protein stability. The outcome effects of these mechanisms include regulating protein stability, increasing and decreasing protein function, altering protein location, and altering protein-protein

interaction ([Fig. 2.11](#)).

FIGURE 2.10 Physiologic and Pathologic Roles of Redox Biology and Reactive Oxygen Species. A, Summary figure of expanding roles of redox biology and reactive oxygen species (ROS). B, ROS regulation of inflammation requires ROS signaling. ROS and redox signaling is crucial to understand because inflammation is associated with many diseases processes. Common patterns associated with pathogens or cell damage (PAMPS or DAMPS) activate immune surveillance receptors (TLR, NLR, RLR), which increase ROS from NAPDH oxidase (NOX) enzymes and mitochondria. The release of proinflammatory cytokines (IL-1 β , TNF- α , IFN β) depends on ROS. C, Low levels of ROS maintain a normal immune system. Decreasing ROS levels inhibit activation or normal immune responses resulting in immunosuppression. Elevated ROS levels contribute to autoimmunity increasing the release of proinflammatory cytokines and proliferation of some adaptive immune cells. D, Moderate levels of ROS are required for proper stem-cell differentiation and renewal through activation of signaling pathways. ROS levels that are elevated lead to stem-cell exhaustion and premature aging through activation of signaling pathways. E, Increased ROS levels are not always detrimental to life span. Slight increases in ROS can drive signaling pathways that counter the normal aging process; conversely, high levels of ROS can cause hyperactive signaling pathways that promote inflammation, cancer and cell death, and an accelerated aging phenotype. The expanding roles of redox biology and ROS present challenges for understanding the use of pro-oxidant therapy to promote physiologic ROS responses or antioxidant therapy to prevent ROS pathologies. (From Schieber M, Chandel NS: *Curr Biol* 24:R453–R462, 2014.)

FIGURE 2.11 Redox-Dependent Signaling: Biologic Mechanisms and Consequences. The oxidation and reduction (redox) of sensitive targets or proteins with cysteine (Cys) residues provide a mechanism to rapidly and reversibly alter protein function. Cys residues can function as redox-

dependent “switches.” Oxidation of Cys residues (SH[thiol]) to SOH (sulfenic acid) leads to alterations in the redox-sensitive target that result in many effects on protein stability, activity, and protein-protein interaction. (Adapted from Homstrom KM, Finkel T: *Nat Rev* 15[6]:411–421, 2014).

Reduction-oxidation (redox)–dependent regulation and the roles of ROS encompass both normal physiologic and pathologic roles. These expanding roles include proliferation and differentiation, immune function, stem cell self-renewal, tumor progression, autoimmunity, stem cell exhaustion, senescence, and longevity (see [Fig. 2.11](#)). These topics are discussed in relevant sections in the textbook, and some aspects of redox signaling are included here with the main emphasis on cell injury.

Cell injury produced by free radicals, particularly reactive oxygen species, is an important mechanism of cell damage in many conditions including chemical and radiation injury, ischemia-reperfusion injury (induced with restoration of blood flow in ischemic tissue), microbial killing by phagocytes (rapid bursts), and cellular aging.¹ A **free radical** is any molecular species capable of independent existence that contains a single unpaired electron in an outer orbit. Having one unpaired electron makes the molecule unstable; the molecule becomes stabilized either by donating or by accepting an electron from another molecule. When the attacked molecule loses its electron, it becomes a free radical. Therefore it is capable of injurious chemical bond formation with DNA, RNA, proteins, lipids, and carbohydrates—many are key molecules in membranes and nucleic acids. Free radicals are difficult to control and initiate chain reactions. With low chemical specificity and high reactivity, free radicals can react with most molecules in their proximity.

Reactive oxygen species (ROS) are chemically reactive molecules from molecular oxygen formed as natural oxidant species in cells during mitochondrial respiration and energy generation. The intracellular sources of oxidants are numerous and include (1) cellular organelles with mitochondria (thought to be the largest contributor), ER (particularly during endoplasmic stress), and peroxisomes; (2) NADPH oxidases (NOX enzymes); and (3) other enzymes ([Fig. 2.12](#)).¹¹ From oxidative phosphorylation, mitochondria utilize oxygen to

generate ATP from organic fuel molecules and in the process produce ROS.¹²

FIGURE 2.12 Intracellular Sources of ROS and Sites of Generation of ROS From Mitochondria. The intracellular sources of reactive oxygen species (ROS) include some organelles: mitochondria, endoplasmic reticulum (ER) (particularly ER stress), and peroxisomes (metabolizing long-chain fatty acids [LCFAs]). As part of the enzymatic reaction cycles, various enzymes generate ROS, including oxidases and oxygenases. H_2O_2 , Hydrogen peroxide; $NADPH$, nicotinamide adenine dinucleotide phosphate. (Adapted from Homstrom KM, Finkel T: *Nat Rev* 15[6]:411–421, 2014).

An important mechanism of membrane damage is injury induced by free radicals, especially by a disturbance in the balance between the production of ROS and antioxidant defenses called **oxidative stress** (Fig. 2.13). Oxidative stress can be caused by an increase of different reactive species or a depletion of antioxidant defense, or both, and results in detrimental oxidation of different molecules including proteins, lipids, nucleic acids, and others. Oxidative stress can activate several intracellular signaling pathways because ROS can modulate enzymes and transcription factors. This process is an important

mechanism of cell damage in many conditions, including cell injury, cancer, certain degenerative diseases (e.g., Alzheimer disease), and aging. ROS can mediate posttranslational modifications of molecules involved in intracellular signaling networks and regulate normal signaling components, a process called **redox signaling**. Although ROS have been appreciated for their damage-promoting, detrimental effects, there is now a greater understanding of their roles as signaling molecules.¹²

FIGURE 2.13 Oxidative Stress in Human Pathogenesis. Reactive oxygen species (ROS) have a role in a wide variety of diseases and age-related

diseases including cancer, neurologic disease, type 2 diabetes, autoimmune and cardiovascular diseases, infertility, and normal aging. Chronic exposure to ROS and decreased DNA repair can result in persistent DNA mutations. Accumulation of DNA lesions can lead to DNA double strand breaks (DSBs) and disease onset/progression. Diseased cells can in turn develop ROS and decrease the efficiency of the DNA repair mechanism. (Adapted from Sedelnikova OA et al: *Mutat Res* 704:152–159, 2010.)

Free radicals are generated within cells in several ways: (1) reduction-oxidation reactions (redox reactions) in normal metabolic processes, such as respiration; (2) absorption of extreme energy sources (e.g., ultraviolet light, radiation); (3) enzymatic metabolism of exogenous chemicals, drugs, and pesticides; (4) the process of transition metals (i.e., iron and copper) donating or accepting free electrons during intracellular reactions and activating the formation of free radicals, such as in the Fenton reaction (Fig. 2.14); and (5) nitric oxide (NO) acting as an important chemical mediator and can act as a free radical. NO is a colorless gas and an intermediate in many reactions generated by endothelial cells, neurons, macrophages, and other cell types. It can be converted to peroxynitrite anion (ONOO^-), NO_2 , and NO_3^- (Table 2.3). All biologic membranes contain redox systems important for cell defense, for example, inflammation.

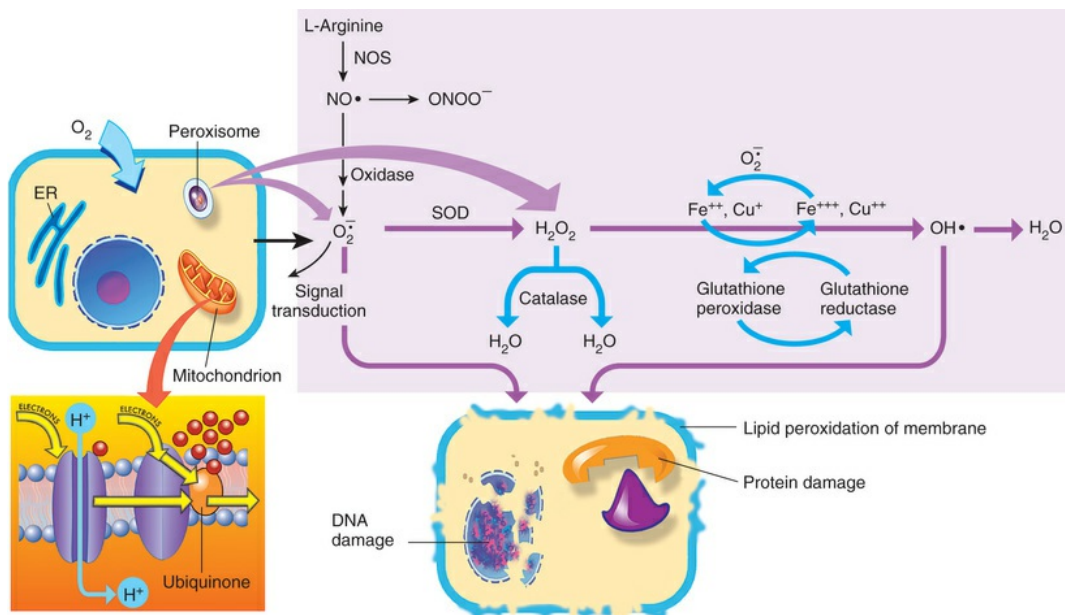

FIGURE 2.14 Generation of Reactive Oxygen Species (ROS) and

Antioxidant Mechanisms in Biologic Systems. Mitochondria have four sites of entry for electrons coming into the electron-transport system: one for reduced nicotinamide adenine dinucleotide (NADH) and three for the reduced form of flavin adenine dinucleotide (FADH₂). These pathways meet at the small, lipophilic molecule ubiquinone (coenzyme Q), at the beginning of the common electron-transport pathway. Ubiquinone transfers electrons in the inner membrane, ultimately enabling their interaction with O₂ and H₂ to yield H₂O. In so doing, the transport allows free energy change and the synthesis of 1 mol of adenosine triphosphate (ATP). With the transport of electrons, free radicals are generated within the mitochondria. ROS (H₂O₂, OH•, and O₂⁻ and nitric oxide [NO]) act as physiologic modulators of some mitochondrial functions but also may cause cell damage. O₂ is converted to superoxide (O₂⁻) by oxidative enzymes in the mitochondria, endoplasmic reticulum (ER), plasma membrane, peroxisomes, and cytosol. O₂ is converted to H₂O₂ by superoxide dismutase (SOD) and further to OH• by the Cu⁺⁺/Fe⁺⁺ Fenton reaction. Superoxide catalyzes the reduction of Fe⁺⁺ to Fe⁺⁺⁺, thus increasing OH• formation by the Fenton reaction. H₂O₂ is also derived from oxidases in peroxisomes. The NO• (radical) is produced by the oxidation of one of the terminal guanido-nitrogen atoms of L-arginine. Depending on the microenvironment, NO can be converted to other reactive nitrogen species including the highly reactive peroxynitrite (ONOO⁻). Both OH• and ONOO⁻ are very reactive and can modify cellular macromolecules and cause toxicity. The less reactive molecules O₂⁻ and H₂O₂ can serve as cellular signaling molecules. The major antioxidant enzymes include SOD, catalase, and glutathione peroxidase. (Data from Dröge W: *Physiol Rev* 82:47–95, 2002; Buetler TM, Krauskopf A, Ruegg UT: *News Physiol Sci* 19:120–123, 2004.)

TABLE 2.3

BIOLOGICALLY RELEVANT FREE RADICALS

FREE RADICAL	COMMENTS
<p>Reactive oxygen species (ROS)</p> <p>Superoxide O₂⁻ O₂ → oxidase O₂⁻</p>	<p>Generated either (1) directly during autooxidation in mitochondria or (2) enzymatically by enzymes in the cytoplasm, such as xanthine oxidase or cytochrome P-450; once produced, it can be inactivated spontaneously or more rapidly by the enzyme superoxide dismutase (SOD):</p> $O_2^- + O_2^- + 2H^+ \rightarrow SOD \ H_2O_2 + O_2$ <p>O₂⁻ ; a signaling molecule in growing or differentiating tissue, including hypertrophy, can alter cellular responses to growth factors and vasoconstrictor hormones; increasing levels of O₂⁻ may lead to apoptosis (see Fig. 2.11)</p>
<p>Hydrogen peroxide (H₂O₂)</p>	<p>Generated by SOD or directly by oxidases in intracellular peroxisomes; SOD is considered an antioxidant because it converts superoxide to H₂O₂; catalase (another antioxidant) can then decompose H₂O₂ to O₂ + H₂O; H₂O₂ can serve as a</p>

$O_2 + O_2^- + 2H^+ \rightarrow SOD\ H_2O_2 + O_2$ <i>or</i> Oxidases present in peroxisomes <small>O_2, peroxisome $O_2^- \rightarrow SOD\ H_2O_2$</small>	cellular signaling molecule
Hydroxyl radicals (OH•) $H_2O \rightarrow H\bullet + OH\bullet$ <i>or</i> $Fe^{++} + H_2O_2 \rightarrow Fe^{+++} + OH\bullet + OH^-$ <i>or</i> $H_2O_2 + O_2^- \rightarrow OH\bullet + OH^- + O_2$	Generated by the hydrolysis of water caused by ionizing radiation or by interaction with metals—especially iron (Fe) and copper (Cu); iron is important in toxic oxygen injury because it is required for maximal oxidative cell damage; OH• is highly reactive and can modify cellular macromolecules and cause toxicity
Nitric oxide (NO) $NO\bullet + O_2^- \rightarrow ONOO^- + H^+$ $\uparrow\downarrow$ $OH\bullet + NO_2 \rightleftharpoons ONOOH \rightarrow NO_3^-$	NO by itself is an important mediator that can act as a free radical; it can be converted to another radical—peroxynitrite anion (ONOO ⁻), as well as NO ₂ • and NO ₃ ⁻ ; NO is formed in neuronal cells, where it modulates neurotransmission; in endothelial cells as a modulator of vessel relaxation; and in neutrophils and macrophages as a factor in vessel relaxation and inactivation of pathogens

Data from Kumer V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders; Buetler TM, Krauskopf A, Ruegg UT: *News Physiol Sci* 19:120–123, 2004.

Emerging data indicate that ROS play roles in the initiation and progression of cardiovascular alterations associated with hypertension, hyperlipidemia, diabetes mellitus, ischemic heart disease, chronic heart failure, and sleep apnea.¹³⁻¹⁵ ROS generation is thought to lead to vascular endothelial injury and consequently atherosclerosis. Upregulation of adhesion molecule production in the endothelium can be accomplished by ROS, which diminishes nitric oxide (NO) synthase activity and promotes NO breakdown. This disturbance of the vascular environment presumably causes a reduction of endothelial-dependent vasodilation.¹⁶ Such reduction in endothelium-dependent vasodilation has been demonstrated through intraarterial infusion of vasoactive agents. Specific mechanisms by which ROS control endothelial function and vascular tone and pathophysiologic consequences include inflammation, hypertrophy,

proliferation, apoptosis, fibrosis, angiogenesis, and vascular remodeling resulting in endothelial dysfunction.¹⁴ Emerging is a better understanding of increased oxidative stress and elevation of ROS in diabetes and hypertension that can lead to dysrhythmia.¹⁵ Oxidative stress-induced arrhythmia can lead to sudden death, and a summary of these mechanisms includes the effect on ion channels, effect on intracellular Ca^{++} , effect on myocyte conduction velocity, and activation of fibrosis with an effect on the extracellular matrix.¹⁷

Development of the placenta during pregnancy is interrelated to oxygen concentration.¹⁸ ROS can regulate gene transcription and affect trophoblast proliferation, invasion, and angiogenesis. Oxidative stress influences autophagy and apoptosis, two processes where an imbalance seems to be linked to pregnancy-related disorders, such as miscarriage, preeclampsia, and intrauterine growth restriction.¹⁸ Oxidative stress observed in maternal smoking, maternal obesity, and preeclampsia has been associated with aberrant angiogenesis and placental dysfunction resulting in adverse pregnancy outcomes.^{19,20}

Although wide-ranging effects can occur from these reactive species, three are particularly important in regard to cell injury: (1) peroxidation of lipids; (2) alterations of proteins causing fragmentation of polypeptide chains that can lead to loss and protein misfolding; and (3) DNA damage causing mutations (Fig. 2.15). **Lipid peroxidation** is the destruction of unsaturated fatty acids. Fatty acids of lipids in membranes possess double bonds between some of the carbon atoms. Such bonds are vulnerable to attack by oxygen-derived free radicals, especially $\text{OH}\bullet$. The lipid-radical interactions themselves yield peroxides. The peroxides instigate a chain reaction resulting in membrane, organelle, and cellular destruction. Because of the increased understanding of free radicals, a growing number of diseases and disorders have been linked either directly or indirectly to these reactive species (Box 2.1).

FIGURE 2.15 Role of Reactive Oxygen Species in Cell Injury. The production of reactive oxygen species (ROS) can be initiated by many cell stressors, such as radiation, toxins, and reperfusion of oxygen. Free radicals are removed by normal decay and enzymatic systems. ROS accumulate in cells because of insufficient removal or excess production leading to cell injury, including lipid peroxidation, protein modifications, and DNA damage or mutations. *SOD*, Superoxide dismutase. (Adapted from Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

Box 2.1

Diseases and Disorders Linked to Oxygen-Derived Free Radicals

Deterioration noted in aging
 Atherosclerosis
 Heart disease
 Stroke
 Brain disorders
 Ischemic brain injury
 Aluminum toxicity
 Alzheimer disease
 Neurotoxins
 AIDS-associated dementia
 Cancer

Cardiac myopathy
 Chronic granulomatous disease
 Diabetes mellitus
 Eye disorders

- Macular degeneration

Table 2.4 summarizes methods that contribute to inactivation or termination of free radicals. The toxicity of certain drugs and

chemicals can be attributed to either the conversion of these chemicals to free radicals or the formation of oxygen-derived metabolites.⁷ This process is discussed under Chemical or Toxic Injury.

TABLE 2.4

METHODS CONTRIBUTING TO INACTIVATION OR TERMINATION OF FREE RADICALS

METHOD	PROCESS
Antioxidants	Endogenous or exogenous; either blocks synthesis or inactivates (e.g., scavenges) free radicals; includes vitamin E, vitamin C, cysteine, glutathione, albumin, ceruloplasmin, transferrin
Enzymes	Superoxide dismutase*, which converts superoxide to H ₂ O ₂ ; catalase* (in peroxisomes) decomposes H ₂ O ₂ •; glutathione peroxidase* decomposes OH• and H ₂ O ₂

*These enzymes are important in modulating the cellular destructive effects of free radicals, also released in inflammation.

Mitochondrial Effects

Mitochondria are the powerhouses of the cell involved in key functions such as ATP production, intracellular Ca⁺⁺ regulation, reactive oxygen species production and scavenging, regulation of apoptotic cell death, and activation of the caspase proteases. Emerging is the role of mitochondria with autophagy (mitophagy), particularly with neurodegenerative diseases. Mitochondria contain their own DNA called **mitochondrial DNA (mtDNA)** and can encode the central proteins involved in energy production. Because mtDNA encodes enzymes involved in oxidative phosphorylation, mutations affecting these genes exert their damaging effects primarily on organs most dependent on oxidative phosphorylation, such as the central nervous system, skeletal muscle, cardiac muscle, liver, and kidneys.¹ New is emerging information that mitochondria act as a central environmental sensor (see [What's New? Mitochondria May Have a Central Role in Mediating Environmental Changes and Genomic Responses](#)). Mitochondria can be damaged by ROS and by increases of cytosolic Ca⁺⁺. During normal metabolism, the mitochondria are the

greatest source and target of ROS (see previous discussion in section [Free Radicals and Reactive Oxygen Species](#) and [Fig. 2.12](#)). Usually the number of ROS is reduced by intracellular antioxidant enzymes, including superoxide dismutase (SOD), glutathione peroxidase, and catalase; as well as antioxidant molecules, such as glutathione and vitamin E. ROS, however, contribute to mitochondria dysfunction and are related to many human diseases and aging. In pathologic conditions, the large numbers of ROS overwhelm the balance by antioxidants. This inefficiency of antioxidants is even more serious in mitochondria because mitochondria in most cells lack catalase.²¹ Consequently, the excessive production of hydrogen peroxide and eventually hydroxyl radicals (OH•) in mitochondria will damage lipid, proteins, and mtDNA, which then causes cells to die.²¹ Mitochondrial oxidative stress has been implicated in heart disease, Alzheimer disease, Parkinson disease, prion diseases, and amyotrophic lateral sclerosis (ALS), as well as aging itself.^{22,23} Accumulating evidence shows ROS are important for cell proliferation and survival.²⁴ Dysfunction of autophagy may result in abnormal mitochondrial function and oxidative or nitrative (i.e., reactive nitrogen species) stress. Investigators have provided new understanding of how autophagy of mitochondria (also known as *mitophagy*) is controlled, and the impact of autophagic dysfunction on cellular oxidative stress. Impaired mitochondrial function, oxidative stress, accumulation of protein aggregates, and autophagic stress are common in many diseases.²⁵ Additionally, investigators are trying to identify the polypeptides (i.e., proteomes) directly involved in diseases associated with mitochondrial dysfunction.

What's New?

Mitochondria May Have a Central Role in Mediating Environmental Changes and Genomic Responses

Mitochondria may be key sensors of environmental changes.

Changes in the environment would affect mitochondrial bioenergetics and alter the production of high-energy mitochondrial molecules. High-energy molecules produced by mitochondria modify the cytoplasmic signaling proteins and epigenomic proteins that regulate nuclear DNA (nDNA) expression. These changes may reprogram gene expression, altering expressions of nDNA-derived and mitochondrial DNA–derived (mtDNA-derived) proteins that act in and on the mitochondria. More simply, mitochondrial physiologic states determined by mtDNA variation sense environmental changes and send specific signals to the nucleus to produce the ideal gene-expression response. These responses influence mitochondrial function, affecting energetic homeostasis and ultimately health, longevity, and disease.

Data from Latorre-Pellicer A et al: *Nature* 535(7613):561–565, 2016; Wallace DC: *Nature* 535:498–500, 2016.

Chemical or Toxic Injury

Mechanisms

Humans are exposed to thousands of chemicals that have inadequate toxicologic data.²⁶ The given societal considerations of time, cost, and reduced animal use have increased the need to develop new methods for toxicity testing. To meet this public health need, many agencies have partnered to investigate how chemicals interact with biologic systems. Advances in molecular and systems biology, computational toxicology, and bioinformatics have increased the development of powerful new tools.

The systems biology approach includes delineation of toxicity pathways that may be defined as cellular response pathways that when disturbed are expected to result in adverse health effects. Using this model of testing, investigators proposed screening and classifying compounds using a “cellular stress response pathway.” Components or mechanisms of these pathways include oxidative stress, heat shock

response, DNA damage response, hypoxia, ER stress, mental stress, inflammation, and osmotic stress. Many chemicals have already been classified under these mechanisms.

Humans are constantly exposed to a variety of compounds termed **xenobiotics** (Greek *xenos*, “foreign”; *bios*, “life”) that include toxic, mutagenic, and carcinogenic chemicals (Figs. 2.16 and 2.17). Some of these chemicals are found in the human diet. Many xenobiotics are toxic to the liver (hepatotoxic). The liver is the initial site of contact for many ingested xenobiotics, drugs, and alcohol, making this organ most susceptible to chemically induced injury. The toxicity of many chemicals results from absorption through the gastrointestinal tract after oral ingestion. A main cause for withdrawing medications from the market is hepatotoxicity. Dietary supplements, for example, chaparral and ma huang, are potent hepatotoxins.²⁷ Other common routes of exposure for xenobiotics are absorption through the skin and inhalation. The severity of chemically induced liver injury varies from minor liver injury to acute liver failure, cirrhosis, and liver cancer.

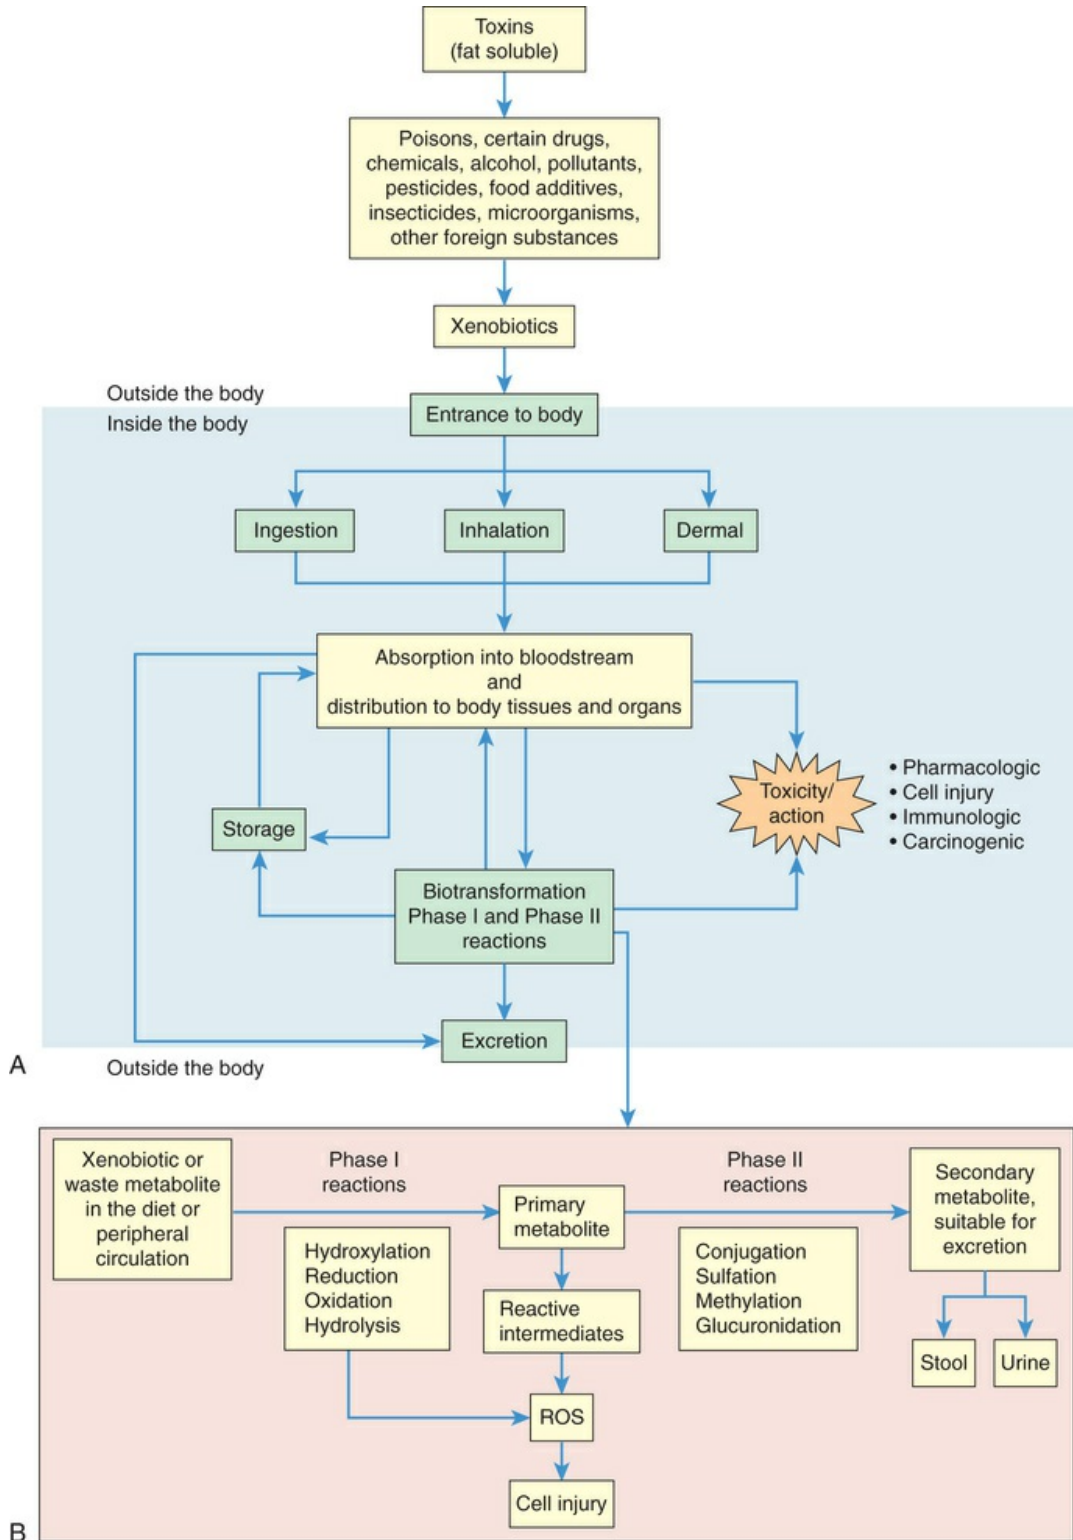

FIGURE 2.16 Fate of Xenobiotics. **A**, Body fate of xenobiotics. **B**, Phase I and Phase II detoxification reactions.

FIGURE 2.17 Human Exposure to Pollutants. Pollutants contained in air, water, and soil are absorbed through the lungs, gastrointestinal (GI) tract, and skin. In the body they may act at the site of absorption but are generally transported through the bloodstream to various organs where they can be stored or metabolized. Metabolism of xenobiotics may result in the formation of water-soluble compounds that are excreted, or a toxic metabolite may be created by activation of the agent. (From Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

The liver as the principal site for xenobiotic metabolism, called *biotransformation*, converts the lipophilic xenobiotics to more

hydrophilic forms for efficient excretion. Biotransformation, however, also can produce short-lived unstable highly reactive chemical intermediates that can lead to adverse effects.²⁸ These harmful intermediates are called **toxiphores**. The intermediates include electrophiles, nucleophiles, free radicals, and redox-active reactants. An **electrophile** (electron lover) is an atom or molecule attracted to electrons and accepts a pair of electrons to make a covalent bond. This process creates a partially or fully charged center in electrophilic molecules.²⁸ A **nucleophile** is an atom or molecule that donates an electron pair to an electrophile to make a chemical bond. All chemical species with a free pair of electrons can act as nucleophiles. Nucleophiles are strongly attracted to positively charged regions in other chemicals and can be oxidized to free radicals and electrophiles.²⁸ In general, the majority of all *reactive* chemical species are electrophilic because the formation of nucleophiles is rare.²⁸ The generation of these excess reactive chemical species leads to molecular damage in liver cells. These reactive intermediates can interact with cellular macromolecules, such as proteins and DNA, forming protein adducts and DNA adducts, or can react directly with cell structures to cause cell damage. Adduct formation can lead to adverse conditions including disruption in protein function, excess formation of fibrous connective tissue (fibrogenesis), and activation of immune responses.²⁸ The identity of proteins modified by xenobiotics can be found in the resource known as the *reactive metabolite target protein database*.²⁹ The body has two major defense systems for counteracting these effects: (1) detoxification enzymes and their cofactors and (2) antioxidant systems. Phases of detoxification include Phase I enzymes, such as cytochrome P-450 (CYP) oxidases, which are the most important oxidative reactions (see [Fig. 2.16, B](#)). Other Phase I detoxification enzymes include those for reduction and hydrolysis. In Phase II detoxification, conjugation enzymes, such as glutathione (GSH), detoxify reactive electrophiles and produce polar metabolites that cannot diffuse across membranes. Most conjugation enzymes are located in the cytosol. Phase III detoxification is often called the *efflux transporter system* because enzymes remove the parent drugs,

metabolites, and xenobiotics from cells. The liver has the highest supply of biotransformation enzymes of all organs and, therefore, has the key role in protection from chemical toxicity.²⁸ Fig. 2.18 is a summary of chemically induced liver injury.

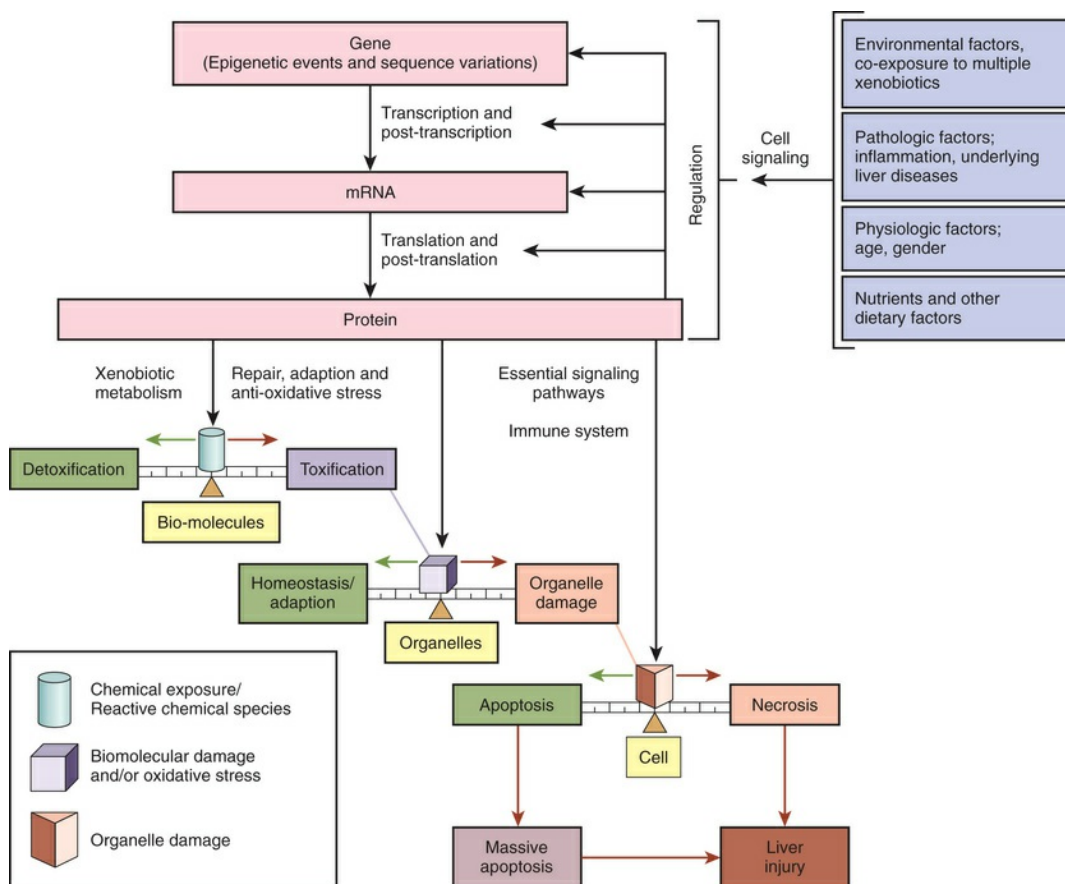

FIGURE 2.18 Chemical Liver Injury. Liver injury is a result of genetic, environmental, biologic, and dietary factors. Certain chemicals can form toxic or chemically reactive metabolites. The risk of liver injury also can increase with increasing doses of a toxicant. Xenobiotic enzyme induction can lead to altered metabolism of chemicals, and drugs can either inhibit or induce drug-metabolizing enzymes. These changes can lead to greater toxicity. The dose at the site of action is controlled by the Phase I to III xenobiotic metabolites, and metabolizing enzymes are encoded by numerous different genes. Therefore, the metabolism and toxicity outcomes can vary greatly among individuals. Additionally, all aspects of xenobiotic metabolism are regulated by certain transcription factors (cellular mediators of gene regulation). Overall, the extent of cell damage depends on the balance between reactive chemical species and protective responses aimed at decreasing oxidative stress, repairing macromolecular damage, or preserving cell health by inducing apoptosis or cell death. Significant clinical outcomes of chemical-induced liver injury occur with necrosis and the immune response. Covalent binding of reactive metabolites to cellular proteins can produce new antigens (haptens) that

initiate autoantibody production and cytotoxic T-cell responses. Necrosis, a form of cell death, can result from extensive damage to the plasma membrane with altered ion transport, changes of membrane potential, cell swelling, and eventual dissolution. Altogether the pathogenesis of chemically induced liver injury is determined by genetics, environmental factors, and other underlying pathologic conditions. Green arrows are pathways leading to cell recovery; red arrows indicate pathways to cell damage or death; black arrows are pathways leading to chemically induced liver injury. (Adapted from Gu X, Manautou JE: *Exp Rev Mol Med* 14:e4, 2013.)

Chemical injury begins with a biochemical interaction between a toxic substance and the cell's plasma membrane, which is ultimately damaged, leading to increased permeability. Not all the mechanisms causing chemically induced membrane destruction are known; however, the two general mechanisms include (1) *direct toxicity* by combining with a molecular component of the cell membrane or organelles and (2) *conversion to toxic intermediates or metabolites*, such as reactive free radicals and membrane lipid peroxidation. Lipid peroxidation is the oxidative degradation of lipids. In this process free radicals “steal” electrons from the lipids in cell membranes resulting in cell damage.

Chemical Agents Including Drugs

Numerous chemical agents cause cellular injury. Minute amounts of some, such as arsenic and cyanide, can rapidly destroy enough cells to cause death of the individual. Long-term exposure to air pollutants, insecticides, and herbicides can cause cellular injury (see [Fig. 2.17](#)). Carbon monoxide, carbon tetrachloride, and social drugs, such as alcohol, can significantly alter cellular function and injure cellular structures. Over-the-counter and prescribed drugs can cause cellular injury, sometimes leading to death. The abuse of and addiction to opioids, such as heroin, morphine, and prescription pain relievers, is a serious global problem that affects the health, social, and economic welfare of all societies.³⁰ It is estimated that between 26.4 million and 36 million people abuse opioids worldwide.³¹ In 2012, it was estimated that 2.1 million people in the United States suffer from substance use disorders related to prescription opioid pain relievers, and an estimated 467,000 people were addicted to heroin.³² The leading cause

of child poisoning is medications. Acetaminophen (known as *paracetamol* outside the United States), commonly used as an analgesic, is one of the most common causes of poisoning worldwide. Drug-induced acute liver failure accounts for about 20% of liver failure in children and a higher percentage in adults.³³

The use of some plants and the consumption of different fruits have played basic roles in human health care, and diverse scientific investigations have indicated that beneficial effects can be attributed to the presence of chemical compounds called *phytochemicals*. Examples of natural products being investigated include some fruits (grapefruit, cranberries, schisandra, and grapes) and plants (cactus pear [nopal] and cactus pear fruit, chamomile, silymarin, and spirulina), resin (propolis), carrot, eleuthero root (Siberian ginseng), ginger root, ginkgo leaf, grape seed/skin, kudzu root, milk thistle seed (silymarin), rosemary leaf, and turmeric.^{34,35} Accidental or suicidal poisonings by chemical agents cause numerous deaths. The injurious effects of some of these agents—lead, carbon monoxide, ethyl alcohol, and mercury—exemplify common cellular injuries.

Air Pollution

The world's largest single environmental health risk is air pollution.³⁶ Household air pollution and ambient air pollution were responsible for 5.5 million deaths worldwide in 2013 (Fig. 2.19). From WHO data, every year 4.3 million deaths occur from exposure to indoor air pollution and 3.7 million deaths to outdoor air pollution.³⁶ **Air pollution** is contamination of the indoor or outdoor environment by any chemical, physical, or biologic agent that modifies natural characteristics of the atmosphere.³⁶ Indoor air pollution (household) occurs when people cook and heat their homes using solid fuels (i.e., wood, charcoal, coal, dung, crop wastes) on open fires or traditional stoves. These inefficient practices produce high levels of household air pollution with fine particles and carbon monoxide.³⁶ In poorly ventilated houses, smoke in and around the house can greatly exceed acceptable levels for fine particles. These exposures are particularly high for women and young children.

Global Burden of Air Pollution

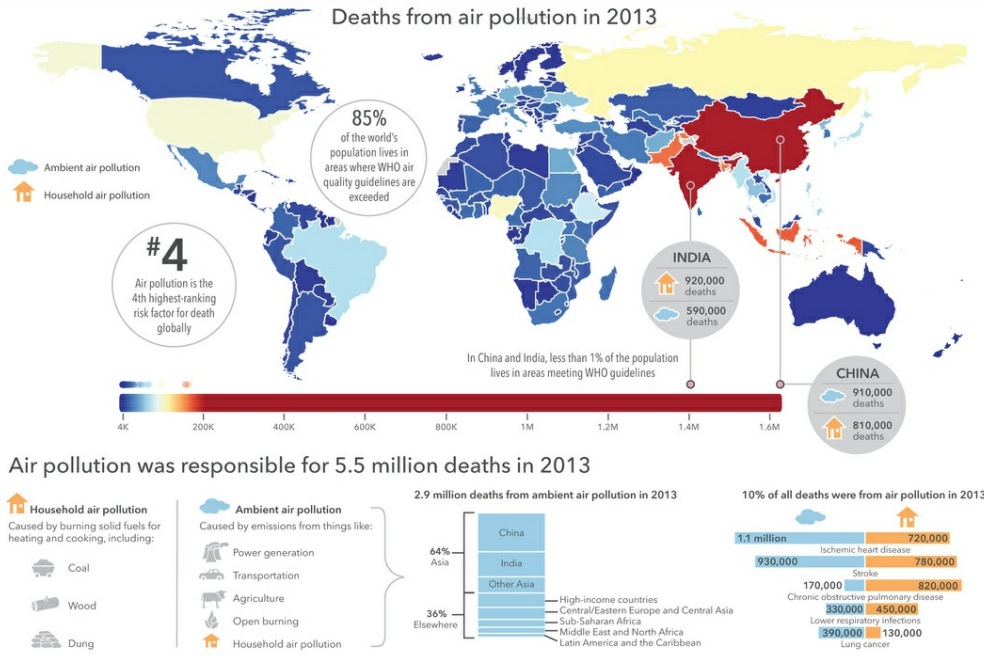

FIGURE 2.19 Global Burden of Air Pollution. (From Brauer M et al: *Environ Sci Technol* 50[1]:79–88, 2016; Forouzanfar MH et al: *Lancet* 386[10010]:2287–2323, 2015.)

By reducing air pollution levels, countries can lower the burden of disease from stroke, heart disease, lung cancer, and chronic and acute respiratory diseases, including asthma.³⁶ As a leading cause of morbidity and mortality worldwide, several studies have found that long-term particulate matter air pollution exposure is associated with cardiovascular disease (CVD) morbidity and mortality.^{37,38} About 88% of premature deaths occurred in low- and middle-income countries; the greatest numbers occur in the WHO Western Pacific and South-East Asia regions. Reducing outdoor emissions from household coal and biomass energy systems, agricultural waste incineration, forest fires, and certain agro-forestry activities (e.g., charcoal production) would reduce key rural and peri-urban air pollution sources in developing regions.³⁶ Reducing outdoor air pollution decreases emissions of CO₂ and short-lived climate pollutants, for example, black carbon particles and methane. These actions would contribute to mitigating climate change.

Various types of studies all support the finding that prompt and

sustained health benefits can come from improved air quality.³⁹ The Environmental Protection Agency (EPA) has identified the following six pollutants as “criteria” air pollutants: carbon monoxide, lead, nitrogen oxides, photochemical oxidants, ground-level ozone particle pollution known as *particulate matter*, and sulfur oxides.⁴⁰ Table 2.5 defines each of the criteria pollutants.

TABLE 2.5

EPA CRITERIA OF AIR POLLUTANTS

POLLUTANT	CRITERIA
Carbon monoxide (CO)	Colorless, odorless gas emitted from combustion processes. Although the majority of CO emissions come from mobile sources, those who (1) breathe air polluted by gasoline engines or defective furnaces and appliances; (2) work in occupations such as coal mining, firefighting, welding, or engine repair; and (3) smoke cigarettes, cigars, or pipes are at risk for CO exposure. At highest risk for CO poisoning are unborn babies, infants, and people with chronic heart disease, respiratory disease, and anemia. Harm from CO is from reduction of oxygen delivery to organs, such as the heart and brain, and at very high levels can cause death. CO can reduce the oxygen-carrying capacity of the blood. Minute amounts of CO can produce significant percentages of carboxyhemoglobin (carbon monoxide bound with hemoglobin [COHb]). Other mechanisms may include disruption of cellular oxidative processes, binding to myoglobin and hepatic cytochromes, and lipid peroxidation of brain lipids. Individuals with several types of heart disease are at increased risk for the effects of CO and can cause them to have ischemia and angina when exercising or under increased stress.
Particle pollution/particulate matter (PM)	PM is a complex mixture of extremely small particles and liquid droplets that get into the air. Inhalation of these particles can affect the heart and lungs and cause serious health effects. Particles less than 10 micrometers in diameter pose the greatest health problems. Fine particles (PM _{2.5}) are the main cause of haze or reduced visibility. Most particles form in the atmosphere as a result of reactions of chemicals from power plants, industries, and automobiles.
Ozone	Ground-level ozone is not emitted directly into the air but is created by chemical reactions between oxides of nitrogen (NOX) and volatile organic compounds (VOCs) in the presence of sunlight. The main sources of NOX and VOC are from emissions from industrial facilities and electrical utilities, motor vehicle exhaust, gasoline vapors, and chemical solvents. Breathing ozone can trigger a variety of health effects, particularly for children, the elderly, and people with lung diseases, such as asthma. Ground-level ozone can have harmful effects on vegetation and ecosystems.

Sulfur dioxide (SO ₂)	SO ₂ is one of a group of gases called <i>sulfur oxides</i> (SO _x). All of the group of gases are harmful but most important is SO ₂ . Short-term exposure to SO ₂ can cause respiratory system dysfunction and difficulty breathing. Children, the elderly, and those who suffer from asthma are most sensitive. High concentration of SO ₂ can lead to SO _x that can form small particles. These particles can contribute to PM pollution, harm trees and plants, and may penetrate deep in the lungs, causing additional health concerns.
Nitrogen dioxide (NO ₂)	NO ₂ is one of a group of highly reactive gases known as <i>nitrogen oxides</i> (NO _x). NO _x forms quickly from emissions from cars, trucks and buses, power plants, and off-road equipment. In addition to forming ground-level ozone, NO ₂ is linked with several adverse respiratory effects, including airway inflammation. NO _x can react with ammonia and other compounds to form small particles. These particles can penetrate deeply in the lungs and worsen respiratory tract diseases, such as emphysema and bronchitis, aggravate existing heart disease, and lead to hospital admissions and premature death. Those at greatest risk from ozone are individuals who work or exercise outside.
Lead	See text on p. 64 .

From U.S. Environmental Protection Agency: *EPA criteria air pollutants*, Washington, DC, 2016, Author.

Heavy Metals as Environmental Pollutants

Heavy metals most commonly associated with harmful effects in humans include lead, mercury, arsenic, and cadmium. Investigators are studying the involvement of metals in DNA repair mechanisms, tumor suppressor functions, and interference with signal transduction pathways.

Lead.

Lead (Pb) is a heavy toxic metal ubiquitous in older homes (built before 1978), the environment, and the workplace. Lead may be found in hazardous concentrations in food, water, and air and it is one of the most common overexposures found in industry.⁴¹ Despite efforts to reduce exposure through government regulation, lead exposure still persists in homes, the environment, and the workplace for many people, and lead toxicity is still a primary hazard to children (see [What's New? CDC Update: Primary Prevention of Lead Exposures for](#)

Children).

What's New?

CDC Update: Primary Prevention of Lead Exposures for Children

In 2012, the CDC updated recommendations on children's blood lead levels. The shift is to focus on primary prevention of lead exposure to reduce or eliminate dangerous and toxic sources in children's environments. At least 4 million households have children living in them where they are being exposed to high levels of lead. Experts now use a reference level of 5 micrograms per deciliter to identify children with blood lead levels that are much higher than most children's levels. (This new level is based on the U.S. population of children ages 1 to 5 years who are in the highest percentile [2.5% of children] when tested for lead.) The CDC will update the reference value every 4 years using the most recent National Health and Nutrition Examination Survey (NHANES) based on the 97.5th percentage of blood lead distribution in children.

Still the same is the recommendation when medical treatment is advised for children with high blood lead levels. Chelation therapy is recommended when a child has a blood lead test result greater than or equal to 45 micrograms per deciliter.

Prevent Childhood Lead Poisoning

Exposure to lead can seriously harm a child's health.

Damage to the brain and nervous system

Slowed growth and development

Learning and behavior problems

Hearing and speech problems

This can cause:

- Lower IQ
- Decreased ability to pay attention
- Underperformance at school

Lead can be found throughout a child's environment.

Homes built before 1978 (when lead-based paints were banned) probably contain lead-based paint.

When the paint peels and cracks, it makes lead dust. Children can be poisoned when they swallow or breathe in lead dust.

Lead can be found in some products such as toys and toy jewelry.

Lead is sometimes in candies imported from other countries or traditional home remedies.

Certain water pipes may contain lead.

Certain jobs and hobbies involve working with lead-based products, like stain glass work, and may cause parents to bring lead into the home.

Data from Centers for Disease Control and Prevention (CDC): *Lead*, Atlanta, GA, 2017, Centers for Disease Control and Prevention, U. S. Department of Health and Human Services, updated February 9, 2017; Centers for Disease Control and Prevention (CDC): *Lead: what do parent's need to know to protect their children?* Atlanta, GA, Author, updated March 15, 2016.

Although Pb was removed from paint in the United States in 1978, many homes in the United States still contain leaded paint, and chipped and peeling leaded paint constitutes a major source of current childhood exposure.^{42,43} The chipped paint can disintegrate at friction surfaces to form Pb dust.⁴³ Another source of contamination is Pb dust dispersed along roadways from previous leaded gasoline emissions.⁴³ When Pb was removed from gasoline, blood lead levels (BLLs) dropped significantly.⁴⁴ Previous emissions of leaded fuel created large dispersions of lead dust in the environment. Particulate lead (2 to 10 μm) does not degrade and persists in the environment, making it a notable source of human exposure.⁴⁵ Other airborne sources include smelters and piston-engine airplanes.⁴⁶ Drinking water exposed to Pb occurs from outdated fixtures, plumbing without corrosion control, and solders.⁴³ Because well water is not subject to EPA regulation it may not be tested for Pb.⁴³ Although the average blood levels of Pb in children in the United States have dropped since the 1970s, there are at-risk populations with higher than average BLLs.⁴³ Children living at or below the poverty line who live in older housing are at greatest risk.⁴² Importantly, the Centers for Disease Control and Prevention (CDC) reports “no safe blood lead level in children has been identified.”⁴² Millions of children are being exposed to lead in their homes, increasing their risks for damage to the brain and nervous system, slowed growth and development, learning and behavior problems (e.g., reduced IQ, attention-deficit/hyperactivity disorder [ADHD], juvenile delinquency, and criminal behavior), and hearing and speech problems.⁴² Common sources of Pb are included in [Table 2.6](#).

TABLE 2.6**COMMON SOURCES OF LEAD**

EXPOSURE	SOURCE
Environmental	Lead paint, soil, or dust near roadways or lead-painted homes; plastic window blinds; plumbing materials (from pipes or solder); pottery glazes and ceramic ware; lead-core candle wicks; leaded gasoline; water (pipes)
Occupational	Lead mining and refining, plumbing and pipe fitting, auto repair, glass manufacturing, battery manufacturing and recycling, printing shop, construction work, plastic manufacturing, gas station attendant, firing-range attendant
Hobbies	Glazed pottery making, target shooting at firing ranges, lead soldering, preparing fishing sinkers, stained-glass making, painting, car or boat repair
Other	Gasoline sniffing, costume jewelry, cosmetics, contaminated herbal products

Data from Sanborn MD et al: *CMAJ* 166(10):1287–1292, 2002.

Lead exposure also remains an important safety and health concern worldwide. Problematic is lead exposure to the fetus during pregnancy because the developing nervous system is especially vulnerable. Compared to adults, developing fetuses and young children absorb lead more easily; the higher intestinal absorption and more permeable blood-brain barrier of children create a high susceptibility to brain damage.¹ Occupational exposure is a common cause of lead poisoning in adults. Approximately 95% of all elevated blood lead levels (BLLs) reported among adults in the United States are work related.^{47,48} Industries with the highest number of lead-exposed workers are battery manufacturing, lead and zinc mining, ammunition, and construction and manufacturing. The most common nonoccupational exposures of lead are shooting firearms, remodeling buildings, renovating, painting, possessing retained bullets in the body (gunshot wounds, especially retained bullet in joints), and lead casting.⁴⁸

The organ systems most affected by lead include the nervous, hematopoietic, reproductive, gastrointestinal, cardiovascular, and musculoskeletal systems as well as the kidneys. Exposure occurs through inhalation, ingestion, and uncommonly skin contact. Lead is taken in through direct contact with the mouth, nose, and eyes (i.e., mucous membranes); and through cuts in the skin. Tetraethyl lead,

still used in aviation fuel, can pass through skin; but inorganic lead, found in the most common sources of paint, food, and consumer products, is only minimally absorbable through skin.^{49,50} Absorption of inorganic lead is primarily from ingestion and inhalation.⁴⁹ Most of the absorbed lead (80% to 85%) is incorporated into bone and teeth where it competes with calcium; the half-life in bone is 20 to 30 years.¹ Lead can move from bone to the bloodstream years after the initial exposure.⁵⁰ Children store about 70% of absorbed lead in their bones and teeth; thus, other tissues in children are more greatly affected compared to adults.⁵¹ Lead can be reintroduced continuously to the blood from bone remodeling.⁵¹ Other tissues can store lead, including the brain, spleen, kidneys, liver, and lungs; however, not at the levels found in blood, bone, and teeth.⁵²

◆Pathophysiology.

The pathogenic effects of lead are multifactorial and complex. The key event underlying effects of Pb exposure in humans is alteration of cellular ion status (disruption of divalent cations, altered ion transport mechanisms, and disruption of protein function from displacement of metal enzyme cofactors) (Fig. 2.20).

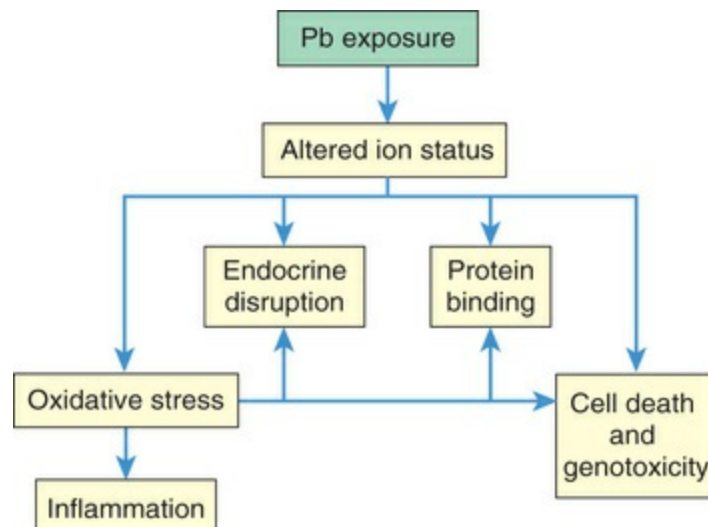

FIGURE 2.20 Key Pathophysiologic Events of Lead Exposure. See text for a discussion of these events and health effects. (Data from Lassiter MG et al: *Toxicology* 330:19–40, 2015.)

An important ion status disruption is calcium (Ca^{++}) homeostasis. Ca^{++} is a crucial cell signal carrier and regulates critical cellular functions.⁵³ Pb exposure alters the intracellular concentration of Ca^{++} in many cell types, including bone, brain, and red and white blood cells. The change in intracellular Ca^{++} concentrations is probably from alterations in ion transport mechanisms and, importantly, the inhibition of transport proteins such as $\text{Na}^{+}\text{-K}^{+}$ ATPase and Ca^{++} channels. Pb interferes with these proteins by displacing or competing with normal metal cofactors (e.g., lead binds to calcium-activated proteins with higher affinity than calcium) or through proteins important in Ca^{++} -dependent cell signaling (protein kinase C or calmodulin).⁵³ Pb disrupts other divalent metals, including zinc and magnesium, leading to alterations in neurotransmitter function, inhibiting heme synthesis, and, from impaired mitochondrial function, decreasing cellular energy. Lead is toxic to multiple enzyme systems. Pb causes abnormal conformational changes in the protein structure resulting in altered protein functions. Antagonism of normal metal ion functions by Pb leads to oxidative stress.⁵³ Pb-induced oxidative stress is possibly the result of a mutipathway process. Pb-induced oxidative stress results from binding to and subsequently inhibition of the function of delta aminolevulinic acid dehydratase (ALAD) because of competition of Pb ions with normal zinc ions leading to the accumulation of delta-aminolevulinic acid (δ -ALA) in blood and urine. With accumulation of δ -ALA, it undergoes conformational protein change and autooxidation resulting in the generation of ROS.⁵³ Other sources of Pb-induced oxidative stress are membrane lipid oxidation, NADPH oxidation, and antioxidant depletion.⁵³ Both abnormalities of cellular ion status and oxidative stress can result in altered inflammation, endocrine disruption, cell death (apoptosis), protein binding, and genotoxicity.⁵³ These *key* events from Pb exposure affect the nervous system, immune system, and reproductive system and have developmental effects, for example, delayed puberty onset, as well as cancer. A causal relationship is determined for Pb and cardiovascular effects and an association between Pb and renal dysfunction.⁵³

◀Clinical Manifestations.

Lead affects all body systems and especially the nervous, cardiovascular, reproductive, endocrine, musculoskeletal, and immune systems, as well as the kidneys and teeth. The recent National Toxicology Program (NTP) has provided the *NTP Monograph: Health Effects of Low-Level Lead* (see Table E 2.1 on Evolve).⁵⁴

◀Evaluation, Prevention, and Treatment.

Diagnosis involves the medical history and clinical signs and determination of routes of exposure. The main method of evaluation is laboratory analysis of the blood lead level (BLL). According to the CDC, experts now use a reference level of 5 micrograms per deciliter to identify children with blood lead levels that are much higher than most children's levels.⁴⁷

The most important strategy for lowering exposures to lead is prevention. Prevention methods include individual and family prevention, preventive medicine, and public health. There is an urgent need to focus on preventive strategies, especially for fetal development and the developing child. The key for adults is prevention of exposures at the workplace and home. The main methods of treatment are removal of the source of exposure and, for those with high blood levels, chelation therapy. Additionally, treatment may include correcting deficiencies of iron, calcium, and zinc; irrigating the bowel; removing strategic bullets or shrapnel; and administering medications for control of seizures.

Cadmium and arsenic.

Table 2.7 summarizes toxic effects of cadmium and arsenic.

TABLE 2.7

SUMMARY OF TOXIC EFFECTS OF CADMIUM AND ARSENIC

METALS KEY CONCEPTS	
Arsenic	Arsenic salts were the poison of choice during the Renaissance in Italy

	Deliberate poisoning by arsenic is rare today; however, its exposure is an important health concern in many areas worldwide
	Arsenic is found naturally in soils and water and used in products (wood preservers, herbicides, agricultural products)
	It can be released from mines and smelting industries and may be present in some Chinese and Indian herbal medicines
	Inorganic arsenic may be present in ground water with large concentrations found in Bangladesh, Chile, and China
	Most toxic forms are the trivalent compounds of arsenic trioxide, sodium arsenite, and arsenic trichloride
	Arsenic trioxide is used as a therapy for acute promyelocytic leukemia; ingestion of large quantities of arsenic causes acute gastrointestinal, cardiovascular, and CNS toxicities that often are fatal
	These effects are partially attributed to replacement of phosphates in ATP and interference of mitochondrial oxidative phosphorylation and the function of some proteins
	Chronic exposure causes skin lesions (hyperpigmentation, hyperkeratosis) and the development of cancers (lung, bladder, skin)
	The mechanism for arsenic carcinogenesis has not been fully defined
	Arsenic present in drinking water has been correlated with nonmalignant respiratory disease
Cadmium	Compared to the other metals discussed, cadmium is a more modern problem
	Pollution in the environment and occupationally is from mining, electroplating, and production of nickel-cadmium batteries, which are often disposed in household waste
	Food is an important source of cadmium because cadmium can contaminate soil and plants directly or from fertilizers and irrigation water
	The most probable mechanism of toxicity is the generation of ROS
	The main toxic effects of excess cadmium are obstructive lung disease and renal tubular damage
	It also can cause skeletal abnormalities associated with calcium loss
	In Japan, cadmium-containing water used to irrigate rice fields caused a disease in postmenopausal women known as "Itai-Itai" (ouch-ouch), which is a combination of osteoporosis and osteomalacia associated with renal disease
	Cadmium is associated with higher risk of lung cancer in populations living near zinc smelters

ATP, adenosine triphosphate; *CNS*, central nervous system; *ROS*, reactive oxygen species.

Data from Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.

Mercury.

Mercury (quicksilver) is a heavy, silvery white metal that is liquid at room temperature and evaporates easily.⁵⁵ Mercury is a global threat to human and environmental health. In nature, mercury is found in the form of cinnabar, a deep red mineral used in the past as a pigment. Cinnabar deposits have been mined for centuries. Mercury also occurs in deposits of other metals, such as lead and zinc, and it is found in small amounts in different rocks including coal and limestone where no cinnabar is found. Mercury can be released into the air, water, and soil through industrial processes including mining, metal and cement production, fuel extraction, and combustions of fossil fuels.⁵⁵ Causes from human activity, called **anthropogenic**, are responsible for about 30% of annual emissions of mercury to air, another 10% from natural geological sources, and the rest (60%) from re-emissions or earlier released mercury that has increased over decades and centuries in surface soil and water.⁵⁵ The major sources of anthropogenic mercury emissions to air are artisanal and small-scale gold mining (ASGM) and coal burning. The next major sources are the production of ferrous and nonferrous metals and cement production. Importantly, investigators report that emissions from industrial sectors have increased since 2005.⁵⁶ Types of aquatic releases of mercury include industrial sites (power plants, factories), old mines, landfills, and waste disposal locations. Artisanal and small-scale gold mining is significant for aquatic releases. It is estimated that more than 90% of mercury in marine animals is from anthropogenic emissions.⁵⁵ Climate change, with thawing of enormous areas of frozen lands, may release even more long-stored mercury and organic matter into lakes, rivers, and oceans.⁵⁵

Mercury is still commonplace in daily life. Consumables used around the world contain mercury, including electrical and electronic devices, switches (including thermostats) and relays, measuring and control equipment, energy-efficient fluorescent light bulbs, batteries, mascara, skin-lightening creams and other cosmetics, and dental amalgams.^{55,56} Mercury is found in food products obtained from fish, terrestrial mammals, and other products, such as rice. It is still widely

used in healthcare equipment, where much of it is used for measuring in blood pressure devices and thermometers, although their use is declining.^{55,56} There are safe and cost-effective replacements for mercury for many healthcare applications and for pharmaceuticals; goals have been set to phase out some mercury-containing devices altogether. Since 2001, no vaccine contains **thimerosal** (a preservative in multidose vials of vaccines containing ethyl mercury) except inactivated influenza vaccines.

There are three forms of mercury: metallic mercury (elemental mercury), inorganic mercury compounds (mostly mercuric chloride), and organic mercury. A major source of mercury is contaminated fish (mostly methylmercury). Inorganic mercury is converted to organic mercury, such as methylmercury, by bacteria. Methylmercury enters the food chain and, in carnivorous fish (especially swordfish and shark), it may be concentrated to exorbitant levels higher than the surrounding water.¹ Acute exposures from release of methylmercury from industrial sources caused the disaster at Minamata Bay and the Agano River in Japan and led to widespread mortality and morbidity. Known as *Minamata disease*, the disorders included deafness, blindness, intellectual disability, cerebral palsy, and central nervous system (CNS) defects in children exposed in utero. For unclear mechanisms, the developing brain is extremely sensitive to methylmercury.¹ Mercury is found in many species of fish, including grouper, tuna, seabass, marlin, halibut, tilefish, swordfish, shark, and king mackerel.⁵⁶ The U.S. Food and Drug Administration (FDA) has recommended that women planning to become pregnant, pregnant women, nursing mothers, and young children avoid eating fish with a high mercury content (>1 part per million [ppm]), such as shark, swordfish, tile fish, and king mackerel. Fish that is lower in methylmercury include shrimp, canned light tuna, salmon, pollock, and catfish.⁵⁷ Like Pb, mercury binds with high affinity to sulfhydryl groups in some proteins, leading to tissue damage in the CNS and kidney.¹ Lipid solubility of methylmercury and metallic mercury increases their accumulation in the brain, altering neuromotor, cognitive, and behavioral functions.¹ An antioxidant, intracellular

glutathione acting as a sulfhydryl donor, is the main protective mechanism from mercury-induced CNS and kidney damage.

Ethanol

Alcohol (*ethanol*) is the number one mood-altering drug used in the United States. It is estimated there are more than 10 million chronic alcoholics in the United States. Alcohol contributes to more than 100,000 deaths annually with 50% of these deaths from drunk-driving accidents, alcohol-related homicides, and suicides.¹ A blood alcohol concentration of 80 mg/dL is the legal definition of drunk driving in the United States. This level of alcohol in an average person may be reached after consumption of three drinks (three 12-ounce bottles of beer, 15 ounces of wine, and 4 to 5 ounces of distilled liquor). The effects of alcohol vary by age, gender, and percentage body fat; the rate of metabolism affects the blood alcohol level. Importantly, alcohol-related problems include family violence and workplace disabilities. Because alcohol is not only a psychoactive drug but also a food, it is considered part of the basic food supply in many societies.

A large intake of alcohol has enormous effects on nutritional status. Liver and nutritional disorders are the most serious consequences of alcohol abuse. Major nutritional deficiencies include magnesium, vitamin B₆, thiamine, and phosphorus. Chronic intake of alcohol and vitamin deficiencies may adversely affect the brain and peripheral nerves (e.g., Wernicke encephalopathy, peripheral neuropathy, Korsakoff psychosis). Folic acid deficiency is a common problem in chronic alcoholic populations. Ethanol alters folic acid (folate) homeostasis by decreasing intestinal absorption of folate, increases liver retention of folate, and increases the loss of folate through urinary and fecal excretion.³³ Folic acid deficiency becomes especially serious in pregnant women who consume alcohol and may contribute to fetal alcohol syndrome.

Most of the alcohol in blood is metabolized to *acetaldehyde* in the liver by three enzyme systems: alcohol dehydrogenase (ADH), the microsomal ethanol-oxidizing system (MEOS; CYP2E1), and catalase (Fig. 2.21). The major pathway involves ADH, an enzyme located in

the cytosol of hepatocytes. The microsomal ethanol-oxidizing system (MEOS) depends on cytochrome P-450 (CYP2E1), an enzyme needed for cellular oxidation. Activation of CYP2E1 requires a high ethanol concentration and thus is thought to be important in the accelerated ethanol metabolism (i.e., tolerance) noted in persons with chronic alcoholism. Acetaldehyde has many toxic tissue effects and is responsible for some of the acute effects of alcohol and for development of oral cancers.⁵⁸ A recent study showed that head and neck cancer risk may be influenced by alcohol-metabolizing genes (*ADH1B* and *ALDH2*) and oral hygiene.^{59,60} Polymorphisms on *ADH1B* and *ALDH2* had significant indirect effects on hepatocellular carcinoma risk.⁶¹

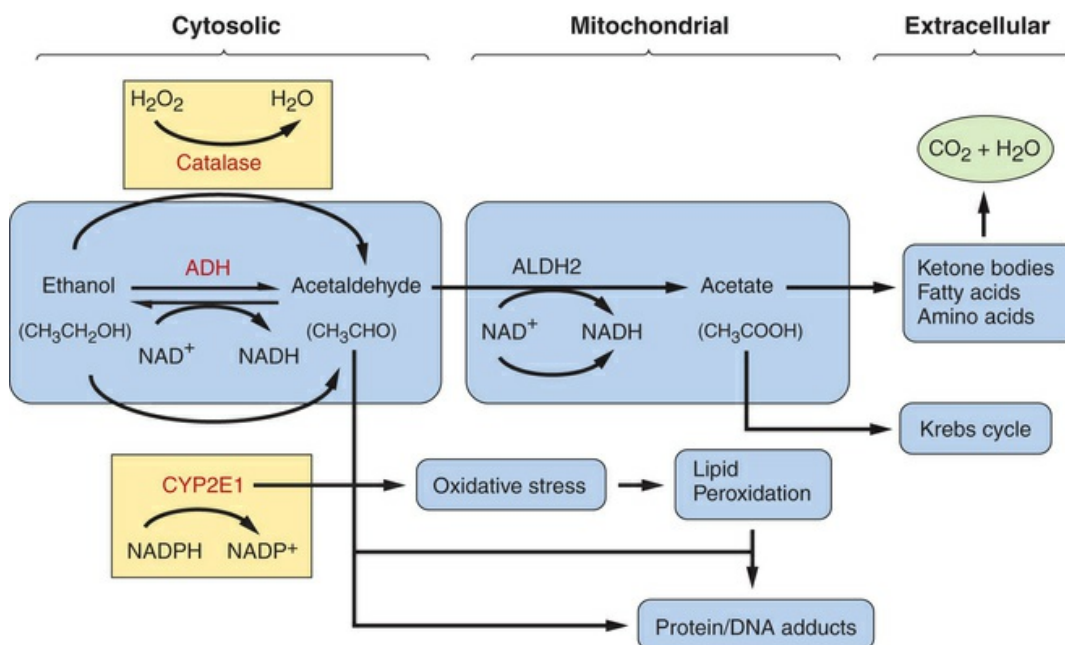

FIGURE 2.21 Ethanol Metabolism Pathway. Ethanol is metabolized into acetaldehyde through the cytosolic enzyme alcohol dehydrogenase (ADH), the microsomal enzyme cytochrome P-450 2E1 (CYP2E1), and the peroxisomal enzyme catalase. The ADH enzyme reaction is the main ethanol metabolic pathway involving an intermediate carrier of electrons, namely, nicotinamide adenine dinucleotide (NAD^+), which is reduced by two electrons to form NADH . Acetaldehyde is metabolized mainly by aldehyde dehydrogenase 2 (ALDH2) in the mitochondria to acetate and NADH before being cleared into the systemic circulation. (Adapted from Zhang Y, Ren J: *Pharmacol Ther* 132[1]:86–92, 2011.)

After ingestion, alcohol is absorbed, unaltered, into the stomach and small intestine from which it is transported to the liver. Fatty foods and milk slow absorption. Alcohol then is distributed to all tissues and fluids of the body in direct proportion to the blood concentration. Individuals differ in their capability to metabolize alcohol. The major effects of acute alcoholism involve the central nervous system (CNS; see below). Genetic differences in metabolism of liver alcohol, including aldehyde dehydrogenases, have been identified. People with chronic alcoholism develop certain levels of tolerance because of enzyme induction, leading to an increased rate of metabolism (e.g., P-450).

Numerous studies have validated the so-called *j*- or *u-shaped* inverse association between alcohol and cardiovascular mortality, such as from myocardial infarction and ischemic stroke. These studies have found that light to moderate (nonbinge) drinkers tend to have lower mortality than nondrinkers, and heavy drinkers have higher mortality.⁶² For both men and women, former drinkers and regular heavy drinkers had higher mortality.⁶² Light to moderate drinkers in the United States may have reduced mortality, but this may be confounded by medical care and social relationships, especially among women.^{62,63} These relationships need further study. The suggested mechanisms for cardioprotection for light to moderate drinkers include increase in levels of high density lipoprotein-cholesterol (HDL-C; recent randomized studies and failure of HDL-C to modify cardiovascular disease have become controversial), decrease in levels of low-density lipoprotein (LDL), prevention of clot formation, reduction in platelet aggregation, decrease in blood pressure, increase in coronary vessel vasodilation, increase in coronary blood flow, decrease in coronary inflammation, decrease in atherosclerosis, a limit in ischemia-reperfusion injury (I/R injury), and a decrease in diabetic vessel pathology.⁶⁴ The American Heart Association recommends no more than two drinks per day for men and one drink per day for women (12 oz of beer, 4 oz of wine, 1.5 oz of 80-proof spirits, or 1 oz of 100-proof spirits).

Acute alcoholism (drunkenness) affects the CNS (Box 2.2). Alcohol

intoxication causes CNS depression. Depending on the amount consumed, depression is associated with sedation, drowsiness, loss of motor coordination, delirium, altered behavior, and loss of consciousness. Toxic amounts (300 to 400 mg/dL) result in a lethal coma or possibly respiratory arrest because of medullary center depression. Studies are underway to determine the extent of the relationship between alcohol level and snoring and obstructive sleep apnea (cessation of breathing). Acute alcoholism may induce reversible hepatic and gastric changes.¹ Acetaldehyde has many toxic effects from alcohol oxidation, including the acute effects of alcohol and the development of oral cancers.¹

Box 2.2

Alcohol: Global Burden, Adolescent Onset, Chronic or Binge Drinking

Alcohol is widely consumed worldwide, and in the United States 50% of the adult population (18 years and older) consumes alcohol regularly. Alcohol continues to be the drug of choice among teens and young adults with one-third of twelfth graders and 40% of college students reporting “binge drinking” (four standard alcohol drinks on one occasion in females and five in males). Alcohol abuse is the leading cause of liver-related morbidity and mortality. Chronic and binge drinking causes alcoholic liver disease (ALD) with a spectrum from hepatic steatosis (fatty change) to steatohepatitis (fatty change and inflammation) and cirrhosis. These alterations can eventually lead to hepatocellular carcinoma. The pathogenesis of ALD is not fully characterized, and recent studies reveal a major role of mitochondrial involvement. Animal studies have shown that alcohol causes mitochondrial DNA damage, lipid accumulation, and oxidative stress. Understanding the role of the mitochondria may help identify therapeutic targets.

Investigation of adolescent drinking behaviors, especially binge drinking, is providing evidence of neurocognitive changes,

including changes in both gray and white matter. These studies are examining risk-taking behaviors that begin in adolescence and coincide with vulnerable and significant neurodevelopmental changes.

Data from Adams PF et al: *Vital Health Stat* 10(255), 2012; available from www.cdc.gov/nchs/data/series/sr_10/sr10_255.pdf; Hicks BM et al: *Addiction* 107:540–548, 2012; Johnston LD et al: *Monitoring the future national results on adolescent drug use: overview of key findings*, Bethesda, MD, 2009, National Institute on Drug Abuse; Lisdahl KM et al: *Front Psychiatry* 4:53, 2013; Mathews S et al: *Am J Physiol Gastrointest Liver Physiol* 306(10):G819–G823, 2014; Nassir F, Ibdah JA: *World J Gastroenterol* 20(9):2136–2142, 2014; White HR et al: *Alcohol Clin Exp Res* 35:295–303, 2010.

Chronic alcoholism causes structural alterations in practically all organs and tissues in the body because most tissues contain enzymes capable of ethanol oxidation or nonoxidative metabolism. The most significant activity occurs in the liver, and alcohol is the leading cause of liver-related morbidity and mortality. Hepatic changes initiated by acetaldehyde include inflammation, deposition of fat, enlargement of the liver, interruption of microtubular transport of proteins and their secretion, increase in intracellular water, decrease in fatty acid oxidation in the mitochondria, increase in membrane rigidity, and development of acute liver necrosis. Chronic or binge alcohol consumption causes alcoholic liver disease (ALD) with a range of alterations from simple fatty liver (steatosis), to steatohepatitis (fatty with inflammation), to cirrhosis. Cirrhosis is associated with portal hypertension and increased risk for hepatocellular carcinoma. A newer hypothesis for the development of ALD is adipose tissue dysfunction, including cell death, inflammation, and insulin resistance.⁶⁵ Inflammation plays a crucial role in ALD, and ethanol is implicated in the onset of a variety of immune defects, including the production of cytokines involved in the inflammatory responses.⁶⁶ Reactive oxygen and nitrogen species (ROS/RNS) and dysregulated redox signaling pathways are associated with alcohol consumption and provide insight into the molecular basis of hepatic cell dysfunction, destruction, and remodeled tissue or fibrosis.^{65,67} Alcohol

can induce epigenetic variations in the developmental pathways of many types of immune cells that promote increased inflammation.⁶⁸ Chronic alcoholism is a major risk factor for cancers of the oral cavity, larynx, and esophagus. The risk is even greater with concurrent smoking or use of smokeless tobacco.¹ Chronic alcoholism can lead to massive bleeding from gastritis, gastric ulcer, and esophageal varices (associated with cirrhosis). Several effects can occur in the cardiovascular system, including dilated congestive cardiomyopathy and hypertension. Excessive alcohol increases the risk of acute and chronic pancreatitis.

The term **fetal alcohol spectrum disorders (FASDs)** is a range of health effects or disorders of prenatal alcohol exposure, with **fetal alcohol syndrome (FAS)** at the more severe end of the spectrum (Box 2.3). The diagnosis of FAS requires documentation of all three facial abnormalities (smooth philtrum, thin vermilion border, and small palpebral fissures [Fig. 2.22]), documentation of growth deficits, and CNS abnormality.

Box 2.3

Conditions and Types of Fetal Alcohol Spectrum Disorders (FASDs)

FASD conditions include

- Abnormal facial features (e.g., smooth philtrum and others)
- Small head size
- Shorter-than-average height
- Low body weight
- Poor coordination
- Hyperactive behavior
- Difficulty with attention
- Poor memory
- Difficulty in school (especially math)

Learning disabilities
Speech and language delays
Intellectual disability or low IQ
Poor reasoning and judgment skills
Sleep and sucking problems as a baby
Vision or hearing problems
Problems with the heart, kidneys, or bones

Types of FASDs

Fetal Alcohol Syndrome (FAS). This is the most involved end of the FASD spectrum. Individuals with FAS may have abnormal facial features, growth problems, and CNS problems; can have problems with learning, memory, attention span, communication, vision, or hearing; and may have a hard time in school and trouble getting along with others.

Alcohol-Related Neurodevelopmental Disorder (ARND). Individuals with ARND may have intellectual disabilities and problems with behavior and learning; might do poorly in school and have difficulties with math, memory, attention, and judgment, and poor impulse control.

Alcohol-Related Birth Defects (ARBDs). People with ARBDs may have problems with the heart, kidneys, or bones, or with hearing; and may have a mix of these problems.

FIGURE 2.22 Diagnostic Facial Features of FAS. Three diagnostic facial features of FAS: (1) short palpebral fissure lengths, (2) smooth philtrum, and (3) thin upper lip. (© 2017 Susan Astley, PhD, University of Washington.)

When the mother drinks so does her baby because of an unimpeded bidirectional movement of alcohol between the fetus and the mother. Alcohol crosses the placenta, reaching the fetus rapidly.⁶⁹ There is no known safe amount of alcohol for the mother to drink before she gets pregnant, when she gets pregnant, or during pregnancy.⁷⁰ Increased prepregnancy binge drinking rates may estimate alcohol use during very early gestation.⁷¹ The fetus may completely depend on maternal hepatic detoxification because the activity of alcohol dehydrogenase (ADH) in the fetal liver is less than 10% of that of the adult liver. Additionally, the amniotic fluid may act as a reservoir for alcohol, prolonging fetal exposure.⁶⁹ Ethanol affects virtually all organ systems and particularly the adult and developing brain. A number of mechanisms have been proposed for ethanol-induced brain damage and include promotion of neuroinflammation, interference of cell signaling by neurotrophic factors, oxidative stress, changes in retinoid acid signaling, thiamine deficiency, ER stress and unfolded or misfolded proteins, and alterations in autophagy.⁷² Acetaldehyde can alter fetal development by disrupting differentiation and growth;

DNA and protein synthesis; modification of carbohydrates, proteins, and fats; and the flow of nutrients across the placenta.^{69,73} Additionally, alcohol may cause fetal disturbances, even preconceptual effects, epigenetically.^{74,75} Recent data identify strong influences of alcohol on methylation and acetylation.⁷⁶

Autopsies of children with FAS have revealed widespread severe damage, including failure of certain brain regions to develop, malformations of brain tissue, and failure of certain cells to migrate to their necessary location during development. Imaging studies reveal that in addition to an overall reduction in brain size, the corpus callosum is reduced in size or missing, the cerebellum is significantly reduced in size, and the basal ganglia and caudate nucleus are significantly reduced.

Social or Street Drugs

The social or “recreational” use of psychoactive drugs is widespread in many parts of the world. Most popular and dangerous are the drugs methamphetamine (“meth”), marijuana, cocaine, and heroin. Illicit use of drugs is a prevalent risk behavior among adolescents. [Table 2.9](#) summarizes the effects of these drugs.

TABLE 2.8

SOCIAL OR STREET DRUGS AND THEIR EFFECTS

TYPE OF DRUG	DESCRIPTION AND EFFECTS
Marijuana (pot)	<p><i>Active substance:</i> Δ^9-Tetrahydrocannabinol (THC), found in resin of <i>Cannabis sativa</i> plant</p> <p>With smoking (e.g., “joints”), about 5% to 10% is absorbed through lungs; with heavy use the following adverse effects have been reported: alterations of sensory perception; impairment of cognitive and psychomotor judgments (e.g., inability to judge time, speed, distance); increases in heart rate and blood pressure; increases in susceptibility to laryngitis, pharyngitis, bronchitis; causes cough and hoarseness; may contribute to lung cancer (dosages levels not determined); contains large number of carcinogens; data from animal studies only indicate reproductive changes include reduced fertility, decreased sperm motility, and decreased levels of circulatory testosterone; fetal abnormalities include low birth weight; increased frequency of infectious</p>

	illness is thought to be the result of depressed cell-mediated and humoral immunity; beneficial effects include decreased nausea secondary to cancer chemotherapy and decreased pain in certain chronic conditions
Methamphetamine (meth)	An amine derivation of amphetamine (C ₁₀ H ₁₅ N) used as crystalline hydrochloride
	CNS stimulant; in large doses causes irritability, aggressive (violent) behavior, anxiety, excitement, auditory hallucinations, and paranoia (delusions and psychosis); mood changes are common and abuser can swiftly change from friendly to hostile; paranoid swings can result in suspiciousness, hyperactive behavior, and dramatic mood swings
	Appeals to abusers because body's metabolism is increased and produces euphoria, alertness, and perception of increased energy
	Stages: <i>Low intensity:</i> User is not psychologically addicted and uses methamphetamine by swallowing or snorting <i>Binge and high intensity:</i> User has psychologic addiction and smokes or injects to achieve a faster, stronger high <i>Tweaking:</i> Most dangerous stage; user is continually under the influence, not sleeping for 3–15 days, extremely irritated, and paranoid
Cocaine and crack	Extracted from leaves of cocoa plant and sold as a water-soluble powder (cocaine hydrochloride) liberally diluted with talcum powder or other white powders; extraction of pure alkaloid from cocaine hydrochloride is “free-base” called <i>crack</i> because it “cracks” when heated
	Crack is more potent than cocaine; cocaine is widely used as an anesthetic, usually in procedures involving oral cavity; it is a potent CNS stimulant, blocking reuptake of neurotransmitters norepinephrine, dopamine, and serotonin; also increases synthesis of norepinephrine and dopamine; dopamine induces sense of euphoria, and norepinephrine causes adrenergic potentiation, including hypertension, tachycardia, and vasoconstriction; cocaine can therefore cause severe coronary artery narrowing and ischemia; reason cocaine increases thrombus formation is unclear; other cardiovascular effects include dysrhythmias, sudden death, dilated cardiomyopathy, rupture of descending aorta (i.e., secondary to hypertension); effects on fetus include premature labor, retarded fetal development, stillbirth, hyperirritability
Heroin	Opiate closely related to morphine, methadone, and codeine
	Highly addictive, and withdrawal causes intense fear (“I’ll die without it”); sold “cut” with similar-looking white powder; dissolved in water it is often highly contaminated; feeling of tranquility and sedation lasts only a few hours and thus encourages repeated intravenous or subcutaneous injections; acts on the receptors enkephalins, endorphins, and dynorphins, which are widely distributed throughout body with high affinity to CNS; effects can include infectious complications, especially <i>Staphylococcus aureus</i> , granulomas of lung, septic embolism, and pulmonary edema—in addition, viral infections from casual exchange of needles and HIV; sudden death is related to overdose

	secondary to respiratory depression, decreased cardiac output, and severe pulmonary edema
Fentanyl	Synthetic opioid analgesic similar to morphine but is 50 to 100 times more potent. The synthetic opioid fentanyl and its analogs have risen across the United States in a variety of forms. Currently, it is documented in connection with a growing number of overdoses and overdose deaths.

CNS, Central nervous system; *HIV*, human immunodeficiency virus.

From Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.; Nahas G et al: *N Engl J Med* 343(7):514, 2000.

Unintentional and Intentional Injuries

About 199,800 people die from injury (not included here is medical errors) each year, and millions of people are injured and survive.⁷⁷ Significant are the numbers of people who face life-long mental, physical, and financial problems. In 2014, 2.5 million people were hospitalized because of injuries and 26.9 million people were treated in an emergency department.⁷⁷ Unintentional injury data include motor vehicle crashes as a leading cause of death in the United States with about 35,647 deaths in 2014 alone.⁷⁷ Opioid overdoses have quadrupled since 1999, with more than 14,800 deaths from prescription opioid overdoses in 2014. About 48,545 people comprised all poisoning deaths. Older adult falls accounted for 2.7 million people treated in emergency departments. In 2012, about 325,000 children were treated in emergency departments for sports- and recreation-related injuries, including a diagnosis of concussion or traumatic brain injury.⁷⁷ All deaths from firearms were about 33,636 people. According to the CDC, unintentional injury ranks fourth in the United States, a change from 2012 where it ranked fifth. Death and injury from medical care itself is presented in [Box 2.4](#).

Box 2.4

Death and Injury From Medical Care

Recently, much attention has been given to death and injury from

medical care itself. A main concern is the lack of a comprehensive, nationwide system for estimating premature deaths and unintentional injury associated with preventable harm to people. A focus on preventable lethal events is absolutely necessary for safety and to assist educators, clinicians, administrators, and boards of trustees to guarantee a culture of safety for individuals. Studies on U.S. death rates from medical error since 1999 are presented in the following table:

DATE	SOURCE OF INFORMATION	PATIENT ADMISSIONS	ADVERSE EVENT RATE (%)	LETHAL ADVERSE EVENT RATES (%)	% OF EVENTS DEEMED PREVENTABLE	NO. OF DEATHS DUE TO PREVENTABLE ADVERSE EVENT	% OF ADMISSIONS WITH A PREVENTABLE LETHAL ADVERSE EVENT*	EXTRAPOLATION TO 2013 U.S. ADMISSIONS [†]
2000-2002	Medicare patients	37,000,000	3.1	0.7	NR	389,576 [‡]	0.71	251,454
2008	Medicare patients	838	13.5	1.4	44	12	0.62	219,579
2004	3 tertiary care hospitals	795	33.2	1.1	100	9	1.13	400,201
2002-2007	10 hospitals	2341	18.1	0.6	63	14	0.38	134,581

	in No rth Ca roli na							
2000 – 0 8	–	–	–	–	–	–	0.71	251,454

* All were considered preventable.

† Total number of U.S. hospital admissions in 2013 was 35,416,020.

‡ Total number of people who died from a preventable lethal adverse event calculated as a point estimate of death rate among hospitalized patients reported in the literature extrapolated to the reported number of patients hospitalized in 2013.

NOTE: Medical error is a common cause of death in the United States. A December 2015 report from an expert panel convened by the National Patient Safety Foundation identified these strategies for accelerating improvements in safety:

- Ensure that leaders establish and sustain a safety culture.
- Create centralized and coordinated oversight of safety.
- Create a common set of safety metrics that reflect meaningful outcomes.
- Increase funding for research in safety and implementation science.
- Address safety across the entire care continuum.
- Support the healthcare workforce.
- Partner with individuals and families for the safest care.
- Ensure that technology is safe and optimized to

improve safety.

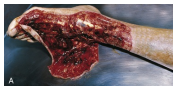

NR, Not reported.

Data from Abbasi J: *J Am Med Assoc* 316(7):698–700, 2016; Makary MA, Daniel M: *BMJ* 353:i2139, 2016.

According to the CDC, the 10 leading causes of death in 2013 were diseases of the heart, malignant neoplasms, chronic lower respiratory tract diseases, unintentional injuries (accidents), cerebrovascular diseases, Alzheimer disease, diabetes mellitus, influenza and pneumonia, nephritis, nephrotic syndrome and nephrosis, and intentional self-harm (suicide).⁷⁸ The more common terms used to describe and classify unintentional and intentional injuries and brief descriptions of important features of these are discussed in [Table 2.9](#).

TABLE 2.9

UNINTENTIONAL AND INTENTIONAL INJURIES

TYPE OF INJURY	DESCRIPTION
 <p>FIGURE A Blunt-force injuries.</p>	<p>Mechanical injury to body resulting in tearing, shearing, or crushing; most common type of injury seen in healthcare settings; caused by blows or impacts; motor vehicle accidents and falls most common cause (Fig. A)</p> <p><i>Contusion (bruise)</i>: Bleeding into skin or underlying tissues; initial color will be red-purple, then blue-black, then yellow-brown or green; duration of bruise depends on extent, location, and degree of vascularization; bruising of soft tissue may be confined to deeper structures; <i>hematoma</i> is collection of blood in soft tissue; <i>subdural hematoma</i> is blood between inner surface of dura mater and surface of brain; can result from blows, falls, or sudden acceleration/deceleration of head as occurs in <i>shaken baby syndrome</i>; <i>epidural hematoma</i> is collection of blood between inner surface of skull and dura; is most often associated with a skull fracture</p> <p><i>Laceration</i>: Tear or rip resulting when tensile strength of skin or tissue is exceeded; is ragged and irregular with abraded edges; an extreme example is <i>avulsion</i>, where a wide area of tissue is pulled away; lacerations of internal organs are common in blunt-force injuries; lacerations of liver, spleen, kidneys, and bowel occur from blows to abdomen; thoracic aorta may be lacerated in sudden</p>

	<p>deceleration accidents; severe blows or impacts to chest may rupture heart with lacerations of atria or ventricles</p>
	<p><i>Fracture:</i> Blunt-force blows or impacts can cause bone to break or shatter</p>
<div data-bbox="332 422 505 579" data-label="Image"> </div> <div data-bbox="370 579 448 695" data-label="Caption"> <p>FIGURE B Sharp-force injuries.</p> </div>	<p>Cutting and piercing injuries accounted for 2609 deaths in 2014; men have a higher rate (1.37/100,000) than women (0.44/100,000)</p> <p><i>Incised wound:</i> Wound that is <i>longer</i> than it is <i>deep</i>; wound can be straight or jagged with sharp, distinct edges without abrasion; usually produces significant external bleeding with little internal hemorrhage; these wounds are noted in sharp-force injury suicides; in addition to a deep, lethal cut, there will be superficial incisions in same area called <i>hesitation marks</i> (Fig. B)</p> <p><i>Stab wound:</i> Penetrating sharp-force injury that is <i>deeper</i> than it is <i>long</i>; if a sharp instrument is used, depths of wound are clean and distinct but can be abraded if object is inserted deeply and wider portion (e.g., hilt of a knife) impacts skin; depending on size and location of wound, external bleeding may be surprisingly small; after an initial spurt of blood, even if a major vessel or heart is struck, wound may be almost completely closed by tissue pressure, thus allowing only a trickle of visible blood despite copious internal bleeding</p> <p><i>Puncture wound:</i> Instruments or objects with sharp points but without sharp edges produce puncture wounds; classic example is wound of foot after stepping on a nail; wounds are prone to infection, have abrasion of edges, and can be very deep</p> <p><i>Chopping wound:</i> Heavy, edged instruments (axes, hatchets, propeller blades) produce wounds with a combination of sharp- and blunt-force characteristics</p>
<div data-bbox="332 1352 505 1472" data-label="Image"> </div> <div data-bbox="332 1562 505 1703" data-label="Image"> </div> <div data-bbox="370 1703 464 1797" data-label="Caption"> <p>FIGURES C AND D Firearms.</p> </div>	<p>All firearm deaths accounted for 33,599 deaths in the United States in 2014; men more likely to die than women (18.16 vs. 2.73/100,000)</p> <p><i>Entrance wound:</i> All wounds share some common features; overall appearance is most affected by range of fire</p> <p><i>Contact range entrance wound:</i> Distinctive type of wound when gun is held so muzzle rests on or presses into skin surface; there is searing of edges of wound from flame and soot or smoke on edges of wound in addition to hole; hard contact wounds of head cause severe tearing and disruption of tissue (because of thin layer of skin and muscle overlying bone); wound is gaping and jagged, known as <i>blow back</i>; can produce a patterned abrasion that mirrors weapon used (Fig. C)</p> <p><i>Intermediate (distance) range entrance wound:</i> Surrounded by gunpowder tattooing or stippling; <i>tattooing</i> results from fragments of burning or unburned pieces of gunpowder exiting barrel and forcefully striking skin; <i>stippling</i> results when gunpowder abrades but does</p>

	not penetrate skin (Fig. D)
	<i>Indeterminate range entrance wound:</i> Occurs when flame, soot, or gunpowder does not reach skin surface but bullet does; <i>indeterminate</i> is used rather than <i>distant</i> because appearance may be same regardless of distance; for example, if an individual is shot at close range through multiple layers of clothing the wound may look the same as if the shooting occurred at a distance
	<i>Exit wound:</i> Has the same appearance regardless of range of fire; most important factors are speed of projectile and degree of deformation; size cannot be used to determine if hole is an exit or entrance wound; usually has clean edges that can often be reapproximated to cover defect; skin is one of toughest structures for a bullet to penetrate; thus, it is not uncommon for a bullet to pass entirely through body but stop just beneath skin on “exit” side
	<i>Wounding potential of bullets:</i> Most damage done by a bullet is a result of amount of energy transferred to tissue impacted; speed of bullet has much greater effect than increased size; some bullets are designed to expand or fragment when striking an object, for example, <i>hollow-point</i> ammunition; lethality of a wound depends on what structures are damaged; wounds of brain may not be lethal; however, they are usually immediately incapacitating and lead to significant long-term disability; a person with a “lethal” injury (wound of heart or aorta) also may not be immediately incapacitated

Asphyxial Injuries

Asphyxial injuries are caused by a failure of cells to receive or use oxygen. Deprivation of oxygen may be partial (*hypoxia*) or total (*anoxia*). Asphyxial injuries can be grouped into four general categories: suffocation, strangulation, chemical asphyxiants, and drowning.

Suffocation.

Suffocation, or oxygen failing to reach the blood, can result from a lack of oxygen in the environment (entrapment in an enclosed space or filling the environment with a suffocating gas) or a blockage of the external airways. Classic examples of these types of asphyxial injuries are a child who is trapped in an abandoned refrigerator or a person who commits suicide by putting a plastic bag over the head. A

reduction in the ambient oxygen level to 16% (normal is 21%) is immediately dangerous. If the level is less than 5%, death can ensue within a matter of minutes. The diagnosis of these types of asphyxial injuries depends on the history of the injury, because there will be no specific physical findings.

Diagnosis and treatment in **choking asphyxiation** (obstruction of the internal airways) depend on locating and removing the obstructing material. Injury or disease also may cause swelling of the soft tissues of the airway, leading to partial or complete obstruction and subsequent asphyxiation. Suffocation also may result from compression of the chest or abdomen (mechanical or compressional asphyxia), preventing normal respiratory movements. Usual signs and symptoms include florid facial congestion and petechiae (pinpoint hemorrhages) of the eyes and face.

Strangulation.

Strangulation is caused by compression and closure of the blood vessels and air passages resulting from external pressure on the neck. This causes cerebral hypoxia or anoxia secondary to the alteration or cessation of blood flow to and from the brain. It is important to remember that the amount of force needed to close the jugular veins (2 kg [4.5 lb]) or carotid arteries (5 kg [11 lb]) is significantly less than that required to crush the trachea (15 kg [33 lb]). It is the alteration of cerebral blood flow in most types of strangulation that causes injury or death—not the lack of airflow. With complete blockage of the carotid arteries, unconsciousness can occur within 10 to 15 seconds.

A noose is placed around the neck, and the weight of the body is used to cause constriction of the noose and compression of the neck in **hanging strangulations**. The body does not need to be completely suspended to produce severe injury or death. Depending on the type of ligature used, there usually is a distinct mark on the neck, an inverted V with the base of the V pointing toward the point of suspension.

In **ligature strangulation**, the mark on the neck is horizontal, without the inverted V pattern seen in hangings. Petechiae may be

more common because intermittent opening and closure of the blood vessels may occur as a result of the victim's struggles. Internal injuries of the neck are rare.

Variable amounts of external trauma on the neck with contusions and abrasions are noted in **manual strangulation** caused either by the assailant or by the victim clawing at one's own neck in an attempt to remove the assailant's hands. Internal damage can be quite severe, with bruising of deep structures and even fractures of the hyoid bone and tracheal and cricoid cartilages. Petechiae are common.

Chemical asphyxiants.

Chemical asphyxiants either prevent the delivery of oxygen to the tissues or block its use. **Carbon monoxide (CO)** is the most common chemical asphyxiant. **Cyanide** acts as an asphyxiant by combining with the ferric iron atom in cytochrome oxidase, thereby blocking the intracellular use of oxygen. A victim of cyanide poisoning has the same cherry-red appearance as a carbon monoxide intoxication victim because cyanide blocks the use of circulating oxyhemoglobin. An odor of bitter almonds also may be detected. (The ability to smell cyanide is a genetic trait that is absent in a significant portion of the general population.) **Hydrogen sulfide (sewer gas)** is a chemical asphyxiant in which victims of hydrogen cyanide poisoning may have brown-tinged blood in addition to the nonspecific signs of asphyxiation.

Drowning.

Drowning is an alteration of oxygen delivery to tissues resulting from the breathing in of fluid, usually water. Each year there are thousands of drowning deaths in the United States. The major mechanism of injury is hypoxemia (low blood oxygen levels). Even in freshwater drownings, where large amounts of water can pass through the alveolar-capillary interface, there is no evidence that increases in blood volume cause significant electrolyte disturbances or hemolysis, or that the amount of fluid loading is beyond the compensatory capabilities of the kidneys and heart. Airway obstruction is the more important pathologic abnormality, underscored by the fact that in up

to 15% of drownings, little or no water enters the lungs because of vagal nerve–mediated laryngospasms. This phenomenon is called **dry-lung drowning**.

No matter what mechanism is involved, cerebral hypoxia leads to unconsciousness in a matter of minutes. Whether this progresses to death depends on a number of factors, including the age and health of the individual. One of the most important factors is the temperature of the water. Irreversible injury develops much more rapidly in warm water than it does in cold water. Submersion times of up to 1 hour with subsequent survival have been reported in children retrieved from very cold water. Complete submersion is not necessary for a person to drown. An incapacitated or helpless individual (such as a person with epilepsy or alcoholism, or an infant) may drown in only a few inches of water.

It is important to remember that there are no specific or diagnostic findings to *prove* that a person recovered from the water is actually a drowning victim. In cases in which water has entered the lung, there may be large amounts of foam coming from the nose and mouth, although this also can be seen in certain types of drug overdoses. A body recovered from water with signs of prolonged immersion could just as easily be a victim of some other type of injury who has been put in the water to obscure the actual cause of death. When working with a living victim recovered from water, it is essential to keep in mind that an underlying condition may have led to the person's becoming incapacitated and submersed—a condition that also may need to be treated or addressed while correcting hypoxemia and dealing with its sequelae.

Infectious Injury

The pathogenicity (virulence) of microorganisms lies in their ability to survive and proliferate in the human body, where they injure cells and tissues. The disease-producing potential of a microorganism depends on its ability to (1) invade and destroy cells, (2) produce toxins, and (3) produce damaging hypersensitivity reactions (see [Chapter 9](#) for further discussion).

Immunologic and Inflammatory Injury

Cellular membranes are injured by direct contact with cellular and chemical components of the immune and inflammatory responses, such as phagocytic cells (lymphocytes, macrophages) and substances such as histamine, antibodies, lymphokines, complement, and proteases. Complement is responsible for many of the membrane alterations that occur during immunologic injury. Membrane alterations are associated with rapid leakage of potassium (K^+) out of the cell and rapid influx of water. Antibodies can interfere with membrane function by binding to and occupying receptor molecules on the plasma membrane. This type of injury is found in certain forms of diabetes mellitus and in myasthenia gravis. Antibodies also can block or destroy cellular junctions, interfering with intercellular communication.

Injurious Genetic/Epigenetic Factors

Genetic disorders may be the result of genetic factors that alter the cell's nucleus and the plasma membrane's structure, shape, receptors, or transport mechanisms. For example, enzymatic genetic defects can lead to abnormalities in membrane transport. Genetic disorders can cause structural alterations of the red blood cell (e.g., sickle cell anemia). Certain human diseases, for example, cancer, can occur because of misregulation of gene expression linked to alterations of epigenetic patterning (see [Chapters 6, 12, and 13](#)).

Injurious Nutritional Imbalances

Essential nutrients—**micronutrients** (vitamins, minerals, trace elements, phytochemicals, and antioxidants) and **macronutrients** (proteins, carbohydrates, fats)—are required for cells to function normally. If these nutrients are not consumed and transported to the body's cells, or if excessive amounts of nutrients are consumed and transported, pathophysiologic cellular effects develop (*What's New? Phytochemicals and Antiinflammation*).

What's New?

Phytochemicals and Antiinflammation

An increasing number of studies indicate that a diet rich in antiinflammatory phytochemicals may have beneficial effects in reducing the risk of development of chronic disease. The specific mechanisms by which these beneficial effects are mediated are not well understood and include such topics as use of antiinflammatory medications, modulation of gene expression, and implementation of chemopreventive and cardioprotection strategies. One area being investigated is that certain phytochemicals inhibit pattern recognition receptors (PRRs), including Toll-like receptors (TLRs) and nucleotide-binding oligomerization domain proteins (NODs), which detect invading pathogens by recognizing pathogen-associated molecular patterns (PAMPs) and activate innate immune responses for host defense. It is now documented that these PRRs also can be activated by a variety of endogenous molecules derived from tissue injury and elicit sterile (e.g., induced by cell death or injury) inflammation to initiate wound-healing processes. Newer and emerging evidence suggests that PRRs can detect metabolic changes and bridge immune responses to maintain metabolic homeostasis. Dysregulation of this system of response can lead to PRRs vulnerable to chronic inflammation, which in turn can promote the development and progression of chronic disease. Examples of phytochemicals being investigated include curcumin, helenalin, cinnamaldehyde, sulforaphane (e.g., mustard, broccoli), flavonoids (e.g., blueberries), silymarin, parthenolide, allicin (garlic), indole-3-carbinol (cruciferous vegetables), lycopene (tomato), and resveratrol.

Data from Aggarwal BB, Shishodia S: *Biochem Pharmacol* 71(10):1397–1421, 2006; Khuda-Bukhsh AR, Das S, Saha SK: *Nutr Cancer* 66(2):194–205, 2014; Maru GB et al: *World J Biol Chem* 7(1):88–99, 2016; Wang PY et al: *J Diabetes Investig* 7(1):56–69, 2016; Zhao L, Lee JY, Hwang DH: *Nutr Rev* 69(9):310–320, 2011.

Proteins, which consist of chains of amino acids, are the major structural units of the cell and participate in many enzymatic and hormonal functions. Protein deficiency causes a reduction in the intestinal mucosal mass, decreasing the absorptive function. The integrity of the pancreas is also affected, resulting in diminished exocrine secretion. With starvation or malnutrition, the lowered levels of plasma proteins, particularly albumin, cause fluid to move into the interstitium (edema). Protein-calorie malnutrition (PCM) is the predominant worldwide type of malnutrition. Malnourished children are very susceptible to disease and often die of infectious diseases. Even with adequate protein intake, cellular injury can occur if amino acid transport mechanisms fail or are defective. In Fanconi syndrome, for example, renal tubular cells may contain accumulated protein droplets that have been absorbed but cannot be transported.

Glucose is the major carbohydrate obtained from the breakdown of starch. **Hyperglycemia** (excessive glucose in the blood) caused by excessive carbohydrate intake may lead to obesity. Deficiencies of glucose result from starvation or from lack of use, as in diabetes. In both conditions the body compensates by metabolizing fat (lipids).

In lipid deficiency, or **hypolipidemia**, the body compensates by mobilizing fatty acids from adipose tissue. This causes an increase in the production and circulation of ketone bodies, which are acidic byproducts of lipid metabolism. The excretion of ketone bodies results in loss of water and electrolytes and causes dehydration and thirst. Severe increases in the concentration of ketone bodies cause ketoacidosis, coma, and death. **Hyperlipidemia**, or an increase in the levels of lipoproteins in the blood, results in deposits of fat in the heart, liver, and muscle.

Vitamins are not sources of energy but are necessary for maintaining normal cellular functions. Adequate vitamin intake is necessary because most vitamins are not synthesized by the body. Research from the 1990s resulted in the identification of 13 vitamins as being essential for humans. These include eight B vitamins (thiamine, niacin, riboflavin, folate, vitamin B₆, vitamin B₁₂, biotin, and pantothenic acid), vitamin C or ascorbic acid, and the fat-soluble

vitamins A, D, E, and K. (Minerals are discussed in [Chapter 3](#).) Vitamins are involved in numerous reactions, including metabolism of visual pigments (vitamin A), calcium and phosphate metabolism (vitamin D), prothrombin synthesis (vitamin K), and antioxidation reactions (vitamins E and C). Pyridoxine (vitamin B₆) affects amino acid transfer reactions; flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), and nicotinamide adenine dinucleotide (NAD) help transfer electrons in various reactions.

Injurious Physical Agents

Injurious physical agents include temperature extremes, atmospheric pressure changes, radiation, illumination, mechanical factors, noise, and prolonged vibration. Physical injury can result from excessive exposure to many environmental agents, as well as to agents used for the diagnosis and treatment of illness.

Climate Change

Climate is changing beyond the range of the recent geological era because levels of carbon dioxide and other greenhouse gases (e.g., methane) in the Earth's atmosphere are exceeding levels recorded in the past millions of years.⁷⁹ Strongly correlated with warming of the Earth are the greenhouse gases, particularly CO₂, produced by the combustion of hydrocarbons in automobiles, air travel, marine transportation, railways, and energy plants (coal, natural gas, and oil).⁸⁰ Climate change affects social and environmental determinants of health including clean air, safe drinking water, sufficient food, and secure shelter.⁸¹ Climate change will seriously impact human health by increasing several diseases including (1) cardiovascular, cerebrovascular, and respiratory diseases from air pollution and heat waves; (2) gastroenteritis and infectious disease epidemics caused by water and food contamination from flooding, disruption of clean water supplies, and sewage treatment; (3) vector-borne communicable diseases, including dengue, malaria, hantavirus, and cholera;⁸² and (4) malnutrition from disruption of crops.¹

Temperature Extremes

Chilling or freezing of cells causes **hypothermic injury**. Hypothermia has proved to be strongly injurious to a variety of cells. *Accidental hypothermia* is an unintentional drop in core body temperature below 35° C (95° F). At these temperatures, the compensatory mechanisms that conserve temperature start to fail. **Primary accidental**

hypothermia is the physiologic result of a previously healthy person to the changes that occur with cold. The mortality rate is higher in those who develop **secondary hypothermia** as a consequence of a serious systemic disorder, for example, endocrine disorders. Primary accidental hypothermia is a worldwide problem with most cases evident in the winter months. Surprisingly, however, it commonly occurs in warmer regions. The highest risks are to the elderly and neonates. The elderly have diminished thermal perception and regulation and are susceptible because of increased likelihood of immobility, impaired nutritional status, the presence of coexisting diseases, and the impact of economic factors. Neonates have high rates of heat loss because of their increased surface-to-mass ratio and lack of shivering and other behavioral responses. Individuals at increased risks for hypothermia include those with occupations or hobbies that have extensive cold weather exposure, such as people in the military, hunters, sailors, skiers, swimmers, and climbers. Prolonged exposure to low ambient temperature is a common risk factor found in homeless persons. Some causes of secondary hypothermia include hypothyroidism, hypoglycemia, adrenal insufficiency, metabolic alterations associated with uremia, neurologic injury, extensive burns, acute myocardial infarction (can be reversed with resuscitation), skin diseases, and hepatic failure.⁸³

Submersion in cold water can induce a high incidence of cardiac dysrhythmias in healthy volunteers.⁸⁴ Immersion in cold water is a common cause of death in children and in adults.⁸⁵ Deaths caused by cold water have historically been ascribed to hypothermia; however, reports of two newer antagonistic responses are emerging—they are called the *cold shock response* and the *diving response* (Box 2.5).

Box 2.5

Cold Water Immersion and Cold Shock Response and the Diving Response

Submersion and breath-holding in cold water can activate two

antagonistic responses called the *cold-shock response* and the *diving response*. The cold-shock response triggers tachycardia from activation of the sympathetic nervous system. Sympathetic activation affects the sinoatrial (SA) and atrioventricular (AV) nodes of the heart and the myocardium. The release of breath-holding may be involved, with many dysrhythmias occurring within 10 seconds of stopping breath-holding. Paradoxically, the diving response promotes a parasympathetically mediated bradycardia. The simultaneous activation of both the sympathetic and the parasympathetic branches of the autonomic nervous system is sometimes called “autonomic conflict.”

Certain individuals may have vulnerable risk factors including ischemic heart disease, myocardial hypertrophy, acquired (drug-induced) long QT syndrome (LQTS), QT interval mismatch to heart rate, atherosclerosis, and conduction pathologies (e.g., LQTS). There is a strong association between sudden cardiac arrest and swimming in children with LQTS. Certain drugs also may prolong QT interval (e.g., antihistamines, antibiotics, class Ia antiarrhythmics, gastrointestinal prokinetics, and antipsychotics). The actual number of immersion-related deaths because of “autonomic conflict” is unknown and may be undiagnosed because of drowning.

Data from Bowes H et al: *Eur J Appl Physiol* 116(4):759–767, 2016; Patton JF et al: *Brain Res Brain Res Rev* 49:399–404, 2010; Shattock MJ, Tipton MJ: *J Physiol* 590(Pt 14):3219–3230, 2012; Tipton MJ et al: *Aviat Space Environ Med* 81:399–404, 2010.

Hypothermic injury has long been attributed to disturbances of cellular ion balance or homeostasis, especially of sodium balance (i.e., increased intracellular sodium levels). Hypothermia increases the level of intracellular Ca^{++} by slowing $\text{Na}^{+}\text{-K}^{+}\text{-ATPase}$ pump activity, leading to Na^{+} accumulation intracellularly.⁸⁶ In the last decade, however, the role for ROS has gained importance.⁸⁷ Hypothermic perfusion of the heart increased superoxide (O_2^-) concentration (see [Table 2.3](#)); in turn, O_2^- reacted with nitric oxide (NO) to form another

radical peroxynitrite anion (ONOO⁻).⁸⁶ In some cell types, such as hepatocytes and liver endothelial cells, hypothermia can cause pronounced cell injury mediated by ROS. During the body's exposure to cold, injury is inhibited by hypoxia and by a number of antioxidants, especially iron chelators.

Indirect forms of injury occur because of changes in small blood vessels (the microcirculation). Slow chilling can cause vasoconstriction followed by paralysis of vasomotor control, resulting in vasodilation and increased membrane permeability causing cellular and tissue swelling. With an abrupt drop in temperature, vasoconstriction and increased viscosity of the blood cause ischemic injury—infarction and necrosis (cellular death)—in affected tissues. With continued exposure to freezing temperatures, vasodilation produces severe swelling that causes degenerative changes in the myelin sheath that surrounds peripheral nerves, resulting in sensory and motor disturbances. Thrombosis also can occur and may lead to gangrene of the affected part. These conditions often are called *frostbite*.

Therapeutically, hypothermia is widely used to protect cells and tissues against injurious processes. Therapeutic hypothermia (TH) has been used clinically to preserve the heart during surgery and to preserve organs before transplantation.⁸⁸ TH in animals to protect the heart against acute infarction has had positive results; however, studies in humans are limited.

Hyperthermia is an uncontrolled increase in body temperature that exceeds the body's ability to lose heat. **Hyperthermic injury** (injury caused by excessive heat) is common and varies depending on the nature, intensity, and extent of the injury. Three types of hyperthermic injury include heat cramps, heat exhaustion (illness), and heat stroke.

Heat cramps (cramping of voluntary muscles) are usually a result of vigorous exercise that causes a loss of salt and water as a consequence of sweat. Treatment is salt replacement.

Heat exhaustion occurs when sufficient salt and water loss results in hemoconcentration. Hypotension occurs secondary to fluid loss (hypovolemia), and the individual feels weak, is nauseated, and can suddenly collapse. Collapsing results from a failure of the

cardiovascular system to compensate for hypovolemia. Heat exhaustion is probably the most common heat-related injury.

Heat stroke is a life-threatening condition associated with high environmental temperatures and humidity. Core body temperature rises as a result of thermoregulatory failures. Clinically, a rectal temperature of 41°C (106°F) is considered a life-threatening sign. Generalized peripheral vasodilation and decreased circulating blood volume are significant. At risk are older adults, athletes, military recruits, and people with cardiovascular disorders.

Malignant hyperthermia occurs in individuals with an inherited disorder (e.g., ryanodine receptor intracellular calcium release channel) of skeletal muscle sarcoplasmic reticulum in response to inhalational anesthetics or to succinylcholine.⁸⁹ This rare condition is often fatal. The condition includes elevated temperature, increased muscle metabolism, muscle rigidity, rhabdomyolysis, acidosis, and cardiovascular alterations.

Drug-induced hyperthermia has become increasingly common because of the increase in abuse of psychotropic drugs and illicit drugs. Examples of drugs include amphetamines, cocaine, phencyclidine (PCP), and methylenedioxymethamphetamine (MDMA; ecstasy). Lysergic acid diethylamide (LSD), salicylates, lithium, anticholinergics, and sympathomimetics also have been implicated.

Neuroleptic malignant syndrome is hyperthermia caused by the administration of neuroleptic drugs (antipsychotics, phenothiazines, haloperidol, prochlorperazine, metoclopramide) or the withdrawal of dopaminergic drugs and is characterized by lead-pipe muscle rigidity, autonomic dysregulation, hyperthermia, and extrapyramidal side effects.⁹⁰

Burns are caused by local heat injury. A *full-thickness burn* is an open wound involving skin layers—epidermis, dermis, and subcutaneous layers—and causing extensive loss of fluids and plasma proteins. Cellular regeneration is not possible; therefore, skin from a donor or from the host must be grafted to the site. *Partial-thickness burns* result in reddening of the area as a result of dilation of small blood vessels

and increased permeability of cellular membranes, with loss of protein-rich fluid, resulting in the typical “burn blister.” In surface epithelial cells, membrane permeability increases, causing both cytoplasmic and nuclear swelling. Temperature-sensitive enzymes within certain cells respond to heat by increasing cellular metabolism, with detrimental effects. Intense heat also damages the vascular endothelium and causes coagulation of the blood vessels.

Epidemiologic investigators have reported a positive relationship between overheating in infants (that is, overdressing infants in the winter) and the prevalence of sudden infant deaths. **Sudden infant death syndrome (SIDS)**, or cot death, is the sudden and unexpected death of an infant less than 1 year of age, with onset of the lethal episode apparently occurring during sleep, that remains unexplained after a thorough investigation.⁹¹ One hypothesis for SIDS is an insufficient cardiorespiratory response to multiple environmental stressors (such as prone sleeping, overwrapping, and infection) during a critical developmental phase in a vulnerable infant.⁹² Investigators using neonatal rats did not find a three-way interaction between infection, hyperthermia, and hypoxia but did find independently that heat stress decreased minute ventilation during normal levels of oxygen and increased the hypoxic ventilator response.⁹² They also found that administration of lipopolysaccharide (LPS, found normally in the outer membrane of gram-negative bacteria) decreased hypoxia-induced tachycardia.⁹² Overall, these investigators found that neonatal cardiorespiratory responses are adversely affected by dual interactions (heat stress and LPS or infection) of environmental stress factors.⁹² Recent recommendations to reduce the risk of all sleep-related infant deaths include positioning the infant supine, using a firm sleep surface, breast-feeding, implementing room-sharing without bed-sharing, performing routine immunizations, considering use of a pacifier, and avoiding soft bedding, overheating, and exposure to tobacco smoke, alcohol, and illicit drugs.⁹³

Changes in Atmospheric Pressure

Sudden increases or decreases in atmospheric pressure cause **blast injury**, which can be transmitted by either air (air blast) or water (immersion blast). With sudden increases in pressure, tissue injury is caused by compressive waves of air impinging on the body, followed by a sudden wave of decreased pressure. The pressure changes may collapse the thorax, rupture internal solid organs, and cause widespread hemorrhage. In increased pressure caused by immersion blast, water pressure is applied suddenly to all sides of the body, forcing the body up out of the water. The positive pressure compresses the abdomen and ruptures hollow internal organs, such as the spleen, kidneys, and liver.

Decompression sickness.

Decompression sickness (DCS) (diver disease, the bends, or caisson disease) is a condition arising with sudden decreases in pressure; carbon dioxide and nitrogen that are normally dissolved in the blood come out of solution and form tiny bubbles called *gas emboli*. Deep-sea divers, scuba divers, and underwater construction workers who return to the surface too quickly develop decompression sickness. Oxygen is quickly redissolved, but nitrogen bubbles may persist and obstruct blood vessels. Ischemia resulting from gas emboli causes cellular hypoxia, particularly in the muscles, joints, and tendons. Emboli and interstitial gas accumulate around the joints and skeletal muscles, causing the individual to bend in pain. Tissues of the heart and brain also may be affected by emboli, causing necrosis. Dehydration increases the risk of decompression sickness because immersion of the body in water increases venous return to the heart.⁹⁴ As a counter-regulatory measure, the cardiac atria secrete atrial natriuretic peptide (ANP), causing diuresis (the Gauer-Henry reflex). At the same time, with a decreased secretion of antidiuretic hormone (ADH) from the hypothalamus, the kidneys excrete water. The result is a reduction of blood volume. During ascent, fluid is lost in expired air. The total volume deficiency changes the rheological (flow of matter) dynamics in blood and promotes the onset of decompression sickness.^{94,95} The gases can be promptly redissolved in blood by

raising the atmospheric pressure, which is accomplished by placing the individual in a decompression chamber and increasing the pressure until it approximates pressure at the depth to which the diver had descended. This redissolves the gas bubbles in the blood. Pressure is then decreased gradually until it equals the pressure at the surface of the water. This slows the release of gas bubbles out of solution.

Nitrogen concentrations can have a crippling anesthetic effect on the brain. This narcosis has been referred to as “rapture of the deep,” where both physical and cognitive abilities may be seriously impaired.⁹⁶ Thus, when diving to great depths, both the volume of nitrogen and the volume of oxygen must be decreased. This is accomplished by the addition of an “inert” gas (one that has no metabolic activity within the body). It has been suggested that problems associated with deep, long-duration dives could be avoided by replacing the nitrogen in a diver's gas supply with helium, an inert gas and nature's second lightest gas.⁹⁷ Helium's great advantage is that it does not lead to nitrogen narcosis—it is less soluble in blood and fat than nitrogen.

Decompression sickness can happen with very rapid ascent to high altitude in an aircraft that is not properly pressurized.⁹⁸ Although decompression sickness is not a concern when people ascend slowly (e.g., on foot) to a low atmospheric pressure environment, such as altitudes higher than 10,000 feet, there is a significant decrease in available oxygen because of decreased partial pressure of the inspired gases. The hypoxemia that occurs may result in pathologic conditions unique to the hypoxic environment at high altitude.

High altitude illness: HAPE, HACE, AMS.

High altitude illness, in the form of **high altitude pulmonary edema (HAPE)** or **high altitude cerebral edema (HACE)**, is potentially fatal. Both conditions, in addition to a less serious, more common form, are known as *acute mountain sickness* (AMS). Several factors, including rate of ascent to altitude, final altitude reached, altitude at which a person sleeps, and individual physiologic differences, are believed to

influence development of these conditions.⁹⁹ Additional risk factors include certain preexisting cardiopulmonary conditions, residence at low altitude, prior history of high altitude illness, and level of exertion at altitude.¹⁰⁰

Acute mountain sickness (AMS) is defined as the presence of a combination of nonspecific symptoms that appear within a few hours after ascent to altitude, and may include headache, loss of appetite, nausea, vomiting, weakness, lassitude, dizziness, and difficulty sleeping.^{100,101} Symptoms are usually most noticeable during the first few days at altitude, but may reappear on further ascent to a higher altitude. AMS is usually a relatively benign, self-limited condition and does not include abnormal neurologic symptoms or signs. An increase in severity of symptoms or signs of neurologic dysfunction, such as ataxia or altered consciousness, indicates transition to high altitude cerebral edema (HACE).¹⁰² HACE is a clinical diagnosis defined as the onset of ataxia, altered consciousness (including confusion, impaired mentation, stupor, and coma), and severe lassitude. Severe headache, nausea, and vomiting are frequently present. In both AMS and HACE, headache is most likely initially produced by hypoxemia-induced cerebral vasodilation and a significant increase in blood flow. In addition, recent magnetic resonance imaging (MRI) studies suggest that in persons ascending to high altitudes and suffering moderate to severe AMS, some degree of cerebral edema occurs. However, in milder forms of AMS (a subjective distinction), brain edema is present in some MRI studies, but not in all.¹⁰⁰ The cerebral edema may be either cytotoxic or vasogenic in nature (see [Chapter 17](#)).

As potentially lethal as HACE can be, HAPE is actually thought to account for most deaths from high altitude illness.¹⁰¹ High altitude pulmonary edema (HAPE) is a noncardiogenic pulmonary edema associated with pulmonary hypertension and elevated capillary pressure. The incidence of HAPE also is related to the rate of ascent, the ultimate altitude reached, and the individual's susceptibility. Victims of HAPE have a relatively exaggerated pulmonary hypertensive response on ascent to altitude as a result of augmented hypoxic pulmonary vasoconstriction. Heightened sympathetic

nervous system activity, vascular endothelial dysfunction, and hypoxemia resulting from a suboptimal ventilatory response to hypoxia are responsible for the pulmonary vasoconstriction and subsequent pulmonary hypertension. Recent evidence suggests HAPE-prone individuals are characterized by a genetic defect in the transepithelial sodium and water transport mechanism that may impair alveolar fluid clearance.¹⁰³ Persons with congenital or acquired pulmonary circulation abnormalities are more susceptible to HAPE, supporting the suggestion that edema results from overperfusion in a restricted pulmonary vascular bed. Another proposed explanation for elevated pulmonary capillary pressure is uneven hypoxic pulmonary vasoconstriction.¹⁰² It is now generally accepted that HAPE is initiated as a noninflammatory unidirectional dysfunction of the alveolar-capillary barrier that is essentially a form of hydrostatic pulmonary edema (i.e., there is an increase in pulmonary capillary pressure, but no elevation in left atrial pressure).

Ionizing Radiation

Ionizing radiation (IR) is any form of radiation capable of removing orbital electrons from atoms, resulting in the production of negatively charged free electrons and positively charged ionized atoms. Ionizing radiation is emitted by x-rays, γ -rays, and alpha and beta particles (which are emitted from atomic nuclei in the process of radioactive decay) and from subatomic particles such as neutrons, deuterons, protons, and pions. Ionizing radiation of three types (x-radiation, gamma radiation, and neutrons) was classified as a carcinogen in 2004.

An important source of exposure to ionizing radiation is the environment. This source includes emission from radioactive material inside the body, cosmic rays from outer space, and radiation emitted from such substances as soil and building materials. Environmental radioactivity is emitted primarily by uranium, thorium, and potassium. Other sources are from medical procedures (e.g., x-rays, computed tomography [CT] scans) used for medical diagnosis and treatment, uranium and thorium mines, nuclear weapons, and nuclear

reactors that generate electricity. Medical radiation now comprises about 48% to 50% of the per capita radiation doses compared with 15% in the 1980s; since 1980 medical radiation exposure has increased 600% in the U.S. population (Fig. 2.23). Table 2.10 includes types of ionizing radiation and their magnitude of tissue penetration. (Box 2.6 defines the radiation units.)

FIGURE 2.23 Ionizing Radiation Exposure of the Population of the United States. (From National Council on Radiation Protection & Measurements. (2015). *Ionizing radiation exposure of the population of the United States*, NCRP report 160, Bethesda, MD.)

TABLE 2.10

TYPES OF IONIZING RADIATION AND THEIR TISSUE PENETRATION

TYPE	TISSUE PENETRATION
x-rays	High
Gamma (γ) rays	High
Beta (β) particles	Low
Alpha (α) particles	Very low
Protons	Intermediate between α and β
Neutrons	High

Data from Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.

Box 2.6

Definitions of Radiation Units

Curie (Ci) is the disintegration per second of a radionuclide (radioisotope). It represents the amount of radiation emitted by a source.

Gray (Gy) is a unit that expresses the energy absorbed by the target tissue per unit mass. One gray equals the absorption of 104 erg/g of tissue. A *centigray (cGy)* is the absorption of 100 erg/g of tissue and is equivalent to the older terminology of 100 rad (radiation absorbed dose). cGy has replaced the term *rad* in medical practice.

Sievert (Sv) is a unit of equivalent dose that depends on the biologic rather than the physical effects of radiation and it replaced the older term *rem*. Equivalent dose controls for the variation of damage produced for the same absorbed dose from different types of radiation. It is a uniform measure of biologic dose. The effective dose of x-rays in radiographs and computed tomography is usually expressed in milliSieverts (mSv). For x-radiation, 1 mSv = 1 mGy.

Data from Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.

The main determinants of the biologic effects of ionizing radiation depend on several factors and include the following:

1. *Rate of delivery*. Because the effect of radiant energy is cumulative, divided doses may allow cells to repair between exposures, called *fractionated doses*.
2. *Field size*. Doses of radiation delivered to shielded smaller fields are safer than smaller doses delivered to larger fields, which may be lethal.¹

3. *Cell proliferation.* Rapidly dividing cells are more vulnerable to injury because ionizing radiation damages DNA. Vulnerable tissues have a high rate of cell division and include *gonads, bone marrow, lymphoid tissue, and the mucosa of the gastrointestinal tract.* Injury is manifested early after exposure.
4. *Oxygen effects and hypoxia.* A main mechanism of damage to DNA by ionizing radiation is from generation of reactive oxygen species from reactions with free radicals by radiolysis of water. Tissue with low oxygenation (hypoxia) is less sensitive to radiation, for example, the center of rapidly growing tumors.
5. *Vascular damage.* Endothelial cell damage is an important effect of radiotherapy and can result in narrowing or occlusion of blood vessels, leading to impaired healing, fibrosis, and chronic ischemic atrophy. These changes can appear months or years after exposure.

Late effects in tissues with a low rate of cell proliferation (brain, kidney, liver, muscle, subcutaneous tissue) may include cell death, atrophy, and fibrosis. These effects are associated with vascular damage from the release of proinflammatory mediators in irradiated tissue.¹

Cellular damage from IR in the absence of effective repair involves two types of damage: (1) early or late tissue reactions (previously called *deterministic*) and (2) stochastic or random effects. High doses of radiation cause substantial cell killing and result in detectable tissue reactions. These reactions occur early (days) or late (months to years) after irradiation (Fig. 2.24).

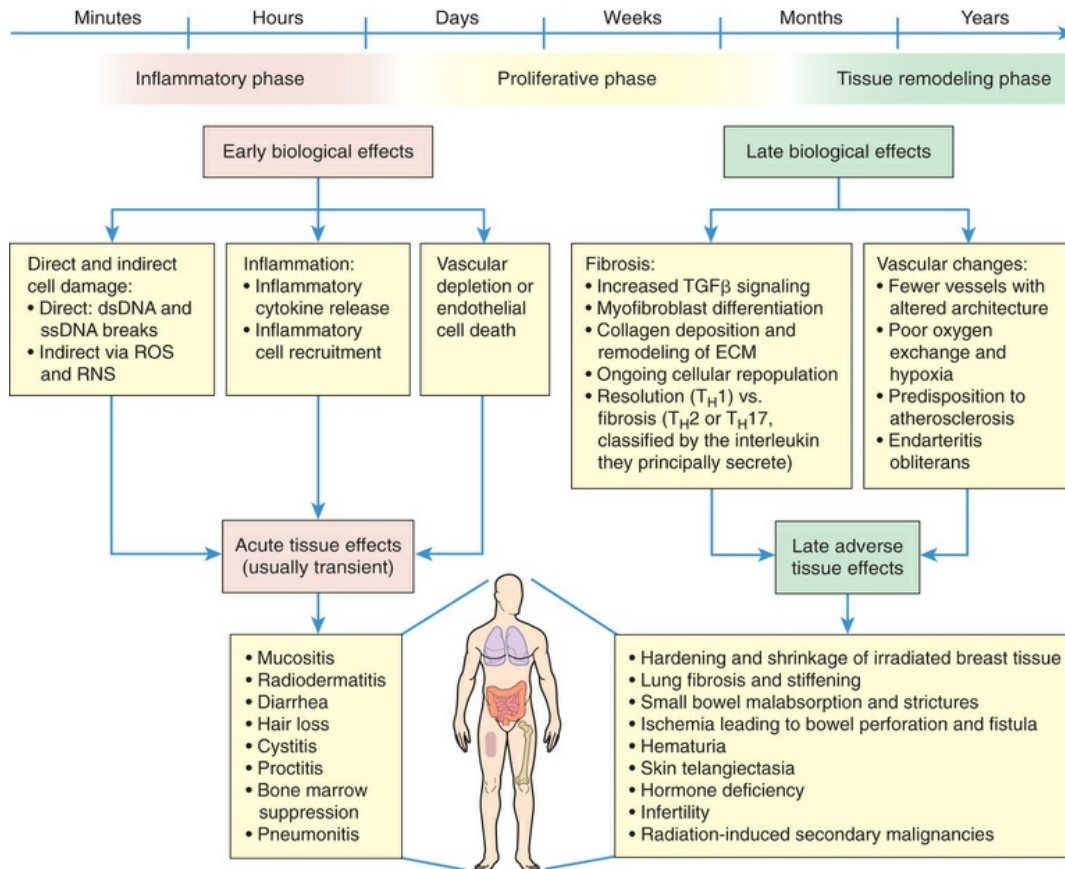

FIGURE 2.24 Early and Late Tissue Effects of Radiation. Early biologic events cause acute effects that are normally transient and resolve within 3 months of completing therapy. These events can lead to biologic effects over time, for example, fibrosis, vascular changes, and secondary malignancies. Severity is increased for these biologic effects with higher radiation dose per fraction. *dsDNA*, Double-stranded DNA; *ECM*, extracellular matrix; *ROS*, reactive oxygen species; *RNS*, reactive nitrogen species; *ssDNA*, single-stranded DNA; *TGFβ*, transforming growth factor-beta; *TH*, T helper cell. (From ICRP: *Ann ICRP* 41[1/2], 2012).

The International Commission on Radiological Protection (ICRP) emphasizes that protection should be optimized for whole body exposures and for specific tissues, particularly the lens of the eye, the heart, and the cerebrovascular system. The threshold in absorbed doses for the lens of the eye is now lower and is considered to be 0.5 gray (Gy). The absorbed dose threshold for circulatory disease may be as low as 0.5 Gy to the brain or heart.¹⁰⁴ The emerging science on low-dose radiation and tissue effects is very complicated; for example, for exposures less than 0.5 Gy, the balance of inflammatory markers may shift toward anti-inflammatory effects.¹⁰⁵ *Stochastic effects* are produced at random, without a threshold dose level, and the main

effects include carcinogenesis and genetic mutation. The severity of the outcome is *not* related to dose but rather the entire tissue and stress response (see below).^{106,107} More simply, ionizing radiation causes damage that initiates DNA repair mechanisms, alterations in gene expression, and various stress responses.

Historically, radiation dose-related cancer risks at low doses were estimated from data of the atomic-bomb survivors and of individuals treated with moderate- to high-dose radiation.¹⁰⁷ The effects of low doses were mathematically extrapolated from high doses. After review from national and international expert committees and publications from 2005 to 2008, the available biologic and biophysical data support a linear no-threshold risk model for cancer.¹⁰⁷ Additionally, this understanding combined with an uncertain dose and a dose rate effectiveness factor for extrapolation from high doses is considered a conservative estimate for radiation protection for low doses and low dose rates.¹⁰⁷ Complicating these standards, however, has been the emerging data from radiobiology suggesting a much more complex understanding regarding low dose and low dose rates because of a complex interplay of various stress response pathways and nontargeted effects (NTEs) of low-dose radiation (e.g., effects in nonirradiated cells near and distant from irradiated cells).^{108,109} The **nontargeted effects** of ionizing radiation include bystander effects and genomic instability. **Bystander effects**, or effects on cells not directly in the radiated field, are affected by the radiation and show high levels of mutations, chromosomal aberrations, and membrane signaling changes leading to what some call “horizontal transmission.” **Genomic instability** is where generations of cells derived from an irradiated progenitor cell appear normal but time-lethal (i.e., irreversible) and nonlethal mutations appear in distant progeny, sometimes called “vertical transmission.”¹¹⁰ Importantly, a new paradigm shift of the effects of IR or radiobiology is occurring. These effects represent a tissue response or cell stress response from IR. The current theory that all radiation damage results from energy deposition in those cells' DNA was challenged by four key lines of evidence reported from 1986 to 1996 and includes the following: (1)

new lethal mutations could occur in cells that had recovered from irradiation and continued dividing for several generations,¹¹¹ (2) a delayed appearance of new chromosome aberrations was demonstrated in bone marrow stem cell lines from irradiated stem cells,¹¹² (3) a very low-dose exposure of alpha radiation resulted in more cells with chromosome damage than would have been predicted mathematically,¹¹³ and (4) the cell medium from irradiated cells was found to cause similar levels of clonogenic genomic instability and cell death as cells *directly* irradiated.¹¹⁴ Thus, from newer evidence are radiobiologic understandings for low-dose radiation, yet many biologic questions remain.¹¹⁰ Importantly, many teams of investigators studying radiation effects have consisted of both physicists *and* biologists. Additionally, much research is now involved concerning the effects of radiation on epigenetics, the entire tissue and organismic “stress” response, and the role of the microenvironment.^{115,116} Radiation alters the components of the microenvironment, affecting cell phenotypes, tissue composition, and the physical interactions and signaling between cells.^{109,117,118} These alterations can contribute to carcinogenesis and therapy resistance.

Ionizing radiation (IR; x-radiation and γ -rays) causes a large spectrum of genetic changes including gene mutations, mini-satellite mutations (altered numbers of tandem repeats of DNA sequences), micronucleus formation (sign of chromosome damage or loss), chromosomal aberrations (structural or number), ploidy changes (number of sets of chromosomes), DNA strand breaks, and chromosomal instability. DNA may be damaged *directly* or *indirectly* by interaction with reactive products (i.e., free electrons, hydroxyl radicals, hydrogen free radicals) from the degradation of water (Fig. 2.25).

FIGURE 2.25 Cellular Damage Caused by Ionizing Radiation. Radiation can damage macromolecules in two ways: (1) directly, in which the micromolecules are ionized and (2) indirectly, in which water is ionized and produces free radicals that in turn damage macromolecules. Cells that are particularly susceptible to damage are those of the gastrointestinal tract, bone marrow, lymph nodes, fetus, and ovarian follicles.

All phases of the cell cycle can be affected by ionizing radiation. Sensitivity of the cell appears to be greatest in G_2 , that gap of the cell just before mitosis; irradiation during this phase retards the onset of cell division. Radio-resistance is greatest in the latter part of the S phase. At the time of therapeutic irradiation those cells in the most sensitive parts of the cell cycle will be killed. Those cells in the radio-resistant part of the cell cycle will continue to proliferate and repopulate the tumor—requiring more radiation for a therapeutic effect or cell killing. Irradiation during mitosis induces chromosomal aberrations. Membrane molecules and enzymes also are damaged by radiation.

Not all cells and tissues have the same sensitivity to radiation, although all cells can be affected. Radiosensitivity depends partly on the rate of mitosis and cellular maturity. Because fetal cells both are immature and are undergoing rapid cycling, the fetus is at great risk for injury caused by ionizing radiation. Particularly vulnerable are embryonic germ cells, which are precursors of ova and sperm. Throughout life, cells of the bone marrow, intestinal mucosa, testicular seminiferous epithelium, and ovarian follicles are susceptible to injury because they are always undergoing mitosis, which ensures the presence of vulnerable, immature daughter cells. Exposure to x-radiation and γ -radiation is most strongly correlated with leukemia and cancers of the thyroid, breast, and lung; these correlates have been reported at absorbed low levels, less than 0.2 Gy. The risk of developing these cancers may to some extent depend on age at exposure. The Life Span Study, which had a wide range in age at exposure and a wide dose range (from less than 0.005 Gy to 2–4 Gy), was evidence of a linear dose response for all solid tumors, with significant radiation-associated excess risks observed in most, but not all, types of solid tumors. In utero radiation exposure in the Japanese A-bomb survivors was associated with an increased adult-onset risk of solid tumors.¹¹⁹ The studies of diagnostic x-rays in utero and the risk of pediatric leukemia and other cancers are characterized by uncertainties, especially a lack of dose measurement data.¹⁰⁷ Ultrasound replaced abdominal x-rays and measurements of the pelvis several decades ago in pregnant women; however, there recently have been reports of increasing levels of radiologic imaging in pregnant women.¹²⁰ At the time of the radiologic examination, all women of childbearing potential should be asked if they could be pregnant.¹²¹ If any doubt exists, the results of a pregnancy test should be obtained before proceeding. Many organizations have specific papers on safety and imaging pregnant women, including the American College of Radiology, the American Congress of Obstetricians and Gynecologists, and internationally, for example, the Health & Safety Executive from Great Britain and the International Commission on Radiological Protection Publication (ICRP). Radiation

exposure to children may increase the incidence of lymphomas, leukemias, melanomas, breast cancers, and others. The increased frequency of pediatric CT exams in the United States is mainly because of the increased use of fast helical CT, which reduces the need for sedation.¹²²

Radiation-induced cancers are found in the “cancer-prone” ages (usually 50 to 80 years of age), independent of age at exposure; therefore, the latency period between radiation exposure and the potential appearance of a cancer decreases significantly with increasing age at exposure.¹²³ From these effects, more recent analyses of cancer incidence among atomic-bomb (A-bomb) survivors suggest that the lifetime risk of radiation-induced cancer is not so different for exposure at age 5 years vs. exposure at age 55 years.^{119,124} Notable research is being done on radiation-induced secondary cancers.

Illumination and Luminance: Light Is Electromagnetic Radiation

Light is electromagnetic radiation, and the portion of the electromagnetic spectrum that interacts with the eye is called **optical radiation** and includes wavelengths from ultraviolet light (100–400 nm), to visible light (400–760 nm), to infrared light (760–10,000+ nm). All radiations like light carry energy, with the shorter wavelengths being the most energetic.¹²⁵ Consequently, the smaller the emitting surface the more concentrated the flux in the viewing direction and the higher the luminance.¹²⁵ The optical system images everything on the retina, a highly specialized sense organ, and most relevant for retinal illumination is the luminance of the viewed objects. The mechanisms of light-induced damage include (1) heat or thermal damage, called *photothermal* damage; (2) *photochemical* damage, of which sources of damage include blue light, ultraviolet light, and laser beams thought to result mainly from oxidative stress by forming ROS and endoplasmic stress (Fig. 2.26); and (3) *photomechanical* damage, which results from mechanical compression or tensile forces generated by rapid introduction of energy. Thermal

damage occurs from absorption of heat and irreversible thermal damage typically occurs after the ambient temperature in the retina is raised by at least 10°C (50°F).¹²⁶ The depth of penetration of the radiant energy depends on the incident wavelength and the primary absorbers—melanin and hemoglobin or oxyhemoglobin.¹²⁵ Photochemical damage occurs at short visible wavelengths; and for exposure longer than ≈1 ns, it is thought to be the result of light absorption to the chromophore, the most sensitive molecule that absorbs the radiation (light leads to the production of ROS and oxidative stress; the retina is very sensitive to oxidative stress).¹²⁵ Investigators showed blue light-emitting diode (LED) light damaged most severely compared to white and green LED light, and N-acetylcysteine (NAC), an antioxidant, was photoreceptor specific and protected against the cellular damage.¹²⁷ Photomechanical damage occurs with light pulses shorter than ≈1 ns and when the light energy is deposited faster than mechanical relaxation can occur. Tissue is disrupted by shear forces or cavitation (i.e., production of a cavity). The most common clinical application of photomechanical damage in ophthalmology is the use of radiation from the Nd:Yag laser. The laser is typically used to create an iridotomy (puncture-type openings through the iris without removal of iris tissue) in individuals with closed-angle glaucoma or cause retraction of an opacified posterior lens capsule in individuals after cataract surgery. Pulsed lasers are rarely used in vitreoretinal surgery because of the potential for collateral retinal damage, particularly full-thickness retinal defects and hemorrhage.^{125,128}

FIGURE 2.26 Photochemical Damage From Blue Light. From an in vitro experiment, blue light induces ROS production and S-opsin (light-sensitive protein) aggregation. The ROS increase is rapid and leads to oxidative damage, cell signaling pathway mitogen-activated protein kinase (MAPK) activation, or the nuclear translocation of NF- κ B. Activated MAPK and NF- κ B induce caspase activation and result in apoptotic cell death. NF- κ B activates autophagy and excessive autophagy leads to cell death. S-opsin aggregation causes endoplasmic (ER) stress. Blue LED light-induced retinal photochemical damage and cell death may be associated with both oxidative stress and ER stress. *ERK*, Extracellular signal-regulated kinases; *NF- κ B*, a transcription factor. (Data from Kuse Y et al: *Sci Rep* 4:5223, 2014.)

Ocular exposures are accidental and intended (for example, in ophthalmic applications). Adherence to standards for ocular safety is a main concern for protection of the eye from laser exposures and light exposures from ophthalmic instruments. Additionally, to improve the energy performances of artificial light sources and to protect the environment, new light sources are available, such as compact fluorescent lamps or light-emitting diodes (LEDs). The

potential risks of these new light sources need safety evaluation to determine health risks, especially hazards to the eye.

Focused light rays can increase oxidative stress, which can be prevented by a wide array of retinal antioxidant mechanisms.¹²⁹ Antioxidant mechanisms can, however, be overwhelmed by excessive light exposure, particularly of short-wavelength, high-frequency blue light, and of ultraviolet light. Since fluorescent lighting was introduced to the workplace, complaints of headaches, eyestrain, and eye discomfort have increased.¹³⁰ The rapid modulation of light from fluorescent lamps is responsible for eyestrain and headaches. The modulation can be reduced by wearing tinted glasses.

Mechanical Stresses

Mechanical stimulation of body tissues and cells is constant. These stresses and strains are from the external environment and internal physiologic conditions. Gravity as an external force and the pumping of the heart as an internal force are continual. Mechanical stimuli can cause cells to respond in a variety of ways; **compression** is a perpendicular-acting force, **tension** is a stretching force, and **torsion** is a twisting force. Fluid **shear forces** or layers rubbing against each other, for example, endothelial cells, can activate hormone release and intracellular signaling, as well as stiffen the cells by inducing rearrangement of the cytoskeleton. Mechanical compression of chondrocytes can modulate proteoglycan synthesis, and tensile stretching of cell structures can alter cell motility and orientation. Mechanical signals or signaling, called **mechanotransduction**, are eventually converted to biologic and chemical responses in the cell. Understanding molecular mechanisms driving cell shape changes is an important topic in cell and tissue structure. Specifically, mechanical forces are sensed by specialized protein complexes at integrin and cadherin adhesions and transformed into biochemical signals that modulate cell shape and function in both development and disease.¹³¹ Mechanical forces at adhesion sites affect gene transcription and protein processes, such as cell proliferation, stemness, and differentiation (Fig. 2.27).¹³¹ Investigators are identifying how

adhesion pathways and mechanotransduction affect tissue development and homeostasis.

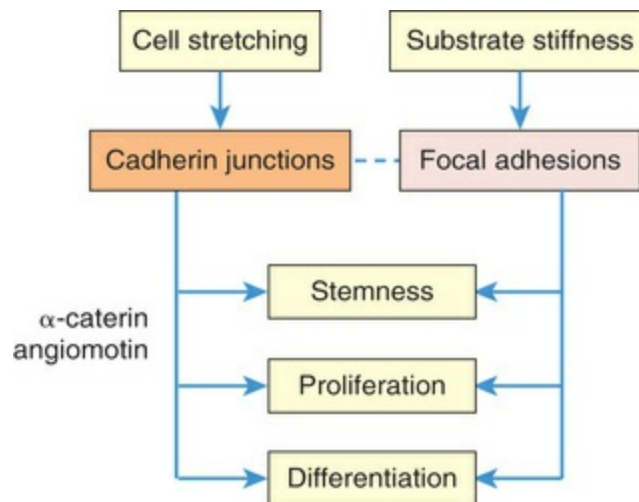

FIGURE 2.27 Mechanotransduction Regulates Gene Transcription. (Adapted from Han MK, de Rooij J: *Trends Cell Biol*, 2016.)

Acutely mechanical forces elicit adaptive responses (to rapidly alter function) chronically; however, the responses may induce tissue remodeling to accommodate load-bearing capabilities.¹³² When the mechanical forces exceed unknown thresholds, injury results.¹³² Injury can initiate more reparative responses, transient or continuous dysfunction, or progressive degenerative changes that incorporate nearby and surrounding tissue. Cellularly, the structural responses to deformation and strain (e.g., biomechanical) are causing investigators to focus on the cell membrane. Disruption of cell membranes, or *mechanoporation*, is central to the biologic progression. Investigators are defining mechanoporation as important for traumatic brain injury because it is a primary source of intraaxonal calcium after contusion. Understanding this physiology is crucial because brain injury is not just an event but rather a process of disruption, and a recoverable state of axon injury persists for hours.¹³³ Mechanical injury can progress to cell death involving both cell necrosis and delayed apoptosis.¹³² The heterogeneous distribution of atherosclerosis in the vasculature is possibly related to biomechanical factors and disturbed

hemodynamic flow; that is, certain arteries (e.g., coronary and carotid arteries) and locations (e.g., bifurcations) are more susceptible to plaque formation than others.^{134,135} Biomechanical forces probably are not systemic and vary with location. Mechanical stimuli include *shear forces* because of blood flow, **strain** from pressure distention of the vessel walls, and strain from **tethering** to a surrounding tissue area (e.g., the heart).¹³⁵

The major focus of occupational biomechanics is the response of tissue to mechanical stress, especially the prevention of overexertion disorders of the lower back and upper extremities. Many mechanical stresses can cause overt injuries (e.g., a head injury when a worker is struck in the head with a dropped object). Most stresses, however, are subtle and can cause *accumulative* injuries and disorders. [Table 2.11](#) summarizes common types of occupational mechanical stresses and associated types of injury. More realistic mechanical models of living cells will contribute greatly to the study of mechanotransduction in humans.

TABLE 2.11

COMMON TYPES OF OCCUPATIONAL MECHANICAL STRESSES AND ASSOCIATED TYPES OF INJURY

MECHANICAL STRESSES	TYPE OF INJURY
Forceful exertions (e.g., lifting, pushing, pulling of heavy loads)	Low back pain
Awkward trunk postures (e.g., flexion, lateral bending, axial twisting, prolonged sitting)	Low back pain
Whole body vibration (e.g., vibrating seat or platform)	Low back pain; bone deformities; alterations in nerve conduction (carpal tunnel syndrome)
Repetitive or prolonged exposure (e.g., to any of the above)	Low back pain; numbness and tingling of wrists and hands
Extreme-reaching low temperatures (e.g., exposure to cold air, tools, materials)	Trauma disorders of upper arms (synovitis, Raynaud phenomenon, bursitis, tendinitis)
Vibration (segmental and whole body)	Carpal tunnel syndrome, rotator cuff syndrome, tendinitis, or Raynaud phenomenon
Forceful exertions (e.g., friction, balance, posture, pace,	Ulnar deviation of the wrist

use of heavy objects)	
Repetitive functions (e.g., walking, climbing stairs, carrying, shoveling, pushing, lifting objects, using computers)	Localized and/or whole body fatigue (shortness of breath, general weakness, hypoxic injury)

Noise

Noise is sound that has the potential for inflicting harm to the body. The most common pathophysiologic effect of noise is hearing impairment. Noise trauma can be caused by acute loud noise, as well as by the cumulative effects of various intensities, frequencies, and durations of noise. Common irritating noise is caused by numerous sources, including lawn care machinery; wood and metal working with electrical equipment; gun target practice; hunting; snowmobiles; outboard motors; chain saws; and high-decibel, low-frequency speakers. According to the National Institutes of Health, more than 10 million Americans suffer some permanent noise-associated hearing loss, and 20 million are exposed to hazardous noise in work environments.¹³⁶ The largest increase in hearing loss from noise occurs in people 45 to 64 years old. Noise pollution is now considered a public health threat. Some evidence exists that noise in hospitals is associated with negative outcomes in patients, both psychologically and physiologically.¹³⁷

Two types of hearing loss are associated with noise: (1) acoustic trauma, or instantaneous damage caused by a single sharply rising wave of sound (e.g., gunfire); and (2) noise-induced hearing loss (NIHL), the more common type, which is the result of prolonged exposure to intense sound (e.g., noise associated with the workplace and leisure-time activities). Acoustic trauma can rupture the eardrum, displace the ossicles of the middle ear, and damage the organ of Corti in the inner ear.

If the offending noise has not been too loud or the exposure to it has not been too long, hearing will return to its original level, a type of hearing loss called a *temporary threshold shift* (TTS). If the noise is louder than a certain value or the exposure time is long, the hearing threshold never returns to its original value, causing a *permanent*

threshold shift (PTS). Structural changes associated with TTS, although not fully established, include intracellular changes in the sensory cells (hair cells) and swelling of the auditory nerve endings. With PTS, cochlear blood flow may be impaired and hair cells are damaged with each exposure. Noise-induced hearing loss is gradual and painless. Investigators report that cyclooxygenase-2 (Cox-2) is involved in the pathogenesis of NIHL.¹³⁸ Symptoms of noise-induced hearing loss include loudness recruitment and tinnitus. In loudness recruitment, soft sounds are not heard but loud sounds are heard normally. Tinnitus is a constant high-pitched ringing that annoys the individual and contributes to loss of sleep. The Occupational Safety and Health Administration (OSHA) requires industries to protect workers when the exposure is more than an 8-hour period and averages 85 decibels.

Manifestations of Cellular Injury

Cellular Manifestations: Accumulations

An important manifestation of cell injury is the resultant metabolic disturbances of intracellular accumulation of abnormal amounts of various substances. **Cellular accumulations**, also known as **infiltrations**, occur as a result of not only sublethal injury sustained by cells but also normal (but inefficient) cell function. Two categories of substances can cause accumulations: (1) *a normal cellular substance* (such as water, protein, lipid, and carbohydrate excesses); or (2) an *abnormal substance*, either endogenous (such as a product of abnormal metabolism or synthesis) or exogenous (e.g., infectious agents or a mineral). These products can accumulate transiently or permanently and can be toxic or harmless. Most accumulations are attributed to four types of mechanisms, all abnormal (Fig. 2.28). Abnormal accumulations of these substances can occur in the cytoplasm (frequently in the lysosomes) or in the nucleus if (1) there is insufficient removal of the normal substance because of altered packaging and transport (for example, fatty change in the liver called *steatosis*); (2) an abnormal substance, often the result of a mutated

gene, accumulates because of defects in protein folding, transport, or abnormal degradation; (3) an endogenous substance (normal or abnormal) is not effectively catabolized, usually because of lack of a vital lysosomal enzyme called *storage diseases*; or (4) harmful exogenous materials, such as heavy metals, mineral dusts, or microorganisms, accumulate because of inhalation, ingestion, or infection.

FIGURE 2.28 Mechanisms of Intracellular Accumulations. (From Kumar V

et al: Cellular responses to stress and toxic insults: adaptation, injury, and death. In Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, St Louis, 2015, Saunders.)

In all storage diseases the cells attempt to digest, or catabolize, the “stored” substances. As a result, excessive amounts of metabolites (products of catabolism) accumulate in the cells and are expelled into the extracellular matrix, where they are taken up by phagocytic cells called *macrophages*. Some of these scavenger cells circulate throughout the body, whereas others remain fixed in certain tissues, such as the liver or spleen. As more and more macrophages and other phagocytes migrate to tissues that are producing excessive metabolites, the affected tissues begin to swell. This is the mechanism that causes enlargement of the liver (hepatomegaly) or the spleen (splenomegaly). Enlargement of one of these organs is a clinical manifestation of many of the storage diseases.

Water

Cellular swelling, the most common degenerative change, is caused by the shift of extracellular water into the cells. In hypoxic injury, movement of fluid and ions into the cell is associated with acute failure of metabolism and loss of ATP production. Normally, the pump that transports sodium ions (Na^+) out of the cell is maintained by the presence of ATP and adenosinetriphosphatase (ATPase), the active transport enzyme. In metabolic failure caused by hypoxia, reduced levels of ATP and ATPase permit sodium to accumulate in the cell, whereas potassium (K^+) diffuses outward. The increase of intracellular sodium concentration increases osmotic pressure, which draws more water into the cell. The cisternae of the ER become distended, rupture, and coalesce to form large vacuoles that isolate the water from the cytoplasm, a process called *vacuolation*. Progressive vacuolation results in cytoplasmic swelling called **oncosis** (which has replaced the old term *hydropic [water] degeneration*) or **vacuolar degeneration** (Fig. 2.29). If cellular swelling affects all cells in an organ, the organ increases in weight and becomes distended and pale.

FIGURE 2.29 The Process of Oncosis (Formerly Known as *Hydropic Degeneration*). *ATP*, Adenosine triphosphate.

Cellular swelling is reversible and is considered to be sublethal. It is, in fact, an early manifestation of almost all types of cellular injury, including severe or lethal cell injury. It is also associated with high fever, hypokalemia (abnormally low concentrations of potassium in the blood), and certain infections.

Lipids and Carbohydrates

Certain metabolic disorders result in the abnormal intracellular accumulation of carbohydrates and lipids. The accumulations are caused by inherited disorders with insufficient enzymes or ineffective forms of enzymes. Carbohydrate excess disorders are called **mucopolysaccharidoses (MPSs)**, and accumulations of both carbohydrates and lipids are called **mucopolipidoses (MLs)**. MPSs and MLs are classified as **lysosomal storage diseases** because they involve increased storage of carbohydrates or lipids, or both, in lysosomes. Substrate accumulation leads to lysosomal distortion with significant pathologic consequences. These substances may accumulate throughout the body but are found primarily in the cells of the spleen, liver, and central nervous system (CNS). Several of the most prevalent disorders include Tay-Sachs disease, Fabry disease, Gaucher disease,

Niemann-Pick disease, the mucopolysaccharidoses, and Pompe disease. Accumulations in cells of the CNS can cause neurologic dysfunction and intellectual disability. The mucopolysaccharidoses are progressive disorders that usually involve multiple organs, including the liver, spleen, heart, and blood vessels. The accumulated mucopolysaccharides are found in reticuloendothelial cells, endothelial cells, intimal smooth muscle cells, and fibroblasts throughout the body. These carbohydrate accumulations can cause corneal clouding, joint stiffness, and intellectual disability.

Although lipids sometimes accumulate in heart, muscle, and kidney cells, the most common site of intracellular lipid accumulation, or **fatty change (steatosis)**, is liver cells. Because hepatic metabolism and secretion of lipids are crucial to proper body function, imbalances and deficiencies in these processes lead to major pathologic changes. The most common cause of fatty change in the liver in developed countries is alcohol abuse. Other causes of fatty change include diabetes mellitus, protein malnutrition, toxins, anoxia, and obesity. As lipids fill the cells, vacuolation pushes the nucleus and other organelles aside. Grossly, the liver looks yellowish and greasy.

Lipid accumulation in liver cells occurs after cellular injury sets one or more of the following mechanisms in motion:

1. Increased movement of free fatty acids into the liver (starvation, for example, increases breakdown of triglycerides in adipose tissue, releasing fatty acids that subsequently enter liver cells)
2. Failure of the metabolic process that converts fatty acids to phospholipids, resulting in the preferential conversion of the fatty acids to triglycerides
3. Increased synthesis of triglycerides from fatty acids (increases in amounts of the enzyme α -glycerophosphatase, which can accelerate triglyceride synthesis)
4. Decreased synthesis of **apoproteins (lipid-acceptor proteins)**
5. Failure of lipids to bind with apoproteins and form lipoproteins

6. Failure of mechanisms that transport lipoproteins out of the cell
7. Direct damage to the endoplasmic reticulum by free radicals released by alcohol's toxic effects

Cholesterol and cholesterol esters can accumulate and are noted in many pathologic states. These states include atherosclerosis, in which atherosclerotic plaques, smooth muscle cells, and macrophages within the intimal layer of the aorta and large arteries are filled with lipid-rich vacuoles of cholesterol and cholesterol esters. Other states include cholesterol-rich deposits in the gallbladder and Niemann-Pick disease (type C), which involve genetic mutations of an enzyme affecting cholesterol transport.

Glycogen

Glycogen storage is important as a readily available energy source in the cytoplasm of normal cells. Intracellular accumulations of glycogen are seen in genetic disorders called *glycogen storage diseases* and in disorders of glucose and glycogen metabolism. Like water and lipid accumulation, glycogen accumulation results in excessive vacuolation of the cytoplasm. The most common cause of glycogen accumulation is diabetes mellitus, a disorder of glucose metabolism.

Proteins

Proteins provide cellular structure and constitute most of the cell's dry weight. The proteins are synthesized on ribosomes in the cytoplasm from the essential amino acids lysine, threonine, leucine, isoleucine, methionine, tryptophan, valine, phenylalanine, and histidine. The accumulation of protein probably damages cells in two ways. First, metabolites (enzymes) produced when the cell attempts to digest some proteins can damage cellular organelles when released from lysosomes. Second, excessive amounts of protein in the cytoplasm push against cellular organelles, disrupting organelle function and intracellular communication.

Excess protein accumulates primarily in the epithelial cells of the renal convoluted tubule of the nephron unit and in the antibody-forming plasma cells (B lymphocytes) of the immune system. Several types of renal disorders cause excessive excretion of protein molecules in the urine (proteinuria). Normally, little or no protein is present in the urine, and its presence in significant amounts indicates cellular injury and altered cellular function in the glomerular membrane.

Accumulations of protein in B lymphocytes can occur during active synthesis of antibodies in the immune response. The excess aggregates of protein are called *Russell bodies*. Russell bodies have been identified in multiple myeloma (plasma cell tumor) (see [Chapter 30](#)).

Mutations in protein can slow protein folding, resulting in the accumulation of partially folded intermediates. An example is α_1 -antitrypsin deficiency, which can cause emphysema. Certain types of cell injury are associated with the accumulation of cytoskeletal proteins. For example, the *neurofibrillary tangle* found in the brain in Alzheimer disease contains cytoskeletal protein fibrils.

Pigments

Pigment accumulations may be normal or abnormal, endogenous (produced within the body) or exogenous (produced outside the body). Endogenous pigments are derived, for example, from amino acids (e.g., tyrosine, tryptophan). They include melanin and the blood proteins—porphyrins, hemoglobin, and hemosiderin (ferritin). Lipid-rich pigments such as lipofuscin (the aging pigment or spots) give a yellow-brown color to cells undergoing slow, regressive, and often atrophic changes. The most common exogenous pigment is carbon (coal dust), a pervasive air pollutant in urban areas. Inhaled carbon interacts with lung macrophages and is transported by lymphatic vessels to regional lymph nodes. This accumulation blackens lung tissues and involved lymph nodes. Other exogenous pigments include mineral dusts containing silica and iron particles, lead, silver salts, and dyes for tattoos.

Melanin.

Melanin accumulates in epithelial cells (keratinocytes) of the skin and retina. It is an extremely important pigment because it protects the skin against long exposure to sunlight and is considered an essential factor in the prevention of skin cancer. Ultraviolet light (e.g., sunlight) stimulates the synthesis of melanin, which probably absorbs ultraviolet rays during subsequent exposure. Melanin also may protect the skin by trapping the injurious free radicals produced by the action of ultraviolet light on skin.

Melanin is a brown-black pigment derived from the amino acid tyrosine. It is synthesized by epidermal cells called *melanocytes* and is stored in membrane-bound cytoplasmic vesicles called *melanosomes*. Melanosomes are particularly abundant in projections of melanocytic cytoplasm, called *dendrites*, from which they are transmitted to neighboring keratinocytes, where melanin accumulation occurs. (Keratinocytes, which constitute 95% of epidermal cells, are discussed with other skin components in [Chapter 47](#).) The dendritic melanocytes form bridges between neighboring keratinocytes and inject melanosomes into the keratinocytes by an unknown mechanism.

Melanin also can accumulate in melanophores (melanin-containing pigment cells), macrophages, or other phagocytic cells in the dermis. Presumably these cells acquire the melanin from nearby melanocytes or from pigment that has been extruded from dying epidermal cells. This is the mechanism that causes freckles.

Although rare, melanin accumulation occurs in the skin of individuals with Addison disease (adrenocortical insufficiency resulting from disorders of the adrenal cortex; see [Chapter 22](#)). The increased melanogenesis (melanin production) seen in Addison disease is caused by the loss of feedback control of adrenocorticotrophic hormone (ACTH). Decreased hormonal secretion from the adrenal gland causes increased release of ACTH from the pituitary gland. In Addison disease the increase in melanin production occurs presumably because a segment of the ACTH molecule contains the melanin-stimulating hormone (MSH).

An increase in melanin concentration also occurs in the benign form of “pigmented moles” called *nevi*. Malignant melanoma is a cancerous

skin tumor that contains melanin and invades normal tissue early and widely and often leads to death.

A decrease in melanin production occurs in the inherited disorder of melanin metabolism called *albinism*. Albinism is often diffuse, involving all the skin, the eyes, and the hair. Albinism is also related to phenylalanine metabolism. In classic forms of this disease, the person with albinism is unable to convert tyrosine to dopa (3,4-dihydroxyphenylalanine), an intermediary in melanin biosynthesis. Melanin-producing cells are present in normal numbers, but they are unable to make melanin. Individuals with albinism are very sensitive to sunlight and quickly become sunburned. They are also at high risk for skin cancer.

Hemoproteins.

Hemoproteins are among the most essential of the normal endogenous pigments. They include hemoglobin and the oxidative enzymes—the cytochromes. Knowledge of iron uptake, metabolism, excretion, and storage is central to an understanding of disorders involving these pigments (see [Chapter 28](#)). Hemoprotein accumulations in cells are caused by excessive storage of iron, which is transferred to the cells from the bloodstream. Iron enters the blood from three primary sources: (1) tissue stores, (2) the intestinal mucosa, and (3) macrophages that remove and destroy dead or defective red blood cells. The amount of iron in blood plasma also depends on the metabolism of the major iron-transport protein, *transferrin*.

Iron is stored in tissue cells in two forms: as ferritin and, when greater levels of iron are present, as hemosiderin. **Hemosiderin** is a yellow-brown pigment derived from hemoglobin. With pathologic states, excesses of iron cause hemosiderin to accumulate within cells. Accumulation of hemosiderin often occurs in areas of bruising and hemorrhage and in the lungs and spleen after congestion caused by heart failure. With a local hemorrhage, the skin first appears red-blue and then lysis of the escaped red blood cells occurs, causing the hemoglobin to be transformed to hemosiderin. The color changes noted in bruising reflect this transformation.

Hemosiderosis is a condition in which excess iron is stored as hemosiderin in the cells of many organs and tissues. This condition is common in individuals who have received repeated blood transfusions or prolonged parenteral administration of iron. Hemosiderosis is also associated with increased absorption of dietary iron, conditions in which iron storage and transport are impaired, and hemolytic anemia. Excessive alcohol ingestion also can lead to hemosiderosis. Normally, absorption of excessive dietary iron is prevented by an iron absorption process in the intestines. Failure of this process can lead to total-body iron accumulations in the range of 60 to 80 grams (g), compared with normal iron stores of 4.5 to 5 g. Excessive accumulations of iron, such as occur in hemochromatosis (a genetic disorder of iron metabolism and the most severe example of iron overload), are associated with liver and pancreatic cell damage.

Bilirubin is a normal yellow-to-green pigment of bile derived from the porphyrin structure of hemoglobin. Excesses of bilirubin within cells and tissues cause jaundice (icterus), or yellowing of the skin. Jaundice occurs when the bilirubin level exceeds 1.5 to 2 mg/dL of plasma, compared with the normal values of 0.4 to 1 mg/dL. Hyperbilirubinemia occurs with (1) diseases that cause destruction of red blood cells (erythrocytes), such as in hemolytic jaundice; (2) diseases affecting the metabolism and excretion of bilirubin in the liver; and (3) diseases that cause obstruction of the common bile duct, such as gallstones or pancreatic tumors.

Certain drugs, specifically chlorpromazine and other phenothiazine derivatives, estrogenic hormones, and halothane (an anesthetic), can cause the obstruction of normal bile flow through the liver.

Because unconjugated bilirubin is lipid soluble, it can injure the lipid components of the plasma membrane. Albumin, a plasma protein, provides significant protection by binding unconjugated bilirubin in plasma. Unconjugated bilirubin causes two cellular effects: uncoupling of oxidative phosphorylation and loss of cellular proteins. These two effects could cause structural injury to the various membranes of the cell.

Calcium

Calcium salts accumulate in both injured and dead tissues (Fig. 2.30). An important mechanism of cellular calcification is the influx of extracellular calcium in injured mitochondria. Another mechanism that causes calcium accumulation in alveoli (gas-exchange airways of the lungs), gastric epithelium, and renal tubules is the excretion of acid at these sites, leading to the local production of hydroxyl ions. Hydroxyl ions result in precipitation of calcium hydroxide ($\text{Ca}[\text{OH}]_2$) and hydroxyapatite ($3\text{Ca}_3[\text{PO}_4]_2\text{Ca}[\text{OH}]_2$), a mixed salt. Damage occurs when calcium salts clump and harden, interfering with normal cellular structure and function.

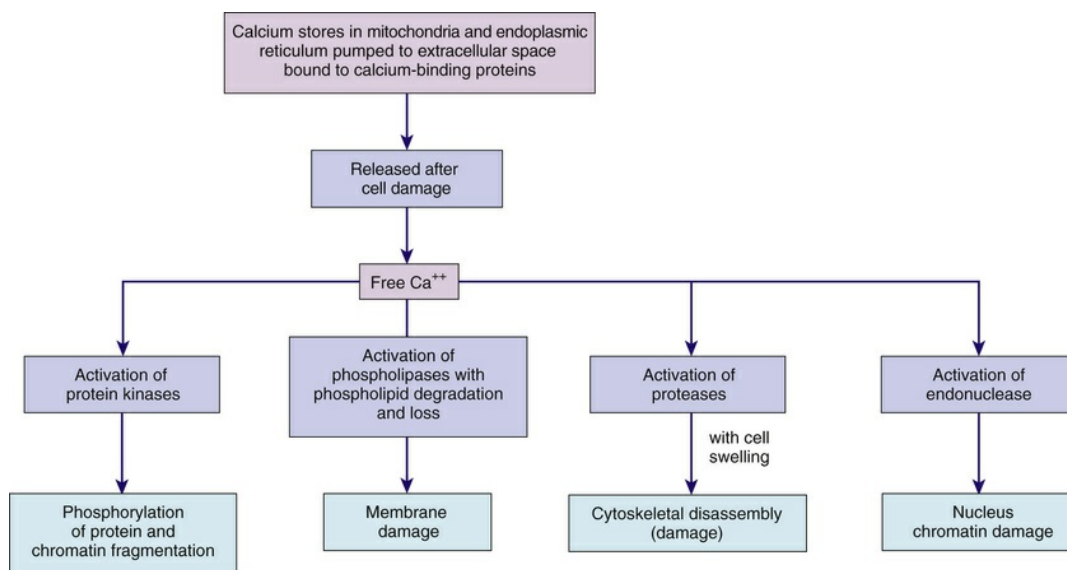

FIGURE 2.30 Free Cytosolic Calcium: A Destructive Agent. Calcium is normally removed from the cytosol by adenosine triphosphate (ATP)-dependent calcium pumps. In normal cells, calcium is bound to buffering proteins, such as calbindin or paralbumin, and is contained in the endoplasmic reticulum and the mitochondria. If there is abnormal permeability of calcium ion channels, direct damage to membranes, or depletion of ATP (i.e., hypoxic injury), calcium level increases in the cytosol. If the free calcium cannot be buffered or pumped out of cells, uncontrolled enzyme activation takes place, causing further damage. Uncontrolled entry of calcium into the cytosol is an important final pathway in many causes of cell death.

Pathologic calcification can be dystrophic or metastatic. **Dystrophic calcification** occurs in dying and dead tissues in areas of necrosis

(types of necrosis: coagulative, caseous, liquefactive, fat). It is present in chronic tuberculosis of the lungs and lymph nodes, in arteries with advanced atherosclerosis (narrowing as a result of plaque accumulation), and often in injured heart valves (Fig. 2.31). Calcification of the heart valves interferes with opening and closing of the valves, causing heart murmurs. Calcification of the coronary arteries predisposes them to severe narrowing and thrombosis, which can lead to myocardial infarction. Another site of dystrophic calcification is the center of tumors. Over time, the center is deprived of oxygen supply, dies, and becomes calcified. The calcium salts appear as gritty, clumped granules that can become hard as stone. When several layers clump together, they resemble grains of sand and are called **psammoma bodies**.

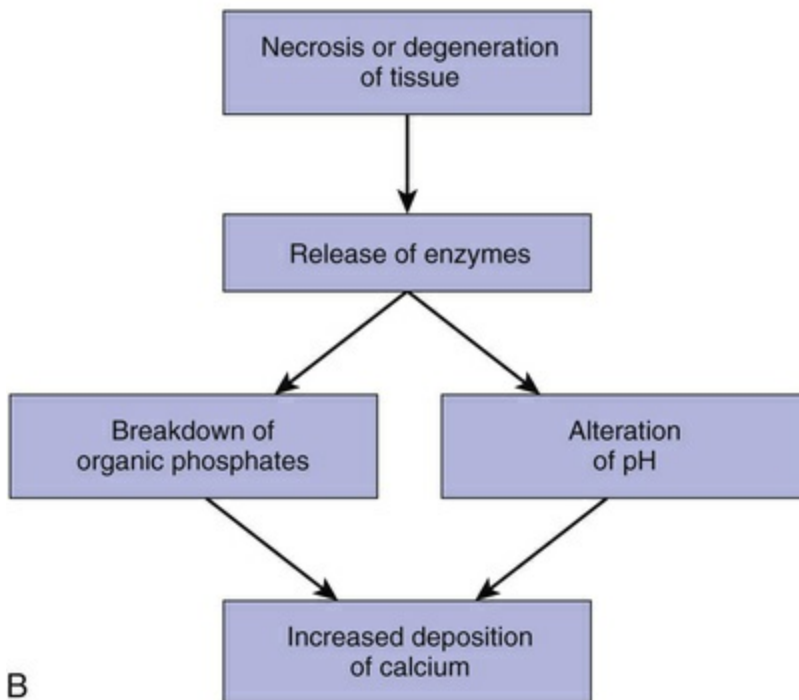

FIGURE 2.31 Aortic Valve Calcification. **A**, Calcified aortic valve. This change is an example of dystrophic calcification. **B**, Algorithm showing the dystrophic mechanism of calcification. (A from Damjanov I: *Pathology for the health professions*, ed 4, St Louis, 2012, Elsevier/Saunders.)

The exact pathogenic mechanisms responsible for dystrophic calcification are unknown. A popular hypothesis is that with progressive deterioration of dead cells, the exposed denatured (changed) proteins preferentially bind with phosphate ions. The phosphate ions then react with calcium ions to form deposits of

phosphate carbonate precipitates and, sometimes, crystalline formations of calcium phosphate. Dystrophic calcification develops slowly and is an explicit marker for the site of dead cells.

Metastatic calcification consists of mineral deposits that occur in undamaged normal tissues as the result of hypercalcemia (excess of calcium in the blood). Conditions that cause hypercalcemia include hyperparathyroidism, toxic levels of vitamin D, hyperthyroidism, idiopathic hypercalcemia of infancy, and Addison disease (adrenocortical insufficiency). Additionally, hypercalcemia is linked with systemic sarcoidosis, milk-alkali syndrome, and the increased bone demineralization that results from bone tumors, leukemia, and disseminated cancers. Hypercalcemia also can occur in some instances of advanced renal failure with phosphate retention, resulting in hyperparathyroidism. As phosphate levels increase, the activity of the parathyroid gland increases, causing higher levels of circulating calcium.

Urate

In humans, uric acid (**urate**) is the major end product of purine catabolism because of the absence of the enzyme urate oxidase. Serum urate concentration is, in general, stable: approximately 5 mg/dL in postpubertal males and 4.1 mg/dL in postpubertal females. Disturbances in maintaining serum urate levels result in hyperuricemia and deposition of sodium urate crystals in the tissues, leading to painful disorders collectively called *gout*. These disorders include acute arthritis, chronic gouty arthritis, tophus (firm nodular subcutaneous deposits of urate crystals surrounded by fibrosis), and nephritis (inflammation of the nephron). Chronic hyperuricemia results in the deposition of urate in tissues, cell injury, and inflammation. Because urate crystals are not degraded by lysosomal enzymes, they persist in dead cells.

Systemic Manifestations

Systemic manifestations of cellular injury include a general sense of

fatigue and malaise, a loss of well-being, and an alteration in appetite. Fever is frequently present because of biochemicals produced during the inflammatory response. [Table 2.12](#) summarizes the most significant systemic manifestations of cellular injury.

TABLE 2.12

SYSTEMIC MANIFESTATIONS OF CELLULAR INJURY

MANIFESTATION	CAUSE
Fever	Release of endogenous pyrogens (interleukin-1, tumor necrosis factor-alpha [TNF- α], prostaglandins) from bacteria or macrophages; acute inflammatory response
Increased heart rate	Increase in oxidative metabolic processes resulting from fever
Increase in number of leukocytes (leukocytosis)	Increase in total number of white blood cells because of infection; normal is 5000–10,000/mm ³ (increase is directly related to the severity of the infection)
Pain	Various mechanisms, such as release of bradykinins, obstruction, pressure
Presence of cellular enzymes in extracellular fluid	Release of enzymes from cells of tissue*
Lactate dehydrogenase (LDH) (LDH isoenzymes)	Release from red blood cells, liver, kidney, skeletal muscle
Creatine kinase (CK) (CK isoenzymes)	Release from skeletal muscle, brain, heart
Aspartate aminotransferase (AST)	Release from heart, liver, skeletal muscle, kidney, pancreas
Alanine aminotransferase (ALT)	Release from liver, kidney, heart
Alkaline phosphatase (ALP)	Release from liver, bone
Amylase	Release from pancreas
Aldolase	Release from skeletal muscle, heart
Troponins	Release from heart

*The rapidity of enzyme transfer is a function of the weight of the enzyme and the

concentration gradient across the cellular membrane. The specific metabolic and excretory rates of the enzymes determine how long levels of enzymes remain elevated.

Cellular Death

In response to significant external stimuli, cell injury becomes irreversible and cells are forced to die. Cell death has historically been classified as necrosis and apoptosis. **Necrosis** is characterized by rapid loss of the plasma membrane structure, organelle swelling, mitochondrial dysfunction, and the lack of typical features of apoptosis.¹³⁹ Apoptosis is known as a regulated or programmed cell process characterized by the “dropping off” of cellular fragments called *apoptotic bodies*. Until recently, only necrosis was considered passive or accidental, occurring after severe and sudden injury. It is the main outcome in several common injuries including ischemia, toxin exposure, certain infections, and trauma. It is now understood that under certain conditions, such as activation of death proteases, necrosis also can be driven by *regulated* or *programmed* molecular pathways.¹⁴⁰ Hence, the new term used is **programmed necrosis**, or **necroptosis**. Historically, programmed cell death only referred to apoptosis; now necrotic cell death is known to depend on genetically defined signaling pathways that have been studied in the pathophysiology of diseases only recently. [Fig. 2.32](#) illustrates the structural changes in cell injury resulting in necrosis or apoptosis. [Table 2.13](#) compares the unique features of necrosis and apoptosis. Other forms of cell loss include autophagy.

FIGURE 2.32 Schematic Illustration of the Morphologic Changes in Cell Injury Culminating in Necrosis or Apoptosis. Myelin figures come from degenerating cellular membranes and are noted within the cytoplasm or extracellularly. (From Kumar V et al: Cellular responses to stress and toxic insults: adaptation, injury, and death. In Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, St Louis, 2015, Saunders.)

TABLE 2.13

FEATURES OF NECROSIS AND APOPTOSIS

FEATURE	NECROSIS	APOPTOSIS
Cell size	Enlarged (swelling)	Reduced (shrinkage)
Nucleus	Pyknosis → karyorrhexis → karyolysis	Fragmentation into nucleosome-size fragments
Plasma membrane	Disrupted	Intact; altered structure, especially orientation of lipids
Cellular contents	Enzymatic digestion; may leak out of cell	Intact; may be released in apoptotic bodies
Adjacent inflammation	Frequent	No

Physiologic or pathologic role	Invariably pathologic (culmination of irreversible cell injury)	Often physiologic, means of eliminating unwanted cells; may be pathologic after some forms of cell injury, especially DNA damage
--------------------------------	---	--

From Kumar V et al: Cellular responses to stress and toxic insults: adaptation, injury, and death. In Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 8, St Louis, 2010, Saunders.

Necrosis

Cellular death eventually leads to cellular dissolution, or necrosis. Necrosis is the sum of cellular changes after local cell death and the process of cellular self-digestion, known as *autodigestion* or **autolysis**. Cells die long before any necrotic changes are noted by light microscopy. The structural signs that indicate irreversible injury and progression to necrosis are dense clumping and progressive disruption of genetic material and disruption of the plasma and organelle membranes. Because membrane integrity is lost, necrotic cell contents leak out and may cause the signaling of inflammation in surrounding tissue. In later stages of necrosis, most organelles are disrupted, and **karyolysis** (nuclear dissolution and lysis of chromatin from the action of hydrolytic enzymes) is underway. In some cells, the nucleus shrinks and becomes a small, dense mass of genetic material (**pyknosis**). The pyknotic nucleus eventually dissolves (by karyolysis) as a result of the action of hydrolytic lysosomal enzymes on DNA.

External cellular injury that can cause necrosis involves damage to mitochondria with the formation of mitochondrial permeability transition pores in the outer membrane. These channels (pores) allow the spreading of the proton potential, resulting in failure of ATP generation and death of the cell. Emerging evidence shows that programmed necrosis is associated with development, tissue damage during acute pancreatitis, and retinal detachment; and provides an innate immune response to viral infection, thus challenging the historic view of necrosis as passive cell death occurring in a disorganized or unregulated manner.^{141,142}

Different types of necroses tend to occur in different organs or tissues and sometimes can indicate the mechanism or cause of cellular

injury. The four major types of necroses are coagulative, liquefactive, caseous, and fatty. Another type, gangrenous necrosis, is *not* a distinctive type of cell death but refers to larger areas of tissue death.

Coagulative necrosis, which occurs primarily in the kidneys, heart, and adrenal glands, commonly results from hypoxia caused by severe ischemia or hypoxia caused by chemical injury, especially ingestion of mercuric chloride (Fig. 2.33, A). Coagulation is caused by protein denaturation, which causes the protein albumin to change from a gelatinous, transparent state to a firm, opaque state, similar to that of a cooked egg white. The necrotic tissues appear firm and slightly swollen. The area of coagulative necrosis is called an **infarct**.

FIGURE 2.33 Types of Necrosis. A, Coagulative necrosis of myocardium of posterior wall of left ventricle of heart. A large anemic (*white*) infarct is readily apparent; note also the necrosis of papillary muscle. B, Liquefactive necrosis of the brain. The area of infarction is softened as a result of liquefactive necrosis. C, Caseous necrosis. Tuberculosis of the lung, with a large area of caseous necrosis containing yellow-white and cheesy debris. D, Fat necrosis of pancreas. Interlobular adipocytes are necrotic; these are surrounded by acute inflammatory cells. (A and D from Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby. B from Damjanov I: *Pathology for the health professions*, ed 5, St Louis, 2016,

Liquefactive necrosis commonly results from ischemic injury to neurons and glial cells in the brain (Fig. 2.33, B). Dead brain tissue is readily affected by liquefactive necrosis because brain cells are rich in the digestive hydrolytic enzymes and lipids, and the brain contains little connective tissue. As the cells are digested by their own hydrolases, the tissue becomes soft, liquefies, and is walled off from healthy tissue, forming cysts.

Liquefactive necrosis can also result from bacterial infection, particularly by staphylococci, streptococci, and *Escherichia coli*. In this case the hydrolases are released from the lysosomes of neutrophils (phagocytes attracted to the infected area to kill the bacteria). Liquefaction of bacterial cells and neighboring tissue cells by neutrophilic hydrolases results in the accumulation of pus.

Caseous necrosis, which commonly results from tuberculous pulmonary infection, particularly *Mycobacterium tuberculosis*, is a combination of coagulative and liquefactive necrosis (Fig. 2.33, C). The dead cells disintegrate, but the debris is not digested completely by hydrolases. Tissues appear soft and granular and resemble clumped cheese, hence its name. A granulomatous inflammatory wall encloses areas of caseous necrosis.

Fat necrosis, which occurs in the breast, pancreas, and other abdominal structures, is cellular dissolution caused by powerful enzymes called *lipases* (Fig. 2.33, D). Lipases break down triglycerides, releasing free fatty acids, which then combine with calcium, magnesium, and sodium ions, creating soaps (a process known as *saponification*). The necrotic tissue appears opaque and chalk white.

Gangrenous necrosis, a term commonly used in surgical clinical practice, refers to death of tissue and results from severe hypoxic injury, commonly occurring because of arteriosclerosis, or blockage, of major arteries, especially in the lower leg. With hypoxia and subsequent bacterial invasion, the tissues can undergo necrosis. **Dry gangrene** is usually the result of coagulative necrosis. The skin becomes very dry and shrinks, resulting in wrinkles, and its color

changes to dark brown or black (Fig. 2.34). **Wet gangrene** develops when neutrophils invade the site, causing liquefactive necrosis. This usually occurs in internal organs, causing the site to become cold, swollen, and black. A foul odor is present, produced by pus, and if systemic symptoms become severe, death can ensue.

FIGURE 2.34 Gangrene of Toes. Dry gangrene. (From Damjanov I: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders.)

Gas gangrene, a special type of gangrene, is caused by infection of injured tissue by one of many species of *Clostridium*. These anaerobic bacteria produce hydrolytic enzymes and toxins that destroy connective tissue and cellular membranes and cause bubbles of gas to form in muscle cells. Gas gangrene can be fatal if enzymes lyse the membranes of red blood cells, destroying their oxygen-carrying capacity. Death is the result of shock. The condition is treated with antitoxins and supplemental oxygen delivered in a hyperbaric (pressurized) chamber.

Apoptosis

Apoptosis (“dropping off”) is an important distinct type of cell death that differs from necrosis in several ways (see Fig. 2.32 and Table 2.13). Apoptosis is an active process of cellular self-destruction—called *programmed cell death (type I)*—in both normal and pathologic tissue changes. It depends on a tightly regulated cellular program for its initiation and execution.¹⁴³ The average adult may create 10 billion

new cells every day and destroy the same number.¹⁴⁴ Normal physiologic death by apoptosis occurs during embryogenesis; involution of hormone-dependent tissue after hormone withdrawal, such as involution of the lactating breast after weaning; cell loss in proliferating cell populations, such as immature lymphocytes in the bone marrow or thymus that do not express appropriate receptors; and elimination of possibly harmful lymphocytes that may be self-reactive and cause death of cells after they perform useful functions (e.g., neutrophils after an acute inflammatory reaction). Death by apoptosis causes loss of cells in many pathologic states including the following:

- *Severe cell injury.* When cell injury exceeds repair mechanisms, the cell triggers apoptosis. DNA damage can result either directly or indirectly from production of free radicals.
- *Accumulation of misfolded proteins.* This may result from genetic mutations or free radicals. Excessive accumulation of misfolded proteins in the ER leads to a condition known as **endoplasmic reticulum stress (ER stress)** (see [Chapter 1](#)). ER stress results in apoptotic cell death. This mechanism has been linked to several degenerative diseases of the CNS and other organs ([Fig. 2.35](#)).

FIGURE 2.35 The Unfolded Protein Response, Endoplasmic Reticulum (ER) Stress, and Apoptosis. **A**, In normal or healthy cells the newly made proteins are folded with help from chaperones and then incorporated into the cell or secreted. **B**, Various stressors can cause ER stress whereby the cell is challenged to cope with the increased load of misfolded proteins. The accumulation of the protein load initiates the *unfolded protein response* in the ER; if restoration of the protein fails, the cell dies by apoptosis. An example of a disease caused by misfolding of proteins is Alzheimer disease. (From Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

- *Infections (particularly viral)*. Apoptosis may be the result of the virus directly or indirectly by the host immune response. Cytotoxic T lymphocytes respond to viral infections by inducing apoptosis and, therefore, eliminating the infectious cells. This process can cause tissue damage and it is the same for cell death in tumors and rejection of tissue transplants.
- *Obstruction in tissue ducts*. In organs with duct obstruction, including the pancreas, kidney, and parotid gland, apoptosis causes pathologic atrophy.

Excessive or insufficient apoptosis is known as *dysregulated apoptosis*. A low rate of apoptosis can permit the survival of abnormal cells, for example, mutated cells that can increase cancer risk. Defective apoptosis may not eliminate lymphocytes that react against host tissue (self-antigens), leading to autoimmune disorders. Increased apoptosis is known to occur in several neurodegenerative diseases, ischemic injury (such as myocardial infarction and stroke), and death of virus-infected cells in many viral infections.

Apoptosis depends on a tightly regulated cellular program for its initiation and execution. This death program involves enzymes that divide other proteins—proteases, which are activated by proteolytic activity in response to signals that induce apoptosis. These proteases are called **caspases**, a family of aspartic acid–specific proteases. The activated suicide caspases cleave and, thereby, activate other members of the family, resulting in an amplifying “suicide” cascade. The activated caspases then cleave other key proteins in the cell, killing the cell quickly and neatly. The two different pathways that converge on caspase activation are called the *mitochondrial (intrinsic) pathway* and the *death receptor (extrinsic) pathway* (Fig. 2.36). Cells that die by apoptosis release chemical factors that recruit phagocytes that quickly engulf the remains of the dead cell, thus reducing chances of inflammation. With necrosis, cell death is not tidy because cells that die as a result of acute injury swell, burst, and spill their contents all over their neighbors, causing a likely damaging inflammatory response.

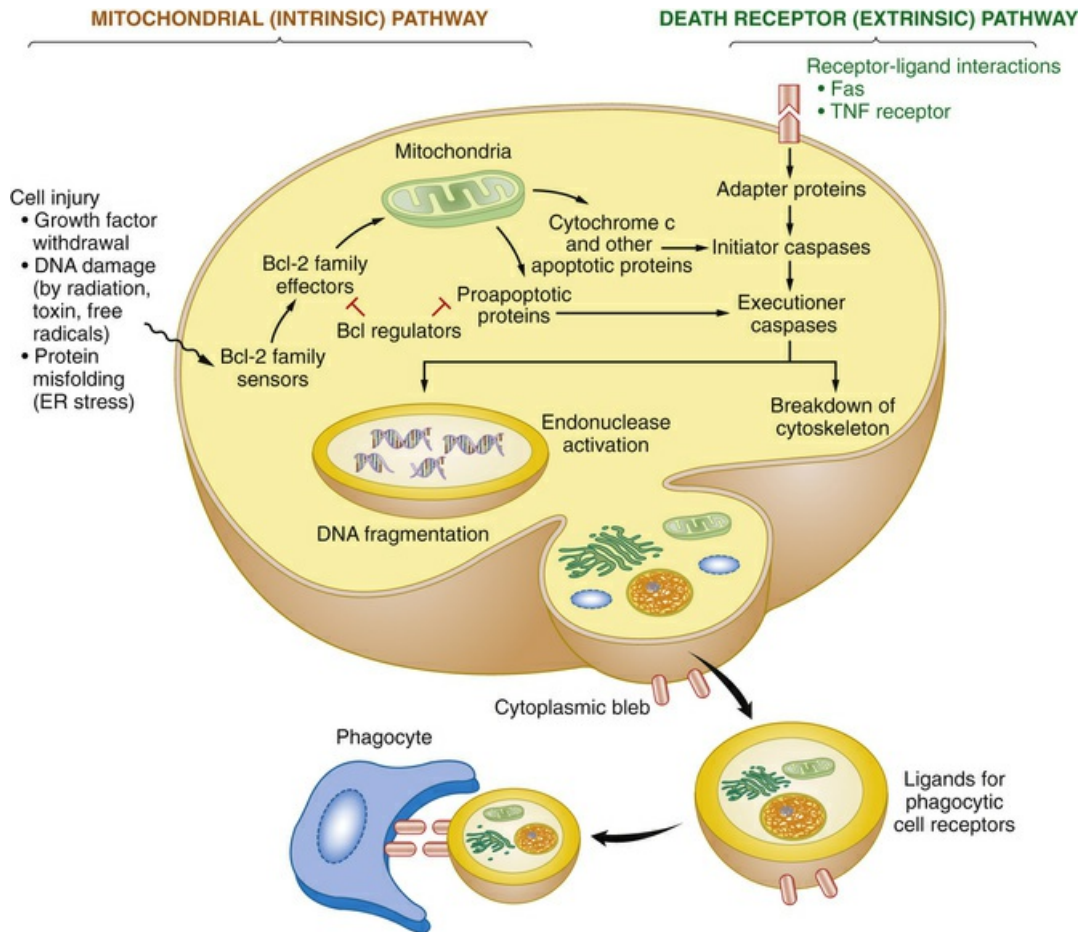

FIGURE 2.36 Mechanisms of Apoptosis. The two pathways of apoptosis differ in their induction and regulation, and both culminate in the activation of “executioner” caspases. The induction of apoptosis by the mitochondrial pathway involves the Bcl-2 family, which causes leakage of mitochondrial proteins. The regulators of the death receptor pathway involve the proteases, called caspases. *Fas*, Transmembrane protein; *TNF*, tumor necrosis factor. (Adapted from Kumar V, Abbas A, Aster J: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

Autophagy

The term **autophagy** is Greek, meaning “eating of self” (Fig. 2.37). Autophagy, as a “recycling factory,” is a self-destructive process and a survival mechanism. It degrades cytoplasmic components and organelles in lysosomes (a catabolic function) and salvages key metabolites to promote metabolic and nutrient homeostasis (an anabolic function).¹⁴⁵ Autophagy with its central role in cell homeostasis is considered important in diverse processes such as

development, cell proliferation, remodeling, aging, cancer, heart disease, neurodegeneration diseases, antigen presentation, inflammation, infection, metabolic diseases, and cell death. Autophagy is very complex and tissue dependent.¹⁴⁶ When cells are starved or nutrient deprived, the autophagic process institutes cannibalization and recycles the digested contents.^{147,148} Autophagy can maintain cellular metabolism under starvation conditions and remove damaged organelles and misfolded proteins under stress conditions, improving the survival of cells.

FIGURE 2.37 Autophagy. Three primary modes of autophagy include macrophagy, microphagy, and chaperone-mediated autophagy. Macrophagy is the formation of an autophagosome, a vacuole of nonlysosomal origin; microphagy involves direct uptake of cytosol, inclusions (e.g., glycogen), and organelles (e.g., ribosomes, peroxisomes at the lysosome vacuole); and chaperone-mediated autophagy (CMA) is a translocation process facilitated by certain proteins that are transported across the lysosomal membrane and degraded. Depending on the cargoes, autophagy can be selective or nonselective. During nonselective autophagy, a part of the cytoplasm is confiscated into a double-membrane autophagosome; it then fuses with the lysosome/vacuole. Specific degradation of peroxisomes can be achieved by either macroautophagy (macropexophagy) or microautophagy (micropexophagy). Piecemeal microautophagy of the nucleus causes degradation of a portion of the nucleus. Mitophagy, or degradation of the mitochondria, also occurs. (From Yen WL, Klionsky DJ: *Pathophysiology [Bethesda]* 23[5]:248–262, 2008.)

With metabolic stress, autophagy provides ATP and other macromolecules as energy sources to enable cell survival; if, however, the stress is excessive, cells may progress to autophagic programmed cell death, which is distinct from apoptosis¹⁴⁹⁻¹⁵¹ (Fig. 2.38).

FIGURE 2.38 Molecular Mechanism of Apoptosis and Autophagic Cell Death. Critical for apoptosis to occur is an increase in the outer mitochondrial membrane. The process is regulated by proapoptotic members of the Bcl-2 family (Bax and Bak) leading to the release of cytochrome c into the cytoplasm. Cytochrome c then associates with apoptotic protease activating factor-1 (Apaf1), which activates the caspase cascade to execute apoptotic cell death. When apoptosis is blocked, certain apoptotic stimuli activate autophagy and c-Jun N-terminal kinase (JNK), resulting in the induction of autophagic cell death. Autophagy also mediates programmed cell death as well as other physiologic and pathologic processes. (From Shigeomi S et al: *Int J Mol Sci* 15:3145–3153, 2014.)

Autophagic cell death (**type II programmed cell death**) is characterized by double- or multiple-membrane cytoplasmic vesicles engulfing bulk cytoplasm/cytoplasmic organelles, such as mitochondria and ER. However, in **type I programmed cell death** apoptosis is largely the result of caspase activation and destruction of the cellular components.

Autophagy has been highlighted in cancer. In some contexts, autophagy suppresses tumor development; in most contexts, autophagy facilitates tumor development.¹⁵² Cancers can use autophagy to survive microenvironmental stresses and to increase growth and aggressiveness. The mechanisms of autophagy that promote cancer include suppressing induction of the p53 tumor suppressor protein and maintaining the function of mitochondria.¹⁵² Research efforts are also directed to inhibit autophagy to improve cancer therapy.

Autophagy has been widely characterized in cardiomyocytes, cardiac fibroblasts, endothelial cells, vascular smooth muscle cells, and macrophages.¹⁵³ Optimal autophagic activity may be critical to the maintenance of cardiovascular homeostasis and function, and excessive or insufficient levels of autophagic flux can each contribute to cardiac disease.¹⁵³

As a critical garbage collecting and garbage recycling process in healthy cells, the process of autophagy decelerates and may become less discriminating as the cell ages. Consequently, harmful agents accumulate in cells, damaging them and leading to aging. For example, failure to clear protein products in neurons of the CNS cause dementia, and failure to clear ROS-producing mitochondria lead to nuclear DNA mutations and cancer. Thus, these processes may even partially define aging. Therefore, normal autophagy may potentially rejuvenate an organism and prevent cancer development as well as other degenerative diseases.¹⁵⁴ Autophagy also may be the last immune defense against infectious microorganisms that penetrate intracellularly.¹⁵⁵

Aging and Altered Cellular and Tissue Biology

The terms aging and life span tend to be used synonymously; however, they are not equivalent. *Aging* is usually defined as a normal physiologic process that is universal and inevitable, whereas *life span* is the time from birth to death and has been used to study the aging process.¹⁵⁶ **Aging** is the progressive loss of tissues and organs over time.¹⁵⁷ Aging also is a risk factor for a wide variety of chronic diseases. Investigators are focused on genetic, epigenetic, inflammatory, oxidative stress, and metabolic origins of aging. Of interest is the study of genetic signatures in humans with exceptional longevity and the identification of epigenetic mechanisms that modulate gene expression. Other areas being investigated include the role of intrauterine environment and lifelong patterns of health; personality, behavior, and social support; hormonal and circulating factors, such as insulin/insulin-like growth factor 1 (IGF-1) signaling; mitochondrial dysfunction; and the contributions of cellular dysfunction and senescence to an inflammatory microenvironment that leads to chronic disease, frailty, and decreased life span. A major challenge of aging research has been to separate the causes of cell and tissue aging from the vast changes that accompany it.^{158,159}

Investigators propose from preclinical data a need for a “unifying aging hypothesis” as a common pathway or pathways that regulate the aging process and associated disease risks.¹⁶⁰ Examples of these pathways include senescence, proteostasis, and changes in metabolism. Yet, a recurring theme in aging is that it is heterogeneous. As noted in a recent World Health Organization (WHO) report,¹⁶¹ people do not age at the same rate with the same prevalence of age-related diseases.¹⁶⁰ A recent study in immune factors in identical twins found increasing differences between identical twins, with increasing age suggesting marked influence of nonheritable factors or environmental factors.¹⁶²

Senescence is a process of permanent proliferative arrest on cells in response to various stressors and may be an important contributor to

aging and age-related disease.¹⁶³ Senescent cells accumulate in various tissues over time and may contribute to tissue dysfunction. Investigators removed senescent cells in aging mice, increasing their healthy life span and reducing many age-related disease-associated abnormalities^{163,164} (see Fig. E 2.1 on Evolve.)

The biologic understanding of senescence in humans is limited, but it seems significant because of two factors: (1) senescence causes a loss of tissue–repair capacity because of cell cycle arrest in progenitor cells and (2) it produces proinflammatory and matrix-degrading molecules in what is known as the *senescence-associated secretory phenotype (SASP)*.¹⁶³ One of the hallmarks of aging is the accumulation of damaged macromolecules from telomere erosion, DNA damage, epigenetic stress, ROS accumulation, ER stress, and other factors. Aged cells that chronically accumulate damage eventually reach a threshold of cellular stress prompting their permanent withdrawal from the cell cycle.¹⁶³ Cellular senescence is a potent anticancer mechanism because senescent cells are permanently arrested and cleared by immune cells recruited because of proinflammatory, chemotactic factors secreted as part of the SASP.¹⁶³ Other beneficial functions of senescence include wound healing (limits tissue fibrosis) and embryogenesis.¹⁶³

Aging is associated with increased levels of circulating cytokines and proinflammatory markers.¹⁶⁵ The changes in the immune system with aging, known as *inflammaging*, include immunosenescence and increased secretion of cytokines by adipose tissue and represent the major causes of chronic inflammation.¹⁶⁵ High levels of interleukin 6 (IL-6), IL-1, tumor necrosis factor-alpha, and C-reactive protein (CRP) are associated in older individuals with increased risk of morbidity and mortality.¹⁶⁵ Studies have indicated TNF- α and IL-6 levels as markers of frailty. Low-grade inflammation underlies sarcopenia, and proinflammatory cytokines from many mechanisms, including platelet activation and endothelial activation, may play a major role in cardiovascular events. Dysregulation of the inflammatory pathways affects the CNS and is associated with many neurodegenerative diseases (e.g., Alzheimer disease, Parkinson disease, amyotrophic

lateral sclerosis, and multiple sclerosis).¹⁶⁶ Besides immunosenescence, adipose tissue, through macrophages, produces IL-6, TNF- α , and adipokines. A large amount of visceral tissue or a high-fat diet is correlated with an increase in CRP and IL-6 in obese individuals, and in some who are not obese.¹⁶⁵ Another mechanism of inflammaging is the role of mitochondria and activation of the Nlrp3 inflammasome.¹⁶⁷ The Nlrp3 inflammasome is a multiprotein complex and, in response to cellular danger, can activate procaspase-1, resulting in the processing and secretion of the proinflammatory cytokines IL-1 β and IL-18. Most activators of the Nlrp3 inflammasome generate mitochondrial ROS.¹⁶⁷ Another mechanism that can increase inflammation is increasing activation of the coagulation system with age. Coagulation is part of the inflammatory response with shared components and strong interactions. The increased hypercoagulable state documented in aging may account for the higher incidence of arterial and venous thrombosis in elderly individuals. The microbiota plays a fundamental role on the induction and function of the immune system.¹⁶⁸ Adaptive immunity declines with age, but innate immunity may result in mild hyperactivity.¹⁶⁹

The microbiota plays a fundamental role in the induction and function of the immune system.¹⁶⁸ In high-income countries, overuse of antibiotics, changes in diet, and the elimination of helpful partners, such as nematodes, may have caused a microbiota that lacks the resilience and diversity to keep a balanced immune system.¹⁶⁸ These changes also are proposed to account for the dramatic increase in autoimmune and inflammatory disorders in certain parts of the world.

Life span can be experimentally changed in animals.^{159,170} Extending life span, however, is not equivalent to delaying aging!¹⁵⁹ For example, treatment of an acute infection can prevent death but the fundamental *rate* of aging continues. Critical is extending *health span* with an increase in life span—some experiments increased the proportion of time spent in a frail state.⁷⁰ Although the passage of time cannot be stopped (*chronological aging*), it may be possible to delay the concurrent decline in health or *biologic aging*.

Restoration of youthfulness to aged cells and tissues has created so-called *rejuvenating interventions*. Experiments to test whether cells and tissues from an old animal can be restored to a younger self include the approach called *heterochronic* (i.e., young-to-old or old-to-young) transplantations and heterochronic parabiosis, when the systemic circulations of two animals are joined. The systemic environment may become more youthful with restoration of protein components in the blood and tissues, especially chemokines and cytokines.¹⁷¹

Diet is believed to have a major influence on both the development and the prevention of age-related diseases. Plant-derived dietary phytochemicals and macro- and micronutrients modulate oxidative stress and inflammatory signaling and regulate metabolic pathways and bioenergetics that can be translated into stable epigenetic patterns of gene expression.¹⁷² Emerging data reveal complex interactions between food components and histone modifications, DNA methylation, non-coding RNA expression, and chromatin remodeling factors that influence inflammaging.^{172,173} Nutrients involved in one-carbon metabolism, such as folate, vitamin B₁₂, vitamin B₆, riboflavin, methionine, choline, and betaine, are involved in DNA methylation by regulating levels of the universal methyl donor S-adenosylmethionine and the methyltransferase inhibitor S-adenosylhomocysteine. Other nutrients and bioactive food components, such as retinoic acid, resveratrol, curcumin, sulforaphane, and tea polyphenols, can modulate epigenetic patterns by altering the levels of S-adenosylmethionine and S-adenosylhomocysteine or by directing the enzymes that catalyze DNA methylation and histone modifications.¹⁷³ Pharmacologic interventions may restore youthfulness at cellular and biochemical levels. The enzyme mammalian target of rapamycin (mTOR) senses cellular nutrient levels, thus regulating rates of protein synthesis and energy utilization.¹⁵⁹ Administration of the drug rapamycin, an mTOR inhibitor, can extend the life span of mice.¹⁷⁴ Some examples of other drugs targeting molecular pathways of aging include metformin, resveratrol, and anticalcitonin gene-regulated peptide (CGRP).

Normal Life Span and Life Expectancy

The **maximal life span** of humans is between 80 and 100 years and does not vary significantly among populations. In primitive societies, few individuals reach the maximal life span. However, in societies with improved sanitation, housing, nutrition, and health care, many individuals attain the maximal life span. **Life expectancy** is the average number of years of life remaining at a given age.

Life Expectancy Differences Across America

Although maximal life span has not changed significantly over time, improved public health strategies and health advances in the United States during the last century added about 30 years to life expectancy between 1900 and 2000. This increase in life expectancy has not affected all Americans. In each successive age group from 65 years and older, women outnumber men; thus, women have a greater life expectancy than men. These historic advances in life expectancy resulted in a larger older adult population and, for some, inherent problems of disability, disease, and socioeconomic hardship.

Although U.S. spending on health care far exceeds that of other developed countries, life expectancy and key measures of health lag behind other high-income countries¹⁷⁵ (Table 2.14). U.S. life expectancy for the first time in more than 20 years has declined. The National Center for Health Statistics finds Americans (on average) with a life expectancy of 78.8 years, a decline from 78.9 in 2014. The decline in life expectancy is attributed to rising fatalities from heart disease and stroke; diabetes; drug overdoses; accidents, including unintentional injuries; and other conditions.¹⁷⁶

TABLE 2.14

U.S. HEALTH RANKINGS FOR LIFE EXPECTANCY, INFANT MORTALITY, AND MATERNAL MORTALITY

	U.S. RANKING (U.S./TOTAL OTHER COUNTRIES)		
SOURCE	LIFE EXPECTANCY	INFANT MORTALITY	MATERNAL MORTALITY

UN	28/146 (2005–2010 data)	32/146 (2005–2010 data)	n/a
OECD	26/34	30/34 (2008 data)	25/34 (2007 data)
CIA	50/221 (2011 estimated data; in 2010 data, U.S. ranked 49th)	47/222 (2011 estimated data)	52/176 (2011 estimated data)

Paris: OECD Publishing; National Research Council. (2011). *Explaining divergent levels of longevity in high-income countries*. Washington, DC: The National Academies Press.

In the United States, chronic health conditions associated with modifiable risk factors, such as smoking, nutrition, weight, and physical activity, represent 6 of the 10 costliest medical conditions.¹⁷⁷ These preventable conditions lead to diseases and injuries and cause soaring medical and labor costs that saddle U.S. employers and bankrupt families. All of these conditions are highly amendable to population-based preventive strategies, which have been slow to develop; 20% of adults still smoke and 50% of adults and 20% of children are overweight or obese.¹⁷⁸ It is estimated that one-third of American adults will develop diabetes by 2050 (up from one-tenth today).¹⁷⁹ The current generation of children and young adults in the United States could become the first generation to have shorter life spans, multiple medical conditions, and fewer healthy years of life than those of their parents.¹⁸⁰

Aging: Degenerative Extracellular Changes

Extracellular factors that affect the aging process include the binding of collagen; the increase in free radicals' effects on cells; the structural alterations of fascia, tendons, ligaments, bones, and joints; and the development of peripheral vascular disease, particularly arteriosclerosis.

Aging affects the extracellular matrix with increased cross-linking, decreased synthesis, and increased degradation of collagen. These changes, together with the disappearance of elastin and changes in proteoglycans and plasma proteins, cause disorders that result in dehydration and wrinkling of the skin. Other age-related defects in the extracellular matrix include skeletal muscle alterations (e.g., atrophy, decreased tone, loss of contractility), cataracts, diverticula, hernias, and rupture of intervertebral disks.

Free radicals of oxygen that result from oxidative stress (e.g., respiratory chain, phagocytosis, prostaglandin synthesis) are known to damage tissues during the aging process. These oxygen products are extremely reactive and can damage nucleic acids, destroy polysaccharides, oxidize proteins, peroxidize unsaturated fatty acids, and kill and lyse cells. Oxidant effects on target cells can lead to malignant transformation, presumably through DNA damage. That progressive and cumulative damage from oxygen radicals may lead to harmful alterations in cellular function is consistent with those alterations of aging. This hypothesis is founded on the wear-and-tear theory of aging, which states that damages accumulate with time, decreasing the organism's ability to maintain a steady state. Because these oxygen-reactive species not only can permanently damage cells but also may lead to cell death, there is new support for their role in the aging process.

Of much interest is the relationship between aging and the disappearance or alteration of extracellular substances important for blood vessel integrity. Advancing age is an important risk factor for the development of cardiovascular diseases. Vascular oxidative stress increases with age without a compensatory increase in antioxidant defenses.¹⁸¹ Vascular endothelial dysfunction is characterized by a shift from a vasodilatory, anticoagulative, antiproliferative, and antiinflammatory state to a proinflammatory, proliferative, and procoagulative state with consequent increased risk for cardiovascular events and diseases (Fig. 2.39).

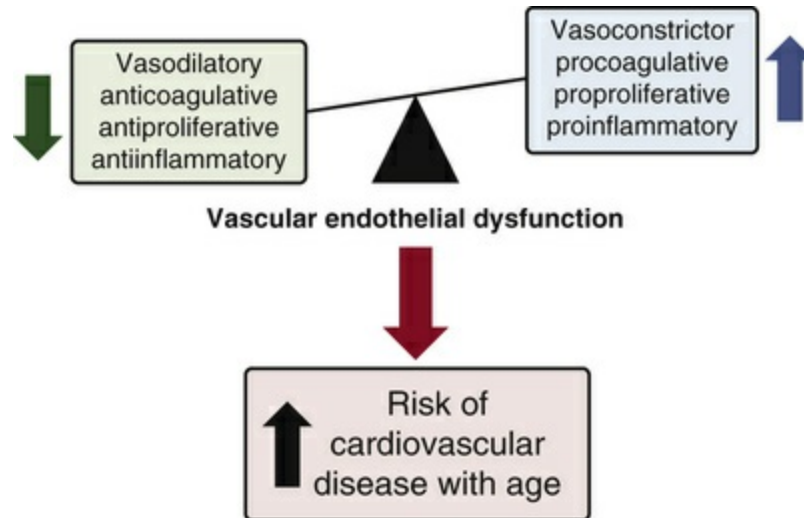

FIGURE 2.39 Vascular Endothelial Function and Increased Risk of Cardiovascular Diseases. Endothelial dysfunction is characterized by a shift from a vasodilatory, anticoagulative, antiproliferative, and antiinflammatory state to a proproliferative and proinflammatory state, leading to an increased risk of cardiovascular disease with aging. (Adapted from Seals DR, Jablonski KL, Donato AJ: *Clin Sci* 120:357–375, 2011.)

Oxidative stress plays an important role in initial atherosclerotic lesion formation: its progression and destabilization.¹⁸² With aging, lipid, calcium, and plasma proteins are deposited in vessel walls. These depositions cause basement membrane thickening and alterations in smooth muscle functioning, resulting in arteriosclerosis (a progressive disease that causes serious problems in the aged, including stroke, myocardial infarction, renal disease, and peripheral vascular disease).

Cellular Aging

Cellular changes characteristic of aging include atrophy, decreased function, and loss of cells, possibly by apoptosis. Loss of cellular function from any of these causes initiates the compensatory mechanisms of hypertrophy and hyperplasia of remaining cells, which can lead to metaplasia, dysplasia, and neoplasia. All these changes can alter receptor placement and function, nutrient pathways, cellular product secretion, and neuroendocrine control mechanisms. In the aged cell, DNA, RNA, cellular proteins, and membranes are most susceptible to injurious stimuli. DNA is particularly vulnerable

to such injuries as breaks, deletions, and additions. Although it can repair itself with time, the aged cell's capacity for DNA repair is decreased. Lack of DNA repair increases the cell's susceptibility to mutations that may be lethal or may promote the development of neoplasia.

Mitochondria are the organelles responsible for the generation of most of the energy used by eukaryotic cells. Mitochondrial DNA (mtDNA) encodes some of the proteins of the electron-transfer chain, the system necessary for the conversion of adenosine diphosphate (ADP) to ATP. Mutations in mtDNA can deprive the cell of ATP, and mutations are correlated with the aging process. The most common age-related mtDNA mutation in humans is a large rearrangement called the *4977 deletion*, or *common deletion*, and it is found in humans more than 40 years old.

The production of ROS under physiologic conditions is associated with activity of the respiratory chain in aerobic ATP production. Therefore, increased mitochondrial activity by itself can be an "oxidative stress" to cells. The production of ROS is markedly increased in many pathologic conditions in which the respiratory chain is impaired. Because mtDNA, which is essential for normal oxidative phosphorylation, is located in proximity to the ROS-generating respiratory chain, it is more oxidatively damaged than is nuclear DNA. Cumulative damage of mtDNA is implicated in the aging process as well as in the progression of such common diseases as diabetes, cancer, and heart failure.

Tissue and Systemic Aging

It is probably safe to say that every physiologic process can be shown to function less efficiently with increasing age. The most characteristic tissue change with age is a progressive stiffness or rigidity that affects many systems, including the arterial, pulmonary, and musculoskeletal systems. A consequence of blood vessel and organ stiffness is a progressive increase in peripheral resistance to blood flow. The movement of intracellular and extracellular substances also usually decreases with age as does the diffusion capacity of the lung. Blood

flow through organs decreases; for example, renal plasma flow decreases.

Changes in the endocrine and immune systems include thymus atrophy. Although this occurs at puberty, it causes a decreased immune response to T-dependent antigens (foreign proteins), increased formation of autoantibodies and immune complexes (antibodies bound to antigen), and an overall decrease in the immunologic tolerance for the host's own cells, which further diminishes the effectiveness of the immune system later in life. The reproductive system loses ova in women, and spermatogenesis in men is decreased. Responsiveness to hormones decreases in the breast and endometrium.

The stomach experiences decreases in the rate of emptying and secretion of hormones and hydrochloric acid. Muscular atrophy diminishes mobility by decreasing motor tone and contractility. **Sarcopenia**, the loss of muscle mass and strength, can occur into old age. The skin of the aged individual is affected by atrophy and wrinkling of the epidermis and by alterations in underlying dermis, fat, and muscle.

Total body changes include a decrease in height; a reduction in circumference of the neck, thighs, and arms; widening of the pelvis; and lengthening of the nose and ears. Several of these changes are the result of tissue atrophy and decreased bone mass caused by osteoporosis and osteoarthritis. Some body composition changes include an increase in body weight, which begins in middle age (men gain until 50 years of age and women until 70 years), and an increase in fat mass followed by a decrease in stature, weight, **fat-free mass (FFM)**, and body cell mass at older ages. FFM includes all minerals, proteins, and water plus all other constituents except lipids. As the amount of fat increases, the percentage of total body water decreases. Increased body fat and centralized fat distribution (abdominal) are associated with non-insulin-dependent diabetes and heart disease. Total body potassium concentration also decreases because of decreased cellular mass. An increased sodium/potassium ratio suggests that the decreased cellular mass is accompanied by an

increased extracellular compartment.

Although some of these alterations are probably inherent in aging, others represent consequences of aging. Advanced age increases susceptibility to disease, and death occurs after an injury or insult because of diminished cellular, tissue, and organic function. To determine that an individual “died of old age” would be a monumental if not impossible task.

Frailty

Frailty is a state of increased vulnerability to poor resolution of homeostasis following a stress, which increases the risk of adverse outcomes including falls, delirium, disability, long-term care, and death.¹⁸³ Worldwide, population aging is accelerating and the most problematic expression of population aging is frailty. As a consequence of frailty, a minor stress event, such as the introduction of a new drug, a minor infection, or minor surgery, can cause a sudden, often serious, health status change.

The pathophysiology of frailty includes many interrelated physiologic systems (Fig. 2.40). Complex and multiple aging mechanisms are influenced by genetic/epigenetic and environmental factors that regulate the differential expression of genes in cells and may be especially important in aging.¹⁸³ For study of the development of frailty, the best-studied systems are the brain and the endocrine, immune, and skeletal muscle systems. Frailty also has been associated with loss of physiologic reserve in the respiratory, cardiovascular, renal, hematopoietic and clotting systems, and nutritional status as important mediating factors.¹⁸³ Several physiologic gender differences may explain differing levels of frailty: (1) higher baseline levels of muscle mass for men may be protective against frailty, (2) testosterone and growth hormone can provide advantages in muscle mass maintenance, (3) cortisol is more dysregulated in older women than in older men, (4) alterations in immune function and immune responsiveness to sex steroids make men more vulnerable to sepsis and infection and women vulnerable to chronic inflammatory conditions and muscle mass loss, and (5) lower levels of activity and

caloric intake may influence greater susceptibility to frailty in women.

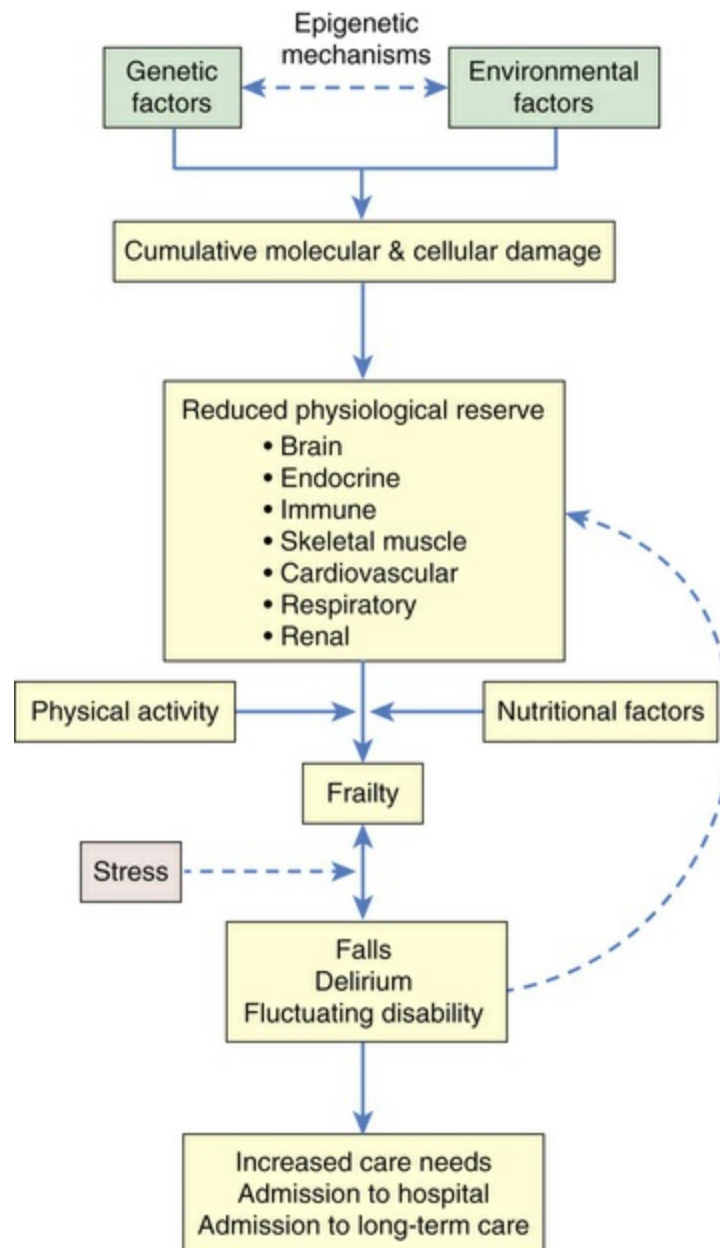

FIGURE 2.40 Frailty. Frailty is a disorder of multiple interrelated physiologic systems. A gradual decline progresses with aging, but in frailty this decline becomes accelerated. Homeostatic mechanisms begin to fail, and vulnerability becomes disproportionate to changes in health status after a relatively minor stressor event. (From Clegg A et al: *Lancet* 381[9868]:752–762, 2013.)

Somatic Death

Somatic death is death of the entire person. Unlike the changes that follow cellular death in a live body, **postmortem change** is diffuse and does not involve components of the inflammatory response. Within minutes of death, manifestations of postmortem change appear, eliminating any difficulty in determining that death has occurred. The most notable manifestations are complete cessation of respiration and circulation. The surface of the skin usually becomes pale and yellowish; however, the lifelike color of the cheeks and lips may persist after death from causes such as carbon monoxide poisoning, drowning, and chloroform poisoning.

Body temperature falls gradually immediately after death and then more rapidly (approximately 1.0° to 1.5° F (-16.9° to -17°C)/hour) until, after 24 hours, body temperature equals that of the environment. After death caused by certain infective diseases, body temperature may continue to rise for a short time. Postmortem reduction of body temperature is called **algor mortis**.

Blood pressure within the retinal vessels decreases, causing muscle tension to decrease and the pupils to become dilated. The face, nose, and chin begin to look “sharp” or “peaked” as blood and fluids drain from these areas. Gravity causes blood to settle in the most dependent, or lowest, tissues, which develop a purple discoloration called **livor mortis**. Incisions at this time usually fail to cause bleeding. The skin loses its elasticity and transparency.

Within 6 hours after death, acidic compounds accumulate within the muscles because of the breakdown of carbohydrate and the depletion of ATP. This interferes with ATP-dependent detachment of myosin from actin (contractile proteins), and muscle stiffening, or **rigor mortis**, develops. The smaller muscles are usually affected first, particularly the muscles of the jaw. Within 12 to 14 hours, rigor mortis usually affects the entire body. Rigor mortis gradually diminishes and the body becomes flaccid in 12 to 14 hours.

Signs of putrefaction—state of decay with foul-smelling odor—are generally obvious about 24 to 48 hours after death. Putrefactive

changes vary depending on the temperature of the environment. The most visible is greenish discoloration of the skin, particularly on the abdomen. The discoloration is thought to be related to the diffusion of hemolyzed blood into the tissues and the production of sulfhemoglobin. Slippage or loosening of the skin from underlying tissues occurs at the same time. After this, swelling or bloating of the body and liquefactive changes occur, sometimes causing opening of the body cavities. At a microscopic level, putrefactive changes are associated with the release of enzymes and lytic dissolution called **postmortem autolysis**.

Summary Review

Cellular Adaptation

1. Injury to cells and their surrounding environment, called the *extracellular matrix*, leads to tissue and organ injury. Cellular adaptation is an alteration that enables the cell to maintain a steady state despite adverse conditions.
2. Atrophy is a decrease in cellular size and can affect any organ, but is most common in skeletal muscle, the heart, secondary sex organs, and the brain. The mechanisms probably include decreased protein synthesis, increased protein catabolism, or both.
3. Physiologic atrophy occurs with early development; for example, the thymus gland involutes and atrophies. Pathologic atrophy occurs as a result of decreases in workload, use, pressure, blood supply, nutrition, hormonal stimulation, and nervous stimulation.
4. Aging causes brain cells and endocrine-dependent organs, such as the gonads, to become atrophic.
5. Hypertrophy is an increase in the size of cells caused by increased work demands or hormonal stimulation. Hypertrophy can be physiologic or pathologic. Amounts of protein in the plasma membrane, endoplasmic reticulum,

microfilaments, and mitochondria are increased.

6. Hyperplasia is an increase in the number of cells caused by an increased rate of cellular division. Compensatory hyperplasia enables certain organs to regenerate. Hormonal hyperplasia is stimulated by hormones to replace lost tissue or support new growth, such as during pregnancy.
7. Pathologic hyperplasia is the abnormal proliferation of normal cells in response to excessive hormonal stimulation or the effects of growth factors on target cells.
8. Dysplasia, or atypical hyperplasia, is an abnormal change in the size, shape, and organization of mature tissue cells. Importantly, the term dysplasia is not cancer and may not progress to cancer. Dysplasias that do not involve the entire thickness of the epithelium may be completely reversible.
9. Metaplasia is the reversible replacement of one mature cell type by another, sometimes less differentiated, cell type. It is found in association with tissue damage, repair, and regeneration. Metaplasia develops from a reprogramming of stem cells existing in most epithelia or of undifferentiated mesenchymal cells in connective tissue.

Cellular Injury

1. Injury to cells and to the extracellular matrix (ECM) leads to injury of tissues and organs, ultimately determining the structural patterns of disease. Injured cells may recover (reversible injury) or die (irreversible injury).
2. Cellular injury is caused by a lack of oxygen (hypoxia), free radicals, caustic or toxic chemicals, infectious agents, unintentional and intentional injury, inflammatory and immune responses, genetic factors, insufficient nutrients, or physical trauma from many causes. Injurious stimuli cause cell stress.
3. Cell injury can be acute or chronic, and it can be reversible or irreversible. It can involve necrosis, apoptosis, autophagy,

accumulation, or pathologic calcification.

4. Four biochemical themes are important to cell injury: (a) depletion of ATP, (b) decreased levels of oxygen and increased levels of oxygen-derived free radicals, (c) increased concentration of intracellular calcium and loss of calcium steady state, and (d) defects in membrane permeability.
5. The sequence of events leading to cell death is commonly decreased ATP production, failure of active transport mechanisms (the Na⁺-K⁺ pump), cellular swelling, detachment of ribosomes from the endoplasmic reticulum, cessation of protein synthesis, mitochondrial swelling as a result of calcium accumulation, vacuolation, leakage of digestive enzymes from lysosomes, autodigestion of intracellular structures, lysis of the plasma membrane, and death.
6. The initial insult in hypoxic injury is usually ischemia—the cessation of blood flow into vessels that supply the cell with oxygen and nutrients. Hypoxia can induce inflammation, and inflamed lesions can become hypoxic.
7. Restoration of oxygen after ischemic injury can result in reperfusion (reoxygenation) injury. Reperfusion injury results from the generation of highly reactive oxygen intermediates or radicals.
8. Inherent reactive oxygen species (ROS) from aerobic metabolism play a crucial biologic role, not just in various diseases but also from cellular communication and cell function. ROS reversibly modulates many intracellular signaling pathways. ROS can affect protein functions through several mechanisms, including regulation of protein expression, posttranslational modifications, and alteration of protein stability.
9. Reduction-oxidation- (redox) dependent regulation and the roles of ROS include both normal physiologic and pathologic roles. These expanding roles include proliferation and differentiation, immune function, stem cell self-renewal, tumor progression, autoimmunity, stem cell exhaustion, senescence,

and longevity.

10. Cell injury produced by free radicals, particularly ROS, is an important mechanism of cell damage in many conditions including chemical and radiation injury, ischemia-reperfusion injury, microbial killing by phagocytes, and cellular aging.
11. A significant mechanism of membrane damage is injury caused by free radicals, including oxidative stress. Oxidative stress can activate several intracellular signaling pathways because ROS can modulate enzymes and transcription factors. Free radicals are difficult to control and initiate chain reactions.
12. Free radicals can cause (a) lipid peroxidation or the destruction of unsaturated fatty acids, (b) alterations of proteins, protein loss, and protein misfolding, and (c) mutations in DNA.
13. Mitochondria contain their own DNA, called *mitochondrial DNA* (mtDNA), and can encode proteins involved in energy production. mtDNA encodes enzymes involved in oxidative phosphorylation, and mutations affecting these genes exert their damaging effects on organs most dependent on oxidative phosphorylation, such as the CNS, skeletal muscle, cardiac muscle, liver, and kidneys. Emerging is the role mitochondria has in mediating environmental changes and genomic responses.
14. Humans are exposed to thousands of chemicals that have inadequate toxicologic data. Toxicity pathways or cellular response pathways result in adverse health effects when disturbed. Components of these pathways include oxidative stress, heat shock response, DNA damage response, hypoxia, ER stress, mental stress, inflammation, and osmotic stress.
15. The initial insult in chemical and toxic injury is damage or destruction of the plasma membrane. Two general mechanisms include direct toxicity and conversion to toxic intermediates or metabolites. Examples of chemical agents that cause cellular injury include air pollutants, insecticides, herbicides, alcohol, lead, carbon monoxide, ethanol, mercury,

opioids (heroin, morphine, prescription drugs for pain), and social or street drugs.

16. Under investigation are the beneficial effects of chemical compounds called *phytochemicals*. Examples of these products include certain fruits and plants, chamomile, silymarin, carrot, ginger root, milk thistle seed, rosemary leaf, turmeric, and others.
17. The world's largest single environmental health risk is air pollution. From WHO data, every year 4.3 million deaths occur from exposure to indoor air pollution and 3.7 million deaths to outdoor air pollution. Air pollution is contamination of the environment by any chemical, physical, or biologic agent that modifies natural characteristics of the atmosphere.
18. By reducing air pollution levels, countries can lower the burden of diseases from stroke, heart disease, lung cancer, and chronic and acute respiratory diseases, including asthma. Prompt and sustained health benefits can come from improved air quality.
19. Heavy metals commonly associated with harmful effects in humans include lead, mercury, arsenic, and cadmium. Studies of the involvement of metals in pathophysiology include DNA repair mechanisms, tumor suppressor functions, and interference with signal transduction pathways.
20. Unintentional and intentional injuries are an important health problem in the United States. Injuries include motor vehicle crashes, opioid overdoses, poisonings, sports and recreation-related injuries, firearms, falls, blunt force (tearing, shearing, crushing of tissues), asphyxia (suffocation, strangulation, chemical asphyxiants, drowning), and others including injury from medical care itself.
21. Injury from microorganisms lies in their ability to survive and proliferate in the human body. Injury depends on the microorganisms' ability to invade and destroy cells, produce toxins, and produce damaging hypersensitivity reactions.
22. Activation of inflammation and immunity, which occurs after

cellular injury or infection, involves powerful biochemicals and proteins capable of damaging normal (uninjured and uninfected) cells.

23. Genetic disorders injure cells by altering the nucleus and the plasma membrane's structure, shape, receptors, or transport mechanisms.
24. Deprivation of essential nutrients (proteins, carbohydrates, lipids, vitamins) can cause cellular injury by altering cellular structure and function, particularly of transport mechanisms, chromosomes, the nucleus, and DNA. Excessive amounts of other nutrients, for example carbohydrates, can lead to obesity, changes with insulin utilization, and diabetes.
25. Injurious physical agents include temperature extremes and climate change, changes in atmospheric pressure, ionizing radiation, illumination, mechanical stresses (e.g., repetitive body movements), and noise.

Manifestations of Cellular Injury

1. Manifestations of cellular injury include accumulations of water, lipids, carbohydrates, glycogen, proteins, pigments, hemosiderin, bilirubin, calcium, and urate.
2. Accumulations harm cells by “crowding” the organelles and by causing excessive (and sometimes harmful) metabolites to be produced during their catabolism. The metabolites are released into the cytoplasm or expelled into the extracellular matrix.
3. Cellular swelling, the accumulation of excessive water in the cell, is caused by the failure of transport mechanisms and is a sign of many types of cellular injury.
4. Accumulations of organic substances—lipids, carbohydrates, glycogen, proteins, and pigments—are caused by disorders in which (a) cellular uptake of the substance exceeds the cell's capacity to catabolize (digest) or use it or (b) cellular anabolism (synthesis) of the substance exceeds the cell's capacity to use or

secrete it.

5. Dystrophic calcification (accumulation of calcium salts) is always a sign of pathologic change because it occurs only in injured or dead cells. Free calcium in the cytosol can cause activation of protein kinases, activation of phospholipases and membrane damage, and damage or disassembly of the cytoskeleton. Metastatic calcification, however, can occur in uninjured cells in individuals with hypercalcemia.
6. Disturbances in urate metabolism can result in hyperuricemia and deposition of sodium urate crystals in tissue, leading to a painful disorder called *gout*.
7. Systemic manifestations of cellular injury include fever, leukocytosis, increased heart rate, pain, and serum elevations of enzymes in the plasma.

Cellular Death

1. Cell death has historically been classified as necrosis and apoptosis. Necrosis is characterized by rapid loss of the plasma membrane structure, organelle swelling, mitochondrial dysfunction, and the lack of typical features of apoptosis. Apoptosis is known as regulated or programmed cell process by the “dropping off” of cellular fragments called *apoptotic bodies*. Under certain conditions, necrosis is driven by regulated or programmed molecular pathways, hence the new term programmed necrosis or necroptosis. Other forms of cell loss include autophagy.
2. The four major types of necrosis are coagulative, liquefactive, caseous, and fat. Different types of necrosis occur in different tissues.
3. Gangrenous necrosis, or gangrene, is tissue necrosis caused by hypoxia and subsequent bacterial invasion.
4. Autophagy is a recycling factory, a self-destructive process, and a survival mechanism. It degrades cytoplasmic components and organelles in lysosomes and salvages key

metabolites to promote metabolic and nutrient homeostasis. Autophagy has a central role in cell homeostasis. It is important in diverse processes and conditions such as development, cell proliferation, remodeling, aging, cancer, heart disease, neurodegenerative diseases, inflammation, infection, metabolic diseases, and cell death.

Aging

1. Aging is the progressive loss of tissues and organs over time. It is difficult to determine the physiologic (normal) from the pathologic changes of aging. One of the hallmarks of aging is the accumulation of damaged macromolecules.
2. Investigators are focused on genetic, epigenetic, inflammatory, oxidative stress, cell renewal by adult stem cells, and metabolic and endocrine origins of aging.
3. Senescence is a process of permanent proliferative arrest on cells in response to various stressors and may be an important contributor to aging and age-related diseases.
4. Aging is associated with increased levels of circulating cytokines and proinflammatory markers. There are changes in the immune system with aging known as *inflammaging*. The microbiota plays a fundamental role in the induction and function of the immune system. Diet is believed to have a major influence on both the development and the prevention of age-related diseases.
5. Humans have an inherent maximal life span (80 to 100 years) that is dictated by currently unknown intrinsic mechanisms.
6. Although the maximal life span has not changed significantly over time, the average life span, or life expectancy, has decreased for the first time in 20 years in the United States.
7. Frailty is a common clinical syndrome in older adults, leaving a person vulnerable to falls, functional decline, disability, disease, and death. The syndrome is complex, involving oxidative stress, dysregulation of inflammatory cytokines and

hormones, malnutrition, physical inactivity, and muscle changes. Women have a higher risk of frailty than men.

Somatic Death

1. Somatic death is death of the entire organism. Postmortem change is diffuse and does not involve the inflammatory response.
2. Manifestations of somatic death include cessation of respiration and circulation, gradual lowering of body temperature, dilation of pupils, loss of elasticity and transparency in the skin, stiffening of muscles (rigor mortis), and discoloration of the skin (livor mortis). Signs of putrefaction are obvious about 24 to 48 hours after death.

The cells of the body live in a fluid environment that requires electrolyte and acid-base concentrations maintained within a very narrow range. A balance is maintained by an integration of renal, hormonal, and neural functions. Changes in electrolyte concentration affect the electrical activity of nerve and muscle cells and cause shifts of fluid from one compartment to another. Fluid fluctuations also affect blood volume and therefore blood pressure. Alterations in acid-base balance disrupt the cellular function of enzyme systems and can cause cell injury. Disturbances in fluid and electrolyte or acid-base balance are common and can be life threatening. Understanding how alterations occur and the body's ability to compensate or correct the disturbance is important for comprehending many pathophysiologic conditions.

Distribution of Body Fluids

Body fluids are distributed among functional compartments, or spaces, and provide a transport medium for cellular and tissue function. Water moves freely among body compartments and is distributed by osmotic and hydrostatic forces. Two-thirds of the body's water is **intracellular fluid (ICF)** and one-third is in the **extracellular fluid (ECF)** compartments. The two main ECF compartments are the **interstitial fluid** and the **intravascular fluid**,

the latter being the blood plasma. Other ECF compartments include the lymph and the transcellular fluids. The major transcellular fluids are summarized in [Table 3.1](#). Other transcellular fluids include pleural, synovial, peritoneal, pericardial, and intraocular fluids ([Table 3.1](#)).

TABLE 3.1

APPROXIMATE CONCENTRATIONS OF ELECTROLYTES IN TRANSCELLULAR FLUIDS

FLUID	Na ⁺ (mEq/L)	K ⁺ (mEq/L)	Cl ⁻ (mEq/L)	HCO ₃ ⁻ (mEq/L)
Saliva	33	20	34	40
Gastric juice*	60	9	84	0
Bile	149	5	101	45
Pancreatic juice	141	5	77	92
Ileal fluid	129	11	116	29
Cecal fluid	80	21	48	22
Cerebrospinal fluid	141	3	127	23
Sweat	45	5	58	0

*The Cl⁻ concentration exceeds the Na⁺, K⁺ concentration by 15 mEq/L in gastric juice. This largely represents the secretions of hydrochloric acid by parietal cells.

The sum of fluids within all compartments constitutes the **total body water (TBW)** ([Table 3.2](#)). The volume of TBW is usually expressed as a percentage of body weight in kilograms. The total volume of body water for a 70-kg person is about 42 liters ([Table 3.3](#)). The rest of the body weight is composed of fat and fat-free solids, particularly bone.

TABLE 3.2

DISTRIBUTION OF BODY WATER

	% OF BODY WEIGHT	VOLUME (L)
Intracellular fluid (ICF)	40	28
Extracellular fluid (ECF)	20	14
Interstitial	(15)	(11)

Intravascular	(5)	(3)
Total body water (TBW)	60	42

TABLE 3.3

TOTAL BODY WATER (%) IN RELATION TO BODY WEIGHT

BODY BUILD	ADULT MALE	ADULT FEMALE	CHILD (1–10 yr)	INFANT (1 mo to 1 yr)	NEWBORN (up to 1 mo)
Normal	60	50	65	70	70–80
Lean	70	60	50–60	80	
Obese	50	42	50	60	

NOTE: Total body water is a percentage of body weight.

Although daily fluid intake may fluctuate widely, the body regulates water volume within a relatively narrow range. The primary sources of body water are drinking of fluids, ingestion of water in food, and derivation of water from oxidative metabolism. Normally, the largest amounts of water are lost through renal excretion. Lesser amounts are eliminated through the stool and through vaporization from the skin and lungs (insensible water loss) (Table 3.4).

TABLE 3.4

NORMAL WATER GAINS AND LOSSES (70-kg MAN)

	DAILY INTAKE (mL)		DAILY OUTPUT (mL)	
Drinking ≈60%	1400–1800		Urine ≈60%	1400–1800
Water in food ≈30%	700–1000		Stool ≈2%	100
Water of oxidation ≈10%	300–400		Skin ≈10%	300–500
			Lungs ≈28%	600–800
TOTAL	2400–3200		TOTAL	2400–3200

Although the amount of fluid within the various compartments is relatively constant, exchange of solutes (e.g., salts) and water occurs between compartments to maintain their unique compositions. The percentage of TBW varies with the amount of body fat and age.

Because fat is water repelling (hydrophobic), very little water is contained in adipose cells. Individuals with more body fat have proportionately less TBW and tend to be more susceptible to fluid imbalances that cause dehydration.

Aging and Distribution of Body Fluids

The distribution and amount of TBW change with age (see [Table 3.3](#)). In newborn infants, TBW is about 70% to 80% of body weight because infants store less fat. In the immediate postnatal period, a physiologic loss of body water occurs, equivalent to about 5% of body weight as the infant adjusts to a new environment. Infants are particularly susceptible to significant changes in TBW because of their high metabolic rate and potential for evaporative fluid loss attributable to their greater body surface area in proportion to total body size. Loss of fluids from diarrhea can represent a significant proportion of body weight in infants. Renal mechanisms that regulate fluid and electrolyte conservation may not be mature enough to counter the losses, so dehydration can develop rapidly.

During childhood, TBW slowly decreases to 60% to 65% of body weight. At adolescence the percentage of TBW approaches adult proportions, and gender differences begin to appear. Males eventually have a greater percentage of body water as a function of increasing muscle mass. Females have more body fat and less muscle as a function of estrogens and therefore have less body water.

With increasing age the percentage of TBW declines further still. The decrease is caused in part by an increased amount of fat and a decreased amount of muscle and by a reduced ability to regulate sodium and water balance. With older age, the kidneys become less efficient at conserving sodium and therefore have difficulty concentrating the urine. Insensible water loss through the skin may increase and thirst perception may be impaired. The normal reduction of TBW in older adults becomes clinically important when the body is under stress, such as development of fever or dehydration; loss of body fluids at such times can be severe and life threatening.

Water Movement Between ICF and ECF

The movement of water between ICF and ECF compartments is primarily a function of osmotic forces. (Osmosis and other mechanisms of passive transport are discussed in [Chapter 1](#).) Water moves freely by diffusion through the lipid bilayer cell membrane and through **aquaporins**, a family of water channel proteins that provide permeability to water.¹ The osmolality (number of osmoles of solute per kilogram of fluid [Osm/kg]) of TBW is normally at equilibrium. Sodium is responsible for the osmotic balance of the ECF space. Potassium maintains the osmotic balance of the ICF space. The osmotic force of ICF proteins and other nondiffusible substances is balanced by the active transport of ions out of the cell. Water crosses cell membranes freely so the osmolality of TBW is normally at equilibrium. Normally the ICF is not subject to rapid changes in osmolality but when ECF osmolality changes, water moves from one compartment to another until osmotic equilibrium is reestablished.

Water Movement Between Plasma and Interstitial Fluid

The distribution of water and the movement of nutrients and waste products between the plasma in the tissue capillaries and interstitial spaces occur as a result of changes in hydrostatic pressure and osmotic forces at the arterial and venous ends of the capillary (see [Fig. 1.33](#)). Water, sodium, and glucose move readily across the capillary membrane. The plasma proteins maintain the effective osmolality (concentration of solutes per kilogram of solution), do not cross the capillary membrane, and generate plasma oncotic pressure. Albumin is the plasma protein that is primarily responsible for the plasma oncotic pressure because it has the highest concentration. Osmotic forces within the capillary are balanced by the hydrostatic pressure, which is primarily determined by blood pressure and blood volume.

As plasma flows from the arterial to the venous end of the capillary, four forces determine if fluid moves out of the capillary and into the interstitial space (filtration) or if fluid moves back into the capillary

from the interstitial space (reabsorption):

1. **Capillary hydrostatic pressure (blood pressure)** facilitates the outward movement of water from the capillary to the interstitial space.
2. **Capillary (plasma) oncotic pressure** osmotically attracts water from the interstitial space back into the capillary.
3. **Interstitial hydrostatic pressure** facilitates the inward movement of water from the interstitial space into the capillary.
4. **Interstitial oncotic pressure** osmotically attracts water from the capillary into the interstitial space.

The movement of fluid back and forth across the capillary wall is called **net filtration** and is best described by the **Starling hypothesis**:

$$\text{Net filtration} = (\text{Forces favoring filtration}) - (\text{Forces opposing filtration})$$

$$\text{Forces favoring filtration} = \text{Capillary hydrostatic pressure and interstitial oncotic pressure}$$

$$\text{Forces opposing filtration} = \text{Capillary oncotic pressure and interstitial hydrostatic pressure}$$

Normally the interstitial forces are negligible because only a very small percentage of plasma proteins crosses the capillary membrane and interstitial fluid moves into cells or is drawn back into the plasma. Thus the major forces for filtration are within the capillary.

As the plasma flows from the arterial to the venous end of the capillary, the force of hydrostatic pressure facilitates the movement of water across the capillary membrane. Oncotic pressure remains fairly constant because plasma proteins normally do not cross the capillary

membrane. At the arterial end of the capillary, hydrostatic pressure is greater than capillary oncotic pressure and water filters into the interstitial space. Because of oncotic forces, some water moves back into the capillary, but the net effect is loss of water from the capillary. This loss of water from the plasma decreases the hydrostatic pressure within the capillary; thus, at the venous end of the capillary, oncotic pressure exceeds hydrostatic pressure. Fluids then are attracted back into the circulation, balancing the movement of fluids between the plasma and the interstitial space. The overall effect is filtration at the arterial end and reabsorption at the venous end (Fig. 3.1). Interstitial hydrostatic pressure promotes the movement of interstitial fluid along with small amounts of protein into lymphatic vessels, which is then returned to the circulation.

Arterial Capillary Pressures		Venous Capillary Pressures	
Capillary hydrostatic pressure	35 mmHg	Capillary hydrostatic pressure	18 mmHg
Interstitial fluid hydrostatic pressure	2 mmHg	Interstitial fluid hydrostatic pressure	1 mmHg
Net hydrostatic pressure	33 mmHg	Net hydrostatic pressure	17 mmHg
Capillary oncotic pressure	24 mmHg	Capillary oncotic pressure	25 mmHg
Interstitial fluid oncotic pressure	0 mmHg	Interstitial fluid oncotic pressure	0 mmHg
Net oncotic pressure	24 mmHg	Net oncotic pressure	25 mmHg
Net filtration pressure	+9 mmHg	Net filtration pressure	-8 mmHg

FIGURE 3.1 Capillary Filtration Forces. Water, electrolytes, and small molecules exchange freely between the vascular compartment and the interstitial space at the site of capillaries and small venules. The rate and amount of exchange are driven by the physical forces of hydrostatic and oncotic pressures and the permeability and surface area of the capillary membranes. The two opposing hydrostatic pressures are capillary hydrostatic pressure and interstitial hydrostatic pressure. The two opposing oncotic pressures are capillary oncotic pressure and interstitial oncotic pressure. The forces that favor filtration from the capillary are capillary hydrostatic pressure and interstitial oncotic pressure, and the

forces that oppose filtration are capillary oncotic pressure and interstitial hydrostatic pressure. The sum is known as *net filtration pressure*. In the example of normal exchange illustrated here, a small amount of fluid moves to the lymph vessels, which accounts for the net filtration difference between the arterial and venous ends of the capillary.

An important factor in capillary filtration of fluid is the integrity of the capillary membrane. Changes in membrane permeability may permit the escape of plasma proteins into the interstitial space. The normal relationship defined by the Starling hypothesis is altered with the osmotic movement of water into the interstitial space, causing tissue edema.

Alterations in Water Movement

Edema

Edema is the excessive accumulation of fluid within the interstitial spaces. It is often a problem of fluid distribution and does not necessarily indicate a fluid excess. In some conditions, sequestered fluids can cause both edema and intravascular dehydration. The pathophysiologic process of edema is related to an increase in the forces favoring fluid filtration from the capillaries or lymphatic channels into the tissues. The four most common mechanisms are:

1. Increased capillary hydrostatic pressure
2. Decreased capillary oncotic pressure
3. Increased capillary membrane permeability
4. Lymphatic obstruction ([Fig. 3.2](#))

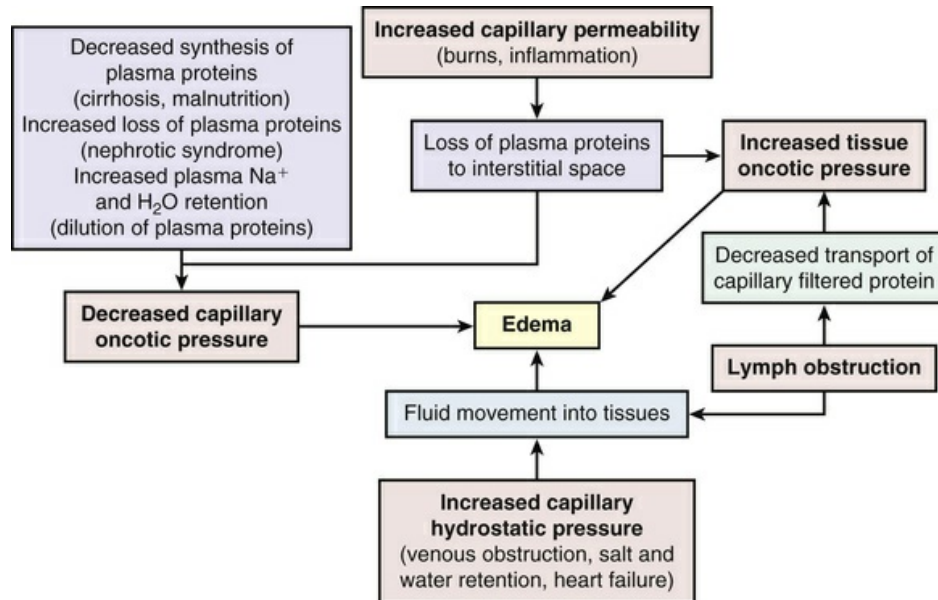

FIGURE 3.2 Mechanisms of Edema Formation.

◆ Pathophysiology.

Increased capillary hydrostatic pressure can result from venous obstruction or sodium and water retention. Venous obstruction causes hydrostatic pressure to increase behind the obstruction, pushing fluid from the capillaries into the interstitial spaces. Venous blood clots, hepatic obstruction, right heart failure, tight clothing around the extremities, and prolonged standing are common causes of venous obstruction. Right congestive heart failure, renal failure, and cirrhosis of the liver are conditions associated with excessive sodium and water retention, which in turn cause volume overload, increased venous pressure, and edema. The volume of interstitial fluid exceeds the capacity of the lymphatics to return fluid to the vascular system.

Decreased plasma oncotic pressure results from *losses or diminished production of plasma albumin*. Decreased oncotic attraction of fluid within the capillary causes fluid to move into the interstitial space, resulting in edema. Decreased synthesis of plasma protein and decreased oncotic pressure may occur with liver disease or protein malnutrition. Losses of plasma proteins occur with glomerular diseases of the kidney (nephrotic syndrome), hemorrhage, and serous drainage from open wounds or burns.

Increased capillary permeability is usually associated with *inflammation and the immune response*. (Immunity is discussed in [Chapters 7, 8, and 9](#); inflammation is discussed in [Chapters 7 and 9](#).) These responses are often the result of trauma such as burns or crushing injuries, neoplastic disease, allergic reactions, and infection. Excess amounts of fluid escape from the plasma to the interstitial space and produce edema. This type of edema is often very severe because of loss of proteins from the vascular space, which decreases capillary oncotic pressure and increases interstitial oncotic pressure with both processes facilitating fluid movement into the interstitial space.

Lymphatic obstruction occurs when the *lymphatic channels are blocked* because of infection or tumor. Proteins and fluids are not reabsorbed and accumulate in the interstitial space, causing **lymphedema**. Lymphedema of the arm or leg also can occur after surgical removal of axillary or femoral lymph nodes, respectively, for treatment of cancer.²

◆Clinical Manifestations.

Edema may be localized or generalized. *Localized edema* is usually limited to the site of tissue injury, as in a sprained joint. Local edema can also occur within particular organs, causing, for example, cerebral edema in the brain, pulmonary edema in the lungs, pleural effusion (fluid accumulation in the pleural space), laryngeal edema, and ascites (accumulation of fluid in the abdomen). Edema of specific organs, such as the brain, lung, or larynx, can be life threatening. *Generalized edema* is manifested by a more uniform distribution of fluid in interstitial spaces throughout the body. *Dependent edema*, in which fluid accumulates in gravity-dependent areas of the body, might appear in the feet and legs when standing and in the sacral area and buttocks when supine. Dependent edema can be identified by using the fingers to press away edematous fluid in tissues overlying bony prominences. A pit will be left in the skin; hence the term *pitting edema* ([Fig. 3.3](#)).

FIGURE 3.3 Pitting Edema. (From Bloom A, Ireland J: *Color atlas of diabetes*, ed 2, St Louis, 1992, Mosby.)

Edema is usually associated with swelling and puffiness, tight-fitting clothes and shoes, and limited movement of the affected area. Weight gain can be significant. The accumulation of fluid increases the distance required for nutrients, oxygen, and wastes to move between capillaries and cells in the tissues. Increased tissue pressure also may diminish capillary blood flow, leading to ischemia. Therefore, wounds heal more slowly and risk of pressure ulcers increase. As edematous fluid accumulates, it is trapped in a “third space” (i.e., the interstitial space) and dehydration can develop as a result of this sequestering of fluid. Such sequestration occurs with severe burns, in which large amounts of vascular fluid are lost to the interstitial spaces, reducing plasma volume and causing shock.

◆ **Evaluation and Treatment.**

Specific conditions causing edema require diagnosis. Edema may be treated symptomatically until the underlying disorder is corrected. Supportive measures include elevating edematous limbs, wearing compression stockings or devices, avoiding prolonged standing,

restricting salt intake, and taking diuretics.

Sodium, Chloride, and Water Balance

The kidneys and hormones have a central role in maintaining sodium and water balance. Because water follows the osmotic gradients established by changes in salt concentration, sodium balance and water balance are intimately related. Sodium is regulated by the renal effects of aldosterone from the adrenal cortex and natriuretic peptides from the heart. Water balance is primarily regulated by the renal response to antidiuretic hormone (ADH; also known as *arginine-vasopressin*) from the posterior pituitary.

Sodium and Chloride Balance

Sodium accounts for 90% of the ECF cations (positively charged ions). The distribution of electrolytes in body compartments is summarized in [Table 3.5](#) and the concentration of electrolytes is summarized in [Table 3.1](#). As the most abundant ECF cation, along with its constituent anions (negatively charged ions) chloride and bicarbonate, sodium regulates extracellular osmotic forces and therefore regulates water balance and ECF volume. Sodium is important in other body functions, including maintenance of neuromuscular irritability for conduction of nerve impulses (in conjunction with potassium and calcium), regulation of acid-base balance (through sodium bicarbonate and sodium phosphate), participation in cellular chemical reactions, and transport of substances across the cellular membrane (see [Chapter 1](#)).

TABLE 3.5

DISTRIBUTION OF ELECTROLYTES IN BODY COMPARTMENTS

EXTRACELLULAR FLUID (mEq/L)		INTRACELLULAR FLUID (mEq/L)
Cations

Anions		
Bicarbonate	24	12
Chloride	104	4
Phosphate	2	40–95
Proteins	16	54
Other anions	8	31–86
TOTAL	_____	_____
	154	196 (average)

The kidney, in conjunction with neural and hormonal mediators, maintains normal serum sodium concentration within a narrow range (135 to 145 mEq/L) primarily through renal tubular reabsorption. Generally, sodium intake matches sodium excretion. The average dietary intake of sodium ranges from 5 to 6 g/day; the minimal daily requirement of sodium is 500 mg. Sweating depletes sodium and water volume and increases the body's sodium requirement.

Hormonal regulation of sodium balance is mediated by **aldosterone**, a mineralocorticoid (steroid) synthesized and secreted from the adrenal cortex as the end product of the renin-angiotensin-aldosterone system (Fig. 3.4). When circulating blood pressure and renal blood flow, or serum sodium concentrations, are reduced, **renin**, an enzyme secreted by the juxtaglomerular cells of the kidney, is released. Renin stimulates the formation of **angiotensin I**, an inactive polypeptide. Angiotensin-converting enzyme (ACE) in pulmonary vessels converts angiotensin I to angiotensin II. **Angiotensin II** causes vasoconstriction, which elevates systemic blood pressure, and stimulates the secretion of aldosterone. Vasoconstriction elevates the systemic blood pressure and restores renal perfusion (blood flow), and aldosterone promotes sodium and water reabsorption by the proximal tubules of the kidneys, thus conserving sodium, blood volume, and blood pressure. Aldosterone also stimulates secretion

(and therefore excretion) of potassium by the distal tubule of the kidney, reducing potassium concentrations in the ECF. The restoration of sodium levels, blood volume, and renal perfusion then inhibits further release of renin.

FIGURE 3.4 The Renin-Angiotensin-Aldosterone System. *BP*, Blood pressure; *ECF*, extracellular fluid; *Na⁺*, sodium ion. (Modified from Herlihy B, Maebius N: *The human body in health and disease*, ed 4, Philadelphia, 2011, Saunders. Borrowed from Lewis et al: *Medical-surgical nursing: assessment and management of clinical problems*, ed 9, St Louis, 2014, Mosby.)

Natriuretic peptides are hormones that include atrial natriuretic peptide (ANP) produced by myoendocrine atrial cells, brain natriuretic peptide (BNP—named brain since it was first discovered in porcine brain) produced by myoendocrine ventricular cells, and urodilatin (renal natriuretic peptide, an ANP analog) synthesized within the kidney. ANP and BNP are released when there is an increase in transmural atrial pressure caused by increased intraatrial volume as may occur with heart failure.³ ANP and BNP increase sodium and water excretion by the kidneys, which lowers blood volume and pressure (Fig. 3.5). Urodilatin is released from distal tubular kidney cells when there is increased arterial pressure and increased renal blood flow. These hormones are natural antagonists to

the renin-angiotensin-aldosterone system. The restoration of lower atrial pressure then inhibits further release of ANP and BNP.

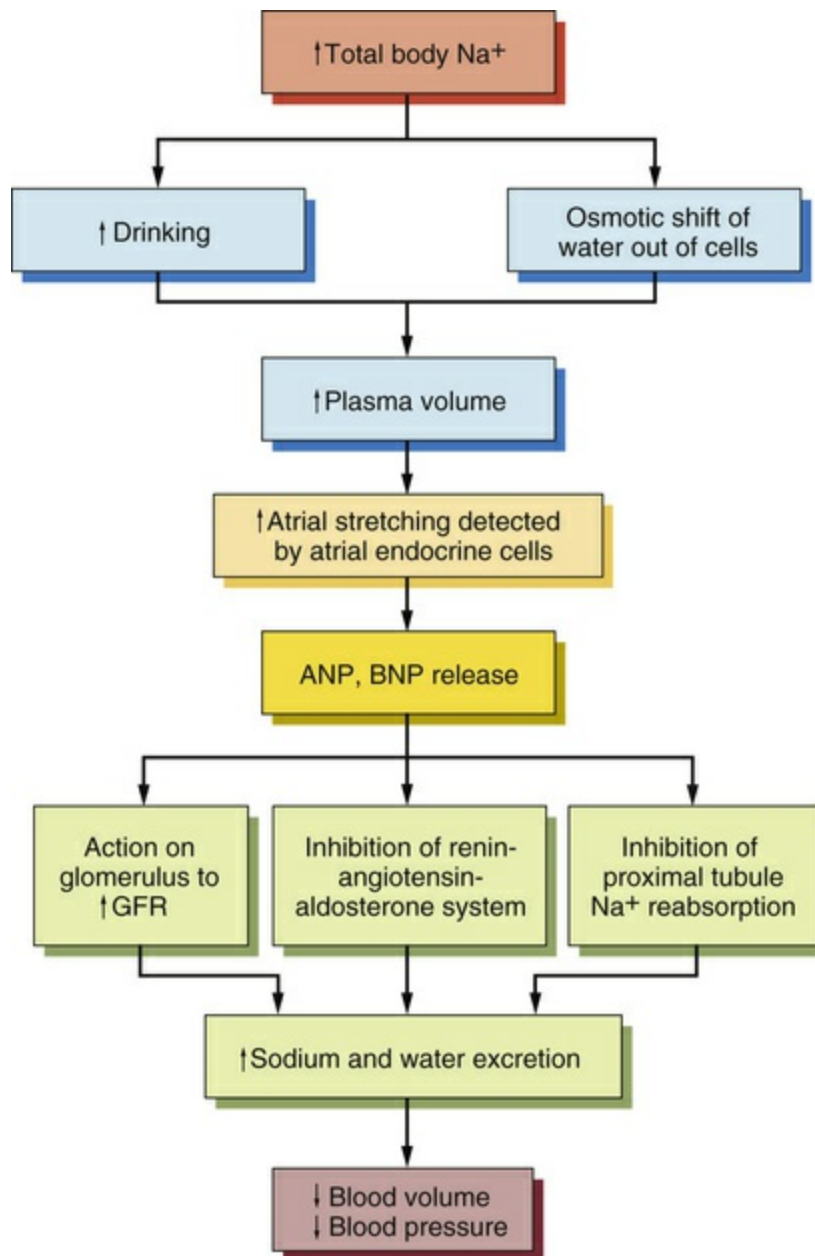

FIGURE 3.5 The Natriuretic Peptide System. *ANP*, atrial natriuretic peptide; *BNP*, brain natriuretic peptide; *GFR*, glomerular filtration rate.

Chloride is the major anion in the ECF and provides electroneutrality, particularly in relation to sodium. Chloride transport is generally passive and follows the active transport of

sodium so that increases or decreases in chloride concentration are proportional to changes in sodium concentration. Chloride concentration tends to vary inversely with changes in the concentration of bicarbonate (HCO_3^-), the other major ECF anion.

Water Balance

Water balance is regulated by interactions between sensory organs (carotid and aortic artery volume/pressure receptors and hypothalamic osmoreceptors), **antidiuretic hormone (ADH)** (also known as **arginine-vasopressin**), and the kidney. ADH is secreted when plasma osmolality increases or circulating blood volume decreases and blood pressure drops ([Fig. 3.6](#)). Increased plasma osmolality occurs with a water deficit or sodium excess in relation to total body water. The increased osmolality stimulates hypothalamic **osmoreceptors**. In addition to causing thirst and water drinking, the stimulated osmoreceptors signal the posterior pituitary to release ADH. The action of ADH is to increase the permeability of distal renal tubular cells to water, increasing water reabsorption and promoting the restoration of plasma volume and blood pressure. Urine concentration increases, and the reabsorbed water decreases plasma osmolality, returning it toward normal. Like most hormones, ADH is regulated by a feedback mechanism. The restoration of plasma osmolality, blood volume, and blood pressure then inhibits ADH secretion.

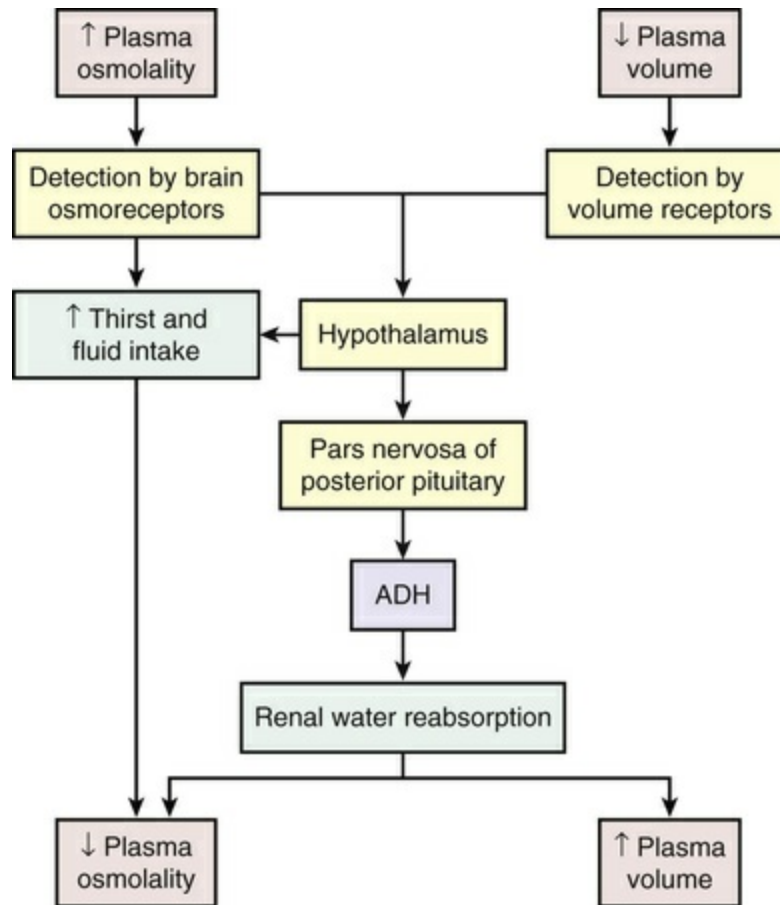

FIGURE 3.6 The Antidiuretic Hormone (ADH) System.

With fluid loss (dehydration) (e.g., from vomiting, diarrhea, or excessive sweating) and a decrease in blood volume and blood pressure, **baroreceptors (volume/pressure sensitive receptors)** (stretch receptors that are sensitive to changes in arterial volume and pressure) also stimulate the release of ADH. Baroreceptors are located in the right and left atria and large veins, and in the aorta, pulmonary arteries, and carotid sinus. When arterial and atrial pressure drops, baroreceptors signal the hypothalamus to release ADH. The reabsorption of water mediated by the renal response to ADH promotes the restoration of plasma volume and blood pressure (see [Fig. 3.6](#)). Higher concentrations of ADH stimulate peripheral arterial vasoconstriction, thus increasing arterial blood pressure.

Alterations in Sodium, Water, and

Chloride Balance

Alterations in sodium and water balance are closely related. Water imbalances may develop because of changes in osmotic gradients caused by gain or loss of salt. Likewise, sodium imbalances occur with gains or losses of body water volume. Alterations are generally classified as changes in tonicity, the change in concentration of electrolytes in relation to water: isotonic, hypertonic, or hypotonic (Table 3.6 and Fig. 3.7). Changes in tonicity also alter the volume of water in the intracellular and extracellular compartments, resulting in hypovolemia, euvoolemia, or hypervolemia.

TABLE 3.6

WATER AND SOLUTE IMBALANCES

TONICITY	MECHANISM
Isotonic (isoosmolar) imbalance	Gain or loss of extracellular fluid (ECF) resulting in a concentration equivalent to a 0.9% sodium chloride (salt) solution (normal saline); no shrinking or swelling of cells
Hypertonic (hyperosmolar) imbalance	Imbalance that results in an ECF concentration >0.9% salt solution; that is, water loss or solute gain; cells shrink in a hypertonic fluid
Hypotonic (hyposmolar) imbalance	Imbalance that results in an ECF <0.9% salt solution; that is, water gain or solute loss; cells swell in a hypotonic fluid

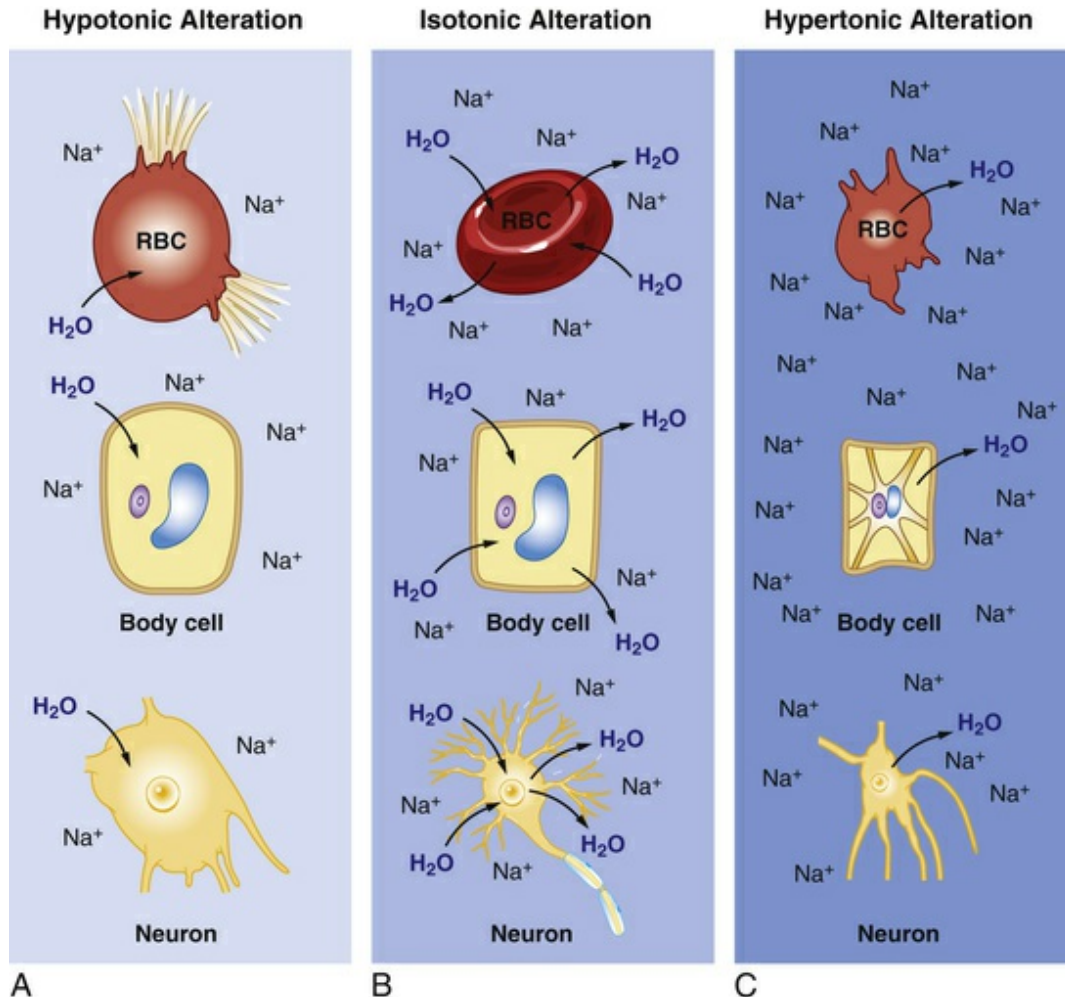

FIGURE 3.7 Effects of Alterations in Extracellular Sodium Concentration in RBCs, Body Cells, and Neurons. **A, Hypotonic Alteration:** Decrease in ECF sodium ion (Na^+) concentration (hyponatremia) results in ICF osmotic attraction of water with swelling and potential bursting of cells. **B, Isotonic Alteration:** Normal concentration of sodium in the ECF and no change in shifts of fluid in or out of cells. **C, Hypertonic Alteration:** An increase in ECF sodium concentration (hypernatremia) results in osmotic attraction of water out of cells with cell shrinkage. *RBC*, Red blood cell.

Isotonic Alterations

Isotonic alterations are the most common and occur when changes in TBW are accompanied by proportional changes in the concentration of electrolytes. *Isotonic fluid loss* causes dehydration and hypovolemia. For example, if an individual loses pure plasma or ECF, fluid volume is depleted but the number and type of electrolytes (e.g., sodium) and the osmolality remain within a normal range (280 to 294 mOsm).

Causes include hemorrhage, severe wound drainage, and excessive diaphoresis (sweating). There is loss of extracellular volume with weight loss, dryness of skin and mucous membranes, decreased urine output, increased hematocrit value, and symptoms of hypovolemia. Indicators of hypovolemia include a rapid heart rate and flattened neck veins, and can present with a normal or decreased blood pressure. In severe states, hypovolemic shock (severe hypotension) can occur. Isotonic fluids containing electrolytes and glucose are given orally, intravenously (i.e., 0.9% saline solution or 5% dextrose in 0.225% saline solution, not commonly used), or, in some cases, subcutaneously (hypodermoclysis).

Isotonic fluid excesses result in hypervolemia. Causes include excessive administration of intravenous fluids, hypersecretion of aldosterone, the effects of drugs such as cortisone, or failure of the kidneys. As plasma volume expands, hypervolemia develops with weight gain. The diluting effect of excess plasma volume leads to decreased hematocrit and decreased plasma protein concentration. The neck veins may distend, and the blood pressure increases. Increased capillary hydrostatic pressure leads to edema formation. If the plasma volume is great enough, pulmonary edema and heart failure develop. Diuretics are commonly used for treatment.

Hypertonic Alterations

Hypertonic fluid alterations develop when the osmolality of the ECF is elevated higher than normal (greater than 294 mOsm). The most common causes are an increased concentration of ECF sodium (hypernatremia) or a deficit of ECF free water, or both. In both instances the hypertonicity of the ECF attracts water from the intracellular space, causing ICF dehydration. A primary increase in the amount of ECF sodium causes an osmotic attraction of water and symptoms of *hypervolemia*. In contrast, a hypertonic state caused primarily by free water loss leads to *hypovolemia* (Table 3.7).

TABLE 3.7

CAUSES AND CONSEQUENCES OF HYPERTONIC IMBALANCES

CAUSES AND CONSEQUENCES OF HYPERTONIC IMBALANCES

CAUSATIVE FACTOR	MECHANISM	ECF EFFECTS	ICF EFFECTS
Increased sodium (hyponatremia)	Excessive hypertonic salt solutions Intravenous hypertonic sodium Saline-induced abortions Select infant formulas Hyperaldosteronism Cushing syndrome	Hypervolemia Weight gain Bounding pulse Increased blood pressure Edema Venous distention Neuromuscular symptoms Muscle weakness Seizures	Intracellular dehydration Thirst Fever Decreased urine output Shrinkage of brain cells Confusion Coma Cerebral hemorrhage
Water deficit	Water deprivation Confusion or coma Inability to communicate Loss of thirst Water loss Watery diarrhea Diabetes insipidus Excessive diuresis Excessive diaphoresis	Hypovolemia Weight loss Weak pulses Postural hypotension Tachycardia	Intracellular dehydration See above
Other factors	Hyperglycemia	Initial dilutional hyponatremia Polyuria Polydipsia Weight loss Hypovolemia Late hyponatremia	Intracellular dehydration See above

ECF, Extracellular fluid; ICF, intracellular fluid.

Hyponatremia

◆ Pathophysiology.

Hyponatremia occurs when serum sodium levels exceed 145 mEq/L. Increased levels of serum sodium cause hypertonicity. Hyponatremia can be hypovolemic, euvolemic, or hypervolemic depending on the accompanying ECF water volume. Risk factors include advanced age, impaired mental state, fever, diarrhea, and vomiting. Other factors

include uncontrolled diabetes mellitus, tube feedings, and use of diuretics.

Hypovolemic hypernatremia occurs where there is loss of body sodium accompanied by a relatively greater loss of body water. Causes include use of loop diuretics, osmotic diuresis (i.e., from hyperglycemia related to uncontrolled diabetes mellitus or use of mannitol), gastrointestinal losses, or failure of the kidneys to concentrate urine.

Euvolemic hypernatremia is the most common and occurs when there is a *loss of free water* with a near normal body sodium concentration. Causes include inadequate water intake; excessive sweating (sweat is hypotonic); fever with hyperventilation and increased water loss from lungs; burns; vomiting; diarrhea; and central or nephrogenic diabetes insipidus (lack of ADH or inadequate renal response to ADH). Infants with severe diarrhea are vulnerable and have increased risk because they cannot communicate thirst. Insufficient water intake occurs particularly in individuals who are comatose, confused, immobilized, or receiving gastric feedings. **Dehydration** refers to water deficit but also is commonly used to indicate both sodium and water loss (isotonic or isoosmolar dehydration).⁴

Hypervolemic hypernatremia is rare and occurs when there is increased total body water and a greater increase in total body sodium level, resulting in hypervolemia. Causes include infusion of hypertonic saline solutions (e.g., because sodium replacement for treatment of salt depletion can occur with renal impairment, heart failure, or gastrointestinal [GI] losses) or oversecretion of adrenocorticotrophic hormone (ACTH) or aldosterone (e.g., Cushing syndrome, adrenal hyperplasia), and near-salt water drowning.⁵ High amounts of dietary sodium rarely cause hypernatremia in a healthy individual because the sodium is eliminated by the kidneys. Symptoms include weight gain, bounding pulse, and increased blood pressure.

Because chloride follows sodium, **hyperchloremia** (elevation of serum chloride concentration greater than 105 mEq/L) often

accompanies hypernatremia, as well as plasma bicarbonate deficits, as in hyperchloremic metabolic acidosis. There are no specific symptoms for chloride excess, and treatment is related to management of the underlying disorder.

◆Clinical Manifestations.

When there is excessive sodium in the extracellular space, water is osmotically attracted to the hypertonic extracellular space from the intracellular space, and intracellular dehydration ensues. Central nervous system signs are the most serious and are related to shrinking of brain cells and alterations in membrane potentials. Signs include weakness, lethargy, muscle twitching, and hyperreflexia (hyperactive reflexes). Confusion, coma, and seizures can occur. Hypernatremia with marked water deficit is manifested by signs and symptoms of both intracellular and extracellular dehydration with volume depletion (Box 3.1).

Box 3.1

Signs and Symptoms of Dehydration

- Increased serum sodium concentration
- Thirst
- Headache
- Weight loss
- Oliguria and concentrated urine
- Hard stools
- Decreased skin turgor
- Dry mucous membranes
- Decreased sweating and tears
- Elevated temperature
- Soft eyeballs
- Sunken fontanelles in infants
- Prolonged capillary refill time
- Tachycardia

- Weak pulses
- Low blood pressure
- Postural hypotension
- Hypovolemic shock
- Lethargy
- Weakness
- Confusion
- Coma

◆Evaluation and Treatment.

Serum sodium levels are greater than 145 mEq/L and urine specific gravity will be greater than 1.030. Hematocrit and plasma protein levels will be elevated with water loss. The history, physical examination, and laboratory values provide information about underlying disorders and events. The treatment of hypernatremia and water deficit is to give oral fluids or an isotonic salt-free fluid (5% dextrose in water) until the serum sodium level returns to normal. Fluid replacement must be given slowly to prevent cerebral edema, and serum sodium levels need to be closely monitored. Hypervolemia and hypovolemia require treatment of the underlying clinical condition. Diuretics may be used to enhance sodium excretion.

Hypotonic Alterations

Hypotonic fluid alterations occur when the osmolality of the ECF is less than normal (less than 280 mOsm). The most common causes are sodium deficit (hyponatremia) or free water excess (water intoxication). Both causes lead to an intracellular overhydration (cellular edema) and cell swelling when water moves into the cell, where the osmotic pressure is greater (see [Fig. 3.7, A](#)). Cerebral and pulmonary edema occur in conjunction with these fluid shifts.⁶ With hyponatremia, the plasma volume then decreases, leading to symptoms of hypovolemia. With free water excess, the ECF volume is elevated, causing symptoms of hypervolemia ([Table 3.8](#)).

TABLE 3.8**CAUSES AND CONSEQUENCES OF HYPOTONIC IMBALANCES**

CAUSATIVE FACTOR	MECHANISM	ECF EFFECTS	ICF EFFECTS
Decreased sodium (hyponatremia)	Inadequate intake Hypoaldosteronism Excessive diuretic therapy Furosemide Ethacrynic acid Thiazides	Extracellular volume contraction and hypovolemia (but may not if there is water excess)	Increased intracellular water; edema Brain cell swelling, irritability, depression, confusion Systemic cellular edema, including weakness, anorexia, nausea, and diarrhea
Water excess	Excessive pure water intake Excessive administration of hypotonic intravenous solutions Drinking water to replace isotonic fluid losses Tap water enemas Psychogenic polydipsia Renal water retention Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)	Extracellular volume expands with hypervolemia (but may not if fluid is trapped in intracellular space)	Edema (see above)
Other factors	Isotonic dehydration treated with intravenous D ₅ W; glucose in D ₅ W solution is metabolized to water, contributing to hyponatremia Nephrotic syndrome Cirrhosis Cardiac failure	Hypervolemia or hypovolemia	Edema (see above)

D₅W, Dextrose 5% in water; *ECF*, extracellular fluid; *ICF*, intracellular fluid.

Hyponatremia

◀Pathophysiology.

Hyponatremia develops when the serum sodium concentration decreases to less than 135 mEq/L. It is the most common electrolyte disorder in hospitalized individuals and increases morbidity and mortality.⁷ Hyponatremia occurs when there is loss of sodium, inadequate intake of sodium, or dilution of sodium by water excess. Hyponatremia can be classified as hypovolemic, euvolemic, or hypervolemic when there are changes in blood volume or as hypotonic, isotonic, or hypertonic when there are changes in effective osmolality. Sodium depletion usually causes hypoosmolality with movement of water into cells (see [Fig. 3.7, A](#)).

Hypovolemic hyponatremia occurs with a loss of total body fluid, and there is a greater loss of body sodium (*hypotonic hyponatremia*) than body water. The extracellular volume is decreased. Causes include prolonged vomiting, severe diarrhea, inadequate secretion of aldosterone (e.g., adrenal insufficiency), and renal losses from diuretics. ADH will be released to facilitate repletion of blood volume.

Euvolemic hyponatremia occurs when there is loss of sodium without a significant loss of water (**pure sodium deficit** and a **hypotonic hyponatremia**). Causes can include syndrome of inappropriate antidiuretic hormone (SIADH [see [Chapter 22](#)]), which enhances water retention), hypothyroidism, pneumonia, and glucocorticoid deficiency. **Inadequate intake of dietary sodium** is rare but possible in individuals consuming low-sodium diets, particularly with use of diuretics.

Dilutional hypotonic hyponatremia (water intoxication) occurs when there is intake of large amounts of free water or replacement of fluid loss with intravenous 5% dextrose in water, which dilutes sodium. The glucose is metabolized to carbon dioxide and water, leaving a hypotonic solution with a diluting effect. Excessive sweating stimulates thirst and intake of large amounts of free water (as can

occur in endurance athletes), which dilutes sodium concentration. Some individuals with psychogenic disorders develop water intoxication from compulsive water drinking. Other causes can include tap water enemas, near-fresh water drowning, use of selective-serotonin reuptake inhibitors (SSRIs), and SIADH. When the body is functioning normally, it is almost impossible to produce an excess of TBW because water balance is regulated by the kidneys.

Hypervolemic hyponatremia occurs when both TBW and sodium levels are increased, but TBW exceeds the increase in sodium levels, producing a *hypotonic hyponatremia*. Causes include congestive heart failure, cirrhosis of the liver, and nephrotic syndrome. Edema is present.

Hypertonic hyponatremia develops with the shift of water from the ICF to the ECF, as occurs with hyperglycemia, hyperlipidemia, and hyperproteinemia. The osmotic fluid shift to the ECF in turn dilutes the concentration of sodium (pseudohyponatremia) and other electrolytes.

◆Clinical Manifestations.

Most individuals are asymptomatic. When serum sodium concentration decreases to less than 120 mEq/L, cellular swelling and deficits of intracellular sodium alter the ability of cells to depolarize and repolarize normally. Nausea and vomiting are more common with less severe hyponatremia (i.e., decreases between 125 and 130 mEq/L). Neurologic symptoms occur with severe hyponatremia (i.e., decreases less than 125 mEq/L) and include lethargy, headache, confusion, apprehension, seizures, and coma.⁸ Hypovolemic hyponatremia with pure sodium loss is accompanied by loss of ECF with symptoms of hypotension, tachycardia, and decreased urine output. Hypervolemic hyponatremia is accompanied by weight gain, edema, ascites, and jugular vein distention. Cerebral edema can be a life-threatening complication of hyponatremia caused by increased shifts of fluid to the intracellular space and increased intracranial pressure.

◆Evaluation and Treatment.

Evaluation of hyponatremia includes the history, physical examination, and laboratory tests for urine and serum. In hyponatremic states, serum sodium concentration falls to less than 135 mEq/L. With pure sodium deficits, the hematocrit and plasma protein levels may be elevated. Urine specific gravity is less than 1.010 when renal function is normal because sodium is maximally conserved. Evaluation of urine sodium concentration and urine osmolality assists with differential diagnosis. High urine sodium level (normal is 40 to 220 mEq/L in 24 hours) and high urine osmolality are associated with cerebral salt wasting syndrome and adrenal insufficiency. Low urine sodium level (30 mEq/L in 24 hours) and high urine osmolality are associated with extrarenal losses, such as vomiting and diarrhea or severe burns, heart failure, or cirrhosis. Serum osmolality is usually decreased, but secondary conditions of hyperlipidemia, hyperglycemia, or hyperproteinemia can increase serum osmolality.

Treatment of hyponatremia is related to the contributing disorder and severity and acuity of sodium loss. Losses of sodium and water volume are calculated from the clinical evaluation, and appropriate solutions then are selected for replacement. Restriction of water intake is required in most cases of dilutional hyponatremia because body sodium levels may be normal or increased even though serum concentrations are low. Hypertonic saline solutions are used cautiously with severe hyponatremia or the presence of symptoms such as seizures. Rapid correction of chronic hyponatremia can lead to osmotic demyelination syndrome with axonal damage in the brain resulting in neurologic disability or death. Arginine-vasopressin (ADH) receptor antagonists (vaptans) are a class of drugs used for the treatment of hypervolemic and euvolemic hyponatremia, particularly with SIADH.⁹ Serum sodium concentration must be monitored.

Hypochloremia

Hypochloremia, a low level of serum chloride (less than 97 mEq/L), usually occurs with hyponatremia or an elevated bicarbonate concentration, as in metabolic alkalosis. Sodium deficit related to

restricted intake, use of diuretics, and vomiting is accompanied by chloride deficiency. Cystic fibrosis is a genetic disease characterized by hypochloremia (see [Chapters 37](#) and [43](#)). In all cases, treatment of the underlying cause is required.

Alterations in Potassium, Calcium, Phosphate, and Magnesium Balance

Potassium

Potassium (K^+) is the major intracellular electrolyte and is found in most body fluids (see [Table 3.5](#)). The ICF concentration of K^+ is about 150 to 160 mEq/L; the ECF concentration is about 3.5 to 5.0 mEq/L. Total body potassium content is about 4000 mEq, with most of it located in the cells. Daily dietary intake of potassium is 40 to 150 mEq/day, with an average of 1.5 mEq/kg body weight.

Potassium balance is highly regulated because of its role in neuromuscular function. About 90% of dietary potassium is absorbed in the gastrointestinal tract. The increased serum K^+ level stimulates insulin, aldosterone, and epinephrine (β -adrenergic stimulation) secretion, which activates K^+ transport into liver and muscle cells. Aldosterone also promotes renal excretion of K^+ by the distal tubules, accounting for 90% to 95% of K^+ excretion (see [What's New? Potassium Intake, Hypertension, and Stroke](#)).

What's New

Potassium Intake, Hypertension, and Stroke

Enriched dietary intake of potassium is associated with a lower risk of hypertension and stroke. Although the American diet often exceeds recommendations for sodium intake, diets are typically deficient in potassium intake. There is increased risk of high blood pressure, cardiovascular disease, and mortality when the plasma ratio of sodium concentration to potassium concentration is high.

Potassium attenuates the effects of high dietary salt intake with reduction in blood pressure, stroke rates, and cardiovascular disease risk. The exact mechanism of how potassium affects blood pressure is unknown but is thought to be related to renal handling of sodium, endothelial cell function, decreased vascular resistance, and reduced oxidative stress. A large prospective study of older women showed they were found to have lower risk of ischemic but not hemorrhagic stroke associated with higher intakes of potassium, especially in women without hypertension. Lower risk of mortality was found in all women with higher intakes of potassium. Increased dietary intake of potassium is recommended for most individuals without impaired renal handling of potassium.

Data from Binia A et al: *J Hypertens* 33(8):1509–1520, 2015; Seth A et al: *Stroke* 45(10):2874–2880, 2014; Vinceti et al: *J Am Heart Assoc* 5(10), 2016.

The difference in the K^+ intracellular to extracellular concentration is maintained by a sodium-potassium active transport system (Na^+K^+ ATPase pump). The ratio of ICF K^+ concentration to ECF K^+ concentration is the major determinant of the resting membrane potential, which is necessary for the transmission and conduction of nerve impulses, maintenance of normal cardiac rhythms, and contraction of skeletal and smooth muscles (see [Fig. 1.34](#)). The constant diffusion of positively charged K^+ out of the cell (i.e., down its concentration gradient) makes the interior of cells electronegative in relation to the ECF. Changes in the ratio of ICF to ECF potassium concentration are responsible for many of the symptoms associated with K^+ imbalance.

As the predominant ICF ion, K^+ exerts a major influence on the regulation of ICF osmolality and fluid balance, as well as on intracellular electrical neutrality in relation to hydrogen (H^+) and Na^+ levels. Potassium also is necessary for a variety of metabolic functions and is required for glycogen deposition in liver and skeletal muscle cells.

Insulin contributes to the regulation of plasma potassium levels by

stimulating the $\text{Na}^+\text{-K}^+$ ATPase pump, thereby promoting the movement of K^+ into liver and muscle cells simultaneously with glucose transport. The intracellular movement of K^+ prevents an acute hyperkalemia related to food intake. Insulin also can be used to treat hyperkalemia. However, dangerously low levels of plasma K^+ can result from the administration of insulin when K^+ levels are depressed. Potassium balance is especially significant in the treatment of conditions requiring insulin administration, such as type 1 diabetes mellitus.

Insulin deficiency, aldosterone deficiency, acidosis, and strenuous exercise facilitate the shift of K^+ out of cells. α -Adrenergics impair K^+ entry into cells. Glucagon blocks entry of K^+ into cells, and glucocorticoids promote K^+ excretion. Potassium also will move out of cells along with water when there is increased ECF osmolarity. If cells lyse, they release their intracellular K^+ into the ECF, which can cause an acute rise in plasma K^+ levels. Elevated plasma K^+ concentration causes adrenal secretion of aldosterone and renal excretion of K^+ . Alkalosis facilitates the shift of K^+ into cells in exchange for H^+ .

The kidney provides the most efficient regulation of K^+ level balance over time. The amount of K^+ excreted varies in proportion to the dietary intake (40 to 150 mEq/day). Potassium is freely filtered by the renal glomerulus, and 90% is reabsorbed by the proximal tubule and loop of Henle. **Principal cells** in the collecting duct secrete K^+ , and **intercalated cells** in the collecting duct reabsorb K^+ . Dietary K^+ intake, aldosterone level, and distal tubule urine flow determine the amount of K^+ excreted from the body. Unlike sodium, the renal mechanism for conserving K^+ is weak, even when total body K^+ stores are depleted. The gut also may sense the amount of K^+ ingested and stimulate renal K^+ excretion.¹⁰ However, a low K^+ intake also suppresses renal K^+ excretion.

The concentration of K^+ in the distal tubular cells is determined primarily by the plasma concentration in the peritubular capillaries. When plasma K^+ concentration increases because of increased dietary intake or shifts from the ICF to the ECF occur, K^+ is secreted into the urine by principal cells in the collecting ducts. Decreased levels of

plasma K^+ result in decreased collecting duct secretion and reabsorption by intercalated cells, although K^+ losses of approximately 5 to 15 mEq/day will continue.

Changes in distal tubule flow rate and distal tubule sodium delivery also influence the concentration gradient for K^+ secretion. When the flow rate and sodium delivery are high, as occurs with the administration of diuretics, the concentration of K^+ in the distal tubular urine is lower, favoring the secretion of K^+ into the tubule. Potassium secretion decreases when distal tubule flow rate and sodium delivery are low. However, aldosterone stimulates K^+ secretion by the distal tubule and serves to preserve K^+ secretion and K^+ balance during dehydration and extracellular volume depletion, when tubular delivery of Na^+ and flow rate are reduced.

Changes in pH and thus in hydrogen ion concentration also affect K^+ balance.¹¹ Hydrogen ions move from the ECF to the ICF during states of acidosis. When hydrogen is moving into the cell, K^+ shifts out of the cell to the ECF to maintain a balance of cations across the cell membrane. This occurs in part because of a decrease in Na^+-K^+ ATPase pump activity. The decreased ICF K^+ level in the distal tubular cells results in decreased secretion of K^+ into the urine, contributing to hyperkalemia (hyperkalemic acidosis), although the total body K^+ level may not change. In contrast, intracellular fluid levels of hydrogen are diminished during states of alkalosis. Alkalosis causes K^+ to shift into the cell, so the distal tubular cells increase their secretion of K^+ into the urine, contributing to hypokalemia (hypokalemic alkalosis). The management of alterations associated with acid-base imbalances requires that the acid-base imbalances must be treated before or concurrently with treatment of changes in K^+ concentration.

In summary, renal regulation of potassium includes:

1. The concentration gradient for K^+ at the distal tubule and collecting duct
2. The distal tubule flow rate and distal tubule sodium delivery
3. The action of aldosterone

4. Changes in pH (causing acidosis or alkalosis)

Potassium loss occurs through normal body functions, but without causing hypokalemia. Average daily losses of K^+ are as follows:

Location	Daily Loss (mEq/L)
Stool	5–10
Sweat	0–20
Urine	40–120

Potassium adaptation is the ability of the body to adapt to increased levels of K^+ intake over time. A sudden increase in K^+ level may be fatal, but if the intake is slowly increased by amounts greater than 120 mEq/day, the kidney can increase the urinary excretion of K^+ and maintain K^+ concentration balance.

Hypokalemia

◆Pathophysiology.

Potassium deficiency, or **hypokalemia**, develops when the serum K^+ concentration decreases to less than 3.5 mEq/L. Because intracellular and total body stores of K^+ are difficult to measure, changes in K^+ balance are described by the plasma concentration, although changes in total body K^+ level are not always reflected in the plasma K^+ concentration. Generally, lowered serum K^+ level indicates a loss of total body K^+ . Because K^+ is lost from the ECF, the change in the concentration gradient favors movement of K^+ from the cell to the ECF. The ICF/ECF concentration ratio is maintained, but the amount of total body K^+ is depleted.

Factors contributing to the development of hypokalemia include reduced intake of potassium, increased entry of K^+ into cells, and increased losses of body K^+ . Dietary deficiency of K^+ is a rare cause but may occur in elderly individuals with both low protein intake (meat) and inadequate intake of fruits and vegetables, and in individuals with alcoholism or anorexia nervosa. Reduced K^+ intake generally becomes a problem when combined with other causes of K^+ depletion.

ECF hypokalemia can develop without losses of total body K^+ when K^+ is redistributed between the ECF and ICF. Alkalosis, particularly respiratory alkalosis, is the most common clinical cause of these shifts. In alkalosis, ECF hydrogen moves out of the cell to correct the alkalosis, which causes K^+ to move into the cell to maintain an ionic balance. Insulin also promotes cellular uptake of K^+ and can cause an ECF potassium deficit, particularly with the intake of high carbohydrate loads. Severe, even fatal, hypokalemia may occur if insulin is administered without also providing K^+ supplements.

Treatment of pernicious anemia with vitamin B_{12} or folate also may precipitate hypokalemia if the formation of new red blood cells causes enough K^+ uptake to effect an extracellular decrease in K^+ concentration. **Familial hypokalemic periodic paralysis** is a rare genetically transmitted disease that causes K^+ to shift into the intracellular space.

Hypokalemia also can occur when K^+ shifts from the ICF to the ECF, as occurs in conjunction with renal losses. For example, in diabetic ketoacidosis, the increased hydrogen ion concentration in the ECF causes H^+ to shift into the cell in exchange for K^+ at the same time diuresis is occurring. A normal level of K^+ is maintained in the plasma, but K^+ continues to be lost in the urine, causing a deficit in the amount of total body potassium. Total body K^+ depletion becomes evident when insulin treatment and rehydration therapy are initiated.

Losses of K^+ from body stores are most commonly caused by gastrointestinal and renal disorders. Diarrhea (from any cause), intestinal drainage tubes or fistulae, and laxative abuse also may result in hypokalemia. Normally, only 5 to 10 mEq of potassium and about 100 mL of water are excreted in the stool each day. With diarrhea, fluid and electrolyte losses can be voluminous, with several liters of fluid and 100 to 200 mEq of K^+ lost per day. Vomiting or applying continuous nasogastric suction frequently is associated with K^+ depletion, partly because of the K^+ lost from the gastric fluid but principally because of renal compensation for volume depletion and the metabolic alkalosis (elevated bicarbonate levels) that occurs from sodium, chloride, and hydrogen ion losses. The loss of fluid and

sodium stimulates the secretion of aldosterone and ADH, which in turn causes renal loss of K^+ . The elevated flow of bicarbonate at the distal tubule contributes to renal excretion of K^+ because of increased tubular lumen electronegativity.

Renal losses of K^+ are related to increased secretion of K^+ by the distal tubule. Use of diuretics, excessive aldosterone secretion, increased distal tubular flow rate, and low plasma magnesium concentration all may contribute to urinary losses of K^+ . Many diuretics, including thiazides, furosemide, ethacrynic acid, and osmotic diuretics, inhibit the reabsorption of sodium chloride, causing the diuretic effect. The distal tubular flow rate then increases, promoting K^+ excretion. If sodium loss is severe, the compensating aldosterone secretion (which causes secondary hyperaldosteronism) may further deplete K^+ stores. Primary hyperaldosteronism with excessive secretion of aldosterone from an adrenal adenoma also causes K^+ wasting. Many kidney diseases result in a reduced ability to conserve sodium. The disordered sodium reabsorption produces a diuretic effect, and the increased distal tubule flow rate favors the secretion of K^+ . Magnesium deficiency and concomitant hypokalemia increase distal potassium excretion sustaining hypokalemia.¹² Several antibiotics, including amphotericin B, gentamicin, and carbenicillin, are known to cause hypokalemia.

◆Clinical Manifestations.

Mild losses of K^+ are usually asymptomatic. A wide range of dysfunctions may result from severe hypokalemia (<2.5 mEq/L).¹³ Neuromuscular excitability is decreased, causing skeletal muscle weakness, smooth muscle atony, and cardiac dysrhythmias. As [Chapter 1](#) describes, the resting membrane potential (E_m) is determined by the *ratio* of extracellular to intracellular K^+ ion concentration. Because the concentration of K^+ in the ECF is small, only small changes in ECF potassium level are required to influence the resting membrane potential and affect neuromuscular excitability (the difference between resting membrane and threshold potentials) ([Fig. 3.8, A](#)). When extracellular K^+ levels decrease rapidly,

intracellular K^+ diffuses more readily out of the cell and the resting membrane potential becomes more negative (i.e., from -90 to -100 millivolts). If the threshold potential (E_t) remains stable, the difference between resting membrane potential and threshold potential increases and the cell membrane becomes **hyperpolarized**, requiring a stronger stimulus (decreased excitability) to initiate depolarization and an action potential (Fig. 3.8, B [low K^+]).

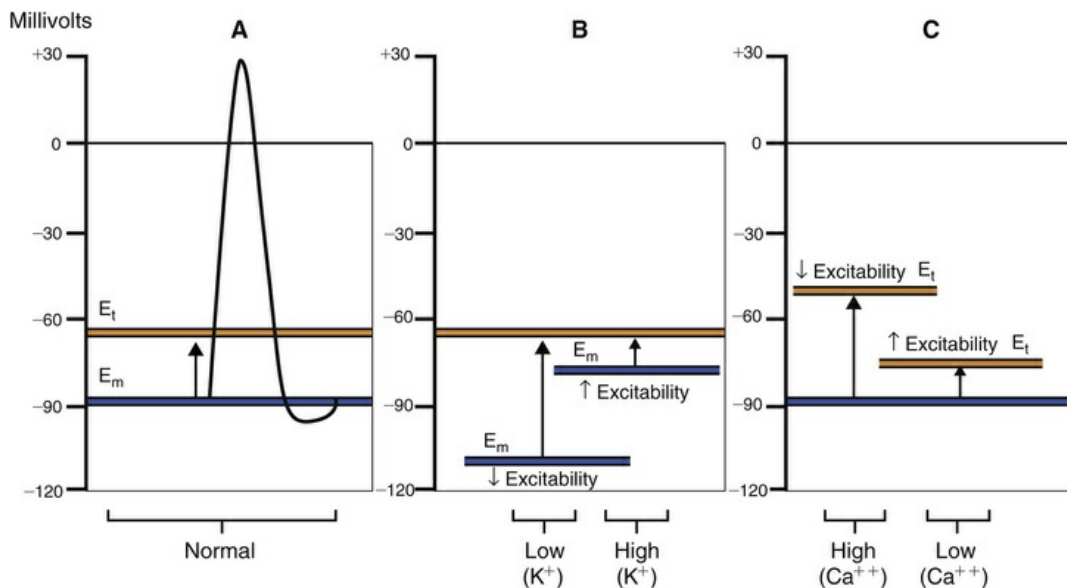

FIGURE 3.8 Effects of Potassium (K^+) and Calcium (Ca^{++}) Ions on Membrane Excitability. A, Normal membrane excitability: Potassium affects the resting membrane potential (E_m), and calcium affects the threshold potential (E_t). B, Effects of potassium ion (K^+) changes on membrane potential. C, Effect of calcium ion (Ca^{++}) on threshold potential. NOTE: *Hyperpolarization* can be caused by either hypokalemia (E_m more negative) or hypercalcemia (E_t less negative)—the distance between E_m and E_t is increased (decreased excitability); and *hypopolarization* can be caused by either hyperkalemia (E_m less negative) or hypocalcemia (E_t more negative)—the distance between E_m and E_t is decreased (increased excitability).

The *cardiac effects of hypokalemia* are related to decreased membrane excitability (see Fig. 3.8, B). Because K^+ contributes to the repolarization phase of the action potential, hypokalemia delays ventricular repolarization and the frequency of action potentials. The membrane potential remains partially depolarized with slowed

conduction and abnormal pacemaker activity. A variety of dysrhythmias may occur, including sinus bradycardia, atrioventricular block, and paroxysmal atrial tachycardia. The characteristic changes in the electrocardiogram reflect delayed repolarization. For instance, flattening of the T wave, ST-segment depression, and the presence of a U wave (Fig. 3.9). In severe states of hypokalemia, P waves peak and the QRS complex is prolonged. Hypokalemia also increases the risk of digitalis toxicity by slowing the sodium-potassium pump, which augments the action of digitalis in cardiac muscle by excessively increasing intracellular calcium and sodium concentrations.

FIGURE 3.9 Electrocardiogram (ECG) Changes With Potassium Imbalance.

Plasma calcium concentration also contributes to changes in neuromuscular excitability associated with hypokalemia. Increases in ECF calcium concentration tend to make the threshold potential (E_t) less negative and decrease membrane excitability, potentiating hyperpolarization, decreased excitability, and the neuromuscular effects of hypokalemia (Fig. 3.8, C).

Carbohydrate metabolism is affected because hypokalemia

depresses insulin secretion and alters hepatic and skeletal muscle glycogen synthesis. Renal function is impaired, with a decreased ability to concentrate urine. Polyuria (increased urine) and polydipsia (increased thirst) are associated with decreased responsiveness to ADH. Chronic potassium deficits lasting more than 1 month may damage renal tissue, with resulting interstitial fibrosis and tubular atrophy.

The onset of symptoms is related to the *rate of potassium depletion*. Because the body can accommodate slow losses of K^+ , the decrease in ECF concentration may be slow enough to allow K^+ to shift from the intracellular space. The extracellular to intracellular K^+ concentration gradient then is restored toward normal, with less severe neuromuscular changes. With acute losses of K^+ , changes in neuromuscular excitability are more profound. Skeletal muscle weakness initially occurs in the larger muscles of the legs and arms and ultimately affects the diaphragm and depresses ventilation. Paralysis and respiratory arrest then can occur. Gastrointestinal manifestations include constipation, anorexia, nausea, vomiting, paralytic ileus, and intestinal distention. [Table 3.9](#) contains a summary of K^+ alterations.

TABLE 3.9

POTASSIUM ALTERATIONS

CAUSES	HYPOKALEMIA <3.5 mEq/L	HYPERKALEMIA >5.0 mEq/L
Intake	Decreased intake: starvation or anorexia nervosa, inadequate replacement	Excess dietary or intravenous intake
Loss	Increased renal loss: renal tubular failure, K^+ -losing diuretics, hyperaldosteronism, vomiting, diarrhea, use of selected antibiotics	Decreased renal loss: renal failure, K^+ -sparing diuretics, hypoaldosteronism
Cellular shifts	Shift from ECF to ICF: metabolic alkalosis, insulin administration	Shift from ICF to ECF: metabolic acidosis, cell injury
ORGAN SYSTEM MANIFESTATIONS		
Cardiovascular	Postural hypotension Dysrhythmias ECG changes (flattened T waves, U waves,	Dysrhythmias ECG changes (peaked T waves, prolonged PR interval, absent

	ST depression, peaked P wave, prolonged QT interval) Weak, irregular pulse rate Ventricular fibrillation Cardiac arrest	P wave with widened QRS complex) Bradycardia Heart block Cardiac arrest
Nervous	Lethargy Fatigue Confusion Paresthesias Decreased tendon reflexes	Anxiety Tingling Numbness
Gastrointestinal	Nausea and vomiting Decreased motility Distention Decreased bowel sounds Ileus	Nausea and vomiting Diarrhea Colicky pain
Kidney	Inability to concentrate urine Water loss Thirst Kidney damage	Oliguria Kidney damage
Skeletal and smooth muscle	Weakness Flaccid paralysis Respiratory arrest Constipation Bladder dysfunction	Early: hyperactive muscles and reflexes Late: weakness and flaccid paralysis

K^+ , potassium; *ECF*, extracellular fluid; *ICF*, intracellular fluid; *ECG*, electrocardiogram.

◆ Evaluation and Treatment.

The diagnosis of hypokalemia is based on serum K^+ levels; however, it is important to examine the medical history and identify disorders associated with K^+ loss or shifts of extracellular K^+ to the intracellular space. An electrocardiogram will identify conduction abnormalities or arrhythmias. Treatment involves an estimation of total body K^+ losses and correction of acid-base imbalances. Further losses of K^+ should be prevented, and the individual should be encouraged to eat foods rich in K^+ . Potassium replacement is instituted cautiously to prevent hyperkalemia. The maximal rate of oral replacement is 40 to 80 mEq/day if renal function is normal. A maximal safe rate of intravenous (IV) replacement is 20 mEq/hr for adults (usually through a central IV line with cardiac monitoring); 10 mEq/hr is replaced if a

peripheral IV is used. Potassium replacement is never given IV push. Because K^+ is irritating to blood vessels, a maximal concentration of 40 mEq/1000 mL should be used. The dosage can range from 10 mEq/hour to 40 mEq/hour depending on the severity of deficiency. The 24-hour dosage should not exceed 200 mEq of potassium. Serum K^+ values can be monitored until normokalemia is achieved. Hypokalemia concurrent with hypomagnesemia is refractory to treatment until magnesium levels are corrected.

Hyperkalemia

◆Pathophysiology.

An elevation of ECF potassium concentration *greater than 5.0 mEq/L* constitutes **hyperkalemia**. Because of efficient renal excretion, excesses of total body potassium are relatively rare. Acute increases in serum K^+ concentration are handled quickly through an increase in cellular uptake and renal excretion of body K^+ excesses.

Excesses of serum K^+ may be caused by *excessive intake*, a *shift of potassium from the ICF to the ECF*, or *decreased renal excretion*.¹⁴ If renal function is normal, slow, long-term increases in K^+ intake are usually well tolerated through K^+ adaptation, although acute K^+ loading can exceed renal excretion rates. Use of stored whole blood, administration of intravenous boluses of penicillin G, or replacement of K^+ can precipitate hyperkalemia, particularly if renal function is impaired. Dietary excesses of K^+ are uncommon, but accidental ingestion of K^+ salt substitutes can cause toxicity.

Potassium shifts from the ICF to the ECF occur with a *change in cell membrane permeability* (e.g., from cell hypoxia, acidosis, or insulin deficiency). Burns, massive crush injuries, and extensive surgeries can cause cell trauma and loss of ICF potassium to the ECF. If renal function is sustained, K^+ will be excreted. As cell repair begins, hypokalemia develops if the excreted K^+ is not replaced.

Hypoxia can lead to hyperkalemia by diminishing the efficiency of cell membrane active transport, resulting in the escape of K^+ to the ECF. In states of *acidosis*, hydrogen ions shift into the cells in exchange

for ICF potassium; hyperkalemia and acidosis therefore often occur together. Because insulin promotes cellular entry of K^+ , *insulin deficits*, which occur with conditions such as diabetic ketoacidosis, are accompanied by hyperkalemia. *Digitalis overdose* may cause hyperkalemia by inhibiting the Na^+-K^+ ATPase pump. This pump normally maintains intracellular K^+ concentration and moves sodium and calcium to the ECF (see [Chapter 1](#)).

Decreased renal excretion of potassium is commonly associated with hyperkalemia. Renal failure that results in oliguria (urine output <30 mL/hr) is accompanied by elevations of serum K^+ concentration. The severity of hyperkalemia is related to the severity of renal dysfunction, the amount of K^+ intake, and the degree of acidosis from the renal failure. In acute renal failure K^+ levels rise more rapidly with more serious consequences than the slower rises associated with chronic renal failure. *Hypoaldosteronism* also can cause decreases in the urinary excretion of K^+ . For example, Addison disease results in decreased production and secretion of aldosterone and thus contributes to hyperkalemia. Drugs that decrease renal potassium excretion (i.e., ACE inhibitors, angiotensin receptor blockers, potassium-sparing diuretics, and aldosterone antagonists) also may contribute to hyperkalemia. Frequently, however, these drugs are used in combination with diuretics that cause K^+ wasting in an attempt to balance renal K^+ gains and losses.

◆Clinical Manifestations.

Symptoms of hyperkalemia vary, but common characteristics are muscle weakness or paralysis and dysrhythmias with changes in the electrocardiogram. During mild attacks, increased neuromuscular irritability may be manifested as tingling of lips and fingers, restlessness, intestinal cramping, and diarrhea. Severe hyperkalemia causes muscle weakness, loss of muscle tone, and paralysis. In mild states of hyperkalemia, the more rapid repolarization is reflected in the electrocardiogram as narrow and taller T waves with a shortened QT interval. Severe hyperkalemia (serum levels ≥ 6 mEq/L) depresses the ST segment, prolongs the PR interval, and widens the QRS

complex (loss of atrial activity) (see [Fig. 3.9](#)). Delayed conduction and bradydysrhythmias are common in hyperkalemia, with alterations in cardiac conduction causing ventricular fibrillation or cardiac arrest.

As with hypokalemia, changes in the ratio of intracellular to extracellular K^+ concentration contribute to the symptoms of hyperkalemia. If extracellular K^+ concentration increases without a significant change in intracellular K^+ concentration, the resting membrane potential becomes more positive (i.e., changes from -90 to -80 millivolts) and the cell membrane is **hypopolarized** (the inside of the cell becomes less negative or partially depolarized [increased excitability]) (see [Fig. 3.8, B](#)). (Electrical properties of cells are discussed in [Chapter 1](#).) With relatively mild elevations in extracellular K^+ concentration, the cell more rapidly repolarizes and becomes more irritable (peaked T waves). An action potential then is initiated more rapidly because the distance between the resting membrane potential and the threshold potential has been shortened. With more severe hyperkalemia, the resting membrane potential approaches or exceeds the threshold potential (wide QRS merging with T wave). In this case the cell is not able to repolarize and therefore does not respond to excitation stimuli. The most serious consequence is cardiac standstill.

Like the effects of hypokalemia, the neuromuscular effects of hyperkalemia are related to the rate of increase in the ECF potassium concentration and the presence of other contributing factors, such as acidosis and calcium balance. Long-term increases in ECF potassium concentration result in shifts of K^+ into the cell because the tendency is to maintain a normal ratio of intracellular/extracellular potassium concentrations. Acute elevations of extracellular K^+ concentration affect neuromuscular irritability because this ratio is disrupted.

Because calcium influences the threshold potential, changes in extracellular fluid calcium concentration can augment or override the effects of hyperkalemia. With hypocalcemia the threshold potential becomes more negative, enhancing the neuromuscular effects of hyperkalemia. Hypercalcemia causes the threshold potential to become less negative, counteracting the effects of hyperkalemia on

resting membrane potential (see Fig. 3.8, C). See Table 3.9 for a summary of potassium alteration.

◆Evaluation and Treatment.

Hyperkalemia should be investigated when there is a history of renal disease, massive trauma, insulin deficiency, Addison disease, use of potassium salt substitutes, or metabolic acidosis. The acuity of the onset of symptoms may be related to the underlying cause. An electrocardiogram will identify conduction abnormalities or arrhythmias.

Management of hyperkalemia is related to treating the contributing causes and correcting the potassium excess. Normalizing the extracellular potassium concentration can be achieved with a variety of methods; the treatment chosen is related to the cause and severity of the problem. Calcium gluconate can be administered to restore normal neuromuscular irritability when serum potassium levels are dangerously high. Administration of glucose, which readily stimulates insulin secretion, or administration of glucose and insulin for those with diabetes, facilitates cellular entry of potassium. Cation exchange resins can be effective for chronic hyperkalemia, and newer potassium binders are available. Buffered solutions correct metabolic acidosis and lower serum potassium level. Dialysis effectively removes potassium when renal failure has occurred.¹⁵

Calcium and Phosphate

The total body content of calcium is about 1200 g. Most calcium (99%) is located in bone as hydroxyapatite (an inorganic compound that contributes to bone rigidity), and the remainder is in the plasma and body cells. The total fraction of calcium circulating in the blood is small (9.0 to 10.5 mg/dL) and about 50% is bound to plasma proteins, primarily albumin. About 40% is in the free or ionized form (5.5 to 5.6 mg/dL). Ionized calcium has the most important physiologic functions.

Calcium (Ca⁺⁺) is a necessary ion for many fundamental metabolic processes. It is the major cation associated with the structure of bones

and teeth. It serves as an enzymatic cofactor for blood clotting and is required for hormone secretion and the function of cell receptors. Plasma membrane stability, permeability, and repair are directly related to calcium ions, as is the transmission of nerve impulses and the contraction of muscles. Intracellular calcium is located primarily in the mitochondria.

Phosphate (HPO_4^-) is found primarily in bone (85%), with smaller amounts found within the intracellular and extracellular spaces. In the plasma, phosphate exists in phospholipids and phosphate esters and as inorganic phosphate, which is the ionized form. The normal serum levels of inorganic phosphate range from 2.5 to 4.5 mg/dL and may be as high as 6.0 to 7.0 mg/dL in infants and young children. Intracellular phosphate has many metabolic forms, including the high-energy structures creatine phosphate and adenosine triphosphate (ATP). Phosphate acts as an intracellular and extracellular anion buffer in the regulation of acid-base balance; in the form of ATP it provides energy for muscle contraction.

Calcium and phosphate concentrations are rigidly controlled. They are related by the product of calcium (Ca^{++}) and phosphate (HPO_4^-) concentrations, which is a constant (K) [$\text{Ca}^{++} \times \text{HPO}_4^- = K$]. Thus, if the concentration of one ion increases or decreases, that of the other increases or decreases.

Calcium and phosphate balance is regulated by three hormones: parathyroid hormone (PTH), vitamin D, and calcitonin. Acting together, these substances determine the amount of dietary calcium and phosphate absorbed from the intestine, the deposition and absorption of calcium and phosphate from bone, and the renal reabsorption and excretion of calcium and phosphate by the kidney.

The parathyroid glands secrete PTH in response to low levels of serum calcium. (The specific actions of PTH in relation to calcium and phosphate are described in [Chapter 21](#).) **Parathyroid hormone** controls levels of ionized calcium and phosphate in the blood and other extracellular fluids. The renal regulation of calcium and phosphate balance requires PTH. PTH stimulates reabsorption of calcium along the distal tubule of the nephron and inhibits phosphate

reabsorption by the proximal tubule of the nephron. The net result is an increase in serum calcium concentration and increased urinary excretion of phosphate. Fig. 3.10 summarizes hormonal regulation of calcium.

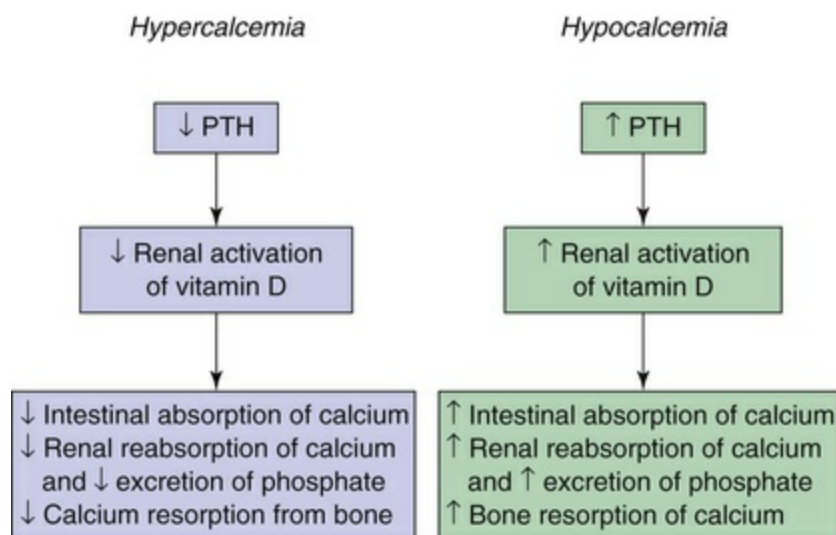

FIGURE 3.10 Hormonal Regulation of Calcium Balance. *PTH*, Parathyroid hormone.

Another compound important to calcium and phosphate regulation is vitamin D. **Vitamin D** (cholecalciferol) is a fat-soluble steroid ingested in food or synthesized in the skin in the presence of ultraviolet light. Several steps of activation are required before vitamin D can act on target tissues. The first step occurs in the liver; final activation is in the kidney. The renal activation of vitamin D begins when the serum calcium level decreases and stimulates secretion of PTH. PTH then acts to increase calcium reabsorption and enhance renal excretion of phosphate, producing decreased phosphate levels. The combination of low calcium level and increased PTH secretion causes the renal activation of vitamin D. The activated vitamin D (vitamin D₃—calcitriol) then circulates as a hormone in the plasma and acts to increase absorption of calcium and phosphate in the small intestine, enhance bone calcification, and increase renal tubular reabsorption of calcium and increase excretion of phosphate. When renal failure occurs, vitamin D is not activated; serum calcium

levels decrease; and phosphate levels increase.

As calcium levels increase, an opposite adaptation occurs, leading to suppression of PTH secretion, decreased renal vitamin D activation, decreased intestinal calcium absorption, and increased renal phosphate reabsorption. **Calcitonin** (produced by C cells of the thyroid gland) primarily decreases calcium levels by inhibiting osteoclastic activity in bone.

The fractions of serum calcium that are freely ionized or bound to plasma proteins are influenced by pH. In states of acidosis, levels of ionized calcium increase. When alkalosis develops, with an increase in pH, the amount of protein-bound calcium increases and the physiologically active, ionized calcium level decreases. The decreased concentration of ionized calcium may be great enough to cause symptoms of hypocalcemia, such as tetany.

Hypocalcemia

◆Pathophysiology.

Hypocalcemia occurs when serum total calcium concentrations are less than 9.0 mg/dL and ionized levels are less than 5.5 mg/dL. In general, deficits in calcium are related to inadequate intestinal absorption, decreases in levels of PTH and vitamin D, or deposition of ionized calcium into bone or soft tissue.

Nutritional deficiencies of calcium can occur in the instance of inadequate sources of dairy products or green, leafy vegetables and eating disorders. Excessive amounts of dietary phosphorus also bind with calcium, so neither mineral is absorbed when such an excess occurs. Removal of the parathyroid glands (e.g., during total thyroidectomy) with the resulting loss of PTH also causes hypocalcemia. Vitamin D deficiency, which can result from inadequate intake or avoidance of sunlight, causes decreased intestinal absorption of calcium. Malabsorption of fat, including fat-soluble vitamin D, also may contribute to calcium deficiency. Neoplastic bone metastases tend to inhibit bone resorption and increase calcium deposition into bone, thereby decreasing serum

calcium levels.

Blood transfusions are also a common cause of hypocalcemia because the citrate solution used in storing whole blood binds with calcium and makes it unavailable to the tissues. Pancreatitis causes release of lipases into soft tissue spaces, so the free fatty acids that are formed bind calcium, causing a decrease in the concentration of ionized calcium. Metabolic or respiratory alkalosis causes symptoms of hypocalcemia because the change in pH enhances protein binding of ionized calcium. Hypoalbuminemia lowers total serum calcium levels by decreasing the amount of bound calcium in the plasma.

◆Clinical Manifestations.

The clinical manifestations of hypocalcemia are caused primarily by an increase in neuromuscular excitability. Calcium deficits cause partial depolarization of nerves and muscle as the threshold potential becomes more negative and approaches the resting membrane potential (hypopolarization) (see [Fig. 3.8, C](#)). Therefore, a smaller stimulus is required for initiating the action potential. The symptoms are related to neuromuscular irritability and include paresthesias around the mouth and in the digits, carpopedal spasm (muscle spasms in the hands and feet), hyperreflexia, and seizures.

Two clinical signs are Chvostek sign and Trousseau sign. *Chvostek sign* is elicited by tapping on the facial nerve just below the temple. A positive sign is a twitch of the nose or lip. *Trousseau sign* is contraction of the hand and fingers when the arterial blood flow in the arm is occluded for 5 minutes with the use of a blood pressure cuff.

Severe symptoms include convulsions and *tetany*, a continuous severe muscle spasm that can cause laryngospasm and death. The characteristic electrocardiogram (ECG) change is a prolonged QT interval, indicating prolonged ventricular depolarization and decreased cardiac contractility. Intestinal cramping and hyperactive bowel sounds also may be present because hypocalcemia affects the smooth muscles of the gastrointestinal tract. [Table 3.10](#) contains a summary of the manifestations of calcium level alterations.

TABLE 3.10**ALTERATIONS IN CALCIUM, PHOSPHATE, AND MAGNESIUM LEVELS**

CAUSES	MANIFESTATIONS
Hypocalcemia (<8.5 mg/dL)	
Inadequate intestinal absorption, deposition of ionized calcium into bone or soft tissue, blood administration, or decreases in PTH and vitamin D levels; nutritional deficiencies occur with inadequate sources of dairy products or green, leafy vegetables; alkalosis, elevated calcitonin level	Increased neuromuscular excitability; tingling, muscle spasms (particularly in hands, feet, and facial muscles), intestinal cramping, hyperactive bowel sounds; osteoporosis and fractures; severe cases show convulsions and tetany; prolonged QT interval, cardiac arrest
Hypercalcemia (>10.5 mg/dL)	
Hyperparathyroidism; bone metastases with calcium resorption from breast, prostate, renal, and cervical cancer; sarcoidosis; excess vitamin D; many tumors that produce PTH; calcium-containing antacids	Many nonspecific; fatigue, weakness, lethargy, anorexia, nausea, constipation; impaired renal function, kidney stones; dysrhythmias, bradycardia, cardiac arrest; bone pain, osteoporosis, fractures
Hypophosphatemia (<2.0 mg/dL)	
Intestinal malabsorption related to vitamin D deficiency, use of magnesium- and aluminum-containing antacids, long-term alcohol abuse, and malabsorption syndromes; respiratory alkalosis; increased renal excretion of phosphate associated with hyperparathyroidism	Conditions related to reduced capacity for oxygen transport by red blood cells and disturbed energy metabolism; leukocyte and platelet dysfunction; deranged nerve and muscle function; in severe cases, irritability, confusion, numbness, coma, convulsions; possibly respiratory failure (because of muscle weakness), cardiomyopathies, bone resorption (leading to rickets or osteomalacia)
Hyperphosphatemia (>4.7 mg/dL)	
Acute or chronic renal failure with significant loss of glomerular filtration; treatment of metastatic tumors with chemotherapy that releases large amounts of phosphate into serum; long-term use of laxatives or enemas containing phosphates; hypoparathyroidism	Symptoms primarily related to low serum calcium levels (caused by high phosphate levels) similar to symptoms of hypocalcemia; when prolonged, calcification of soft tissues in lungs, kidneys, joints
Hypomagnesemia (<1.5 mEq/L)	
Malnutrition, malabsorption syndromes, alcoholism, urinary losses (renal tubular dysfunction, loop diuretics)	Behavioral changes, irritability, increased reflexes, muscle cramps, ataxia, nystagmus, tetany, convulsions, tachycardia, hypotension
Hypermagnesemia (>3.0 mEq/L)	

Usually renal insufficiency or failure; also excessive intake of magnesium-containing antacids, adrenal insufficiency	Lethargy, drowsiness; loss of deep tendon reflexes; nausea and vomiting; muscle weakness; hypotension; bradycardia; respiratory distress; heart block, cardiac arrest
---	---

PTH, Parathyroid hormone.

◆ Evaluation and Treatment.

The health history may signify underlying pathologic conditions that require further evaluation and treatment. Severe symptoms of hypocalcemia require emergency treatment with intravenous 10% calcium gluconate. Oral calcium replacement should be initiated, and serum calcium levels should be monitored. Decreasing phosphate intake facilitates long-term management of hypocalcemia.¹⁶

Hypercalcemia

◆ Pathophysiology.

Hypercalcemia with total serum calcium concentrations exceeding 10.5 mg/dL can be caused by a number of diseases.¹⁷ The most common among these are hyperparathyroidism (which can be associated with thyrotoxicosis); bone metastases with calcium resorption from breast, prostate, or cervical cancer, or hematologic malignancy; sarcoidosis; and excess vitamin D. Many tumors produce PTH and elevate the serum calcium levels. Sarcoidosis appears to increase vitamin D levels. Prolonged immobilization can also lead to hypercalcemia from enhanced bone resorption and decreased calcium deposition into bone. Acidosis decreases serum binding of calcium to albumin, increasing ionized calcium levels.

◆ Clinical Manifestations.

Many symptoms of hypercalcemia are nonspecific. Because serum calcium levels are increased, a greater amount of calcium is also contained inside the cells. The threshold potential becomes more positive (hyperpolarized) (e.g., moves from -60 to -50 millivolts) and the cell membrane becomes refractory to depolarization (decreased

excitability) because there is a greater difference between threshold potential and resting membrane potential (see Fig. 3.8, C). Thus many of the symptoms are related to loss of cell membrane excitability. (Membrane potentials and membrane excitability are discussed in Chapter 1.) Fatigue, weakness, lethargy, anorexia, nausea, and constipation are common.

Mental status changes and confusion may occur. Impaired renal function frequently develops, and kidney stones form as precipitates of calcium salts. A shortened QT segment and depressed widened T waves also may be observed on the ECG, with bradycardia and varying degrees of heart block. Table 3.10 contains a summary of the manifestations of alterations in calcium levels.

◆Evaluation and Treatment.

With elevated serum calcium levels, often a reciprocal decrease in serum phosphate values occurs. Specific diagnostic procedures to identify the contributing pathologic condition are required.

Treatment is related to the severity of symptoms and the underlying disease. When renal function is normal, oral phosphate administration is effective. When acute illness and high calcium levels are present, treatment options include intravenous administration of large amounts of normal saline to enhance renal excretion of calcium, administration of bisphosphonates in the absence of renal failure, and administration of calcitonin. Denosumab is given for hypercalcemia related to malignancies.¹⁸ Ultimately, the underlying pathologic condition must be treated.

Hypophosphatemia

◆Pathophysiology.

Hypophosphatemia is a serum phosphate level less than 2.0 mg/dL and is usually an indication of phosphate deficiency. In some conditions, total body phosphate concentration is normal but serum concentrations are low. The most common causes are intestinal malabsorption and increased renal excretion of phosphate. Inadequate

absorption is associated with vitamin D deficiency, use of magnesium- and aluminum-containing antacids (which bind with phosphorus), long-term alcohol abuse, malabsorption syndromes, and refeeding syndromes after starvation. Respiratory alkalosis can cause severe hypophosphatemia because of cellular use of phosphorus for accelerated glycolysis (ATP) formation. Increased renal excretion of phosphorus is associated with hyperparathyroidism.

◆Clinical Manifestations.

The consequences of phosphate deficiency are not clinically evident until hypophosphatemia is severe. There is reduced capacity for oxygen transport by red blood cells and disturbed energy metabolism. Transport and release of oxygen are associated with 2,3-diphosphoglycerate (2,3-DPG) and ATP levels. When phosphate is depleted, 2,3-DPG and ATP levels become low and diminish release of oxygen to the tissues, leading to hypoxia with bradycardia and varying degrees of heart block.

Leukocyte and platelet dysfunctions also are associated with hypophosphatemia. There is a greater risk of infection and blood-clotting impairment, with potential for hemorrhage. Nerve and muscle function can be affected because of derangement in energy metabolism. Muscle weakness may become serious enough to cause respiratory failure, and cardiomyopathies also can develop. Irritability, confusion, numbness, coma, and convulsions develop with severe phosphate losses. In response to low phosphate levels, bone resorption occurs and may lead to rickets or osteomalacia. (Table 3.10 contains a summary of the manifestations of phosphate level alterations.)

◆Evaluation and Treatment.

To correct the condition, the underlying cause must be identified and treated. The rate and amount of replacement are determined by the cause and presenting symptoms.¹⁹ (Table 3.10 contains a summary of the manifestations of alterations in phosphate levels.)

Hyperphosphatemia

◆Pathophysiology.

Hyperphosphatemia, or an elevated serum phosphate level of more than 4.7 mg/dL, develops with exogenous or endogenous addition of phosphorus to the ECF or with significant loss of glomerular filtration and chronic kidney disease. Because most phosphate is located in cells, the cell destruction associated with treatment of metastatic tumors with chemotherapy can release large amounts of phosphate into the ECF. Long-term use of phosphate-containing enemas or laxatives also may lead to hyperphosphatemia. Hypoparathyroidism can cause elevated phosphate levels by increasing renal tubular reabsorption of phosphate.

High levels of serum phosphate also lower serum calcium levels, and increased amounts of phosphate and calcium are deposited in bone and soft tissues. Serum calcium levels may become low enough to cause symptoms of hypocalcemia, including tetany.

◆Clinical Manifestations.

Symptoms of hyperphosphatemia are related primarily to low serum calcium levels and thus are comparable to symptoms of hypocalcemia. With prolonged hyperphosphatemia, calcification of soft tissues occurs in the lungs, kidneys, and joints. (Table 3.10 contains a summary of the manifestations of alterations in phosphate concentration.)

◆Evaluation and Treatment.

To correct hyperphosphatemia, the underlying pathologic condition must be identified and treated. Aluminum hydroxide may be administered because it binds phosphate in the gastrointestinal tract and is then eliminated; however, aluminum can be toxic, causing encephalopathy and osteomalacia. Non-aluminum, non-calcium phosphate binders (lanthanum carbonate or sevelamer), and iron-based binders are being evaluated, but cost and toxicity are concerns.²⁰ Dialysis is required for management of renal failure.

Magnesium

Magnesium (Mg⁺⁺) is a major intracellular cation, second to potassium. About 40% to 60% is stored in muscle and bone with 30% in the cells. A small amount (1%) is in the serum. Plasma concentration is 1.5 to 3.0 mg/dL with about one-third bound to plasma proteins and the rest in ionized form. Regulation of magnesium metabolism is balanced by the small intestine and kidney. Low serum levels cause renal conservation of magnesium. Magnesium is a cofactor in intracellular enzymatic reactions, protein synthesis, nucleic acid stability, and neuromuscular excitability. Calcium and magnesium often interact in reactions at the intracellular level with magnesium being an antagonist of calcium.²¹

Hypomagnesemia occurs when serum magnesium concentration is less than 1.5 mEq/L and clinical symptoms are present.²² Malnutrition, malabsorption syndromes, alcoholism, renal tubular dysfunction, metabolic acidosis, use of loop and thiazide diuretics, and prolonged use of proton pump inhibitors can cause magnesium losses. Hypomagnesemia is associated with insulin resistance, diabetes mellitus, left ventricular hypertrophy, systemic inflammation, hypoalbuminemia, and osteoporosis. Because magnesium inhibits potassium channels, loss of magnesium results in movement of potassium out of the cell, with renal excretion resulting in hypokalemia. Signs and symptoms of hypomagnesemia are similar to those of hypocalcemia. Depression, confusion, irritability, increased reflexes, muscle weakness, ataxia, nystagmus, tetany, convulsions, and tachydysrhythmias may be observed. Treatment is intramuscular or intravenous administration of magnesium sulfate. Magnesium supplementation may be beneficial in the treatment of preeclampsia, migraine, depression, coronary artery disease, and asthma.²¹ Magnesium improves myocardial metabolism and cell function; improves vascular smooth muscle tone (reduces peripheral vascular resistance and afterload); reduces cardiac dysrhythmias; and improves lipid and glucose metabolism. Magnesium also reduces vulnerability to oxygen-derived free radicals and systemic inflammation, improves human endothelial function, and inhibits

platelet function, including platelet aggregation and adhesion.

Hypermagnesemia, in which magnesium concentration is greater than 3.0 mEq/L, is rare and usually is caused by renal failure. Magnesium-containing antacids (e.g., Gaviscon, Gelusil) can potentiate excess magnesium levels. Excess magnesium concentration depresses skeletal muscle contraction and nerve function. Signs and symptoms include nausea and vomiting, muscle weakness, hypotension, bradycardia, and respiratory depression. Treatment is avoidance of magnesium-containing substances and removal of magnesium by dialysis.²³ (Table 3.10 contains a summary of the manifestations of magnesium level alterations.)

Acid-Base Balance

Acid-base balance and hydrogen ion concentration must be regulated within a narrow range for the body to function normally. Slight changes in amounts of hydrogen and pH changes can significantly alter biologic processes in cells and tissues. Hydrogen ion is necessary to maintain membrane integrity and the speed of enzymatic reactions. Most pathologic conditions disturb acid-base balance, and the degree of severity may be more harmful than the disease process.

Hydrogen Ion and pH

The hydrogen ion concentration, $[H^+]$, is commonly expressed as the pH, the negative logarithm of hydrogen ions in solution. The symbol **pH** represents the acidity or alkalinity of a solution. The logarithmic value means that as the pH changes 1 unit (e.g., from 7.0 to 6.0), the $[H^+]$ changes 10-fold (i.e., from 0.0000001 to 0.000001). The relationship is commonly expressed as follows:

$$\text{pH} = \log \frac{1}{[H^+]} \text{ or } \text{pH} = -\log_{10}[H^+]$$

As the $[H^+]$ increases, the pH decreases; likewise, as the $[H^+]$ decreases, the pH increases. The greater the $[H^+]$, the more acidic the solution and the lower the pH. The lower the $[H^+]$, the more basic the solution and the higher the pH. In biologic fluids, a pH of less than 7.4 is defined as acidic and a pH greater than 7.4 is defined as basic.

Different body fluids have different pH values as follows:

Body Fluid	pH
Gastric juices	1.0–3.0
Urine	5.0–6.0
Arterial blood	7.38–7.42
Venous blood	7.32–7.36
Cerebrospinal fluid	7.28–7.32
Pancreatic fluid and bile	7.8–8.0
Small intestinal fluid	6.5–7.5

Body acids are formed as end products of cellular metabolism. The average person generates 50 to 100 mEq/day of acid from the metabolism of proteins, carbohydrates, and fats and from loss of alkaline fluids in the stools. To maintain a normal pH, an equal amount of acid therefore must be neutralized or excreted. The lungs, kidneys, and bone are the major organs involved in the regulation of acid-base balance. The systems are interrelated and work together to regulate short- or long-term changes in acid-base status. Body acids exist in two forms: **volatile** (respiratory acids—eliminated as carbon dioxide $[CO_2]$ gas) and **nonvolatile** (metabolic acids—eliminated by the kidney or metabolized by the liver). The volatile acid is carbonic acid (H_2CO_3), which is formed from the hydration of carbon dioxide:

Carbonic acid is a weak acid, and in the presence of carbonic anhydrase, it readily dissociates into carbon dioxide and water. CO_2 is

produced as an end product of oxidative metabolism. The more oxygen that is consumed, the more CO₂ is produced. The carbon dioxide is then eliminated by pulmonary ventilation. Sulfuric, phosphoric, and other metabolic acids (lactic acid, pyruvic acid, and keto acids [such as acetoacetic acid and β-hydroxybutyric acid, associated with diabetes mellitus]) are nonvolatile strong acids produced from the incomplete metabolism of proteins, carbohydrates, and fats. (Strong acids are those that readily give up their hydrogen; weak acids do not.) Nonvolatile acids are eliminated by the renal tubules in conjunction with the regulation of the concentration of bicarbonate (HCO₃⁻). Thus the lungs and kidneys, with the help of body buffer systems, are the prime regulators of acid-base balance.

Buffer Systems

Buffering occurs in response to changes in acid-base status. **Buffers** can absorb excessive H⁺ (acid) or hydroxyl ion (OH⁻) (base) to minimize fluctuations in pH. The buffer systems are located in both the ICF and the ECF compartments, and they function at different rates. Buffer systems exist as buffer pairs, consisting of a weak acid and its conjugate base (Table 3.11). The most important plasma buffer systems are bicarbonate–carbonic acid and hemoglobin. Phosphate and protein are the most important intracellular buffers and provide a first line of defense. Ammonia and phosphate can attach hydrogen ion and are important renal buffers.

TABLE 3.11

BUFFER SYSTEMS

BUFFER PAIRS	BUFFER SYSTEM	pK VALUES	REACTION	RATE
HCO ₃ ⁻ / H ₂ CO ₃	Bicarbonate	6.1	H ₂ O + HCO ₃ ⁻ ⇌ H ₂ O + CO ₂	Instantaneous
Hb ⁻ / HHb	Hemoglobin	7.3	HHb ⇌ H ⁺ + Hb ⁻	Instantaneous
HPO ₄ ⁻ / H ₂ PO ₄	Phosphate	6.8	HPO ₄ ⁻ + H ₂ O ⇌ H ₂ PO ₄	Instantaneous
Pr ⁻ / HPr	Plasma proteins	6.7	HPr ⇌ H ⁺ + Pr ⁻	Instantaneous

ORGANS	MECHANISM	RATE
Lungs	Regulates retention or elimination of CO ₂ and therefore H ₂ CO ₃ concentration	Minutes to hours
Ionic shifts	Exchange of intracellular potassium and sodium for hydrogen	2–4 hours
Kidneys	Bicarbonate reabsorption and regeneration, ammonia formation, phosphate buffering	Hours to days
Bone	Exchanges of calcium and phosphate, release of carbonate	Hours to days

H^+ , Hydrogen ion; HCO_3^- , bicarbonate; H_2CO_3 , carbonic acid; Hb^- , hemoglobin; HHb , hydrogenated hemoglobin; $H_2PO_4^-$, monobasic phosphate; HPO_4^{2-} , dibasic phosphate; HPr , hydrogenated protein; Pr^- , protein.

An important factor for effective buffering is a function known as the *pK value*, which represents the pH at which a buffer pair is half dissociated. Buffer pairs can associate and dissociate (see [Table 3.11](#)).

The pK provides a rate constant for the chemical reaction. A buffer system is most effective when the pK for the buffer is close to the pH of the fluid in which the buffer is acting. There is an equal concentration of acid and its conjugate base when pK equals pH. For the bicarbonate–carbonic acid buffer system, the pK is 6.1. This value is not as high as the pK for other buffer systems (see [Table 3.11](#)), but this buffer system is still very effective because carbon dioxide is rapidly removed from the blood by the lungs.

The pK value is also a term in the equation used to determine pH. The relationships among pH, pK, and the ratio of bicarbonate to carbonic acid can be expressed as follows by the *Henderson-Hasselbalch equation*:

$$pH = pK + \log \frac{[HCO_3^-]}{[H_2CO_3]}$$

The pH then can be determined when specific values are included in the equation:

$$\begin{aligned}
\text{pH} &= \text{pK} + \log \frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]} \\
&= 6.1 + \log \frac{24}{1.2} \\
&= 6.1 + \log \frac{20}{1} \\
&= 6.1 + 1.3 \\
&= 7.40
\end{aligned}$$

Carbonic Acid–Bicarbonate Buffering

The **carbonic acid–bicarbonate buffer** pair operates in both the lung and the kidney. The greater the carbon dioxide partial pressure (PCO_2), the more carbonic acid is formed. The relationship that exists between carbonic acid concentration ($[\text{H}_2\text{CO}_3]$) and carbon dioxide partial pressure (PCO_2) can be expressed as follows:

$$[\text{H}_2\text{CO}_3] = 0.03 \times \text{PCO}_2 (\text{mmHg})$$

The 0.03 represents the solubility coefficient for carbon dioxide in water. The PCO_2 of arterial blood (PaCO_2) is normally about 40 mmHg. Therefore, the amount of H_2CO_3 is equal to about 1.2 mmol/L (0.03×40). As the amount of carbon dioxide increases or decreases, the amount of H_2CO_3 changes in the same direction.

The relationship between the levels of bicarbonate and carbonic acid is usually expressed as a ratio. When the pH is 7.40, this ratio is 20 : 1 (bicarbonate/carbonic acid) (Fig. 3.11). The ratio is defined by the amount of bicarbonate and carbon dioxide (carbonic acid) in the arterial blood. Bicarbonate concentration ($[\text{HCO}_3^-]$) is normally about 24 mEq/L. Therefore, the 20 : 1 ratio can be developed as follows:

FIGURE 3.11 Ratio of Carbonic Acid and Bicarbonate Concentration in Maintaining pH Within Normal Limits. An increase in H_2CO_3 or decrease in HCO_3^- concentration causes acidosis. A decrease in H_2CO_3 or increase in HCO_3^- concentration causes alkalosis. *NL*, Normal. (From Monahan FD et al: *Medical-surgical nursing: health and illness perspectives*, ed 8, St Louis, 2007, Mosby.)

$$\frac{[\text{HCO}_3^-] = 24 \text{ mEq/L}}{[\text{H}_2\text{CO}_3] = (0.03 \times 40 \text{ mmHg})} = \frac{24}{1.2} = \frac{20}{1}$$

When the values for $[\text{HCO}_3^-]$ and PaCO_2 ($[\text{H}_2\text{CO}_3]$) increase or decrease proportionately, the 20 : 1 ratio is maintained.

The lungs can decrease the amount of carbonic acid by exhaling CO_2 and leaving water. The kidneys can reabsorb bicarbonate or regenerate new bicarbonate from CO_2 and water. The renal mechanism does not act as rapidly as the lungs, but the two systems are very effective together because acid concentration can be rapidly adjusted by the lungs and bicarbonate is easily reabsorbed or regenerated by the kidneys. The pH equation can be symbolically expressed as follows:

$$\text{pH} = \frac{\text{Base}}{\text{Acid}} \text{ or } \text{pH} = \frac{\text{Renal regulation (slow)}}{\text{Pulmonary regulation (fast)}}$$

or

$$\text{pH} = \frac{\text{Metabolic acid-base function}}{\text{Respiratory acid-base function}}$$

Changes in either the numerator or the denominator will change the pH. For example, if the amount of bicarbonate is decreased, the pH also decreases, causing a state of acidosis. The pH can be returned to a normal range if the value of the denominator or the amount of carbonic acid also decreases. When a disease process causes an alteration in the bicarbonate/carbonic acid ratio, the kidneys or lungs (i.e., the organ not responsible for causing the alteration) respond to restore the ratio and maintain a normal pH. Renal and respiratory adjustments to *primary* changes in pH are known as **compensation**. With compensation, a 20:1 ratio may be achieved, but the actual values for HCO_3^- and H_2CO_3 concentrations are not normal. The respiratory system compensates for changes in pH by increasing or decreasing ventilation, a rapid response occurring within minutes to hours. The renal system compensates by producing more acidic or more alkaline urine, which may take hours to days. **Correction** occurs when the values for both components of the buffer pair ratio (bicarbonate and carbonic acid) return to normal (Fig. 3.12).

FIGURE 3.12 Compensated Maintenance of $[\text{HCO}_3^-]/\text{PCO}_2$ (H_2CO_3) Ratio in Metabolic Acidosis.

Protein Buffering

Both intracellular and extracellular proteins have negative charges and can serve as buffers for H^+ , but because most proteins are inside cells, they are primarily an intracellular buffer system. Hemoglobin (Hb) is an excellent intracellular blood buffer because of its ability to bind with H^+ (forming HHb) and carbon dioxide (forming HHbCO₂). Hemoglobin bound to H^+ becomes a weak acid. Less oxygen-saturated hemoglobin (venous blood) is a better buffer than hemoglobin

saturated with oxygen (arterial blood). The pH control system is illustrated in Fig. 3.13.

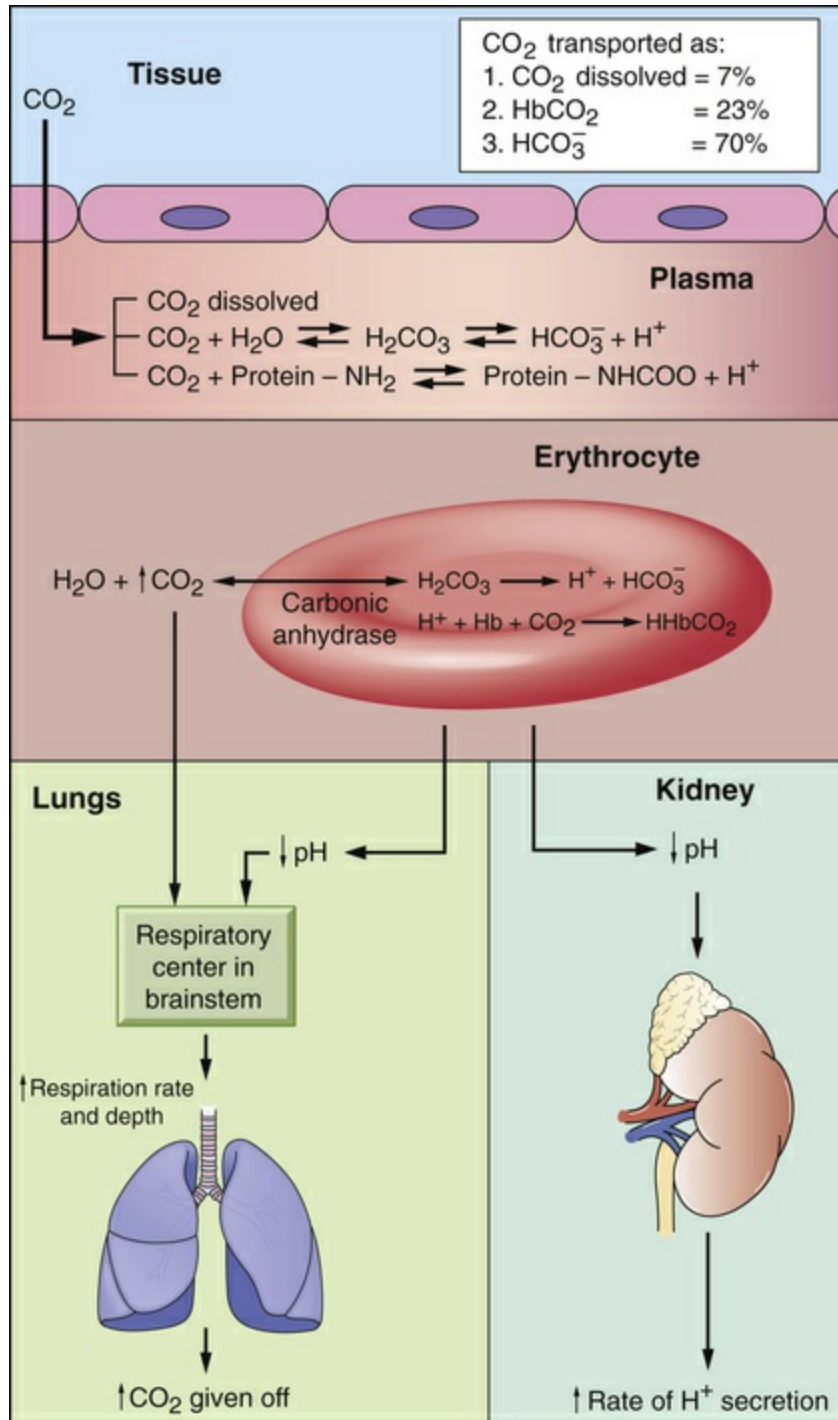

FIGURE 3.13 Integration of pH Control Mechanisms. CO₂ is produced in tissue cells and diffuses to plasma, where it is transported as dissolved

CO₂, or it combines with water to form carbonic acid (H₂CO₃), or it combines with protein from which hydrogen has been released. Most of the CO₂ diffuses into the red blood cells and combines with water to form H₂CO₃. The H₂CO₃ dissociates to form hydrogen ion (H⁺) and bicarbonate (HCO₃⁻). Hydrogen ion combines with hemoglobin that has released its oxygen to form HHb, which buffers the hydrogen ion and makes venous blood slightly more acidic than arterial blood. The increase in H⁺ concentration coupled with elevated CO₂ levels results in HHbCO₂ and an increase in the respiratory rate (eliminates CO₂) and secretion of H⁺ by the kidneys.

Respiratory and Renal Buffering

The respiratory system regulates acid-base balance by controlling the rate of ventilation when there is metabolic acidosis or alkalosis. Central chemoreceptors sense increases or decreases in pH and PaCO₂. When acidemia exists, the respiratory rate increases (eliminating CO₂ and reducing carbonic acid concentration) (see Fig. 3.13). When alkalemia occurs, the respiratory rate decreases (retaining CO₂ and increasing carbonic acid concentration).

The distal tubule of the kidney regulates acid-base balance by secreting hydrogen into the urine and regenerating bicarbonate with a maximum urine acidity of a pH of about 4.4 to 4.7. Buffers in the tubular fluid combine with hydrogen ions, allowing more H⁺ to be secreted before the limiting pH value is reached. Dibasic phosphate (HPO₄⁻) and ammonia (NH₃) are two important renal buffers because they can attach hydrogen ions and be secreted into the urine. Dibasic phosphate is filtered at the glomerulus. About 75% is reabsorbed, and the remainder is available for buffering H⁺. Secreted H⁺ combines with HPO₄⁻ to form monobasic phosphate (H₂PO₄⁻). The remaining negative charge on the molecule makes it lipid insoluble, preventing it from diffusing back across the tubular cells and into the blood. Thus the H₂PO₄⁻ containing the secreted H⁺ is excreted in the urine (Fig. 3.14).

FIGURE 3.14 Renal Excretion of Acid. 1, *Conservation of Filtered*

Bicarbonate. Filtered bicarbonate (HCO_3^-) combines with secreted hydrogen ion (H^+) in the presence of carbon anhydrase (CA) to form carbonic acid (H_2CO_3), which then dissociates to water (H_2O) and carbon dioxide (CO_2); both diffuse into the renal tubular cell. The CO_2 and H_2O combine to form

H_2CO_3 in the presence of CA, and the resulting bicarbonate ion (HCO_3^-) is reabsorbed into the blood. 2, *Formation of Titratable Acid.* Hydrogen ion

(H^+) is secreted and combines with dibasic phosphate (HPO_4^{2-}) to form monobasic phosphate (H_2PO_4^-). The secreted hydrogen ion (H^+) is formed

from the dissociation of H_2CO_3 , and the remaining HCO_3^- is reabsorbed into the blood. 3, *Formation of Ammonium.* Ammonia (NH_3) is produced from

glutamine in the renal tubular cell and diffuses to the urine where it combines with H^+ to form ammonium ion (NH_4^+). Once NH_4^+ has been formed it cannot return to the renal tubular cell (diffusional trapping) and the bicarbonate remaining in the renal tubular cell is reabsorbed into the blood. NOTE: The white circles with the arrows on top represent a renal tubular cell active transport pump.

Ammonia (NH_3) is an important renal buffer; it is not ionized (does not carry a charge), and therefore it is lipid soluble and can cross the tubular cell membrane. The presence of NH_3 in the tubular cells creates a concentration gradient, and it diffuses into the renal tubular fluid, where it combines with hydrogen to form ammonium ion (NH_4^+), which is eliminated in the urine (see Fig. 3.14). NH_4^+ is lipid insoluble and does not readily diffuse back into the tubular cells. The renal buffering of hydrogen ions requires the use of CO_2 and H_2O to form H_2CO_3 . The enzyme carbonic anhydrase catalyzes the formation of H^+ + HCO_3^- . The hydrogen is secreted from the tubular cell and buffered in the lumen by phosphate and ammonia. The bicarbonate is reabsorbed. The end effect is the addition of new bicarbonate, which contributes to the alkalinity of the plasma, because the hydrogen ion is excreted from the body (see Fig. 3.14).

Other Buffers

A cellular ion exchange mechanism is also an important buffering system. The best example is the shift of potassium in exchange for hydrogen during states of acidosis or alkalosis. During acidosis, potassium tends to leave the intracellular space in exchange for hydrogen. The reverse occurs during alkalosis. Although the ionic shifts facilitate buffering, the changes in intracellular or extracellular potassium concentrations may have serious consequences (e.g., hyperkalemia or hypokalemia).

Acid-Base Imbalances

Pathophysiologic changes in the concentration of hydrogen ion or base in the blood lead to acid-base imbalances. **Acidemia** is a state in

which the pH of arterial blood is less than 7.35. A systemic increase in hydrogen ion concentration or a loss of base is termed **acidosis**. **Alkalemia** is a state in which the pH of arterial blood is greater than 7.45. A systemic decrease in hydrogen ion concentration or an excess of base is termed **alkalosis**. Acid-base imbalances may have a metabolic or respiratory etiology or may be of mixed etiology. Acid-base imbalances are assessed using a measurement of arterial blood gases that includes the reporting of pH, PaCO₂, and HCO₃⁻ concentration. The medical history is important to determining the cause of the disorder.²⁴ Fig. 3.15 summarizes the relationships among pH, PaCO₂, and bicarbonate concentration during different primary acid-base alterations and the associated renal and respiratory compensatory changes. The ratio of the concentration of HCO₃⁻ and PCO₂ is altered.

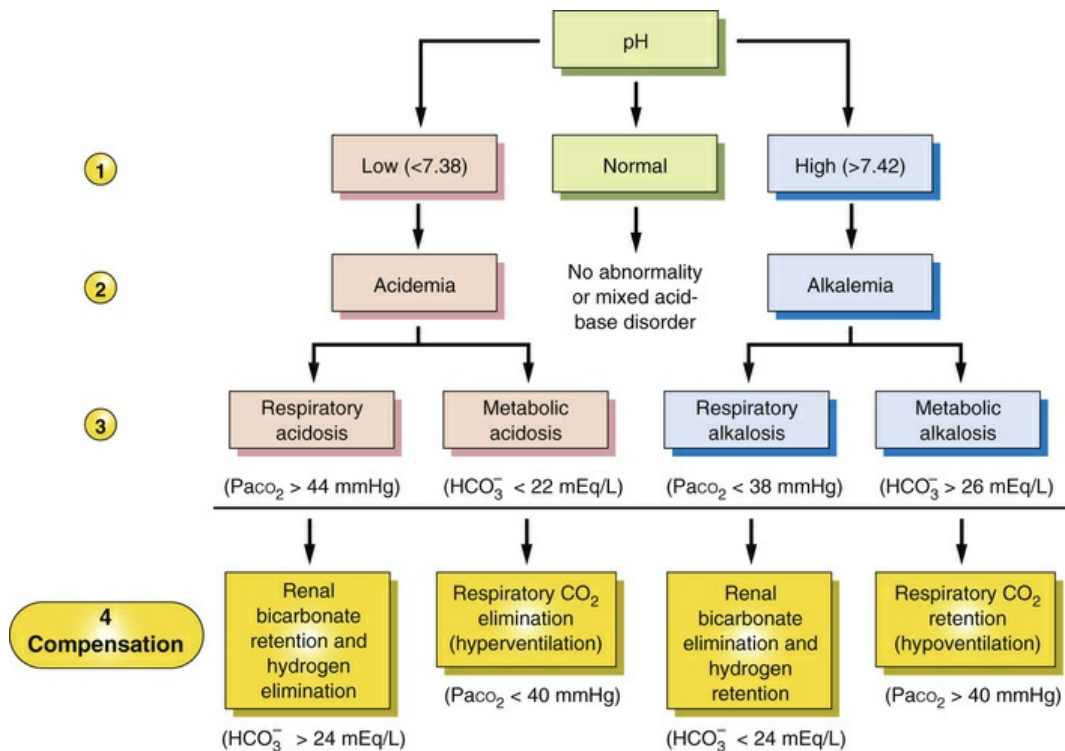

FIGURE 3.15 Primary and Compensatory Acid-Base Changes. A systematic approach can be used to interpret the cause of an acid-base imbalance. 1, Is the pH low or high? 2, If the pH is low there is acidemia; if the pH is high there is alkalemia. 3, If the pH is low (acidemia), is the cause

respiratory (high PaCO₂) or metabolic (low HCO₃⁻)? If the pH is high (alkalemia), is the cause respiratory (low PaCO₂) or metabolic (high HCO₃⁻)?

4. Is there compensation for the primary acid-base disorder? (a) HCO₃⁻ will be ≥24 mEq/L if there is renal compensation for a primary respiratory acidosis; (b) PaCO₂ will be <40 mmHg if there is respiratory compensation of a primary metabolic acidosis; (c) HCO₃⁻ will ≤24 mEq/L if there is renal compensation for primary respiratory alkalosis; (d) PaCO₂ will be >40 mmHg if there is respiratory compensation for primary metabolic alkalosis. NOTE: Examine the pH first. Then examine the changes in HCO₃⁻ and PaCO₂. HCO₃⁻ concentration will be elevated when there is primary metabolic alkalosis or renal compensation for primary respiratory acidosis. HCO₃⁻ concentration will be decreased when there is primary metabolic acidosis or renal compensation for primary respiratory alkalosis. PaCO₂ will be elevated when there is primary respiratory acidosis or respiratory compensation for primary metabolic alkalosis. PaCO₂ will be decreased when there is primary respiratory alkalosis or respiratory compensation for metabolic acidosis.

Metabolic Acidosis

◀Pathophysiology.

In **metabolic acidosis**, the concentration of non-carbonic acids increases or bicarbonate (base) is lost from the extracellular fluid or cannot be regenerated by the kidney (Table 3.12). This can occur quickly, as in from poor perfusion or hypoxemia, or more slowly, as in renal failure (failure to excrete acid), starvation states, or diabetic ketoacidosis (excess production of keto acids from lack of insulin) (see Chapter 22). There is a decrease in the 20 : 1 ratio of HCO₃⁻ and H₂CO₃.

TABLE 3.12

CAUSES OF METABOLIC ACIDOSIS

INCREASED NON-CARBONIC ACIDS (ELEVATED ANION GAP)	BICARBONATE LOSS (NORMAL ANION GAP)
Increased H ⁺ load—overproduction of acid	Diarrhea
Ketoacidosis (e.g., diabetes mellitus, alcoholic ketoacidosis,	Ureterosigmoidoscopy

starvation)	Early renal failure
Lactic acidosis (e.g., shock)	Proximal renal tubule acidosis
Ingestions (e.g., ammonium chloride, ethylene glycol, methanol, salicylates, paraldehyde)	
Decreased H ⁺ excretion	
Advanced renal failure	
Distal renal tubule acidosis	

The buffer systems compensate for the excess acid and attempt to maintain the arterial pH within a normal range. Hydrogen ions will move to the intracellular space, and potassium will move to the extracellular space to maintain an ionic balance. Buffering by bicarbonate lowers the serum value of hydrogen ions and increases the pH. The respiratory system compensates for a metabolic acidosis as the reduced pH stimulates hyperventilation, lowering the PaCO₂ and the amount of H₂CO₃ circulating in the blood. The kidneys excrete the excess acid as NH₄⁺ and titratable acid (H₂PO₄⁻). When acidosis is severe, buffers become depleted and cannot compensate for the increasing H⁺ load and the pH continues to decrease. The ratio of bicarbonate to carbonic acid decreases to less than 20:1 (Fig. 3.16). In states of metabolic acidosis, potassium is redistributed from the intracellular to the extracellular space, and is reabsorbed at the apical membrane of the renal collecting tubule. There is also an increase in the levels of ionized calcium because acidosis decreases the amount of calcium bound to albumin.

FIGURE 3.16 Metabolic Acidosis With Compensation and Correction. See text for abbreviations. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

The evaluation of the **anion gap** can be helpful when used cautiously to distinguish different types of metabolic acidosis.²⁵ Normally, the concentrations of cations and anions in the plasma are equivalent. Some anions, such as protein, sulfates, phosphates, and organic acids, however, are not measured in the common laboratory evaluations of the blood. Therefore the normal anion gap represents these unmeasured negative ions (sulfate, phosphate, lactate, keto acids, albumin). A convenient measure of the anion gap is the difference between the sum of Na⁺ and K⁺ concentrations and the sum of HCO₃⁻ and Cl⁻ concentrations, or about 10 to 12 mEq/L:

$$\text{Anion gap} = [\text{Na}^+ (140) + \text{K}^+ (4.0)] - [\text{HCO}_3^- (24) + \text{Cl}^- (110)] = 10 - 12 \text{ mEq/L}$$

In metabolic acidosis a **normal anion gap** is characteristic of conditions related to bicarbonate loss with retention of chloride to maintain an ionic balance. This is called **hyperchloremic metabolic acidosis** and it occurs with renal failure or prolonged diarrhea with bicarbonate loss. An elevated anion gap is characteristic of acidosis associated with accumulation of anions other than chloride (see [Table 3.12](#)).

◆Clinical Manifestations.

Metabolic acidosis is manifested by changes in the neurologic, respiratory, gastrointestinal, and cardiovascular systems. Headache and lethargy are early symptoms, which progress to confusion and coma with severe acidosis. Deep, rapid respirations (Kussmaul respirations) are indicative of respiratory compensation. Anorexia, nausea, vomiting, diarrhea, and abdominal discomfort are common. Severe acidosis can compromise ventricular contraction and produce life-threatening dysrhythmias.

◆Evaluation and Treatment.

The diagnosis of metabolic acidosis is established from the health

history, clinical symptoms, and laboratory findings. Arterial blood pH is below 7.35, and bicarbonate concentration is less than 22 mEq/L. The anion gap can isolate the specific cause. The oxyhemoglobin curve is shifted to the right (see Fig. 35.16), reducing hemoglobin affinity for oxygen.

The underlying condition must be diagnosed to establish effective treatment with a buffering solution. During severe acidosis (pH \leq 7.1), base administration is required to elevate the pH to a safe level, particularly if there is renal failure. Accompanying sodium and water deficits must also be corrected.²⁶

Metabolic Alkalosis

◆Pathophysiology.

Metabolic alkalosis occurs when bicarbonate concentration is increased, usually caused by excessive loss of metabolic acids. There is an increase in the 20 : 1 ratio of HCO_3^- and H_2CO_3 . Conditions that can result in metabolic alkalosis are hydrogen and chloride depletion (i.e., prolonged vomiting, gastric suctioning), excessive bicarbonate intake, hyperaldosteronism with hypokalemia, and diuretic therapy.²⁷

Respiratory compensation for metabolic alkalosis occurs when the elevated pH inhibits the respiratory center. The rate and depth of ventilation are decreased, causing retention of carbon dioxide. The ratio of HCO_3^- concentration to H_2CO_3 concentration is reduced toward normal. Respiratory compensation is not very efficient, however, and chronic or severe metabolic alkalosis requires therapeutic intervention (Fig. 3.17).

FIGURE 3.17 Metabolic Alkalosis With Compensation and Correction. See text for abbreviations. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

Hypochloremic metabolic alkalosis occurs when acid loss is caused by vomiting or gastric suctioning with depletion of ECF sodium, chloride, and potassium. Renal compensation is not very effective because the volume depletion and loss of electrolytes stimulate a paradoxical response by the kidneys. The kidneys increase bicarbonate reabsorption to maintain an anionic balance because the ECF chloride concentration is decreased. The resulting excretion of H^+ and reabsorption of bicarbonate prevent correction of the alkalosis (Fig. 3.18). The kidneys also increase sodium reabsorption. When potassium concentration is depleted, hydrogen ion moves to the intracellular space and is excreted to maintain an electrochemical balance.

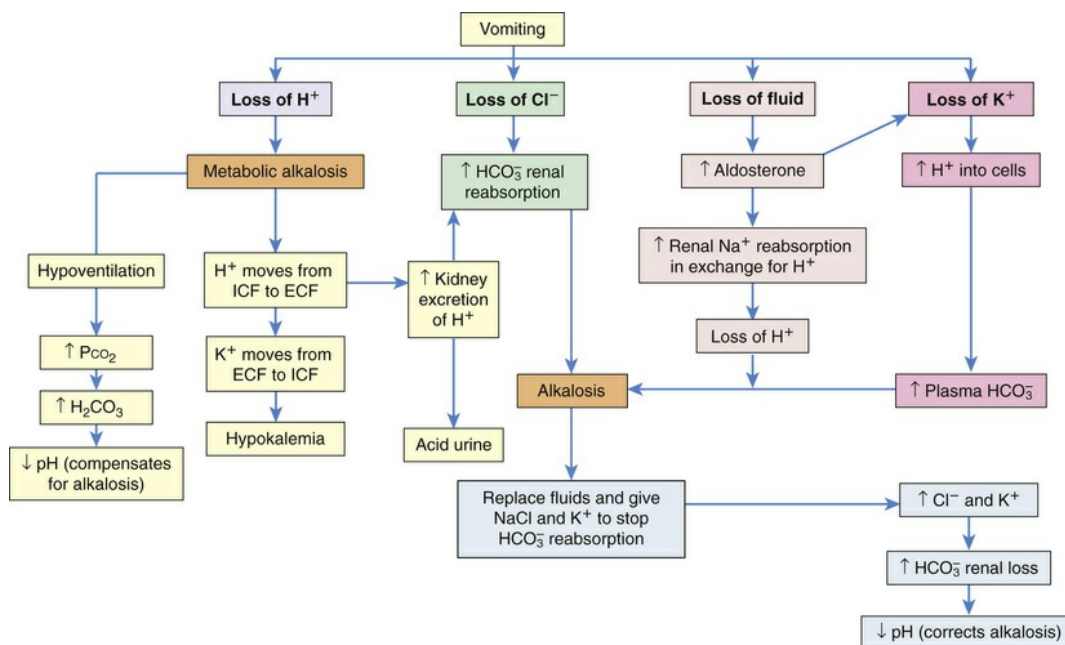

FIGURE 3.18 Hypochloremic Metabolic Alkalosis. See text for abbreviations.

With alkalemia, hydrogen ions are redistributed from the intracellular to the extracellular space and potassium moves to the intracellular space to preserve electroneutrality. With hyperaldosteronism, the excess aldosterone causes sodium retention and loss of hydrogen and potassium ions. Mild volume expansion

ensues, and bicarbonate is retained along with the sodium, thereby causing alkalosis. Diuretics, such as thiazides, ethacrynic acid, and furosemide, produce mild alkalosis by enhancing sodium, potassium, and chloride excretion more than bicarbonate excretion.

◆Clinical Manifestations.

Because of the many causes of metabolic alkalosis, the symptoms vary. Some common symptoms, such as weakness, muscle cramps, and hyperactive reflexes, are related to volume depletion and electrolyte losses. Because alkalosis increases binding of Ca^{++} to plasma proteins (albumin), ionized calcium concentration decreases, causing excitable cells to become hypopolarized, which initiates an action potential more easily. Paresthesias (especially numbness/tingling of the fingertips and perioral area), tetany, and seizures may develop (see [Hypocalcemia](#)).

Respirations are slow and shallow to increase carbon dioxide retention. Confusion and convulsions occur with severe alkalosis. Atrial tachycardia is a potential problem. The oxyhemoglobin curve is shifted to the left (see [Fig. 35.16](#)), decreasing the dissociation of oxyhemoglobin and increasing the risk of dysrhythmias.

◆Evaluation and Treatment.

The health history provides significant clues to the diagnosis of metabolic alkalosis. The arterial pH is greater than 7.45, and bicarbonate levels exceed 26 mEq/L. With respiratory compensation, the PaCO_2 rises above 40 mmHg. With hypochloremic metabolic alkalosis, serum chloride values are below normal. Serum potassium levels are usually depleted because hydrogen is released from the cells in exchange for potassium to help regulate the pH level. The potassium is then secreted from renal distal tubule cells into the urine.

With hypochloremic alkalosis or contraction alkalosis with volume depletion, a sodium chloride solution is required for *correction*. The renal stimulus to increase ECF volume by retaining Na^+ is diminished, and HCO_3^- can be excreted as NaHCO_3 in the urine. The administration of potassium corrects alkalosis caused by hyperaldosteronism or

hypokalemia. The potassium causes hydrogen to move back into the ECF and decreases loss of hydrogen from the distal tubule.

Respiratory Acidosis

◆Pathophysiology.

Respiratory disorders of acid-base balance are caused by increases or decreases of alveolar ventilation in relation to the metabolic production of carbon dioxide. **Respiratory acidosis** occurs when there is alveolar hypoventilation. Carbon dioxide is retained, increasing $[H^+]$ (as H_2CO_3), thus decreasing the ratio of HCO_3^- to PCO_2 , and producing acidosis. Carbon dioxide excess in the blood is called **hypercapnia**. The common causes include depression of the respiratory center (brainstem trauma, oversedation), paralysis of the respiratory muscles, disorders of the chest wall (kyphoscoliosis, pickwickian syndrome, flail chest), and disorders of the lung parenchyma (e.g., pneumonitis, pulmonary edema, and chronic obstructive lung disease).

Respiratory acidosis may be acute or chronic.²⁸ Airway obstruction is the most common cause of acute respiratory acidosis. Acute compensation for respiratory acidosis is not effective because the renal buffer mechanism takes time to function. Further, the protein buffers provide marginal compensation, and HCO_3^- is not a good buffer for CO_2 . Acute uncompensated respiratory acidosis is characterized by decreased arterial pH, elevated $PaCO_2$, and normal or slightly increased bicarbonate concentration.

Chronic respiratory acidosis is commonly associated with chronic obstructive pulmonary disease and deformities of the chest wall or neuromuscular disorders. Renal compensation is effective and is established over several days. The acidosis produced from CO_2 retention stimulates the kidney to secrete hydrogen ions and regenerate bicarbonate. Serum bicarbonate and $PaCO_2$ levels are elevated, and pH is restored toward normal (Fig. 3.19).

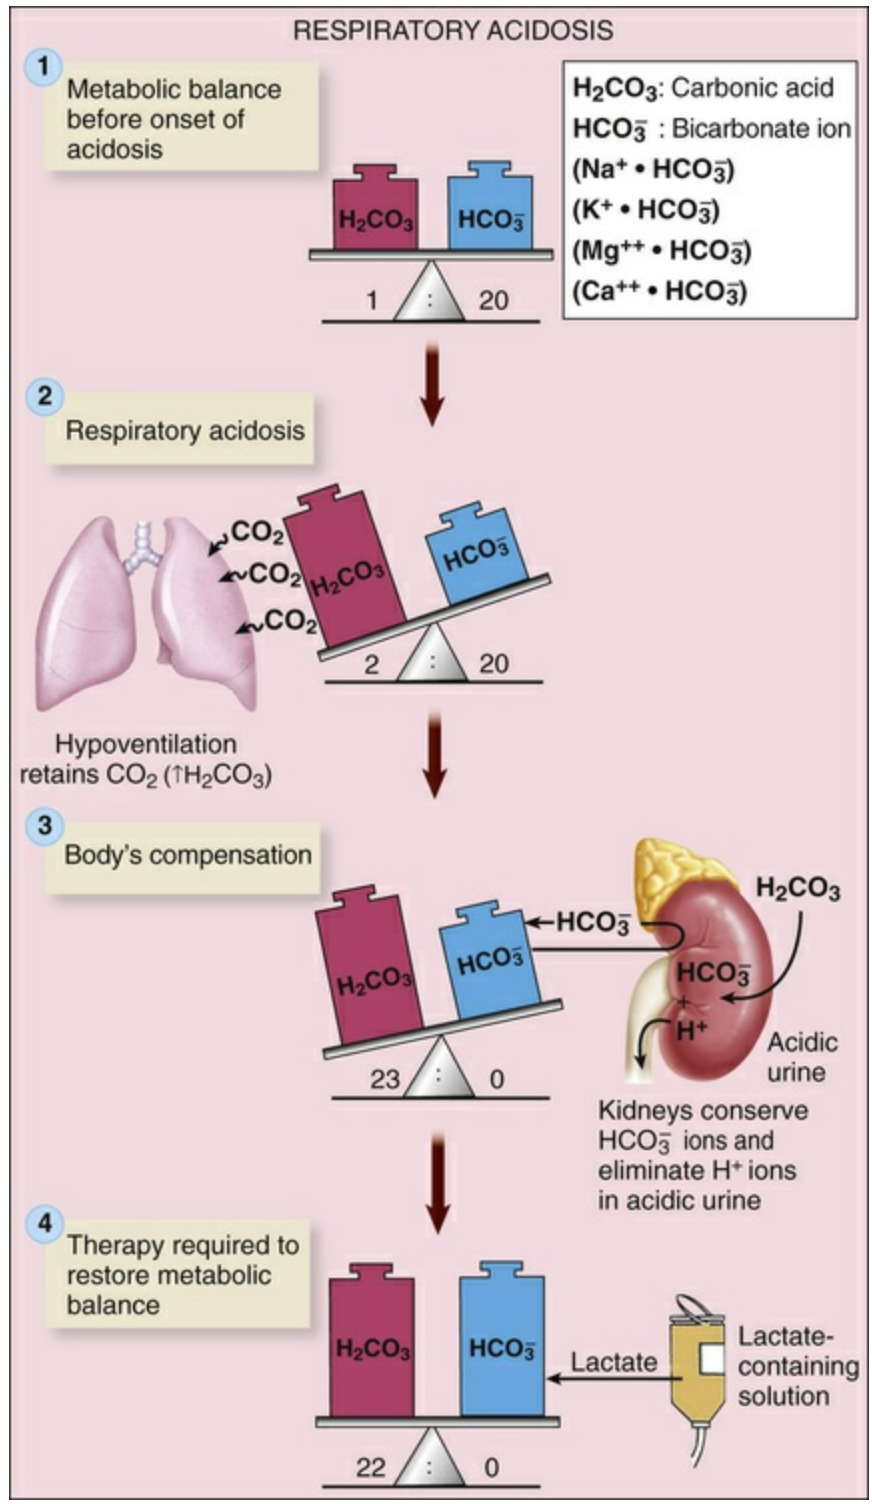

FIGURE 3.19 Respiratory Acidosis With Compensation and Correction. See text for abbreviations. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

◀ **Clinical Manifestations.**

The symptoms of respiratory acidosis are related to acuity of onset and severity of PaCO₂ retention. Initial symptoms include headache, restlessness, blurred vision, and apprehension. Lethargy, muscle twitching, tremors, convulsions, and coma follow. Chronic acidosis causes myocardial depression, arrhythmias, and hypotension. Neurologic symptoms are caused by a decrease in the pH of cerebrospinal fluid and vasodilation because CO₂ readily crosses the blood-brain barrier. The respiratory rate is rapid at first and gradually becomes depressed because over time, the respiratory center adapts to increasing levels of CO₂. Cyanosis does not occur unless there is an accompanying hypoxemia, and the skin may instead be pink from vasodilation caused by the elevated CO₂ level.

◆Evaluation and Treatment.

The primary diagnostic indicators are an arterial pH less than 7.35 and hypercapnia. Acute respiratory acidosis must be distinguished from chronic acidosis; the health history and clinical laboratory data are therefore helpful.

In many cases, restoration of adequate alveolar ventilation removes excess CO₂. If alveolar ventilation cannot be maintained spontaneously because of drug overdose or neuromuscular disorders, mechanical ventilation is required. When the hypercapnia is caused by alterations in gas diffusion at the alveolar-capillary membrane, ventilation may not be effective. The values of arterial pH, PCO₂, PO₂, and HCO₃⁻ must be carefully monitored. Rapid reduction of PaCO₂ can cause respiratory alkalosis with seizures and death.

The underlying diseases are treated to achieve maximal ventilation. In the presence of hypoxemia and hypercapnia, oxygen can function as a respiratory depressant when the respiratory center is no longer stimulated by the lower pH and elevated PaCO₂ value. Therefore, when oxygen is administered in this situation, the individual should be monitored for respiratory depression.

Respiratory Alkalosis

◀Pathophysiology.

Respiratory alkalosis occurs when there is alveolar hyperventilation and decreased concentration of plasma carbon dioxide (termed **hypocapnia**), thus increasing the ratio of HCO_3^- to PCO_2 (H_2CO_3). Stimulation of ventilation is precipitated by hypoxemia (i.e., high altitudes); hypermetabolic states such as fever, anemia, and thyrotoxicosis; early salicylate intoxication; or anxiety or panic disorder. Improper use of mechanical ventilators can cause iatrogenic respiratory alkalosis. Secondary respiratory alkalosis may develop from hyperventilation stimulated by metabolic acidosis, causing a mixed acid-base disorder.

The onset of acute respiratory alkalosis occurs within minutes of hyperventilation. Cellular buffers provide immediate compensation (i.e., protein and shifts of H^+ from ICF to ECF). The H^+ shifts are not very effective, however, if the PaCO_2 level is significantly decreased. When chronic respiratory alkalosis is present, renal compensation restores pH toward normal by decreasing H^+ excretion and bicarbonate absorption (Fig. 3.20).

FIGURE 3.20 Respiratory Alkalosis With Compensation and Correction. See text for abbreviations. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

◀ **Clinical Manifestations.**

Respiratory alkalosis, like metabolic alkalosis, is irritating to the central and peripheral nervous systems. Symptoms include dizziness, confusion, tingling of extremities (paresthesias), convulsions, and coma. Carpopedal spasm and other symptoms of hypocalcemia are similar to those of metabolic alkalosis. Deep and rapid respirations (tachypnea) are primary symptoms of the disorders that cause respiratory alkalosis.

◆Evaluation and Treatment.

The underlying disturbance must be identified. The arterial pH is greater than 7.45, and the PaCO₂ is less than 38 mmHg. In acute states, bicarbonate levels are normal. With chronic respiratory alkalosis, a compensatory decrease in the bicarbonate level occurs and the pH is closer to normal.

Treating the underlying disturbance is the most effective treatment. Hypoxemia must be corrected and hypermetabolic states reversed. Symptoms from hysterical hyperventilation can be corrected by rebreathing from a paper bag, which increases the concentration of inspired carbon dioxide and reverses the respiratory alkalosis.

Mixed Acid-Base Disorders

Mixed acid-base disorders are two or more primary acid-base disorders occurring at the same time. They are more common in hospitalized individuals, often those in critical care with comorbid conditions (i.e., combined metabolic and respiratory disorders or combinations of acute and chronic disorders). For these individuals the clinical history and analysis of electrolytes, medications, the anion gap, and plasma and urine osmolality are informative. The primary disorder is assessed and then the degree of compensation is evaluated to determine if it is adequate or greater or lesser than expected. Renal and respiratory compensation rarely returns the pH to normal. Therefore, mixed acid-base disorders can have alterations in PaCO₂ and bicarbonate and a normal pH.^{29,30}

Summary Review

Distribution of Body Fluids

1. Body fluids are distributed among functional compartments and are classified as ICF or ECF.
2. The sum of all fluids is the TBW, which varies with age and amount of body fat and is higher in infants because they have less body fat.
3. Water moves between the ICF and ECF compartments principally by osmosis.
4. Water moves between the plasma and interstitial fluid by osmosis and hydrostatic pressure, which occur across the capillary membrane.
5. Movement across the capillary wall is called *net filtration* and is described according to the Starling law (forces favoring filtration minus forces opposing filtration).

Alterations in Water Movement

1. Edema is a problem of fluid distribution that results in accumulation of fluid within the interstitial spaces.
2. Edema is caused by venous or lymphatic obstruction (increases hydrostatic pressure), plasma protein losses (decreases plasma oncotic pressure), increased capillary permeability, and increased vascular volume.
3. The pathophysiologic process that leads to edema is related to an increase in forces favoring fluid filtration from the capillaries into the tissues.
4. Edema may be localized or generalized and usually is associated with swelling and puffiness, tighter-fitting clothes and shoes, limited movement of the affected area, and, in severe cases, weight gain.

Sodium, Chloride, and Water Balance

1. Sodium balance and water balance are intimately related; chloride levels are generally proportional to changes in sodium levels.
2. Sodium balance is regulated by aldosterone, which increases reabsorption of sodium by the distal tubule of the kidney.
3. Renin and angiotensin are enzymes that promote or inhibit secretion of aldosterone and thus regulate sodium and water balance.
4. Atrial natriuretic hormone is also involved in decreasing renal tubular resorption and promoting urinary excretion of sodium.
5. Water balance is regulated by the sensation of thirst and by the level of antidiuretic hormone, which is initiated by an increase in plasma osmolality or a decrease in circulating blood volume.

Alterations in Sodium, Water, and Chloride Balance

1. Alterations in water balance may be classified as isotonic, hypertonic, or hypotonic.
2. Isotonic alterations occur when changes in TBW are accompanied by proportional changes in concentrations of electrolytes.
3. Hypertonic alterations develop when the osmolality of the ECF is elevated above normal, usually because of an increased concentration of ECF sodium or a deficit of ECF water.
4. Hypernatremia (sodium levels >145 mEq/L) may be caused by an acute increase in sodium level or a loss of water.
5. Water deficit, or hypertonic dehydration, can be caused by lack of access to water, pure water losses, hyperventilation, arid climates, or increased renal clearance.
6. Hyperchloremia is caused by an excess of sodium or a deficit of

bicarbonate.

7. Hypotonic alterations occur when the osmolality of the ECF is less than normal.
8. Hyponatremia occurs when the serum sodium concentration decreases to less than 135 mEq/L, and may be caused by inadequate intake of sodium or dilution of the body's sodium level.
9. Water excess is rare but can be caused by compulsive water drinking, decreased urine formation, or the syndrome of inappropriate secretion of ADH.
10. Hyponatremia usually causes movement of water into cells.
11. Hypochloremia is usually the result of hyponatremia or elevated bicarbonate concentrations.

Alterations in Potassium, Calcium, Phosphate, and Magnesium Balance

1. Potassium is the predominant ICF ion; it functions to regulate ICF osmolality, maintain the resting membrane potential, and deposit glycogen in liver and skeletal muscle cells.
2. Potassium balance is regulated by the kidney, by aldosterone and insulin secretion, and by changes in pH.
3. A mechanism known as *potassium adaptation* allows the body to accommodate slowly to increased levels of potassium intake.
4. Hypokalemia (serum potassium concentration <3.5 mEq/L) indicates loss of total body potassium, although ECF hypokalemia can develop without losses of total body potassium, and plasma K^+ levels may be normal or elevated when the amount of total body potassium is depleted.
5. Hypokalemia may be caused by reduced potassium intake, increased ICF to ECF potassium concentration, loss of potassium from body stores, increased aldosterone secretion (e.g., caused by hypernatremia), and increased renal excretion.
6. Hyperkalemia (potassium levels >5.0 mEq/L) may be caused by increased potassium intake, a shift from ICF to ECF potassium,

- or decreased renal excretion.
7. Calcium is a necessary ion in the structure of bones and teeth, in blood clotting, in hormone secretion and the function of cell receptors, and in membrane stability.
 8. Phosphate acts as a buffer in acid-base regulation and provides energy for muscle contraction.
 9. Calcium and phosphate concentrations are rigidly controlled by PTH, vitamin D, and calcitonin.
 10. Hypocalcemia (total serum calcium concentration <9.0 mg/dL) is related to inadequate intestinal absorption, deposition of ionized calcium into bone or soft tissue, blood administration, or decreased PTH and vitamin D levels.
 11. Hypercalcemia (serum calcium concentration >10.5 mg/dL) can be caused by a number of diseases, including hyperparathyroidism, bone metastases, sarcoidosis, and excess vitamin D.
 12. Hypophosphatemia is a serum phosphate level less than 2.0 mg/dL and is usually caused by intestinal malabsorption and increased renal excretion of phosphate.
 13. Hyperphosphatemia is a serum phosphate level more than 4.7 mg/dL and develops with acute or chronic renal failure with significant loss of glomerular filtration.
 14. Magnesium is a major intracellular cation and is principally regulated by PTH.
 15. Magnesium functions in enzymatic reactions and often interacts with calcium at the cellular level.
 16. Hypomagnesemia (serum magnesium concentrations <1.5 mEq/L) may be caused by malabsorption syndromes.
 17. Hypermagnesemia (serum magnesium concentrations >3.0 mEq/L) is rare and is usually caused by renal failure.

Acid-Base Balance

1. Hydrogen ions, which maintain membrane integrity and the speed of enzymatic reactions, must be concentrated within a

narrow range if the body is to function normally.

2. Hydrogen ion concentration is expressed as pH, which represents the negative logarithm of hydrogen ions in solution.
3. Different body fluids have different pH values.
4. The renal and respiratory systems, together with the body's buffer systems, are the principal regulators of acid-base balance.
5. Buffers are substances that can absorb excessive acid or base to minimize fluctuations in pH.
6. Buffers exist as acid-base pairs; the principal plasma buffers are bicarbonate, protein (hemoglobin), and phosphate.
7. Buffer pairs can associate and dissociate; the pK value is the pH at which a buffer pair is half dissociated.
8. The lungs and kidneys act to compensate for changes in pH by increasing or decreasing ventilation and by producing more acidic or more alkaline urine.
9. Correction is a process different from compensation; correction occurs when the values for both components of the buffer pair are returned to normal.
10. Acid-base imbalances are caused by changes in the concentration of H^+ in the blood; an increase causes acidosis, and a decrease causes alkalosis.
11. An abnormal increase or decrease in bicarbonate concentration causes metabolic acidosis or metabolic alkalosis; changes in the rate of alveolar ventilation produce respiratory acidosis or respiratory alkalosis.
12. Metabolic acidosis is caused by an increase in the concentrations of non-carbonic acids or by loss of bicarbonate from the extracellular fluid.
13. Metabolic alkalosis occurs with an increase in bicarbonate concentration usually caused by loss of metabolic acids from conditions such as vomiting, gastrointestinal suctioning, excessive bicarbonate intake, hyperaldosteronism, and diuretic therapy.
14. Respiratory acidosis occurs with a decrease of alveolar

- ventilation and an increase in levels of carbon dioxide, or hypercapnia.
15. Respiratory alkalosis occurs with alveolar hyperventilation and excessive reduction of carbon dioxide concentration, or hypocapnia.

In the nineteenth century, microscopic studies of cells led scientists to

suspect that the nucleus of the cell contained the important mechanisms of inheritance. Scientists found that chromatin, the substance that gives the nucleus a granular appearance, is observable in nondividing cells. Just before the cell divides, the chromatin condenses to form microscopically observable, threadlike structures called *chromosomes*. (Cell division and chromosomes are discussed in [Chapter 1](#).) With the rediscovery of Gregor Mendel's important breeding experiments at the turn of the twentieth century, it soon became apparent that the chromosomes contained **genes**, the basic units of inheritance. Genes are composed of sequences of **deoxyribonucleic acid (DNA)**, a primary constituent of chromosomes; the other primary constituent consists of **proteins**, such as histones, that cause the DNA to coil into a highly compressed structure ([Fig. 1.2, Chapter 1](#)). By serving as the blueprints of proteins in the body, genes ultimately influence all aspects of body structure and function. Humans have approximately 20,000 to 25,000 genes. An error in one of these genes can lead to a recognizable genetic disease.

To date, more than 23,000 human genetic traits have been identified and cataloged.¹ About one-third of pediatric inpatients are children with genetic diseases.^{2,3} In addition, many common diseases that affect primarily adults, such as hypertension, coronary heart disease, diabetes, and cancer, are now known to have important genetic components. (These diseases are also affected by environmental factors. The interaction between genetic and environmental components is discussed in [Chapter 5](#).)

Great progress is being made in the diagnosis of genetic diseases and the understanding of genetic mechanisms underlying them. Genetic testing is used increasingly to guide drug choice and dosage, and gene therapy—the direct alteration of genes in cells—is now carried out effectively for some diseases. Genetics is now one of the most rapidly advancing fields of medicine ([Boxes 4.1 and 4.2](#)).

Box 4.1

Genetic Testing

The genetic causes of several thousand different diseases have now been identified, and the pace of discovery is accelerating. Consequently, it is now possible to perform genetic tests to help determine whether an individual carries specific disease-causing mutations. Chromosome disorders, such as trisomy 21, are routinely detected using karyotypes or other, more automated approaches. Nearly 5000 diseases can now be diagnosed by testing for specific mutations (www.ncbi.nlm.nih.gov/sites/GeneTests/). In addition, genetic tests have been developed to help predict susceptibility for a number of common, genetically complex diseases. Genetic testing can be applied in a variety of contexts, including the following:

1. *Carrier screening*. Genetic tests can identify heterozygous carriers for many recessive diseases, such as cystic fibrosis, sickle cell disease, and Tay-Sachs disease. It is becoming increasingly common for couples to undergo carrier screening to help make reproductive decisions, especially in populations in which specific diseases are relatively common (e.g., Tay-Sachs disease in the Ashkenazi Jewish population, β -thalassemia in Mediterranean populations). As a result, the prevalence of some of these diseases has declined dramatically in the past two decades.
2. *Prenatal diagnosis*. Several forms of prenatal genetic diagnosis are available, including the following:
 - a. *Amniocentesis*. This procedure, which is usually carried out at about 16 weeks' gestation, involves the withdrawal of a small amount of amniotic fluid from the uterus. This fluid contains fetal cells, which can be cultured and karyotyped to detect chromosome abnormalities. In addition, genetic testing for single-gene disorders can be undertaken using DNA from these cells. Neural tube defects (spina bifida and anencephaly) can be detected as an elevation of α -fetoprotein level in amniotic fluid. The risk of fetal loss

as a result of this procedure is now estimated to be about 1/500 higher than the background loss rate.

- b. *Chorionic villus sampling (CVS)*. Carried out at 10 to 12 weeks' gestation, CVS is performed by extracting a small amount of villous tissue directly from the chorion. This procedure does not require in vitro culturing of cells for chromosome analysis because sufficient numbers of dividing cells are directly available in the extracted tissue. Chorionic villus sampling involves a slightly higher fetal loss rate (approximately 1%) than that of amniocentesis.
 - c. *Preimplantation genetic diagnosis (PGD)*. This relatively new procedure is carried out on early embryos (typically 8 to 12 cells) created by in vitro fertilization. One or two cells are removed from the embryo (which causes no damage), and these cells can be tested for chromosome abnormalities or single-gene disorders. If a genetic disorder is found in the cell, the embryo is not implanted in the mother's uterus and another embryo is chosen.
 - d. *Analysis of fetal DNA in maternal circulation*. By approximately 6 to 8 weeks' gestation, fetal cells, as well as cell-free fetal DNA, can be found in the mother's bloodstream and can be tested for disease-causing mutations. This approach is developing rapidly and has the advantages of early diagnosis and minimal risk to the mother and fetus. Recently, whole-genome fetal DNA sequences have been obtained from a small sample of maternal blood.
- In addition to these diagnostic procedures, prenatal screening is now routinely carried out by measuring various analytes in maternal serum samples to assess the risk of conditions, such as trisomies 21, 13, and 18, and neural tube defects. Newborn screening also is commonly performed for a variety of genetic conditions

such as PKU and galactosemia. A positive screening result is an indication for a subsequent diagnostic test (e.g., amniocentesis for a positive prenatal screening result or DNA sequencing for a positive newborn screening result).

3. *Presymptomatic diagnosis.* Many hereditary diseases, such as familial breast or colon cancer, can be tested genetically before an individual develops the disease. For some of these conditions, measures can be taken either to diagnose the disease early (e.g., colonoscopy or mammography) or to minimize the risk of developing the disease.
4. *Testing for drug efficacy or sensitivity.* A number of genes are now known to be associated with sensitivity to specific therapeutic drugs, and people are sometimes tested for variants in these genes to help guide drug treatment. For example, abacavir, an antiviral drug used in treating human immunodeficiency virus (HIV) infection, can cause severe adverse reactions in those who have a specific HLA-B variant (HLA-B*57:01, seen in about 7% of persons of European ancestry). The Food and Drug Administration now recommends testing for this variant before administering abacavir. For other drugs, such as warfarin, genetic testing for variants in specific genes (*CYP2C9* and *VKORC1*) may help to guide drug dosage.

Although genetic testing can be very informative, it also has limitations. Genetic testing usually reveals the presence or absence of a disease-causing mutation, but many genetic diseases have incomplete penetrance. For example, a woman who carries a mutation in the *BRCA1* or *BRCA2* genes has a lifetime breast cancer risk of approximately 70% to 80% (but not 100%). In addition, the absence of a disease-causing mutation does not guarantee that the disease in question will not occur (e.g., a woman who does not have a *BRCA1* or *BRCA2* mutation still has nearly the same risk of developing breast cancer as do other women because these genes

account for only a few percent of all cases of breast cancer). Individuals and families should be advised of these and other limitations of genetic testing.

Data from Katsanis SH, Katsanis N: *Nat Rev Genet* 14:415–426, 2013.

Box 4.2

Gene Therapy

Gene therapy, in which the harmful effects of a disease-causing mutation are corrected by altering the person's DNA, has been a long-sought goal in human genetics. Hundreds of individuals are currently enrolled in dozens of clinical trials of gene therapy. Many technical challenges have arisen, but gene therapy is now beginning to yield positive therapeutic results.

In somatic cell gene therapy, the DNA of a specific set of an individual's somatic cells is altered. (It is also possible to perform germline therapy, which affects all cells, including reproductive cells; however, for technical and ethical reasons, this is not being pursued in humans.) Most commonly, somatic cell therapy is used for conditions in which a mutation has caused the absence of a gene product in a cell (e.g., adenosine deaminase in T cells, which leads to immunodeficiency). A “vector” is used to carry a normal copy of the mutated gene into the individual's cells. These vectors are usually viruses, such as retroviruses, lentiviruses, or adenoviruses, which have been genetically modified so that they contain the normal human gene and cannot make copies of themselves (otherwise they could cause a viral infection). Once inside the individual's cells, the normal human gene begins to encode the missing gene product.

This approach faces a number of technical hurdles, including immune responses against the vector and difficulties in producing sufficient quantities of the desired gene product. In one case, an immune response against an adenoviral vector proved fatal.

Another challenge is that commonly used retroviral vectors integrate randomly into the genome. In several people with severe combined immunodeficiency, a modified retrovirus was inserted near an oncogene, activating it and causing leukemia. This issue has been addressed by designing alternative vectors and by implementing new developments in targeted genome modification using the CRISPR/Cas genome editing system.

Gene therapy has now been successful in treating a number of inherited conditions, including two forms of severe combined immunodeficiency (SCID), Wiskott-Aldrich syndrome, Leber congenital amaurosis, β -thalassemia, hemophilia B, and X-linked adrenoleukodystrophy. In some cases, symptoms have been completely reversed through gene therapy. When hematopoietic stem cells are altered, the beneficial effects of gene therapy can be permanent. In addition to the treatment of hereditary diseases, gene therapy is being used to alter cells of the immune system to combat specific tumor cells, improving the treatment of various types of cancer. It is hoped that further research will lead to safe, efficient, and cost-effective treatment of many human diseases through gene therapy.

DNA, RNA, and Proteins: Heredity at the Molecular Level

DNA

Composition and Structure

Genes are composed of DNA, and the most important constituent of DNA is four types of nitrogenous bases (Fig. 4.1). The four bases, **adenine**, **cytosine**, **guanine**, and **thymine**, are commonly represented by their first letters: A, C, G, and T, respectively.

FIGURE 4.1 Structure of DNA. **A**, Double helix. Shown with the phosphodiester backbone as a ribbon on top and a space-filling model on the bottom. The bases protrude into the interior of the helix where they hold it together by base pairing. The backbone forms two grooves, the larger major groove and the smaller minor groove. **B**, Base pairing holds strands together. The hydrogen (H)-bonds that form between A and T and between G and C are shown with dashed lines. These produce AT and GC base pairs that hold the two strands together. This always pairs a purine with a pyrimidine, keeping the diameter of the double helix constant. *A*, Adenine; *C*, cytosine; *G*, guanine; *T*, thymine. (From Raven PH et al: *Biology*, ed 8, New York, 2008, McGraw-Hill.)

In the early 1950s, James Watson and Francis Crick determined the physical structure of DNA. They proposed the now-famous **double-helix model**, in which DNA can be envisioned as a twisted ladder with chemical bonds as its rungs (see Fig. 4.1). Projecting from each side of the ladder, at regular intervals, are the nitrogenous bases. The base projecting from one side is bound to the base projecting from the other by a weak hydrogen bond. Therefore, the nitrogenous bases

form the rungs of the ladder; adenine pairs with thymine, and guanine pairs with cytosine. Each DNA subunit—consisting of one deoxyribose molecule, one phosphate group, and one base (Fig. 4.2)—is called a **nucleotide**.

FIGURE 4.2 Chemical Structure of Nucleotides. Chemical structure of the four bases, which shows hydrogen bonds between base pairs. Three hydrogen bonds are formed between cytosine–guanine pairs, and two bonds are formed between adenine–thymine pairs. (From Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

DNA as the Genetic Code

To serve as the basis of genetic inheritance, DNA must be able to provide a code for all the body's proteins. **Proteins** are composed of one or more **polypeptides** (intermediate protein compounds), which are in turn composed of sequences of **amino acids** (organic acids containing NH_2). The body contains 20 different types of amino acids, and the amino acid sequences that make up polypeptides must in some way be specified by the DNA molecule.

Because there are 20 possible amino acids and only 4 bases, each single nucleotide cannot specify an amino acid. Similarly, the amino

acids cannot be specified by couplets of bases (e.g., adenine-guanine, thymine-guanine, guanine-cytosine) because there are only 4×4 , or 16, possible couplets. If series of 3 bases are translated into amino acids, however, there are $4 \times 4 \times 4$, or 64, possible combinations—more than enough to specify each different amino acid. By manufacturing synthetic nucleotide sequences and allowing them to direct the formation of amino acids in the laboratory, it was proved that amino acids were specified by these triplets of bases, or **codons**.

Of the 64 possible codons, 3 signal the end of a gene and are known as **stop**, or **nonsense, codons**. The remaining 61 all specify amino acids, which means that most amino acids can be specified by more than 1 codon. The genetic code is thus said to be redundant, although each codon can specify only one amino acid.

Another significant feature of the genetic code is that it is nearly universal: with the exception of ciliated protozoa and some plants, all organisms use precisely the same DNA codes to specify proteins. Within cells, a general exception to this rule occurs in mitochondria—cytoplasmic organelles that are the sites of cellular respiration (see [Chapter 1](#)). The mitochondria have their own extranuclear DNA. Several codons of **mitochondrial DNA (mtDNA)** encode different amino acids than do the same nuclear DNA codons.

Replication

In addition to having the ability to specify amino acid sequences, DNA must be able to replicate itself accurately during cell division so that the genetic code can be preserved in subsequent cell generations. DNA replication consists of the breaking of the weak hydrogen bonds between the bases, leaving a single strand with each base unpaired. The consistent pairing of adenine with thymine and of guanine with cytosine, known as **complementary base pairing**, is the key to accurate replication. The principle of complementary base pairing dictates that the unpaired base will attract a free nucleotide only if the nucleotide has the proper complementary base. Thus a portion of a single strand with a sequence of bases labeled ATTGCT will bond with a series of free nucleotides with the bases TAACGA. When

replication is complete, a new double-stranded molecule identical to the original is formed (Fig. 4.3, A). The single strand is said to be a **template (guide)**, or molecule on which a complementary molecule is built, and is the basis for synthesizing the new double strand.

A

FIGURE 4.3 Replication and Action of DNA. **A**, Replication of DNA. **B**, Action of DNA polymerase. DNA polymerases add nucleotides to the 3' end of a growing chain. The nucleotide added depends on the base that is in the template strand. Each new base must be complementary to the base in the template strand. With the addition of each new nucleotide, triphosphate, two of its phosphates are cleaved off as pyrophosphate. **A**, Adenine; **T**, thymine; **G**, guanine; **C**, cytosine. (A from Herlihy **B**: *The human body in health and illness*, ed 5, St Louis, 2015, Saunders; **B** adapted from Raven PH et al: *Biology*, ed 8, New York, 2008, McGraw-Hill.)

Several different proteins are involved in DNA replication. One protein unwinds the double helix, one holds the strands apart, and others perform different distinct functions. The most important of these proteins is the enzyme known as **DNA polymerase**. This enzyme travels along the single DNA strand, adding the correct nucleotides to the free end of the new strand (see [Fig. 4.3, B](#)). Besides adding the new nucleotides, the DNA polymerase performs a proofreading procedure. After the new nucleotide has been added to the chain, the DNA polymerase checks to make sure that its base is actually complementary to the template base. If it is not, the incorrect nucleotide is excised and replaced with a correct one. This procedure, one of the mechanisms of DNA repair, substantially enhances the accuracy of DNA replication.

Mutation

A **mutation** is any inherited alteration of genetic material. Microscopically observable alterations of chromosome number or structure are examples of mutations. Some mutations are much too small to be observed under a microscope. An example is the **base pair substitution**, in which one base pair is replaced by another. Because of the redundancy of the genetic code, a base pair substitution sometimes has no consequence (i.e., it does not alter the amino acid sequence). When the substitution alters a single amino acid, it is termed a **missense mutation** (Fig. 4.4, A). When the substitution produces any of the three stop or nonsense codons, it is termed a **nonsense mutation** (Fig. 4.4, B). Missense and nonsense mutations can have profound consequences, and they cause many of the serious genetic diseases discussed later.

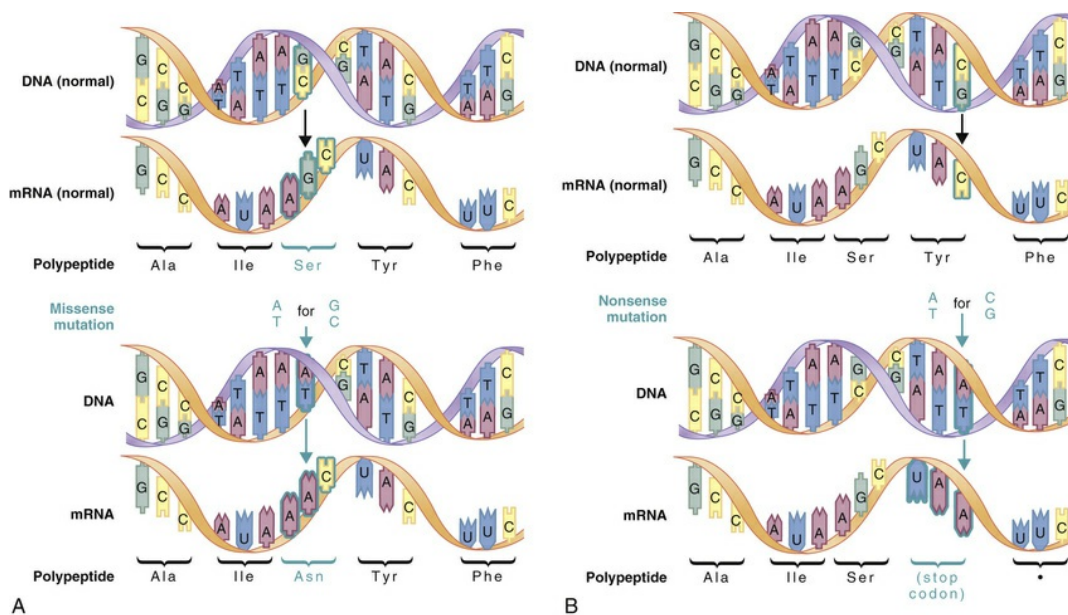

FIGURE 4.4 Base Pair Substitution. Missense mutations (A) produce a single amino acid change, whereas nonsense mutations (B) produce a stop codon in the mRNA. Stop codons terminate translation of the polypeptide. (From Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

A second major type of mutation is the **frameshift mutation**. This alteration involves the insertion or deletion of one or more base pairs to the DNA molecule. As Fig. 4.5 shows, these mutations can change the entire “reading frame” of the DNA sequence because codons

consist of groups of three base pairs. A frameshift mutation thus can greatly alter the resulting amino acid sequence and typically results in a premature stop codon.

FIGURE 4.5 Frameshift Mutations. Frameshift mutations result from the addition or deletion of a number of bases that is not a multiple of 3. This mutation alters all of the codons downstream from the site of insertion or deletion. (From Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

A large number of agents, known collectively as **mutagens**, can increase the frequency of mutations. Radiation, such as that produced by x-rays and nuclear fallout, is an important mutagen and is known to cause cell damage (see [Chapters 12](#) and [13](#)). Radiation can fragment the DNA molecule and it can cause chemical reactions that can alter a DNA base. A variety of chemicals also can induce mutations, often because they are chemically similar to DNA bases. Other chemicals

mimic the effects of ionizing radiation, and still others interfere with the process of base pairing. Hundreds of chemicals (some of which are human-generated and some of which occur naturally) are now known to be mutagenic in humans or laboratory animals, such as nitrogen mustard, vinyl chloride, alkylating agents, formaldehyde, and sodium nitrite. Some of these chemicals, however, are much more potent mutagens than others. Nitrogen mustard, for example, is extremely mutagenic, whereas sodium nitrate is a weak mutagen.

Measurement of the mutation rate in humans is difficult, in part because mutations are very rare events. Current estimates are that the **mutation rate** in humans is about 10^{-4} to 10^{-7} per gene per generation. This rate appears to vary from one gene to another, with greater mutation rates for larger genes. At the nucleotide level, the human mutation rate is approximately 10^{-8} per nucleotide per generation. Certain DNA sequences have particularly high mutation rates and are known as **mutational hot spots**. In particular, sequences consisting of a cytosine base followed by a guanine base (CG) are highly susceptible to mutation and are known to account for a disproportionately large percentage of disease-causing mutations.⁴

From Genes to Proteins

Whereas DNA is formed and replicated in the cell nucleus, protein synthesis takes place in the cytoplasm. The transport of the DNA code from nucleus to cytoplasm and the subsequent protein formation involve two basic processes: transcription and translation. Both of these processes are mediated by **ribonucleic acid (RNA)**, a type of nucleic acid that is chemically very similar to DNA. RNA differs from DNA in that uracil rather than thymine is one of the four nitrogenous bases. The other bases of RNA, as in DNA, are adenine, cytosine, and guanine. Uracil is structurally very similar to thymine, so it also can pair with adenine. Whereas DNA usually occurs as a double strand, RNA usually occurs as a single strand.

Transcription

Transcription is the process by which RNA is synthesized from a DNA template. The result is the formation of **messenger RNA (mRNA)** from the base sequence specified by the DNA molecule. Transcription of a gene begins when an enzyme called **RNA polymerase** binds to a **promoter site** on the DNA. A promoter site is a sequence of DNA that specifies the beginning of a gene. In addition to RNA polymerase, proteins called **transcription factors** bind to DNA sequences called **transcription factor binding sites** near genes to regulate the timing of transcription, as well as the specific tissues in which genes are actively transcribed (e.g., clotting factor VIII primarily in hepatocytes) (Fig. 4.6). Transcription factors can either activate or repress the expression of genes. In addition, transcription is sometimes up-regulated by the binding of nearby DNA sequences called **enhancers**. The RNA polymerase pulls a portion of the DNA strands apart from one another, allowing unattached DNA bases to be exposed. One of the DNA strands then provides the template for the sequence of mRNA nucleotides.

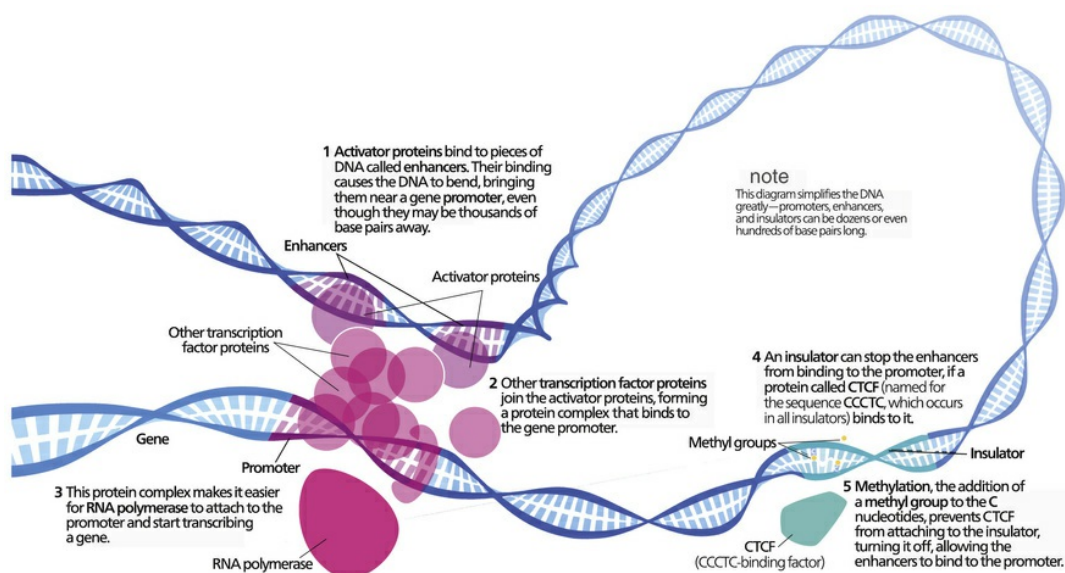

FIGURE 4.6 Transcription Factors and Simplified Schematic of Gene Expression. Transcription factors are proteins and bind to specific sites on DNA. They read and interpret the genetic blueprint of the DNA, thereby controlling transcription or the flow of genetic information from DNA to mRNA. Transcription factors are essential for gene expression (e.g., proteins that function as receptors, enzymes, or biomarkers). Not only do transcription factors act downstream from biological stimuli but they can

be downstream of signaling cascades promoted by various environmental stimuli (hormones, temperature). Transcription factors can alter gene expression to promote pathophysiology. (From Song K: Transcription Factors. *Wikimedia Commons*. Dec 20, 2012. https://commons.wikimedia.org/wiki/File:Transcription_Factors.svg.)

The sequence of bases in the mRNA is thus complementary to that of the template strand, and with the exception of the presence of uracil instead of thymine, the mRNA sequence is identical to that of the other DNA strand. Transcription continues until a DNA sequence called a **termination sequence** is reached. Then the RNA polymerase detaches from the DNA, and the transcribed mRNA is freed to move out of the nucleus and into the cytoplasm. Fig. 4.7 summarizes the process of transcription.

FIGURE 4.7 General Scheme of RNA Transcription. In transcription of messenger RNA (*mRNA*), a DNA molecule “unzips” in the region of the gene to be transcribed. RNA nucleotides already present in the nucleus

temporarily attach themselves to exposed DNA bases along one strand of the unzipped DNA molecule according to the principle of complementary pairing. As the RNA nucleotides attach to the exposed DNA, they bind to each other and form a chainlike RNA strand called a *messenger RNA (mRNA)* molecule. Notice that the new mRNA strand is an exact copy of the base sequence on the opposite side of the DNA molecule. As in all metabolic processes, the formation of mRNA is controlled by an enzyme—in this case, the enzyme is called *RNA polymerase*. (From Ignatavicius DD, Workman LD: *Medical-surgical nursing*, ed 6, St Louis, 2010, Saunders.)

RNA Splicing

After the mRNA first has been transcribed from the DNA template, it reflects exactly the base sequence of the DNA. In eukaryotes an important step takes place before this RNA leaves the nucleus. Many of the RNA sequences are removed, and the remaining sequences are spliced together to form the functional mRNA that will migrate to the cytoplasm (Fig. 4.8). The excised sequences are called **introns**, and the sequences that are left to code for proteins are called **exons**. The functions of most introns remain poorly understood.

FIGURE 4.8 RNA Splicing. Gene splicing. Introns are precisely removed from the primary mRNA transcript to produce a mature mRNA transcript. Consensus sequences mark the sites at which splicing occurs. (From Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

Translation

Translation is the process by which RNA directs the synthesis of a polypeptide (Fig. 4.9). However, mRNA cannot code directly for amino acids. Instead, it interacts with **transfer RNA (tRNA)**, a cloverleaf-shaped strand of about 80 nucleotides. The tRNA molecule has a site for the attachment of an amino acid. At the opposite side of the cloverleaf is a sequence of three nucleotides called the **anticodon**. The anticodon undergoes complementary base pairing with an appropriate codon in the mRNA. The mRNA thus specifies the sequence of amino acids by acting through the tRNA. As each codon is processed, an amino acid is translated by the interaction of mRNA

and tRNA, which is aided by cytoplasmic structures called **ribosomes**. Bonds are formed between adjacent amino acids to make a growing polypeptide. When the ribosome arrives at a termination signal on the mRNA sequence, translation and polypeptide formation cease. The mRNA, ribosome, and polypeptide separate from one another, and the polypeptide is released into the cytoplasm to perform its required function.

FIGURE 4.9 Protein Synthesis. The site of transcription is the nucleus, and the site of translation is the cytoplasm. See the text for details.

Noncoding RNA.

The progression from DNA to RNA to proteins, as described here, is a core concept in genetics and molecular biology. However, several forms of RNA are never translated into amino acid sequences but have key functions. **MicroRNAs (miRNAs)** are small RNA sequences, 17 to 27 nucleotides in length, that bind to specific mRNA sequences and down-regulate their expression. More than 1000 miRNAs have been identified, and some of them play important roles in regulating genes involved in cancer. Each miRNA can bind to multiple mRNA targets and therefore can regulate many different genes. In contrast, **small interfering RNAs (siRNAs)**, another type of short RNA sequence, have single, specific binding targets and are used in cancer therapy and some forms of gene therapy (see [Box 4.2](#)). Another nontranslated RNA, classified as having a length greater than 200 nucleotides, is termed **long noncoding RNA (lncRNA)**. The genome contains at least 10,000 lncRNAs and, like miRNA and siRNA, some lncRNAs are involved in gene regulation.

Chromosomes

Human cells can be categorized into two types: **germline cells** (sperm and egg cells, or **gametes**, and their precursor cells) and **somatic cells** (which include all other cells). Mutations in germline cells can be transmitted to the next generation, whereas mutations in somatic cells are not. Each somatic cell has 46 chromosomes in its nucleus. These are **diploid cells**, meaning that the chromosomes occur in pairs. Thus each cell contains 23 pairs of chromosomes. One member of each pair comes from an individual's mother, and one comes from the father. New somatic cells are formed through mitosis and cytokinesis, through which the cell nucleus and cytoplasm are replicated. (The division process that creates new copies of somatic cells is described in [Chapter 1](#).) Gametes are **haploid cells**: they have only 1 member of each chromosome pair, giving them a total of 23 chromosomes. The process by which these haploid cells are formed from diploid cells is called **meiosis** ([Fig. 4.10](#)).

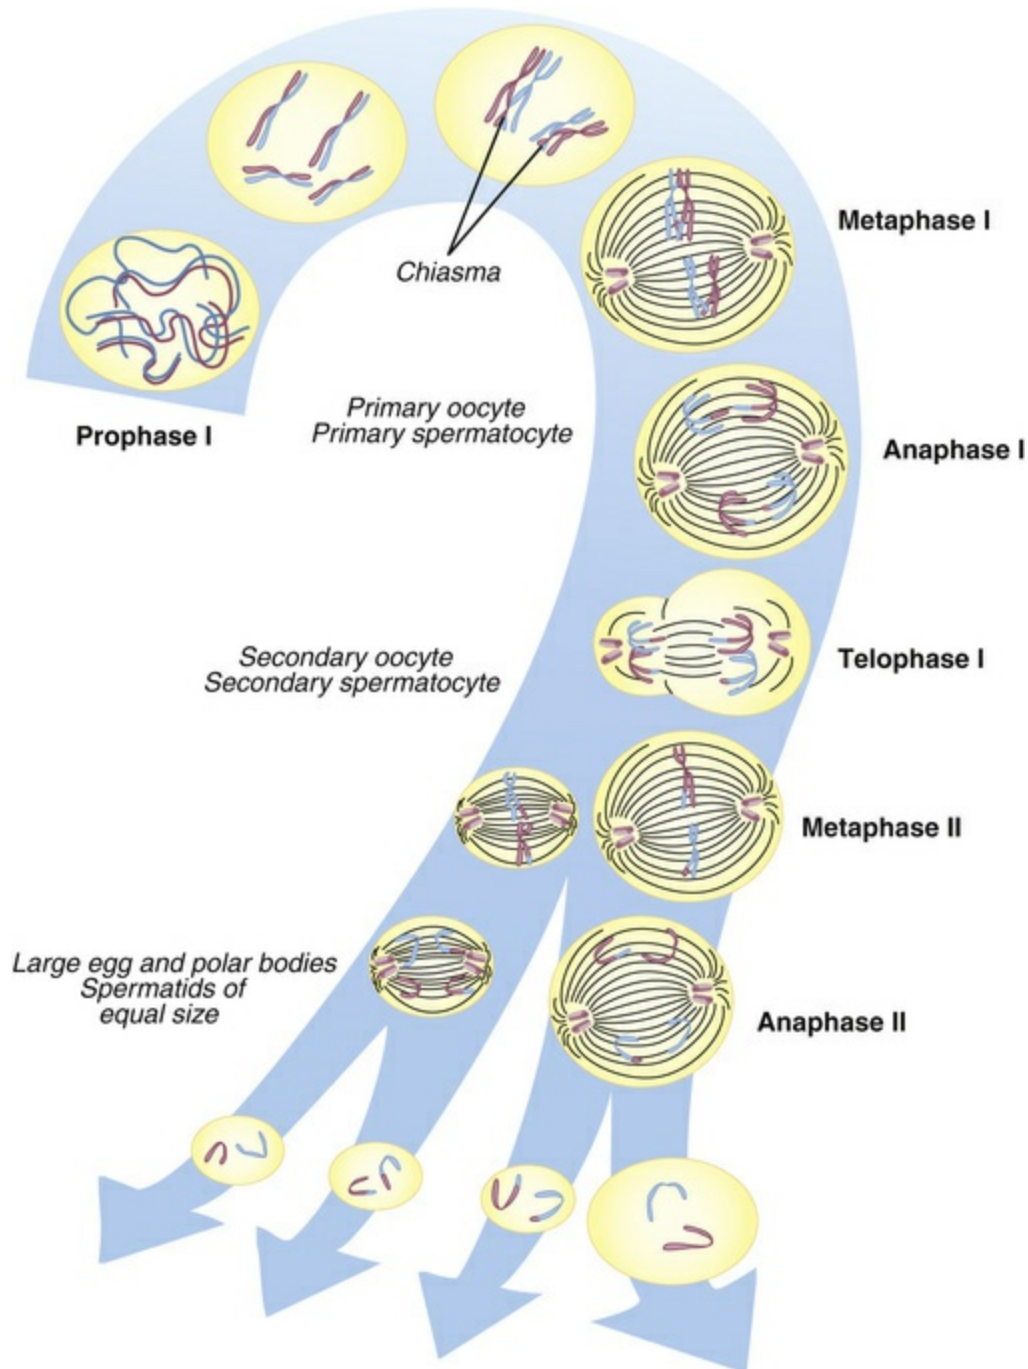

FIGURE 4.10 Stages of Meiosis. From these stages, haploid gametes are formed from a diploid stem cell. For brevity, prophase II and telophase II are not shown. Note the relationship between meiosis and spermatogenesis and oogenesis. (From Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

In 22 of the 23 chromosome pairs, the 2 members of each pair are virtually identical in microscopic appearance and DNA sequence and are thus said to be **homologous** to each other. These 22 chromosome

pairs are homologous in both males and females and are termed **autosomes**. The remaining pair of chromosomes, the **sex chromosomes**, consists of two homologous X chromosomes in females and a nonhomologous pair, X and Y, in males.

Fig. 4.11, A, illustrates a **metaphase spread**, which is a photograph of the chromosomes as they appear in the nucleus of a somatic cell during metaphase. (Chromosomes are easiest to visualize during this stage of mitosis.) A **karyogram** (also termed a **karyotype**) is an ordered display of chromosomes. In **Fig. 4.11, B**, the chromosomes are arranged according to size, with the **homologous chromosomes** paired. The 22 autosomes are numbered according to length, with chromosome 1 as the longest and chromosome 22 as the shortest. Some natural variation in relative chromosome length can be expected from person to person, however, so it is not always possible to distinguish each chromosome by its length. Therefore, the position of the centromere is also used to classify the chromosomes (**Fig. 4.12**).

FIGURE 4.11 Karyogram of Chromosomes. **A**, Metaphase Spread; human karyogram. **B**, Homologous chromosomes and sister chromatids. (A courtesy the Clinical Cytogenetics Section, Laboratory of Pathology, National Cancer Institute, National Institutes of Health, Bethesda, MD. B from Raven PH et al: *Biology*, ed 8, New York, 2008, McGraw-Hill.)

FIGURE 4.12 Structure of Chromosomes. **A**, Human chromosomes 2, 5, and 13. Each is replicated and consists of two chromatids. Chromosome 2 is a metacentric chromosome because the centromere is close to the middle; chromosome 5 is submetacentric because the centromere is set off from the middle; chromosome 13 is acrocentric because the centromere is at or very near the end. **B**, During mitosis, the centromere divides and chromosomes move to opposite poles of the cell. At the time of centromere division, the chromatids are designated chromosomes.

The chromosomes in [Fig. 4.11, A](#), were stained with a substance that binds preferentially to certain areas of chromosomes. The resulting distinctive **chromosome bands** are evident in various patterns in the different chromosomes so that each chromosome can be distinguished easily. One of the most commonly used stains is **Giemsa stain**. By using banding techniques, chromosomes can be unambiguously numbered, and individual variation in chromosome composition can be studied. Missing or duplicated portions of chromosomes, which often result in serious diseases, also can be readily identified.

Chromosome Aberrations and Associated Diseases

Chromosome abnormalities are the leading known cause of intellectual disability and spontaneous pregnancy loss. A major chromosome aberration occurs in more than half of conceptions. Most of these fetuses do not survive to term; in fact, about 50% of all recovered first-trimester spontaneous abortuses have major chromosomal aberrations.⁵ About 1 in 150 live births has a major diagnosable chromosome abnormality.⁶

Polyploidy

Cells that have a multiple of the normal number of chromosomes are said to be **euploid cells** (Greek *eu*, “good” or “true”; *ploid*, “number”). Because normal gametes are haploid and most normal somatic cells are diploid, they are both euploid forms. When a euploid cell has more than the diploid number of chromosomes, it is said to be a **polyploid cell**. Several types of body tissues, including some liver, bronchial, and epithelial tissues, are normally polyploid. A zygote having three copies of each chromosome, rather than the usual two, has a form of polyploidy called **triploidy**. **Tetraploidy**, a condition in which euploid cells have 92 chromosomes, also has been observed. Nearly all triploid and tetraploid conceptions are spontaneously aborted or stillborn, and the small proportion that survive to term die shortly after birth. Triploidy and tetraploidy are relatively common conditions at conception, accounting for approximately 10% of all known miscarriages.⁵

Aneuploidy

Aneuploid cells are defined as those that do not contain a multiple of 23 chromosomes. An aneuploid cell containing three copies of one chromosome is said to be trisomic (a condition termed **trisomy**). **Monosomy**, the presence of only one copy of a given chromosome in a diploid cell, is the other common form of aneuploidy. Among the autosomes, monosomy of any chromosome is lethal, but newborns with trisomy of chromosomes 13, 18, or 21 can survive. This difference illustrates an important principle: loss of chromosome material has more serious consequences than duplication of chromosome material.

Aneuploidy of the sex chromosomes is usually less serious than that of the autosomes. For the Y chromosome, this is true because very little genetic material is located on this chromosome. For the X chromosome, inactivation of extra chromosomes largely diminishes their effect. A zygote bearing *no* X chromosome, however, will not survive.

Aneuploidy is usually the result of **nondisjunction**, an error in

which homologous chromosomes or sister chromatids fail to separate normally during meiosis or mitosis (Fig. 4.13). Nondisjunction during either stage of meiosis produces some gametes that have two copies of a given chromosome and others that have no copies of the chromosome. When such gametes unite with normal haploid gametes, the resulting zygote is monosomic or trisomic for that chromosome.

FIGURE 4.13 Nondisjunction Causes Aneuploidy When Chromosomes or Sister Chromatids Fail to Divide Properly. (From Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

Autosomal Aneuploidy.

Trisomy can occur for any chromosome at conception, but the only forms seen with an appreciable frequency in live births are trisomies of the thirteenth, eighteenth, or twenty-first chromosome. Fetuses with most other chromosomal trisomies do not survive to term. Trisomy 16, for example, is the most commonly known trisomy

among abortuses, but it is not seen in live births.⁵

Partial trisomy, in which only an extra portion of a chromosome is present in each cell, also can occur. The consequences of partial trisomies are not as severe as those of complete trisomies. Trisomies also may occur in only some cells of the body. Individuals thus affected are said to be **chromosomal mosaics**, meaning that the body has two or more different cell lines, each of which has a different karyotype. Mosaics are usually formed by early mitotic nondisjunction occurring in one embryonic cell but not in others.

The most well-known example of aneuploidy in an autosome is trisomy of the twenty-first chromosome, which causes **Down syndrome** (named after J. Langdon Down, who first described the disease in 1866). Down syndrome was formerly called *mongolism*, but this inappropriate term is no longer used. Down syndrome is seen in 1 in 800 live births.⁵ Individuals with this disease typically have intelligence quotients (IQs) between 25 and 70. The facial appearance is distinctive ([Fig. 4.14](#)), with a low nasal bridge, epicanthal folds, protruding tongue, and flat, low-set ears. Poor muscle tone (hypotonia) and short stature are both characteristic. Congenital heart defects affect about one-third to one-half of live-born children with Down syndrome; a reduced ability to fight respiratory tract infections and an increased susceptibility to leukemia also contribute to reduced survival rate. By 40 years of age, individuals with Down syndrome virtually always develop symptoms that are nearly identical to those of Alzheimer disease because one of the genes that can cause Alzheimer disease is located on chromosome 21. About three-fourths of fetuses known to have Down syndrome are spontaneously aborted or stillborn. About 10% to 20% of infants born with Down syndrome die during their first 10 years of life. For those who survive beyond 10 years, average life expectancy is now about 60 years.

FIGURE 4.14 Down Syndrome. A, The karyotype of Down syndrome consists of 47 chromosomes and shows trisomy 21. B, A child with Down syndrome. (A from Damjanov I: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders; B courtesy Olney A, MacDonald M, University of Nebraska Medical Center, Omaha, NE.)

Approximately 97% of Down syndrome cases are caused by nondisjunction during the formation of one of the parent's gametes or during early embryonic development. The remaining 3% result from translocations (discussed later). In 90% to 95% of cases, the nondisjunction occurs in the formation of the mother's egg cell. Paternal nondisjunction is responsible for the remaining cases. Among individuals with Down syndrome, about 1% to 3% are known to be mosaics. Because mosaics have a large number of normal cells, the effects of the trisomic cells are attenuated and symptoms are sometimes less severe.

The risk of having a child with Down syndrome increases greatly with maternal age. As Fig. 4.15 demonstrates, women younger than 30 years have a risk ranging from about 1 in 1000 births to 1 in 2000 births. The risk begins to rise substantially after 35 years of age, and it reaches 3% to 5% for women older than 45 years of age. This dramatic increase in risk is a consequence of the age of maternal egg cells, which are held in an arrested state of prophase I from the time they are formed in the female embryo until they are shed in ovulation.

Thus an egg cell formed by a 45-year-old woman is itself 45 years old. This long suspended state may allow for the accumulation of errors leading to nondisjunction. The risk of Down syndrome, as well as that of other trisomies, does not appear to increase with paternal age.⁷

FIGURE 4.15 Down Syndrome Risk Increases With Maternal Age. Rate is per 1000 live births related to maternal age.

Sex Chromosome Aneuploidy.

Among live births, about 1 in 400 males and 1 in 650 females have a form of sex chromosome aneuploidy.⁸ Because these conditions are generally less severe than autosomal aneuploidies, all forms except complete absence of an X chromosome allow at least some individuals to survive.

One of the most common sex chromosome aneuploidies, affecting about 1 in 1000 newborn females, is trisomy X. Instead of two X chromosomes, these females have three X chromosomes in each cell. Most of them have no overt physical abnormalities, although sterility, menstrual irregularity, or cognitive deficits are sometimes seen. A very small proportion of females have four or even five X chromosomes, and their mental function is more severely

compromised. Another sex chromosome aneuploidy is the presence of a single X chromosome and no homologous X or Y chromosome, resulting in a total of 45 chromosomes. The karyotype is designated 45,X, and it causes a set of symptoms known as **Turner syndrome** (Fig. 4.16). Because they have no Y chromosome, persons with Turner syndrome are always female. They are usually sterile, however, and have gonadal streaks rather than ovaries. These streaks of connective tissue are susceptible to cancer in mosaic fetuses who have some cells containing a Y chromosome. Other features of the disorder include short stature, webbing of the neck in about half of cases, widely spaced nipples, coarctation (narrowing) of the aorta (in 15% to 20% of cases), edema of the feet in newborns, and sparse body hair. Their IQs are typically in the normal range, although they often have some impairment of spatial and mathematical reasoning ability. About three-fourths of recognized 45,X conceptions inherit their X chromosome from the mother. Thus most cases are caused by a loss of the paternally transmitted X chromosome.

FIGURE 4.16 Turner Syndrome. A sex chromosome is missing, and the person's chromosomes are 45,X. Characteristic signs are short stature, female genitalia abnormality, webbed neck, shieldlike chest with underdeveloped breasts and widely spaced nipples, and imperfectly developed ovaries. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

The frequency of Turner syndrome is low compared with that of other sex chromosome aneuploidies: only about 1 in 2500 newborn females is affected.⁹ The 45,X karyotype is more common among conceptions, however, and about 15% to 20% of spontaneous abortions with chromosome abnormalities have this karyotype, making it one of the most common single-chromosome aberrations. Thus the condition is highly lethal during gestation: less than 1% of 45,X conceptions survive to term. Most fetuses that survive to term are mosaics, with combinations of 45,X cells and XX, XXX, or XY cells. It is likely that the presence of some normal cells in mosaic fetuses enhances fetal survival.

Teenagers with Turner syndrome are typically treated with estrogen to promote the development of secondary sexual characteristics. The dose is then continued at a reduced level to

maintain these characteristics and to help avoid osteoporosis. Human growth hormone is sometimes administered to increase stature.

Individuals with at least two X chromosomes and a Y chromosome in each cell (47,XXY karyotype) have a disorder known as **Klinefelter syndrome** (Fig. 4.17). Because of the presence of a Y chromosome, these individuals have a male appearance, but they are usually sterile, and about half develop female-like breasts (a condition called *gynecomastia*). The testes are small, body hair is sparse, the voice is often somewhat high pitched, stature is elevated, and a moderate degree of mental impairment may be present. Klinefelter syndrome is found in about 1 in 1000 male births. About two-thirds of the cases are caused by nondisjunction of the X chromosomes in the mother, and the frequency of the disorder rises with maternal age. Individuals with the 48,XXXYY and 49,XXXXYY karyotypes also are considered to have Klinefelter syndrome, and the degree of physical and mental impairment increases with each additional X chromosome. Regardless of the number of X chromosomes, however, these individuals have a male appearance. The presence of a single Y chromosome, which causes the undifferentiated gonads to become testes, always produces a male. Mosaicism is sometimes seen in Klinefelter syndrome and results in less severe disease; the most prevalent combination is XXY and XY cells.

FIGURE 4.17 Klinefelter Syndrome. This young man exhibits many characteristics of Klinefelter syndrome: small testes, some development of the breasts, sparse body hair, and long limbs. This syndrome results from the presence of two or more X chromosomes with one Y chromosome (genotypes XXY or XXXY, for example). (Courtesy Nancy S. Wexler, PhD, Columbia University. Picked up from Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

About 1 in 1000 males has an extra Y chromosome, producing the 47,XYY karyotype. Individuals with this karyotype tend to be taller than average, and they have a 10- to 15-point reduction in average IQ. This condition, which causes few serious physical problems, achieved notoriety when it was found that its incidence was significantly elevated in prison populations. This discovery led to the suggestion that this chromosome might predispose affected individuals to violent, criminal behavior. Several dozen studies have addressed this issue, and they have shown that 47,XYY males are not inclined to commit violent crimes. However, even after adjusting for the effects of decreased IQ, some evidence exists for an increased incidence of

behavioral disorders.

Abnormalities of Chromosome Structure

In addition to the loss or gain of whole chromosomes, parts of chromosomes can be lost or duplicated as gametes are formed, and the arrangement of genes on chromosomes can be altered. Unlike aneuploidy and polyploidy, these changes sometimes do not have serious consequences for an individual's health. Some of them can even remain entirely unnoticed, especially when very small pieces of chromosomes are involved. Nevertheless, abnormalities of chromosome structure also can produce serious disease in individuals or their offspring.

During meiosis and mitosis, chromosomes usually maintain their structural integrity very well, but **chromosome breakage** occasionally does occur. Mechanisms exist to “heal” these breaks, and generally the break is repaired perfectly with no damage resulting to the daughter cell. Sometimes, however, the breaks remain, or they heal in a fashion that alters the structure of the chromosome. Chromosome breakage occurs spontaneously, but it also can be caused by ionizing radiation, some viral infections, and certain chemicals.

Deletions.

Broken chromosomes and loss of DNA cause **deletions** (Fig. 4.18, A). Usually a gamete with a deletion unites with a normal gamete to form a zygote. The zygote thus has one chromosome with the normal complement of genes and one with some missing genes. Because a fairly large number of genes can be lost in a deletion, serious consequences can result even though one copy of the chromosome is normal. An often-cited example of a disease caused by a chromosomal deletion is the **cri du chat syndrome** (Fig. 4.19). The term, which literally means “cry of the cat,” describes the characteristic cry of the affected child. Other symptoms include low birth weight, severe intellectual disability, microcephaly (smaller than normal head size), heart defects, and the typical facial appearance shown in Fig. 4.19. The disease is caused by a deletion of part of the short arm of chromosome

5.

FIGURE 4.18 Chromosome Structural Alterations. Larger-scale changes in chromosomes are also possible. Material can be deleted (A), duplicated (B), and inverted (C). Translocations occur when one chromosome is broken and becomes part of another chromosome. This often occurs where both chromosomes are broken and exchange material, an event called a *reciprocal translocation* (D). (From Raven PH et al: *Biology*, ed 8, New York, 2008, McGraw-Hill.)

FIGURE 4.19 Infant With Cri Du Chat Syndrome. This syndrome is caused by deletion of part of the short arm of chromosome 5. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson genetics in medicine*, ed 7, Philadelphia, 2007, Saunders.)

Duplications.

Duplications of chromosome material are, like deletions, a form of chromosome aberration (see [Fig. 4.18, B](#)). Because a deficiency of genetic material is more harmful than an excess, duplications usually have less serious consequences than deletions. For example, a deletion of a region of chromosome 5 causes cri du chat syndrome, but a duplication of the same region causes less severe disease.

Inversions.

An **inversion** is the occurrence of two breaks on a chromosome, followed by the reinsertion of the missing fragment at its original site but in inverted order (see [Fig. 4.18, C](#)). Thus a chromosome symbolized as ABCDEFG might become ABEDCFG after an inversion.

Unlike deletions and duplications, inversions result in no loss or gain of genetic material. They are thus said to be a “balanced” alteration of chromosome structure, and they often have no apparent physical effect. Genes are sometimes influenced by neighboring DNA sequences, however, and this **position effect**, a change in a gene's expression caused by its position, does sometimes result in disease in persons with inversions.

The serious problems caused by inversions usually occur in the offspring of individuals who carry the inversion. Because chromosomes must align in perfect order during prophase I, a chromosome with an inversion must form a loop to align with its normal homolog. Crossing over within this loop can result in duplications or deletions in the chromosomes of daughter cells. Thus the offspring of individuals who carry inversions often have chromosome deletions or duplications.

Translocations.

The interchanging of genetic material between nonhomologous chromosomes is called **translocation**, and the most clinically significant type of translocation is termed a **Robertsonian translocation**. In this translocation the long arms of two nonhomologous chromosomes fuse at the centromere, forming a single chromosome ([Fig. 4.20](#)). Robertsonian translocations are confined to chromosomes 13, 14, 15, 21, and 22 because the short arms of these chromosomes are very small and contain no essential genetic material. When a Robertsonian translocation takes place, the short arms are usually lost during subsequent cell divisions. Because the carriers of Robertsonian translocations (about 1 in 500 individuals) lose no important genetic material, they are normal, although they have only 45 chromosomes in each cell. Their offspring, however, may have serious deletions or duplications (see [Fig. 4.20](#)). For example, a common Robertsonian translocation involves the fusion of the long arms of chromosomes 21 and 14. An offspring who inherits a gamete carrying the fused chromosome receives an extra copy of the long arm of chromosome 21 and thus develops Down syndrome. Robertsonian

translocations are responsible for approximately 3% to 5% of Down syndrome cases. Parents who carry a Robertsonian translocation involving chromosome 21 have an increased risk for producing multiple offspring with Down syndrome.

FIGURE 4.20 Possible Segregation Patterns for the Gametes Formed by a Carrier of a Robertsonian Translocation. Alternate segregation (quadrant a alone, or quadrant b with quadrant c) produces either a normal chromosome constitution or a translocation carrier with a normal phenotype. Adjacent segregation (quadrant a with b, quadrant c alone, quadrant a with c, or quadrant b alone) produces unbalanced gametes and results in conceptions with translocation Down syndrome, monosomy 21, trisomy 14, or monosomy 14, respectively. For example, monosomy 14 is produced when the parent who carries the translocation transmits a copy of chromosome 21 but does not transmit a copy of chromosome 14 (as in the lower right corner). (From Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

A **reciprocal translocation** occurs when breaks take place in two different chromosomes and the material is exchanged (see Fig. 4.18, D). As with Robertsonian translocations, the carrier of a reciprocal translocation is usually normal because the individual has a normal complement of genetic material. However, the carrier's gametes can be normal, can carry the translocation, or can have duplications and deletions.

Fragile Sites.

A number of areas on chromosomes develop microscopically observable breaks and gaps when the cells are cultured in a folate-deficient medium. Most of these **fragile sites** have no apparent relationship to disease. However, one fragile site, located on the long arm of the X chromosome, is associated with a disorder of considerable importance, both clinically and genetically. This disorder is known as *fragile X syndrome*, and it is associated with substantial cognitive impairment. With a relatively high population prevalence (affecting approximately 1 in 4000 males and 1 in 8000 females), fragile X syndrome is the second most common genetic cause of intellectual disability (after Down syndrome).¹⁰

Fragile X syndrome is usually caused by an elevated number (more than about 200) of repeated DNA sequences in the first exon of the fragile X gene. These “repeats” consist of CGG sequences that are duplicated many times. Most individuals have fewer than 50 of these repeats, but those who have 50 to 200 are more likely to produce affected offspring because DNA replication becomes unstable.¹⁰ An

increase in the number of these repeated sequences in successive generations can lead to expression of fragile X syndrome. More than 20 other genetic diseases also are caused by this mechanism.¹¹

Elements of Formal Genetics

Many traits can be attributed primarily to single genes and are often called *mendelian traits* (after Gregor Mendel). Each gene occupies a position along a chromosome known as a **locus**. The genes at a particular locus can take different forms (i.e., they can be composed of different nucleotide sequences) called **alleles**. For example, most people have a type of hemoglobin known as *hemoglobin A*. A few individuals have an alternative form of hemoglobin, termed *hemoglobin S*, which differs from hemoglobin A by a single amino acid substitution in the β -globin component of the hemoglobin molecule. The β -globin locus thus has two different alleles, one that encodes hemoglobin A and another that encodes hemoglobin S. A locus containing two or more alleles that each occur with an appreciable frequency in a population is said to be **polymorphic** or a **polymorphism**.

Because humans are diploid organisms, each chromosome is represented twice, with one member of the chromosome pair contributed by the father and one by the mother. At a given locus an individual has one allele whose origin is paternal and one whose origin is maternal. When the two alleles are identical, the individual is **homozygous** at that locus. When the alleles are not identical, the individual is **heterozygous** at the locus.

Phenotype and Genotype

The composition of genes at a given locus is known as the **genotype**. The outward appearance of an individual, which is the result of both genotype and environment, is the **phenotype** (see also [Chapter 6](#), Epigenetics). For example, an infant who is born with an inability to metabolize the amino acid phenylalanine has the single-gene disorder

known as *phenylketonuria* (PKU) and thus has the PKU genotype. If the condition is left untreated, abnormal metabolites of phenylalanine will begin to accumulate in the infant's brain and irreversible intellectual disability will occur. Intellectual disability is thus one aspect of the PKU phenotype. By imposing dietary restrictions to limit the intake of food containing phenylalanine, however, cognitive impairment can be prevented. Although the child still has the PKU genotype, a modification of the environment (in this case the child's diet) produces an outwardly normal phenotype.

Dominance and Recessiveness

In many loci the effects of one allele mask those of another when the two are found together in a **heterozygote**. The allele whose effects are observable is said to be **dominant**. The allele whose effects are hidden is said to be **recessive** (from the Latin root for "hiding"). Traditionally, for loci having two alleles, the dominant allele is denoted by an uppercase letter and the recessive allele is denoted by a lowercase letter. When one allele is dominant over another, the heterozygote genotype Aa has the same phenotype as the dominant homozygote AA . For the recessive allele to be expressed, it must exist in the **homozygote** form, aa .

When the heterozygote is distinguishable from both homozygotes, the locus is said to exhibit **codominance**. For example, in the MN blood group, both alleles, M and N , of the heterozygote are detectable and therefore codominant. Another example is the ABO blood group, in which heterozygotes having the A and B alleles express both of them as A and B antigens on their red cells (forming blood group AB).

A **carrier** is an individual who has a disease-causing allele but is phenotypically normal. Most recessive disease-causing alleles occur in heterozygotes who carry one copy of the allele but do not express the disease. Because many recessive alleles are lethal in the homozygous state, they are eliminated from the population when they occur in homozygotes. By "hiding" in carriers, however, most recessive alleles survive to be passed on to the next generation.

Transmission of Genetic Diseases

An important aspect of a genetic disease is the pattern in which it is inherited through the generations of a family, or its **mode of inheritance**. Once the mode of inheritance is known, much can be learned about the disease-causing gene itself, and more reliable genetic counseling can be given to members of families in which the disease is present.

Modes of inheritance were systematically studied by Mendel, who formulated two basic laws of inheritance. His **principle of segregation** states that homologous genes separate from one another during reproduction and that each reproductive cell carries only one of the homologous genes. Mendel's second law, the **principle of independent assortment**, states that the hereditary transmission of one gene has no effect on the transmission of another. Mendel discovered these laws in the mid-nineteenth century by performing breeding experiments with garden peas. He had no knowledge of chromosomes. Early in the twentieth century geneticists found that the behavior of chromosomes does essentially correspond to Mendel's laws, which now form the basis for the **chromosome theory of inheritance**.

The known single-gene diseases can be classified into four major modes of inheritance: autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive. The first two types involve genes known to occur on the 22 pairs of autosomes. The last two types occur on the X chromosome; only a few disease-causing genes, primarily affecting male fertility, are found on the Y chromosome. The number of diseases assigned to each category is growing rapidly. Current catalogs of single-gene traits, which include disease-producing and nonclinical traits (e.g., attached earlobes), list nearly 22,000 known autosomal traits and nearly 1200 X-linked traits.¹

An important tool in the analysis of modes of inheritance is the **pedigree** chart. It summarizes family relationships and shows which members of a family are affected by a genetic disease (Fig. 4.21). Generally, the pedigree begins with one individual in the family, the

proband, also termed the **propositus** (male) or **proposita** (female). This individual is usually the first person in the family diagnosed or seen in a clinic.

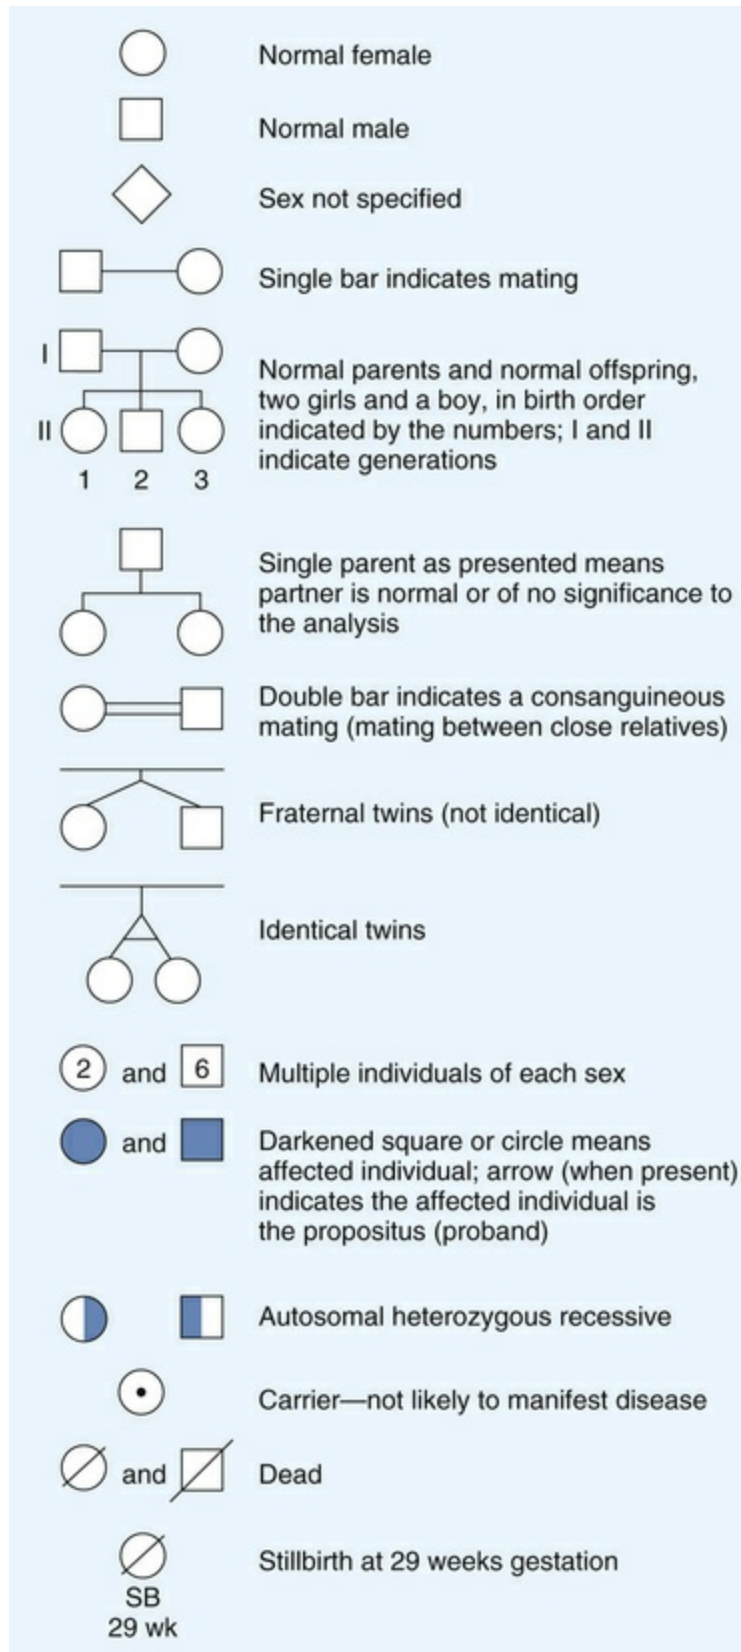

FIGURE 4.21 Symbols Commonly Used in Pedigrees.

Autosomal Dominant Inheritance

Characteristics of Pedigrees

Diseases caused by autosomal dominant genes are relatively rare. The most common occur in fewer than 1 in 500 individuals, so it is uncommon for 2 individuals both affected by the same autosomal dominant disease to produce offspring together. Fig. 4.22, A, illustrates this unusual pattern. More often, affected offspring are produced by the union of a normal parent with an affected heterozygous parent. The diagram (Punnett square) in Fig. 4.22, B, illustrates this mating. The affected parent can pass either a disease gene or a normal gene to the children. Each event has a probability of 0.5; thus, on average, half of the children will be heterozygous and will express the disease, and half will be normal.

FIGURE 4.22 Punnett Square and Autosomal Dominant Traits. A, Punnett square for the mating of two individuals with an autosomal dominant gene.

Here both parents are affected by the trait. B, Punnett square for the mating of a normal individual with a carrier for an autosomal dominant gene.

Fig. 4.23, A, is a typical pedigree showing the transmission of an autosomal dominant allele. The allele shown here causes achondroplasia (Fig. 4.23, B). Several important characteristics of this pedigree support the conclusion that the trait is caused by an autosomal dominant allele:

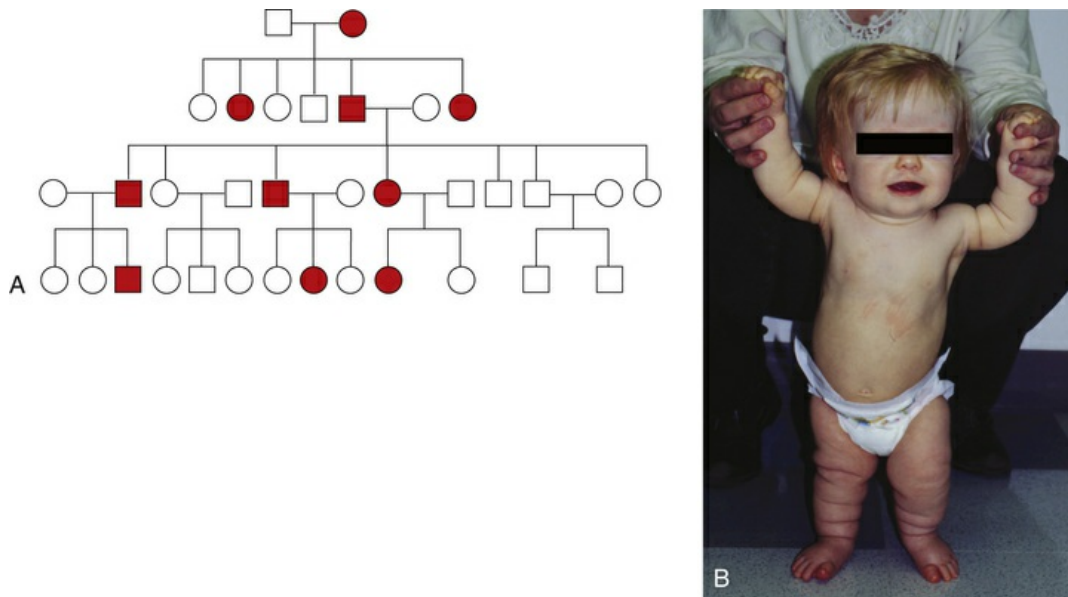

FIGURE 4.23 Achondroplasia. A, Pedigree showing the transmission of an autosomal dominant disease. B, Achondroplasia. This girl has short limbs relative to trunk length. She also has a prominent forehead, a low nasal bridge, and redundant skin folds in the arms and legs. (B from Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

1. The two sexes exhibit the trait in approximately equal proportions, and males and females are equally likely to transmit the trait to their offspring.
2. There is no skipping of generations. If an individual has achondroplasia, one parent must also have it. If neither parent has the trait, none of the children has it (with the exception of new mutations, as discussed later).
3. Affected heterozygous individuals transmit the trait to

approximately half of their children, but because gamete transmission is subject to chance fluctuations, it is possible that all or none of the children of an affected parent may have the trait. When large numbers of matings of this type are studied, however, the proportion of affected children will closely approach one-half.

Recurrence Risks

Parents at risk for producing children with a genetic disease nearly always ask the question, "What is the *chance* that the child will have this disease?" The probability that a family member will have a genetic disease is termed the **recurrence risk**. When one parent is affected by an autosomal dominant disease (and is a heterozygote) and the other is unaffected, the recurrence risks for each child are one-half.

An important principle is that each birth is an independent event, much like a coin toss. Thus, even though parents may already have had a child with the disease, their recurrence risk remains one-half. If they have had several children, all affected (or all unaffected) by the disease, the law of independence dictates that the probability that their next child will have the disease is still one-half. Parents' misunderstanding of this principle is a common problem encountered in genetic counseling.

If a child has been born with an autosomal dominant disease and there is no history of the disease in the family, the child is probably the product of a new mutation. The gene transmitted by one of the parents has thus undergone a mutation from a normal to a disease-causing allele. The alleles at this locus in most of the parent's other germ cells would still be normal. In this situation the recurrence risk for the parent's subsequent offspring is not greater than that of the general population. The offspring of the affected child, however, will have a recurrence risk of one-half. Because these diseases often reduce the potential for reproduction, a large proportion of the observed cases of many autosomal dominant diseases are the result of new mutations. For example, approximately seven-eighths of all cases of

achondroplasia are caused by new mutations.

Occasionally, two or more offspring will present symptoms of an autosomal dominant disease when there is no family history of the disease. Because mutation is a rare event, it is unlikely that this disease would be a result of multiple mutations in the same family. The mechanism most likely to be responsible is termed **germline mosaicism**. During the embryonic development of one of the parents, a mutation occurred that affected all or part of the germline but few or none of the somatic cells of the embryo. Thus the parent carries the mutation in the germline but does not actually express the disease. As a result, the unaffected parent can transmit the mutation to multiple offspring. This phenomenon, although relatively rare, can have significant effects on recurrence risks.¹²

Penetrance and Expressivity

An important variation seen in some genetic diseases is incomplete penetrance. The **penetrance** of a trait is the percentage of individuals with a specific genotype who also exhibit the expected phenotype. Incomplete penetrance means that individuals who have a disease-causing allele may not exhibit the disease phenotype at all, even though the allele and the associated disease may be transmitted to the next generation. A pedigree illustrating the transmission of an autosomal dominant allele with incomplete penetrance is given in [Fig. 4.24](#). Retinoblastoma, the most common malignant eye tumor affecting children, typically exhibits incomplete penetrance. About 10% of the individuals who are **obligate carriers** of the allele (i.e., those who have an affected parent and affected children and therefore must themselves carry the allele) do not have the disease. The penetrance of the disease-causing genotype is then said to be 90%.

FIGURE 4.24 Pedigree for Retinoblastoma Showing Incomplete Penetrance. The female with the marked arrow in line II must be heterozygous, but the trait is not expressed.

The gene responsible for retinoblastoma encodes a **tumor-suppressor gene**, the normal function of which is to regulate the cell cycle so that cells do not divide in an uncontrollable manner. When a mutation alters the protein, its tumor-suppressing capacity is lost and a tumor can form^{13,14} (see [Chapter 12](#)).

Huntington disease is another well-known autosomal dominant condition, and its main features are progressive dementia and increasingly uncontrollable movements of the limbs (discussed further in [Chapter 17](#)). The latter is known as chorea (Greek *khoreia*, “dance”; the disease is sometimes called *Huntington chorea*).

One of the key features of this disease is that symptoms are not usually seen until age 40 years or later, a pattern known as **age-dependent penetrance**. Thus people who develop the disease often have had children before they are aware that they have the disease-causing allele. If the disease was present at birth, nearly all those affected would die before reaching reproductive age, and the occurrence of the allele in the population would be much lower. Individuals whose parent has the disease have a 50% chance of developing it during middle age. Individuals are thus confronted with a torturous question: “Should I have children, knowing that there is a 50-50 chance that I may have this disease gene and pass it to half my children?” Age-dependent penetrance characterizes a number of important genetic diseases, including familial breast cancer, familial colon cancer, hemochromatosis, and polycystic kidney disease.

Most genetic diseases exhibit variable expressivity. **Expressivity** is the extent of variation in phenotype associated with a particular genotype. If the expressivity of a disease is variable, the penetrance

may be complete but the severity of the disease can vary greatly. A well-known example of variable expressivity in an autosomal dominant disease is type 1 neurofibromatosis, or von Recklinghausen disease. Like the retinoblastoma gene, the neurofibromatosis gene normally encodes a tumor suppressor.¹⁵ The expression of this condition can vary from a few harmless café-au-lait spots (“coffee with milk,” describing the light brown color) on the skin to malignant tumors, scoliosis, seizures, gliomas, hypertension, learning disabilities, and neuromas (Fig. 4.25). A parent with mild expression of the disease—so mild that the individual is not aware of it—can transmit the gene to a child, who can then exhibit severe expression of the disease. Several factors can cause variation in expressivity. Genes at other loci can sometimes modify the expression of a disease-causing gene (these are termed *modifier genes*). Environmental factors also can influence the expression of a disease-causing gene. Finally, different types of mutations at a locus can cause variation in severity. For example, a base substitution resulting in a single amino acid change (a missense mutation) usually produces a mild form of the clotting disorder hemophilia A. A nonsense mutation (which produces a stop codon and thus premature termination of translation) usually produces a more severe form of hemophilia A.

Autosomal Recessive Inheritance

Characteristics of Pedigrees

Like autosomal dominant diseases, those caused by autosomal recessive alleles are rare in populations, although the frequency of carriers for recessive diseases can be high. The most common lethal recessive disease in white children, cystic fibrosis, occurs in about 1 in 2500 births. Approximately 1 in 25 whites carries 1 copy of an allele that can cause cystic fibrosis (see [Chapter 35](#)). Because an individual must be homozygous for a recessive allele to express the disease, the carriers are phenotypically normal. Because most recessive alleles are maintained in normal carriers, they are able to survive in the population from one generation to the next. As with many autosomal dominant diseases, many autosomal recessive diseases are characterized by delayed age of onset, incomplete penetrance, and variable expressivity.

[Fig. 4.26](#) shows a pedigree for cystic fibrosis. The cystic fibrosis gene encodes a protein product that forms chloride channels in the membranes of specialized epithelial cells.¹⁶ Defective transport of chloride ions leads to a salt imbalance that results in secretions of abnormally thick, dehydrated mucus. Some of the digestive organs, particularly the pancreas, become obstructed, causing malnutrition, and the lungs become clogged with mucus, making them highly susceptible to bacterial infections (especially *Pseudomonas*). Death from lung disease or heart failure occurs on average by about 40 years of age. In the pedigree shown, the two affected individuals are the offspring of the marriage of two first cousins. Marriage between related individuals, termed **consanguinity** (from the Latin root meaning “with blood”), is often a factor in producing children with recessive diseases because related individuals are more likely to share the same recessive disease-causing alleles. Consanguinity is seen most often in rare recessive diseases because carriers of common recessive

diseases (such as cystic fibrosis) have a fairly high probability of encountering one another just by chance.

FIGURE 4.26 Pedigree for Cystic Fibrosis.

Important criteria for discerning autosomal recessive inheritance include the following:

1. Males and females are affected in equal proportions.
2. Consanguinity is sometimes present.
3. The disease is seen in siblings but usually not in their parents.
4. On average, one-fourth of the offspring of carrier parents will be affected.

Recurrence Risks

In most cases of recessive disease, both parents of affected individuals are heterozygous carriers. On average, one-fourth of their offspring will be normal homozygotes, one-half will be phenotypically normal carrier heterozygotes, and one-fourth will be homozygotes with the disease (Fig. 4.27). Thus the recurrence risk for the offspring of carrier parents is 25%. In any given family, chance fluctuations are likely, but a study of a large number of families would yield figures close to these proportions.

	D	d
D	DD Homozygous normal	Dd Heterozygous carrier
d	Dd Heterozygous carrier	dd Homozygous affected

FIGURE 4.27 Punnett Square for the Mating of Heterozygous Carriers. This is typical of most cases of recessive disease.

If two parents have a recessive disease, they each must be homozygous for the disease. Therefore, when two parents are affected by a recessive disease, all their children also must be affected. This observation helps to distinguish recessive from dominant inheritance, because two parents both affected by a dominant disease are nearly always both heterozygotes, and thus one-fourth of their children will be unaffected.

Because carrier parents usually are unaware that they both carry the same recessive gene, they often produce an affected child before realization of their condition. **Carrier detection tests** can identify heterozygotes by direct examination of the disease locus for a mutation. Such testing is especially valuable for siblings of known carriers, who may themselves be carriers. Genetic testing is now available for nearly 5000 diseases.

Consanguinity

Consanguinity and **inbreeding** are related concepts. *Consanguinity* refers to the mating of two related individuals, and the offsprings of such matings are said to be *inbred*. Consanguinity is often an important characteristic of pedigrees for recessive diseases because relatives share a certain proportion of alleles received from a common ancestor. The proportion of shared alleles depends on the closeness of their biologic relationship. For example, siblings share one-half of their DNA, on average, because of their descent from the same parents. With each decreasing degree of relationship, this proportion

is reduced by one-half. Uncles share one-fourth of their DNA with nephews and nieces; first cousins share one-eighth; first cousins once removed (offspring of one's own first cousins) share one-sixteenth; second cousins share one-thirty-second; and so on. The frequency of recessive disorders increases significantly in the offspring of consanguineous unions. Most empirical studies show that the proportion of offspring of marriages of first cousins who are affected by genetic diseases is approximately double that of the general population.¹⁷ Marriages between first cousins are prohibited in most states of the United States. (*First cousins* are the offspring of two siblings and thus share a set of grandparents.) Marriages between closer relatives are prohibited throughout the United States.

X-Linked Inheritance

Not all genetic diseases are caused by genes located on the 22 autosomes. Some conditions are instead caused by genes located on the sex chromosomes, and that mode of inheritance is referred to as **sex-linked**. The Y chromosome contains only a few dozen genes, so most sex-linked traits are located on the X chromosome and are said to be X-linked. With the exception of fragile X syndrome (discussed earlier), which is considered to be X-linked dominant with incomplete penetrance, X-linked dominant diseases are relatively rare. Only the more common X-linked recessive diseases are discussed here.

Females receive two X chromosomes, one from the father and one from the mother, so they can be homozygous for a disease allele at a given locus, homozygous for the normal allele at the locus, or heterozygous. Males, having only one X chromosome, are said to be **hemizygous** for genes on this chromosome. A male who inherits a recessive disease allele on the X chromosome will be affected by the disease because the Y chromosome does not carry a normal allele to counteract the effects of the disease-causing allele. Consequently, males are more frequently affected by X-linked recessive diseases, with the difference becoming more pronounced as the disease becomes rarer.

X Inactivation

In the late 1950s, Mary Lyon proposed that one X chromosome in the somatic cells of females is permanently inactivated, a process termed **X inactivation**.¹⁸ This explains why most gene products coded by the X chromosome are present in roughly equal amounts in males and females, even though males have only one X chromosome and females have two X chromosomes. This phenomenon is called **dosage compensation**. The inactivated X chromosomes are observable in many interphase cells as highly condensed chromatin bodies, termed **Barr bodies** (after Barr and Bertram, who discovered them in the late 1940s). Normal females have one Barr body in each somatic cell, whereas normal males have no Barr bodies.

The process of inactivation occurs very early in embryonic development—approximately 7 to 14 days after fertilization. In each somatic cell, one of the two X chromosomes is inactivated. In some cells the X chromosome contributed by the father is inactivated; in others the maternally contributed X chromosome is inactivated. Because the inactivation process is random, the maternal X chromosome is inactivated in approximately half the cells and the paternal X chromosome is inactivated in approximately half the cells. Once the X chromosome has been inactivated in a cell, all the descendants of that cell have the same chromosome inactivated. Thus inactivation is said to be *random* but *fixed*.

Some individuals do not have the normal number of X chromosomes in their somatic cells. For example, males with Klinefelter syndrome typically have two X chromosomes and one Y chromosome and they have one Barr body in each cell. Females whose cell nuclei have three X chromosomes have two Barr bodies in each cell, and females whose cell nuclei have four X chromosomes have three Barr bodies in each cell. Females with Turner syndrome have only one X chromosome and no Barr bodies. Thus the number of Barr bodies is always one less than the number of X chromosomes in the cell. All but one X chromosome are always inactivated.

People with abnormal numbers of X chromosomes, such as those with Turner syndrome or Klinefelter syndrome, are not physically

normal. This situation presents a puzzle because they presumably have only one active X chromosome, the same as individuals with normal numbers of chromosomes. However, the distal portions of the short and long arms of the X chromosome, as well as other regions on the chromosome, are not inactivated. In total, about 15% of the genes on the human X chromosome escape inactivation. Thus X inactivation is also said to be *incomplete*.

Although the mechanism underlying X inactivation is still incompletely understood, the gene responsible for initiating X inactivation, *XIST*, has been located.¹⁹ This gene encodes a lncRNA that coats the copy of the X chromosome on which it is expressed, which then inactivates most of the genes on the chromosome. Methylation of X chromosome DNA, a process in which DNA is inactivated when cytosine bases are enzymatically converted to 5-methylcytosine, occurs on the inactivated X chromosome. Inactive X chromosomes can be at least partially reactivated in vitro by administering 5-azacytidine, a demethylating agent.

Sex Determination

The process of sexual differentiation, in which the embryonic gonads become either testes or ovaries, begins during the sixth week of gestation. A key principle of sex determination in mammals is that one copy of the Y chromosome is sufficient to initiate the process of gonadal differentiation that produces a male fetus (Fig. 4.28, A). The number of X chromosomes does not alter this process. For example, an individual with two X chromosomes and one Y chromosome in each cell is still phenotypically a male. Thus it is logical that the Y chromosome must contain a gene that begins the process of male gonadal development.

FIGURE 4.28 The Distal Short Arms of the X and Y Chromosomes Exchange Material During Meiosis in the Male. A, X and Y chromosomes. B, The region of the Y chromosome in which this crossover occurs is called the *pseudoautosomal region*. (Xp and Yp refer to the short arms of each chromosome.) The *SRY* gene, which triggers the process leading to male gonadal differentiation, is located just outside the pseudoautosomal region. Occasionally, the crossover occurs on the centromeric side of the *SRY* gene, causing it to lie on an X chromosome instead of a Y chromosome. An offspring receiving this X chromosome will be an XX male, and an offspring receiving the Y chromosome will be an XY female. (A from Raven PH et al: *Biology*, ed 8, New York, 2008, McGraw-Hill. B from Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

This gene, termed *SRY* (for “sex-determining region on the Y”), has been located on the short arm of the Y chromosome.^{20,21} The *SRY* gene lies immediately proximal to the distal tip of the Y chromosome, known as the **pseudoautosomal** region (see Fig. 4.28, B). This portion of the Y chromosome is so named because it pairs with the distal tip of the short arm of the X chromosome during meiosis and exchanges genetic material with it (crossover), just as autosomes do. The DNA sequences of these regions on the X and Y chromosomes are highly similar. The remainder of the X and Y chromosomes, however, do not exchange material and are not similar in DNA sequence. An important piece of evidence that supports *SRY* as the male-determining gene is that female mouse embryos injected with this gene develop as phenotypic males.

Although the *SRY* gene is located on the Y chromosome, the other genes that contribute to male differentiation are located on other chromosomes. Thus *SRY* appears to act as a trigger that initiates the action of genes on other chromosomes (e.g., those that control Sertoli cell differentiation or secretion of müllerian-inhibiting substance). This concept is supported by the fact that the *SRY* gene is similar in sequence to other genes that are known to regulate the transcription of DNA (i.e., they turn other genes on and off).

Occasionally the crossover between X and Y occurs closer to the centromere than it should, placing the *SRY* gene on the X chromosome after crossover (see Fig. 4.28, B). This event can result in offspring with an apparently normal XX karyotype but a male phenotype. Such XX males are seen in about 1 in 20,000 live births and closely resemble males with Klinefelter syndrome, although their stature is normal. Conversely, it is possible to inherit a Y chromosome that has lost the *SRY* gene (because of either a crossover error or a deletion of the gene). This situation produces an XY female. Such females have gonadal streaks rather than ovaries and have poorly developed secondary sex characteristics.

Characteristics of Pedigrees

Pedigrees for X-linked recessive conditions show the following

distinctive features:

1. The trait is seen much more often in males than in females because females must inherit two copies of the recessive allele (one from each parent) to express the disease, whereas males need only inherit one copy (from their mother) to express the disease.
2. Because a father can give a son only a Y chromosome, the trait is never transmitted from father to son.
3. The gene can be transmitted through a series of carrier females, causing the appearance of “skipped generations.”
4. The gene is passed from an affected father to all his daughters, who, as phenotypically normal carriers, transmit it to approximately half their sons, who are affected.

The most common and severe of all X-linked recessive disorders is Duchenne muscular dystrophy (DMD), which affects approximately 1 in 3500 males. As its name suggests, this disorder is characterized by progressive muscle degeneration. Affected individuals are usually unable to walk by 10 to 12 years of age. The disease affects the heart and respiratory muscles, and death caused by respiratory or cardiac failure usually occurs before 20 years. For many years, the underlying pathologic origin of this disorder was a mystery. However, identification of the disease-causing gene has greatly increased our understanding of DMD.²¹ The *DMD* gene is the largest gene known in the human, spanning about 2.5 million DNA bases. It encodes a previously undiscovered muscle protein, termed **dystrophin**. Extensive study of dystrophin indicates that it plays an essential role in maintaining the structural integrity of muscle cells: one end of the protein binds to actin filaments in the cytoplasm of the cell, and the other end binds to a group of membrane-spanning proteins known as the *dystrophin-associated glycoproteins*. When dystrophin is absent, as in individuals with DMD, the muscle cell cannot survive, and muscle deterioration ensues.

Most cases of Duchenne muscular dystrophy are caused by

deletions of portions of the *DMD* gene. They usually involve frameshift deletions in which all the amino acids following the deletion are altered and a premature stop codon occurs. An “in frame” deletion (in which a multiple of three bases is deleted, and the amino acids following the deletion are not altered) produces a milder form of muscular dystrophy, the Becker type. These two types of muscular dystrophy are examples of a disease in which different types of mutations at the same locus produce variable expression of the disease.

Recurrence Risks

The most common mating type involving X-linked recessive genes is the combination of a carrier female and a normal male. On average, the carrier mothers will transmit the disease-causing allele to half their sons and half their daughters. As [Fig. 4.29, A](#), shows, half the daughters in such a mating will be carriers, whereas half will be normal. Half the sons will be normal, on average, whereas half will have the disease.

		Mother	
		X_H	X_h
Father	X_H	X_HX_H	X_hX_H

B

		Mother	
		X_H	X_h
Father	X_h	X_HX_h	X_hX_h
	Y	X_HY	X_hY

C

□ Normal □ Carrier ■ Affected

FIGURE 4.29 Punnett Square and X-Linked Recessive Traits. A, Punnett square for the mating of a normal male (X_HY) and a female carrier of an X-linked recessive gene (X_HX_h). B, Punnett square for the mating of a normal female (X_HX_H) with a male affected by an X-linked recessive disease (X_hY). C, Punnett square for the mating of a female who carries an X-linked recessive gene (X_HX_h) with a male who is affected with the disease caused by the gene (X_hY).

The other common mating type is an affected father and a normal mother (see Fig. 4.29, B). In this situation all the sons must be normal because the father can transmit only his Y chromosome to them. Because all the daughters must receive the father's X chromosome, they will all be heterozygous carriers. None of the children will express the disease.

The final mating pattern, less common than the other two, involves an affected father and a carrier mother (see Fig. 4.29, C). With this pattern, on average, half the daughters will be heterozygous carriers and half will be homozygous for the disease allele and thus affected. Half the sons will be normal, and half will be affected. Some X-linked recessive diseases, such as DMD, are fatal or incapacitating before the affected individual reaches reproductive age, and therefore affected fathers are rare or nonexistent.

Sex-Limited and Sex-Influenced Traits

Confusion sometimes exists regarding the difference between traits that are sex-linked and those that are sex-limited or sex-influenced. A **sex-limited trait** is one that can occur in only one of the sexes, often because of anatomic differences. Inherited uterine and testicular defects are two obvious examples.

A **sex-influenced trait** is one that occurs much more often in one sex than in the other. A good example of a sex-influenced trait is male-pattern baldness, which occurs in both males and females but is much more common in males. Another example is breast cancer, which is approximately 70 times more common in females than males.

Evaluation of Pedigrees

With complications such as incomplete or age-dependent penetrance, variable expressivity, and sex-influenced traits, it is not always possible simply to look at a disease pedigree and determine the mode of inheritance. Sophisticated statistical approaches have evolved to deal with such complications. Incorporated into computer programs, these statistical techniques assess the probability of observing a certain pedigree if a particular mode of inheritance (e.g., autosomal dominant with incomplete penetrance) is in effect.

Linkage Analysis and Gene Identification

Locating the positions of genes on chromosomes has been one of the most important endeavors in human genetics. It is often an important first step in identifying a disease-causing gene and can be used to predict the likelihood that certain individuals will develop a genetic disease.

Mendel's second law, the principle of independent assortment, states that an individual's genes will be transmitted to the next generation independently of one another. This law is only partly true, however, because genes located close together on the same chromosome *do* tend to be transmitted together to the offspring. Thus Mendel's principle of independent assortment holds true for most pairs of genes but not those that occupy the same region of a chromosome. Such loci demonstrate **linkage** and are said to be linked.

During the first meiotic stage, the arms of homologous chromosome pairs intertwine and sometimes exchange portions of their DNA ([Fig. 4.30](#)) in a process known as **crossing over**. During crossing over, new combinations of alleles can be formed. For example, two loci on a chromosome have alleles *A* and *a* and alleles *B* and *b*. Alleles *A* and *B* are located together on one chromosome arm, and alleles *a* and *b* are located on the other arm. The genotype of this individual is denoted as *AB/ab*.

FIGURE 4.30 The Genetic Results of Crossing Over. **A**, No crossing over: A₁ and B₁ remain together after meiosis. **B**, Crossing over between A and B results in a recombination: A₁ and B₂ are inherited together on one chromosome, and A₂ and B₁ are inherited together on another chromosome. **C**, A double crossover between A and B results in no recombination of alleles.

As Fig. 4.30, A, shows, the allele pairs AB and ab would be transmitted together when no crossing over occurs. However, when crossing over does occur (see Fig. 4.30, B), all four possible pairs of alleles can be transmitted to the offspring: AB , aB , Ab , and ab . The process of forming such new arrangements of alleles is called **recombination**. Crossing over does not necessarily lead to recombination, however, because double crossing over between two loci can result in no actual recombination of the alleles at the loci (see Fig. 4.30, C).

The rate of crossing over can be used to infer the distance between two loci on a chromosome because the probability of crossovers occurring between two loci increases as the loci become more distant. For example, if an individual with genotype AB/ab produces recombinant offspring gametes (composition of Ab and aB) 2% of the time, it is said that the two loci are two map units apart. One **map unit**

equals a 1% recombination rate between two loci. When loci on the same chromosome are 50 or more map units apart, they are considered unlinked because their recombination frequency is just as great as it would be if they were on different chromosomes (where the probability of being transmitted together must equal one-half). Recombination frequencies provide a good estimate of actual physical distance between loci: on average, each map unit is equal to approximately 1 million DNA base pairs.

An important early goal of the Human Genome Project was to establish a “map” of markers (polymorphic loci with known chromosome locations that could be assayed easily in laboratories) spanning the entire genome. In pedigrees in which a mendelian disease is being transmitted, the recombination rate between the disease-causing gene and each marker locus is assessed. When a marker locus shows little or no recombination with the disease locus, we know that the disease locus must be located near the position of the marker, and an approximate location for the disease locus has been established. This principle was used to establish the chromosome locations of most of the diseases shown in [Fig. 4.31](#).

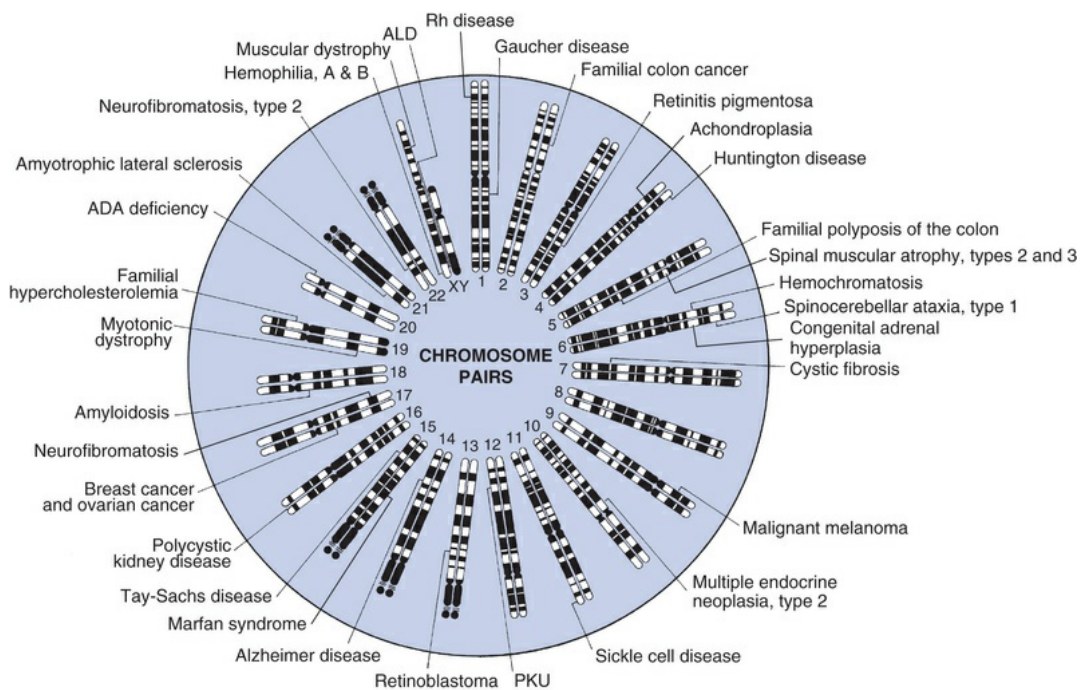

FIGURE 4.31 Example of Diseases: A Gene Map. *ADA*, Adenosine deaminase; *ALD*, adrenoleukodystrophy; *PKU*, phenylketonuria.

Once a close linkage has been established between a disease locus and a marker, it can be predicted whether a relative of an affected individual will develop the disease. If, for example, the recombination rate between a disease locus and a **marker polymorphism** is less than 1%, family members can simply have the marker locus assayed to determine, with 99% or greater certainty, whether each member carries the disease-causing allele.

For most genetic diseases, it is now possible to test directly for the disease-causing mutation, often by sequencing the germline DNA in family members. In some cases, however, the actual disease-causing mutation cannot be identified, but linked marker loci can be assayed to provide an indirect genetic test. Genetic tests are now used routinely to confirm diagnosis of a genetic disease, to identify carriers of recessive diseases, and to presymptomatically identify individuals who are at risk for inheriting a disease with delayed age of onset, such as autosomal dominant breast or colon cancer, Huntington disease, and many others. In some cases, testing can help provide preventive treatment, such as prophylactic oophorectomy in women who have inherited a dominant allele that can cause breast or ovarian cancer.

As the cost of sequencing whole human genomes has declined, it is now common to search for a disease-causing mutation in an individual or a family by evaluating their entire germline DNA sequence (genome).²² Their sequences are compared with those of unaffected individuals, and statistical methods are used to determine which, if any, of their DNA variants cause disease. Linkage results, as discussed previously, can help to define a specific chromosome region that contains a disease-causing variant in a family. Currently, the genetic causes of about 4700 mendelian conditions have been determined,¹ enabling genetic testing, more accurate diagnosis, and in some cases more effective treatment of disease (Box 4.3).

Box 4.3

Genetics and Precision Medicine

Precision medicine, also known as *personalized* medicine, is a healthcare model in which each person's unique genetic and environmental risk factors are taken into account in the diagnosis and management of disease. Because genes contribute to susceptibility to nearly all human diseases, and because each individual is genetically unique, it follows that genetics is an important component of precision medicine. As the technology to interrogate the genome becomes more advanced and more affordable, genetics will play an increasingly prominent role in precision medicine.

Genetic analysis, including genetic testing (see [Box 4.2](#)), has become integral to the diagnosis of many diseases. For example, genetic testing of tumor samples is done frequently to help diagnose cancer subtypes and to guide therapeutic treatment. Tumor cells from people with breast cancer are tested for overexpression of the *HER2* gene, which is seen in approximately 20% to 30% of primary breast tumors. Trastuzumab, a monoclonal antibody drug, inhibits the activity of the cell surface receptor encoded by *HER2* and significantly improves survival.

As the price of whole-genome DNA sequencing continues to decline, it is becoming increasingly common to diagnosis disease by searching for disease-causing variants in the person's entire DNA sequence (or in the **exome**, which is the 1.5% of the genome that contains protein-coding exons). This approach can be particularly powerful in those individuals in whom the cause of disease is unknown. Currently, “diagnostic odysseys,” which can continue for years and can cost hundreds of thousands of dollars, can sometimes be resolved quickly and accurately through whole-genome sequencing. The challenges encountered in whole-genome sequencing include the interpretation of “variants of unknown significance” and the appropriate management of incidental genetic findings (e.g., a person referred because of an undiagnosed neurologic disorder who is found to have a *BRCA1* or *BRCA2* mutation that has a high probability of causing breast or ovarian

cancer or, perhaps more problematically, a mutation that causes familial Alzheimer disease).

Perhaps the area in which genetics is contributing most significantly to precision medicine is in the guidance of therapeutic drug prescription. Of the 1200 drugs approved by the FDA, about 15% have recommendations on their labels for genetic testing to guide administration and dosage. Genetic testing can help to avoid severe adverse drug reactions, which are estimated to cause 2 million hospitalizations and 100,000 deaths per year in the United States. For example, a variant in the *TPMT* gene, seen in homozygous form in 1 in 300 Europeans, causes severe and potentially lethal bone marrow suppression upon exposure to thiopurine drugs used to treat acute lymphocytic leukemia. Consequently, genetic testing to avoid this reaction is done routinely in the administration of thiopurine drugs. In addition to avoiding drugs harmful to the individual, genetic testing can be used to formulate drug dosage more precisely. Variants in the *CYP2D6* gene (which encodes a cytochrome P-450 enzyme) influence the metabolism of more than 25% of all prescribed drugs, including tricyclic antidepressants, beta-adrenergic receptor blockers, and neuroleptics. Testing of *CYP2D6*, as well as other genes involved in drug metabolism, can reduce trial-and-error in estimating appropriate drug dosage levels.

Summary Review

DNA, RNA, and Proteins: Heredity at the Molecular Level

1. Genes, the basic units of inheritance, are composed of DNA and are located on the chromosomes.

2. The most important constituent of DNA is the four types of nitrogenous bases, labeled A, C, G, and T. The physical structure of DNA is a double helix.
3. The DNA bases code for amino acids, which in turn make up proteins. The amino acids are specified by triplet codons of nitrogenous bases.
4. DNA replication is based on complementary base pairing, in which a single strand of DNA serves as the template for attracting bases that form a new strand of DNA.
5. DNA polymerase is the primary enzyme involved in replication. It adds bases to the new DNA strand and performs “proofreading” functions.
6. A mutation is an inherited alteration of genetic material (i.e., DNA).
7. Substances that cause mutations are called *mutagens*.
8. The mutation rate in humans varies from locus to locus and ranges from 10^{-4} to 10^{-7} per gene per generation.
9. Transcription and translation, the two basic processes in which proteins are specified by DNA, both involve RNA. RNA is chemically similar to DNA, but it is single stranded and has uracil rather than thymine as one of its four nitrogenous bases.
10. Transcription is the process by which DNA specifies a sequence of mRNA.
11. Much of the RNA sequence is spliced from the mRNA before the mRNA leaves the nucleus. The excised sequences are called *introns*, and those that remain to code for proteins are called *exons*.
12. MicroRNAs (miRNAs) are small RNA sequences, 17 to 27 nucleotides in length, that bind to specific mRNA sequences and down-regulate their expression. Another nontranslated RNA, classified as having a length greater than 200 nucleotides, is termed *long noncoding RNA* (lncRNA). The genome contains at least 10,000 lncRNAs, and, like miRNA, some lncRNAs are involved in gene regulation.
13. Transcription factors bind to DNA sequences called

transcription factor binding sites near genes to regulate the timing of transcription, as well as the specific tissues in which genes are actively transcribed.

14. Translation is the process by which RNA directs the synthesis of polypeptides. This process takes place in the ribosomes.
15. During translation, mRNA interacts with tRNA, a molecule that has an attachment site for a specific amino acid.

Chromosomes

1. Human cells consist of diploid somatic cells (body cells) and haploid gametes (sperm and egg cells).
2. Humans have 23 pairs of chromosomes: 22 of these pairs are autosomes. The remaining pair consists of the sex chromosomes. Females have two homologous X chromosomes as their sex chromosomes; males have an X and a Y chromosome.
3. A karyotype is an ordered display of chromosomes arranged according to length and the location of the centromere.
4. Various types of stains can be used to make chromosome bands more visible.
5. About 1 in 150 live births has a major diagnosable chromosome abnormality. Chromosome abnormalities are the leading known cause of intellectual disability and miscarriage.
6. Polyploidy is a condition in which a euploid cell has some multiple of the normal number of chromosomes. Humans have been observed to have triploidy (three copies of each chromosome) and tetraploidy (four copies of each chromosome); both conditions are lethal.
7. Somatic cells that do not have a multiple of 23 chromosomes are aneuploid. Aneuploidy is usually the result of nondisjunction.
8. Trisomy is a type of aneuploidy in which one chromosome is present in three copies in somatic cells. A partial trisomy is one in which only part of a chromosome is present in three copies.

9. Monosomy is a type of aneuploidy in which one chromosome is present in only one copy in somatic cells.
10. In general, monosomies cause more severe physical defects than do trisomies, illustrating the principle that the loss of chromosome material has more severe consequences than the duplication of chromosome material.
11. Down syndrome, a trisomy of chromosome 21, is the most well-known disease caused by a chromosome aberration. It affects 1 in 800 live births and is much more likely to occur in the offspring of women older than 35 years of age.
12. Most aneuploidies of the sex chromosomes have less severe consequences than those of the autosomes.
13. The most commonly observed sex chromosome aneuploidies are the 47,XXX karyotype; 45,X karyotype (Turner syndrome); 47,XXY karyotype (Klinefelter syndrome); and 47,XYY karyotype.
14. Abnormalities of chromosome structure include deletions, duplications, inversions, and translocations.

Elements of Formal Genetics

1. Mendelian traits are caused by single genes, each of which occupies a position, or locus, on a chromosome.
2. Alleles are different forms of genes located at the same locus on the chromosome.
3. At any given locus in a somatic cell, an individual has two genes, one from each parent. An individual may be homozygous or heterozygous for a locus.
4. An individual's genotype is the person's genetic makeup, and the phenotype reflects the interaction of genotype and environment.
5. At a heterozygous locus, a dominant gene's effects mask those of a recessive gene. The recessive gene is expressed only when it is present in two copies.

Transmission of Genetic Diseases

1. Genetic diseases caused by single genes usually follow autosomal dominant, autosomal recessive, or X-linked recessive modes of inheritance.
2. Pedigree charts are an important tool in the analysis of modes of inheritance.
3. Recurrence risks specify the probability that future offspring will inherit a genetic disease. For single-gene diseases, recurrence risks remain the same for each offspring, regardless of the number of affected or unaffected offspring.
4. The recurrence risk for autosomal dominant diseases is usually 50%.
5. Germline mosaicism can alter recurrence risks for genetic diseases because unaffected parents can produce multiple affected offspring. This situation occurs because the germline of one parent is affected by a mutation but the parent's somatic cells are unaffected.
6. Skipped generations are not seen in classic autosomal dominant pedigrees.
7. Males and females are equally likely to exhibit autosomal dominant diseases and to pass them on to their offspring.
8. A gene that is not always expressed phenotypically is said to have incomplete penetrance.
9. Penetrance may be age-dependent, as in Huntington disease and familial breast cancer.
10. Variable expressivity is a characteristic of many genetic diseases.
11. Most commonly, parents of children with autosomal recessive diseases are both heterozygous carriers of the disease gene. In this case, the recurrence risk for autosomal recessive diseases is 25%.
12. Males and females are equally likely to be affected by autosomal recessive diseases.
13. Consanguinity is sometimes present in families with

autosomal recessive diseases, and it becomes more prevalent with rarer recessive diseases.

14. Carrier detection tests for an increasing number of autosomal recessive diseases are available.
15. The frequency of genetic diseases approximately doubles in the offspring of first-cousin matings.
16. In each normal female somatic cell, one of the two X chromosomes is inactivated early in embryogenesis.
17. X inactivation is random, fixed, and incomplete (i.e., only part of the chromosome is actually inactivated). It may involve methylation.
18. Gender is determined embryonically by the presence of the *SRY* gene on the Y chromosome. Embryos that have a Y chromosome (and thus the *SRY* gene) become males, whereas those lacking the Y chromosome become females. When the Y chromosome lacks the *SRY* gene, an XY female can be produced. Similarly, an X chromosome that contains the *SRY* gene can produce an XX male.
19. X-linked genes are those that are located on the X chromosome. Nearly all known X-linked diseases are caused by X-linked recessive genes.
20. Males are hemizygous for genes on the X chromosome.
21. X-linked recessive diseases are seen much more often in males than in females because males need only one copy of the gene to express the disease.
22. Fathers cannot pass X-linked genes to their sons.
23. Skipped generations are often seen in X-linked recessive disease pedigrees because the gene can be transmitted through carrier females.
24. Recurrence risks for X-linked recessive diseases depend on the carrier and affected status of the mother and father.
25. A sex-limited trait is one that occurs in only one of the sexes.
26. A sex-influenced trait is one that occurs more often in one sex than in the other.

Linkage Analysis and Gene Identification

1. During meiosis I, crossing over occurs and can cause recombinations of alleles located on the same chromosome.
2. The frequency of recombinations can be used to infer the map distance between loci on the same chromosome.
3. A marker locus, when closely linked to a disease-gene locus, can be used to predict whether an individual will develop a genetic disease.
4. The complete human genome sequence will facilitate gene identification, diagnosis, and disease treatment.

Chapter 4 focuses on diseases that are caused by single genes or by abnormalities of single chromosomes. Much progress has been made in identifying specific mutations that cause these diseases, leading to better risk estimates and, in some cases, more effective treatment of the disease. However, these conditions form only a small portion of the total burden of human genetic disease. Most congenital malformations are not caused by single genes or chromosome defects. Many common adult diseases, such as cancer, heart disease, and diabetes, have genetic components, but again they are usually not caused by single genes or by chromosomal abnormalities. These diseases, whose treatment collectively occupies the attention of most healthcare practitioners, are the result of a complex interplay of multiple genetic and environmental factors.

Factors Influencing Incidence of Disease in Populations

Concepts of Incidence and Prevalence

How common is a given disease, such as diabetes, in a population? Well-established measures are used to answer this question.¹ The **incidence rate** is the number of new cases of a disease reported during a specific period (typically 1 year) divided by the number of individuals in the population. The denominator is often expressed as *person-years*. The incidence rate can be contrasted with the **prevalence rate**, which is the proportion of the population affected by a disease at a specific point in time. Prevalence is thus determined by both the incidence rate and the length of the survival period in affected individuals. For example, the prevalence rate of acquired immunodeficiency syndrome (AIDS) is larger than the yearly incidence rate because most people with AIDS survive for at least several years after diagnosis.

Many diseases vary in prevalence from one population to another. Cystic fibrosis is relatively common among Europeans, occurring about once in every 2500 births. In contrast, it is quite rare in Asians,

occurring only once in every 90,000 births. Similarly, sickle cell disease affects approximately 1 in 600 American blacks, but it is seen much less frequently in whites. Both of these diseases are single-gene disorders, and they vary among populations because disease-causing mutations are more or less common in different populations. (This is in turn the result of differences in the evolutionary history of these populations.) Nongenetic (environmental) factors have little influence on the current prevalence of these diseases.

The picture often becomes more complex with the common diseases of adulthood. For example, colon cancer was until recently relatively rare in Japan, but it is the second most common cancer in the United States. Stomach cancer, on the other hand, is common in Japan but relatively rare in the United States. These statistics, in themselves, cannot distinguish environmental from genetic influences in the two populations. However, because large numbers of Japanese emigrated first to Hawaii and then to the U.S. mainland, we can observe what happens to the rates of stomach and colon cancer among the migrants. It is important that the Japanese émigrés maintained a genetic identity, marrying largely among themselves. Among first-generation Japanese in Hawaii, the frequency of colon cancer rose several-fold— not yet as high as in the U.S. mainland but higher than that in Japan. Among second-generation Japanese on the U.S. mainland, colon cancer rates rose to 5%, equal to the U.S. average. At the same time, stomach cancer has become relatively rare among Japanese-Americans.

These observations strongly indicate an important role for environmental factors in the etiology of cancers of the colon and stomach. In each case, diet is a likely culprit—a high-fat, low-fiber diet in the United States is thought to increase the risk of colon cancer, whereas techniques used to preserve and season the fish commonly eaten in Japan are thought to increase the risk of stomach cancer. It is interesting that the incidence of colon cancer in Japan has increased dramatically during the past several decades as the Japanese population has adopted a more “Western” diet. These results do not, however, rule out the potential contribution of genetic factors in

common cancers. Genes also play a role in the etiology of colon and other cancers.

Analysis of Risk Factors

The comparison just discussed is one example of the analysis of risk factors (in this case, diet) and their influence on the prevalence of disease in populations. A common measure of the effect of a specific risk factor is the **relative risk**. This quantity is expressed as a ratio:

$$\frac{\text{Increased rate of the disease among individuals} \\ \text{exposed to a risk factor}}{\text{Incidence rate of the disease among individuals} \\ \textit{not} \text{ exposed to a risk factor}}$$

A classic example of a relative risk analysis was carried out in a sample of more than 40,000 British physicians to determine the relationship between cigarette smoking and lung cancer. This study compared the incidence of death from lung cancer in physicians who smoked with those who did not. The incidence of death from lung cancer was 1.66 (per 1000 person-years) in heavy smokers (more than 25 cigarettes daily), but it was only 0.07 in the nonsmokers. The ratio of these two incidence rates is $1.66/0.07$, which yields a relative risk of 23.7 deaths. Thus, it is concluded that the risk of dying from lung cancer increased by about 24-fold in heavy smokers compared with nonsmokers. Many other studies have obtained similar risk figures.

Although cigarette smoking clearly increases one's risk of developing lung cancer (as well as heart disease, as will be seen later), it is equally clear that *most* smokers do not develop lung cancer. Other lifestyle factors are likely to contribute to one's risk of developing this disease (e.g., exposure to cancer-causing substances in the air, such as asbestos fibers). In addition, differences in genetic background may be involved. Smokers who have variants in genes that are involved in the metabolism of components of tobacco smoke (such as *CYP1A1* and

GSTM1) are at significantly increased risk of developing lung cancer.

Many factors can influence the risk of acquiring a common disease such as cancer, diabetes, or high blood pressure. These include age, gender, diet, amount of exercise, and family history of the disease. Usually, complex interactions occur among these genetic and nongenetic factors. The effects of each factor can be quantified in terms of relative risks. The following discussion demonstrates how genetic and environmental factors contribute to the risk of developing common diseases.

Principles of Multifactorial Inheritance

Basic Model

Traits in which variation is thought to be caused by the combined effects of multiple genes are **polygenic** (“many genes”). When environmental factors are also believed to cause variation in the trait, which is usually the case, the term **multifactorial trait** is used.² Many **quantitative traits** (those, such as blood pressure, that are measured on a continuous numeric scale) are multifactorial. Because they are caused by the additive effects of many genetic and environmental factors, these traits tend to follow a normal, or bell-shaped, distribution in populations.

An example illustrates this concept. To begin with the simplest case, suppose (unrealistically) that height is determined by a single gene with two alleles, *A* and *a*. Allele *A* tends to make people tall, whereas allele *a* tends to make them short. If there is no dominance at this locus, then the three possible genotypes (*AA*, *Aa*, *aa*) will produce three phenotypes: tall, intermediate, and short, respectively. Assume that the gene frequencies of *A* and *a* are each 0.50. When looking at a population of individuals, the height distribution depicted in [Fig. 5.1](#), *A*, will be observed.

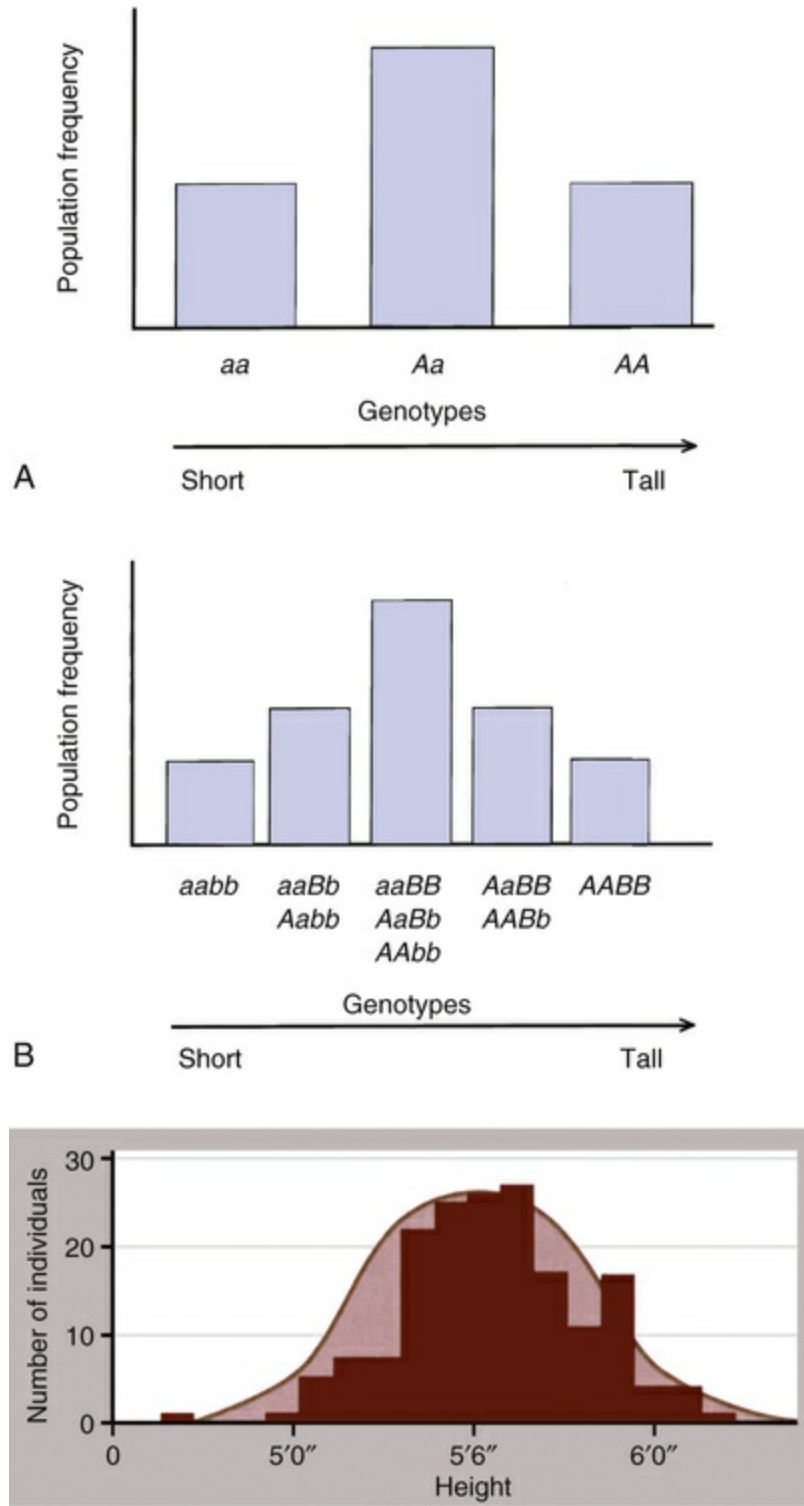

FIGURE 5.1 Distribution of Height. **A**, Distribution of height in a population, assuming that height is controlled by a single locus with genotypes *AA*, *Aa*, and *aa*. **B**, Distribution of height, assuming that height is controlled by two loci. Five distinct genotypes are shown instead of three,

and the distribution begins to look more like the normal distribution. C, Height is portrayed, realistically, as a trait with a continuous statistical distribution. Because many genes contribute to height and tend to segregate independently of one another, the cumulative contribution of different combinations of alleles to height forms a continuous distribution of possible heights, in which the extremes are much rarer than the intermediate values. Variation also can be caused by environmental factors such as nutrition. (A and B adapted from Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier; C from Raven PH et al: *Biology*, ed 8, New York, 2008, McGraw-Hill.)

Now suppose, a bit more realistically, that height is determined by two loci instead of one. The second locus also has two alleles, *B* (tall) and *b* (short), and they affect height in exactly the same way as alleles *A* and *a*. There are now nine possible genotypes in our population: *aabb*, *aaBb*, *aaBB*, *Aabb*, *AaBb*, *AaBB*, *AAbb*, *AABb*, and *AABB*. An individual may have zero, one, two, three, or four “tall” alleles, so now five distinct phenotypes are possible (see Fig. 5.1, B). Although the height distribution in this fictional population is still not normal compared with an actual population, it approaches a normal distribution more closely than in the single-gene case just described.

From extension of this example, *many* genes and environmental factors influence height, each having a small effect. Then many phenotypes are possible, each differing slightly from the others, and the height distribution of the population approaches the bell-shaped curve shown in Fig. 5.1, C.

It should be emphasized that the individual genes underlying a multifactorial trait such as height follow the mendelian principles of segregation and independent assortment, just like any other gene. The only difference is that many of them *act together* to influence the trait. More than 200 genes have now been shown to be associated with variation in human height.

Blood pressure is another example of a multifactorial trait. A correlation exists between parents' blood pressures (systolic and diastolic) and those of their children. The evidence is good that this correlation is partially caused by genes, but blood pressure is also influenced by environmental factors, such as diet, exercise, and stress. Two goals of genetic research are the identification and measurement of the relative roles of genes and environment in the causation of

multifactorial diseases.

Threshold Model

A number of diseases do not follow the bell-shaped distribution. Instead, they appear to be either present or absent in individuals, yet they do not follow the inheritance patterns expected of single-gene diseases. A commonly used explanation for such diseases is that there is an underlying **liability distribution** for the disease in a population (Fig. 5.2). Those individuals who are on the “low” end of the distribution have little chance of developing the disease in question (i.e., they have few of the alleles or environmental factors that would cause the disease). Individuals who are closer to the “high” end of the distribution have more of the disease-causing genes and environmental factors and are more likely to develop the disease. For diseases that are either present or absent, it is thought that a **threshold of liability** must be crossed before the disease is expressed. Below the threshold, an individual appears normal; above it, he or she is affected by the disease.

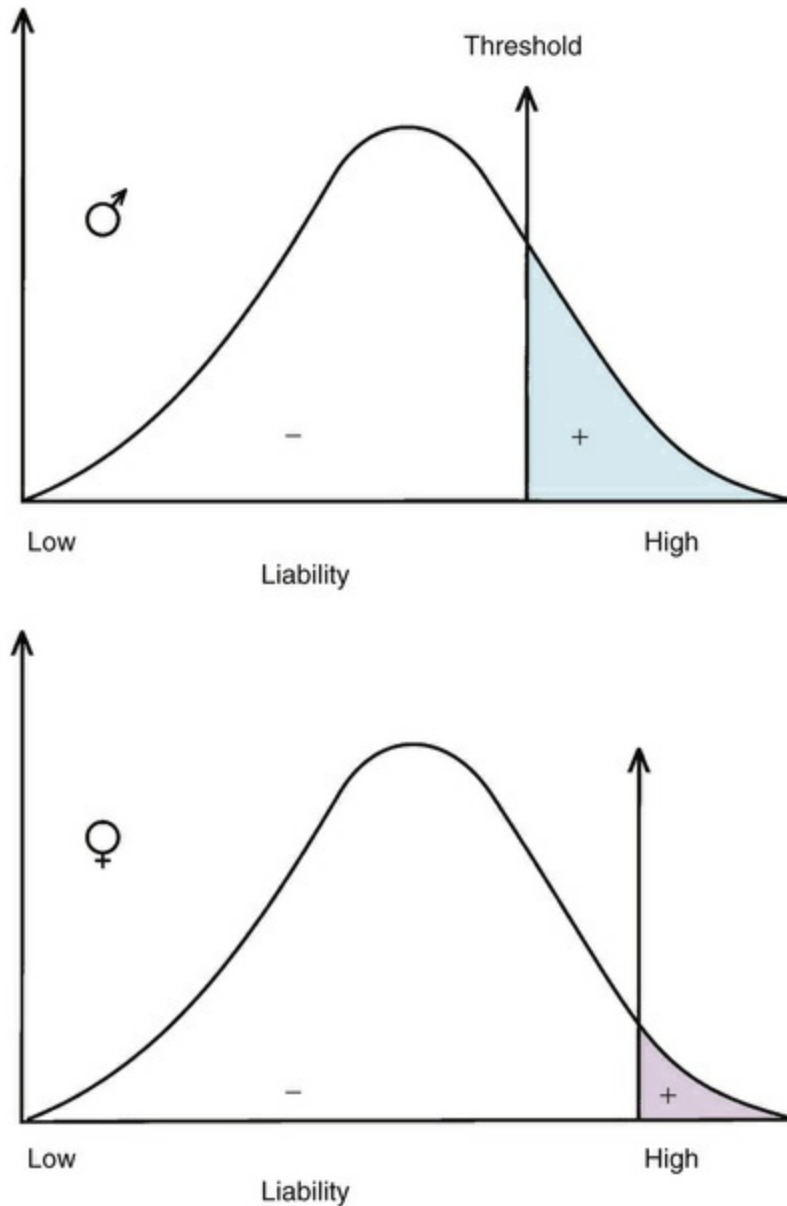

FIGURE 5.2 A Liability Distribution in a Population for a Multifactorial Disease. To be affected with the disease, an individual must exceed the threshold on the liability distribution. This figure shows two thresholds, a lower one for males and a higher one for females (as in pyloric stenosis; see text). (From Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

A disease that is thought to correspond to this threshold model is *pyloric stenosis*, a disorder that presents shortly after birth and is caused by a narrowing or obstruction of the pylorus, the area between the stomach and intestine. Chronic vomiting, constipation, weight loss, and imbalance of electrolyte levels result from the condition, but

it sometimes resolves spontaneously or can be corrected by surgery. The prevalence of pyloric stenosis is about 3 per 1000 live births in whites. It is much more common in males than females, affecting 1 of 200 males and 1 of 1000 females. It is thought that this difference in prevalence reflects two thresholds in the liability distribution—a lower one in males and a higher one in females (see Fig. 5.2). A lower male threshold implies that fewer disease-causing factors are required to generate the disorder in males.

The liability threshold concept may explain the pattern of recurrence risks for pyloric stenosis seen in Table 5.1. Note that males, having a lower threshold, always have a higher risk than females. However, the sibling recurrence risk also depends on the sex of the proband (i.e., the first affected individual diagnosed in a family). It is higher when the proband is female than when the proband is male. This reflects the concept that females, having a higher liability threshold, must be exposed to more disease-causing factors than males to develop the disease. Thus a family with an affected female must have more genetic and environmental risk factors, producing a higher recurrence risk for pyloric stenosis in future offspring. It would be expected that the highest risk category would be *male* relatives of *female* probands; Table 5.1 shows that this is the case.

TABLE 5.1

RECURRENCE RISKS (%) FOR PYLORIC STENOSIS, SUBDIVIDED BY GENDERS OF AFFECTED PROBANDS AND RELATIVES

RELATIVES	MALE PROBANDS		FEMALE PROBANDS	
	LONDON	BELFAST	LONDON	BELFAST
Brothers	3.8	9.6	9.2	12.5
Sisters	2.7	3.0	3.8	3.8

NOTE: The risks differ somewhat between the two populations.

Data from Carter CO: *Br Med Bull* 32(1):21–26, 1976.

A similar pattern has been observed in studies of *autism spectrum disorder*, a behavioral disorder in which the male to female ratio is approximately 4:1. As expected for a multifactorial disorder, the

recurrence risk for siblings of male probands (10%) is lower than that of siblings of female probands (12%).³ When the sex ratio for a disease is reversed (i.e., more affected females than males), one would expect a higher recurrence risk when the proband is male.

A number of other congenital malformations are thought to correspond to this model. They include isolated *cleft lip and/or cleft palate (CL/P)*, *neural tube defects (anencephaly, spina bifida)*, *clubfoot (talipes)*, and some forms of congenital heart disease. In this context, “isolated” means that this is the only observed disease feature (i.e., the feature is not part of a larger constellation of findings, as in CL/P secondary to trisomy 13). In addition, many common adult diseases, such as *hypertension*, *coronary heart disease*, *stroke*, *diabetes mellitus* (types 1 and 2), and *some cancers*, are caused by complex genetic and environmental factors and can thus be considered multifactorial diseases.

Recurrence Risks and Transmission Patterns

Whereas sibling recurrence risks can be given with confidence for single-gene diseases (e.g., 50% for typical autosomal dominant diseases, 25% for autosomal recessive diseases), the situation is more complicated for multifactorial diseases. This is because the number of genes contributing to the disease is usually not known, the precise allelic constitution of the parents is not known, and the extent of environmental effects can vary substantially. For most multifactorial diseases, **empirical risks** (i.e., risks based on direct observation of data) have been derived. To estimate empirical risks, a large series of families is examined in which one child has developed the disease (the proband). Then the siblings of each proband are surveyed to calculate the percentage of siblings who also have developed the disease. For example, in the United States about 3% of siblings of individuals with neural tube defects also have neural tube defects ([Box 5.1](#)). Thus the recurrence risk for parents who have had one child with a neural tube defect is 3% in the United States. For conditions such as CL/P that are not lethal or severely debilitating, recurrence risks also can be estimated for the offspring of affected parents. Because each

multifactorial disease has different numbers and types of risk factors, empirical recurrence risks vary for each disease.

Box 5.1

Neural Tube Defects

Neural tube defects (NTDs), which include *anencephaly*, *spina bifida*, and *encephalocele* (as well as several other less common forms), are one of the most important classes of birth defects, and they are seen in 0.5 to 2 of 1000 pregnancies. The prevalence of NTDs among different populations varies considerably, with an especially high rate among some northern Chinese populations (as high as 6 or more per 1000 births). The prevalence of NTDs has been decreasing in many parts of the United States and Europe during the past three decades, partly because of dietary changes.

Normally the neural tube closes at about the fourth week of gestation. A defect in closure, or a subsequent reopening of the neural tube, results in a neural tube defect. Spina bifida ([Fig. 5.3, A](#)) is the most commonly observed NTD and consists of a protrusion of spinal tissue through the vertebral column (the tissue usually includes meninges, spinal cord, and nerve roots). About 75% of individuals with spina bifida have secondary hydrocephalus, which sometimes in turn produces intellectual disability. Paralysis or muscle weakness, lack of sphincter control, and clubfeet are often observed. A study conducted in British Columbia showed that survival rates for people with spina bifida have improved dramatically over the past several decades. Less than 30% of people born between 1952 and 1969 survived to 10 years of age, whereas 65% of those born between 1970 and 1986 survived to this age. Anencephaly (see [Fig. 5.3, B](#)) is characterized by partial or complete absence of the cranial vault and calvarium and partial or complete absence of the cerebral hemispheres. At least two-thirds of newborns with anencephaly are stillborn; term deliveries do not survive more than a few hours or days.

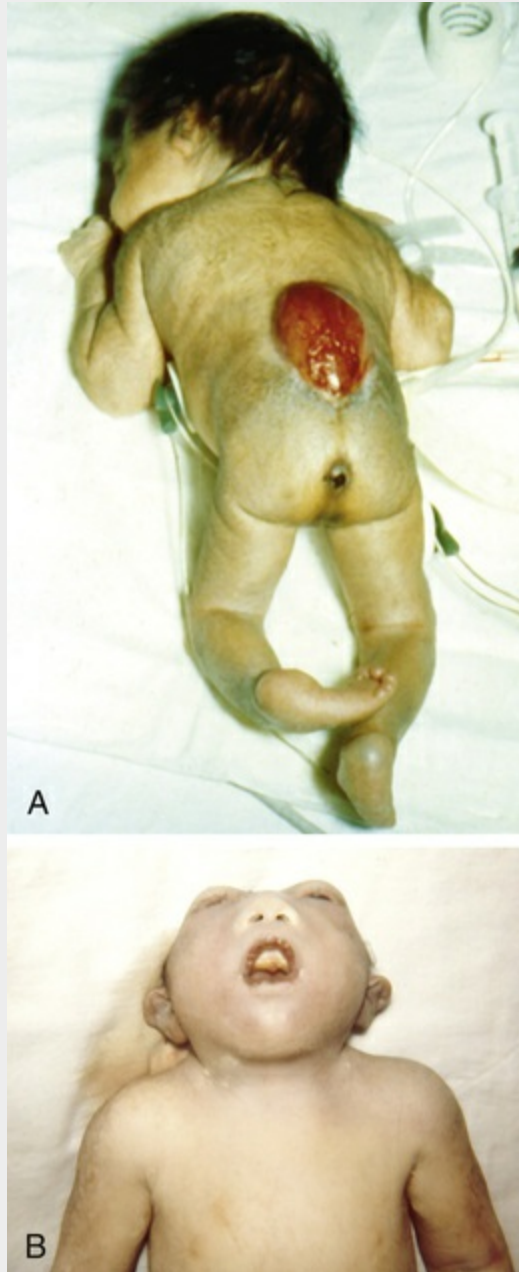

FIGURE 5.3 Spina Bifida and Anencephaly. A, Spina bifida in a newborn. B, Anencephaly, showing the absence of the cranial vault. (From Jones KL: *Smith's recognizable patterns of human malformation*, ed 6, Philadelphia, Saunders, 2006, p. 705.)

NTDs are thought to arise from a combination of genetic and environmental factors. In most populations surveyed thus far, empirical recurrence risks for siblings of affected people range from 2% to 5%. Consistent with a multifactorial model, the recurrence risk increases with additional affected siblings. Studies conducted

in Great Britain showed that the sibling recurrence risk was approximately 5% when one sibling was affected and 10% when two were affected. A Hungarian study showed that the overall prevalence of NTDs was 1 in 300 births and that the sibling recurrence risks were 3%, 12%, and 25% after one, two, and three affected offspring, respectively. Recurrence risks tend to be slightly lower in populations with lower NTD prevalence rates, as predicted by the multifactorial model. Recurrence risk data support the idea that the major forms of NTDs are caused by similar factors. An anencephalic conception increases the recurrence risk for subsequent spina bifida conceptions, and vice versa.

NTDs can usually be diagnosed prenatally, sometimes by ultrasound and usually by an elevation in α -fetoprotein (AFP) level in the maternal serum or amniotic fluid (see [Chapter 20](#)). A spina bifida lesion can be either open or closed (i.e., covered with a layer of skin). Fetuses with open spina bifida are more likely to be detected by AFP assays.

A major epidemiologic finding is that mothers who supplement their diet with folic acid at the time of conception are less likely to produce children with NTDs. This result has been replicated in several different populations and thus appears to be well confirmed. It has been estimated that as many as 50% to 70% of NTDs can be avoided simply by dietary folic acid supplementation. (Traditional prenatal vitamin supplements have little effect because administration does not usually begin until well after the time that the neural tube closes.) It is now recommended that all women of reproductive age supplement their diet with 0.4 mg of folic acid each day; many foods in the United States are supplemented with folic acid. Consequently, average folate levels in U.S. females have doubled, and the incidence of neural tube defects has declined by 30% to 50% in the past decade.

Because mothers would be likely to ingest similar amounts of folic acid from one pregnancy to the next, folic acid deficiency could well account for at least part of the elevated sibling recurrence risk for NTDs. This is an important example of a *nongenetic* factor that

contributes to familial clustering of a disease. It is likely that there is genetic variation in response to folic acid, which helps to explain why most mothers with folic acid deficiency do not bear children with NTDs and why some who ingest adequate amounts of folic acid nonetheless bear children with NTDs. To address this issue, researchers are testing for associations between NTDs and variants in several genes whose products (e.g., methylene tetrahydrofolate reductase) are involved in folic acid metabolism.

Data from Copp AJ, Stanier P, Greene NDE: *Lancet Neurol* 12:799–810, 2013; Daly LE et al: *JAMA* 274(21):1698–1702, 1995.

In contrast to most single-gene diseases, recurrence risks for multifactorial diseases can change substantially from one population to another because gene frequencies as well as environmental factors can differ among populations (note the differences between the London and Belfast populations in [Table 5.1](#)).

It is sometimes difficult to distinguish polygenic or multifactorial diseases from single-gene diseases that have reduced penetrance or variable expression. Large data sets and good epidemiologic data are necessary to make the distinction. Several criteria are commonly used to define multifactorial inheritance.

First, *the recurrence risk becomes higher if more than one family member is affected*. For example, the sibling recurrence risk for a *ventricular septal defect* (VSD, a type of congenital heart defect) is 3% if one sibling has been affected by a VSD but increases to approximately 10% if two siblings have been diagnosed with VSDs.⁴ The same trend is seen for other multifactorial diseases like neural tube defects and autism. In contrast, the recurrence risk for single-gene diseases remains the same regardless of the number of affected siblings. It should be emphasized that this increase does not mean that the family's risk has actually *changed*. Rather, it means that there is more information about the family's true risk; because they have had two affected children, they are probably located higher on the liability distribution than a family with only one affected child. In other words, they have more risk

factors (genetic or environmental) and are more likely to produce an affected child.

Second, *if the expression of the disease in the proband is more severe, the recurrence risk is higher*. This is again consistent with the liability model because a more severe expression indicates that the affected individual is at the extreme tail end of the liability distribution (see Fig. 5.2). His or her relatives are thus at a higher risk for inheriting disease genes. For example, the occurrence of a bilateral (both sides) CL/P confers a higher recurrence risk on family members than does the occurrence of a unilateral (one side) cleft.

Third, *the recurrence risk is higher if the proband is of the less commonly affected sex* (see the preceding discussion of pyloric stenosis). This is because an affected individual of the less susceptible sex is usually at a more extreme position on the liability distribution.

Fourth, *the recurrence risk for the disease usually decreases rapidly in more remotely related relatives* (Table 5.2). Whereas the recurrence risk for single-gene diseases decreases by 50% with each degree of relationship (e.g., an autosomal dominant disease has a 50% recurrence risk for siblings, 25% for uncle-nephew relationships, 12.5% for first cousins), it decreases much more quickly for multifactorial diseases. This reflects the fact that many genes and environmental factors must combine to produce a trait. All the necessary risk factors are unlikely to be present in less closely related family members.

TABLE 5.2

RECURRENCE RISKS (%) FOR FIRST-, SECOND-, AND THIRD-DEGREE RELATIVES

DEGREE	RISK			
	FIRST DEGREE	SECOND DEGREE	THIRD DEGREE	GENERAL POPULATION
Cleft lip/palate	4	0.7	0.3	0.1
Clubfoot	2.5	0.5	0.2	0.1
Congenital hip dislocation	5	0.6	0.4	0.2

Finally, if the prevalence of the disease in a population is f , the risk for offspring and siblings of probands is approximately \sqrt{f} . This does not hold true for single-gene traits because their recurrence risks are largely independent of population prevalence. It is not an absolute rule for multifactorial traits either, but many such diseases tend to conform to this prediction. Examination of the risks given in [Table 5.2](#) shows that the first three diseases follow the prediction fairly well. However, the observed sibling risk for the fourth disease, infantile autism, is substantially higher than that predicted by \sqrt{f} .

Nature and Nurture: Disentangling the Effects of Genes and Environment

Family members share genes and a common environment. Family resemblance in traits such as blood pressure reflects both genes (nature) and environment (nurture). For centuries people have debated the relative importance of these two types of factors. It is a mistake, of course, to view them as mutually exclusive. Few traits are influenced only by genes or only by environmental factors. Most are influenced by both. It is useful to try to determine the *relative* influence of genetic and environmental factors ([Fig. 5.4](#)). This can lead to a better understanding of disease etiology. It can also help in planning public health strategies. A disease in which the genetic influence is relatively small, such as lung cancer, may be prevented most effectively through emphasis on lifestyle changes (avoidance of tobacco). When a disease has a relatively larger genetic component, as in breast cancer, examination of family history should be emphasized in addition to lifestyle modification. Here, two research strategies are reviewed that often are used to estimate the relative influence of genes and environment: twin studies and adoption studies.

FIGURE 5.4 Continuum of Genetic Diseases. Some diseases (e.g., cystic fibrosis) are strongly determined by genes, whereas others (e.g., infectious diseases) are strongly determined by environmental factors. (Adapted from Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

Twin Studies

Twins occur with a frequency of about 1 in 100 births in white populations. They are a bit more common in blacks and a bit less common among Asians. **Monozygotic (MZ, identical) twins** originate when the developing embryo divides to form two separate but identical embryos. Because they are genetically identical, MZ twins are an example of natural clones. **Dizygotic (DZ, fraternal) twins** are the result of a double ovulation followed by the fertilization of each egg by a different sperm. Thus dizygotic twins are genetically no more similar than siblings. Because two different sperm cells are required to fertilize the two eggs, it is possible for each DZ twin to have a different father. Whereas MZ twinning rates are constant across populations, DZ twinning rates vary somewhat. DZ twinning increases with maternal age until about 40 years, after which it declines.

Because MZ twins are genetically identical, any differences between them should be caused only by environmental effects.⁵ MZ twins should thus resemble one another very closely for traits that are strongly influenced by genes. DZ twins provide a convenient comparison because their environmental differences should be similar to those of MZ twins, but their genetic differences are as great as those between siblings. Twin studies thus usually consist of comparisons between MZ and DZ twins.⁶ If both members of a twin pair share a trait (e.g., a cleft lip), they are said to be **concordant**. If they do not share the trait, they are **discordant**. For a trait determined totally by

genes, MZ twins should always be concordant, whereas DZ twins should be concordant less often, because they, like full siblings, share only 50% of their DNA. Concordance rates may differ between opposite-sex DZ twin pairs and same-sex DZ pairs for some traits, such as those that have different frequencies in males and females. For such traits, only same-sex DZ twin pairs should be used when comparing MZ and DZ concordance rates, because MZ twins are necessarily of the same sex.

Table 5.3 gives concordance rates for a number of traits. Note that the concordance rates for contagious diseases such as measles are quite similar in MZ and DZ twins. This is expected because a contagious disease is unlikely to be influenced markedly by genes. On the other hand, the concordance rates are quite dissimilar for *schizophrenia* and *bipolar affective disorder*, suggesting a sizable genetic component for these diseases. The MZ correlations for dermatoglyphics (fingerprints), which are determined almost entirely by genes, are close to 1.0.

TABLE 5.3

CONCORDANCE RATES IN MZ AND DZ TWINS FOR SELECTED TRAITS AND DISEASES

TRAIT OR DISEASE	CONCORDANCE RATE		
	MZ TWINS	DZ TWINS	HERITABILITY
Affective disorder (bipolar)	0.79	0.24	>1*
Affective disorder (unipolar)	0.54	0.19	0.7
Alcoholism	>0.6	<0.3	0.6
Autism	0.92	0	>1
Blood pressure (diastolic) [†]	0.58	0.27	0.62
Blood pressure (systolic) [†]	0.55	0.25	0.6
Body fat percentage [†]	0.73	0.22	>1
Body mass index [†]	0.95	0.53	0.84
Cleft lip/palate	0.38	0.08	0.6
Clubfoot	0.32	0.03	0.58
Dermatoglyphics (finger ridge count) [†]	0.95	0.49	0.92

Diabetes mellitus	0.45–0.96	0.03–0.37	>1
Diabetes mellitus (type 1)	0.55	–	–
Diabetes mellitus (type 2)	0.9	–	–
Epilepsy (idiopathic)	0.69	0.14	>1
Height [†]	0.94	0.44	1
Intelligence quotient (IQ) [†]	0.76	0.51	0.5
Measles	0.95	0.87	0.16
Multiple sclerosis	0.28	0.03	0.5
Myocardial infarction (males)	0.39	0.26	0.26
Myocardial infarction (females)	0.44	0.14	0.6
Schizophrenia	0.47	0.12	0.7
Spina bifida	0.72	0.33	0.78

*Several heritability estimates exceed 1. Because it is impossible for >100% of the variance of a trait to be genetically determined, these values indicate that other factors, such as shared environmental factors, must be operating.

†Because these are quantitative traits, correlation coefficients are given rather than concordance rates.

NOTE: Heritability, which is defined as the proportion of the variation in a trait that is due to genetic factors, can be measured as $2(C_{MZ} - C_{DZ})$, where C_{MZ} and C_{DZ} are the concordance rates for MZ twins and DZ twins, respectively. These figures were compiled from a large variety of sources and represent primarily European and U.S. populations.

DZ, Dizygotic; *MZ*, monozygotic.

At one time, twins were thought to provide a perfect “natural laboratory” in which to determine the relative influences of genetics and environment, but several difficulties arose. One of the most important is the assumption that the environments of MZ and DZ twins are equally similar. As one would expect, MZ twins are often treated more similarly than DZ twins. A greater similarity in environment can make MZ twins more concordant for a trait, inflating the apparent influence of genes. In addition, MZ twins may be more likely to seek the same type of environment, further reinforcing environmental similarity. On the other hand, it has been suggested that MZ twins tend to develop personality differences in an attempt to assert their individuality.

Adoption Studies

Studies of adopted children also are used to estimate the genetic contribution to a multifactorial trait. Children born to parents who have a disease but are then subsequently adopted by parents lacking the disease can be studied to find out whether these children develop the disease. In some cases such children develop the disease more often than a comparative control population (i.e., adopted children who were born to parents who do *not* have the disease). This provides some evidence that genes may be involved in the causation of the disease, because the adopted children do not share an environment with their affected natural parents. For example, about 8% to 10% of adopted children of a schizophrenic parent develop *schizophrenia*, whereas only 1% of adopted children of unaffected parents develop schizophrenia.

As with twin studies, several precautions must be exercised in interpreting the results of adoption studies. First, prenatal environmental influences could have long-lasting effects on an adopted child. Second, children are sometimes adopted after they are several years old, ensuring that some environmental influence would have been imparted by the natural parents. Finally, adoption agencies sometimes try to match the adoptive parents with the natural parents in terms of background, socioeconomic status, and other factors. All of these factors could exaggerate the apparent influence of biologic inheritance.

These reservations, as well as those summarized for twin studies, underscore the need for caution in basing conclusions on twin and adoption studies. These approaches do not provide definitive measures of the role of genes in multifactorial disease, nor can they identify specific genes responsible for disease. Instead, they serve a useful purpose in providing a preliminary indication of the extent to which a multifactorial disease may be caused by genetic factors. Sophisticated molecular techniques are being used to identify the specific genes that underlie predisposition to multifactorial diseases.

This discussion should make clear that most common diseases are not the result of either genetics *or* environment. Instead, genetic and

nongenetic factors usually interact to influence one's likelihood of developing a common disease. In some cases a genetic predisposition may interact with an environmental factor to increase the risk of disease acquisition to a much higher level than would either factor acting alone. A good example of a **gene-environment interaction** is given by α_1 -antitrypsin deficiency, a genetic condition that causes pulmonary emphysema and is greatly exacerbated by cigarette smoking (Box 5.2).

Box 5.2

α_1 -Antitrypsin Deficiency: the Interaction of Genes and Environment-Lifestyle

α_1 -Antitrypsin (AAT) deficiency is one of the most common autosomal recessive disorders among whites, affecting approximately 1 in 2500 members of this ethnic group. AAT, synthesized primarily in the liver, is a serine protease inhibitor. It does bind trypsin, as its name suggests. However, AAT binds much more strongly to neutrophil elastase, a protease that is produced by neutrophils (a type of leukocyte) in response to infections and irritants. It carries out its binding and inhibitory role primarily in the lower respiratory tract, where it prevents elastase from digesting the alveolar septi of the lung.

Individuals with less than 10% to 15% of the normal level of AAT activity will experience significant lung damage and typically develop emphysema during their 30s, 40s, or 50s. In addition, at least 10% develop liver cirrhosis as a result of the accumulation of variant AAT molecules in the liver; AAT deficiency accounts for nearly 20% of all nonalcoholic liver cirrhosis cases in the United States. An important feature of this disease is that cigarette smokers with AAT deficiency develop emphysema much earlier than do nonsmokers. This is because cigarette smoke irritates lung tissue, increasing secretion of neutrophil elastase. At the same time it inactivates AAT, so there is also less inhibition of elastase. One

study showed that the median age of survival of nonsmokers with AAT deficiency was 62 years, whereas it was only 40 years for smokers with this disease. Because the combination of cigarette smoking (an environmental factor) and the AAT mutation (a genetic factor) produces more severe disease than either factor alone, it is an example of a gene-environment interaction.

Typically, AAT deficiency is tested first by a straightforward assay for reduced serum AAT concentration. Because a variety of conditions can reduce serum AAT level, additional testing, through a type of protein electrophoresis or DNA testing, is carried out to confirm a diagnosis of AAT deficiency. Direct DNA testing became feasible with the identification of *SERPINA1*, the gene that encodes AAT. More than 100 *SERPINA1* mutations have been identified, but only 2 missense variants, labeled the S and Z alleles, are common and clinically significant. Approximately 95% of cases of AAT deficiency are either ZZ homozygotes or SZ compound heterozygotes. The latter genotype generally produces less severe disease symptoms. Two large studies have indicated that the risk of developing emphysema among ZZ homozygotes is 70% for nonsmokers and 90% for smokers.

Data from Abboud RT et al: *Appl Clin Genet* 4:55–65, 2011; Stockley RA, Turner AM: *Trends Mol Med* 20:105–115, 2014.

Genetics of Common Diseases

Some common multifactorial disorders, the congenital malformations, are by definition present at birth. Others, including heart disease, cancer, diabetes, and most psychiatric disorders, are seen primarily in adolescents and adults. Because these disorders are complex, unraveling their genetics is a daunting task. Nonetheless, significant progress is being made.

Congenital Malformations

Congenital diseases are present at birth. Approximately 2% of newborns present with a congenital malformation; most of these are multifactorial in etiology. [Table 5.4](#) lists some more common congenital malformations. Sibling recurrence risks for most of these disorders range from 1% to 5%.

TABLE 5.4

PREVALENCE RATES OF COMMON CONGENITAL MALFORMATIONS IN WHITES

DISORDER	PREVALENCE PER 1000 BIRTHS (APPROXIMATE)
Cleft lip/palate	1
Clubfoot	1
Congenital heart defects	4–8
Hydrocephaly	0.5–2.5
Isolated cleft palate	0.4
Neural tube defects	1–3
Pyloric stenosis	3

Some congenital malformations, such as CL/P and pyloric stenosis, are relatively easy to repair and thus are not considered to be serious problems. Others, such as neural tube defects, usually have more severe consequences. Although some cases of congenital malformations occur in the absence of any other problems, it is quite common for them to be associated with other disorders. For example, hydrocephaly and clubfoot are often seen secondary to spina bifida, CL/P is often seen in babies with trisomy 13, and congenital heart defects are seen in children with many other disorders, including Down syndrome.

Environmental factors also cause some congenital malformations. An example is thalidomide, a sedative used during pregnancy in the early 1960s. When ingested during early pregnancy this drug often caused **phocomelia** (severely shortened limbs) in babies. Maternal exposure to retinoic acid, which is used to treat acne, can cause congenital defects of the heart, ear, and central nervous system. Maternal rubella infection can cause congenital heart defects.

Multifactorial Disorders in the Adult Population

Until quite recently, very little was known about specific genes responsible for common adult diseases. With the more powerful laboratory and analytic techniques now available, this situation is changing. This section reviews recent progress in understanding the genetics of the major common adult diseases. [Table 5.5](#) gives approximate prevalence figures for these disorders in the United States.

TABLE 5.5

PREVALENCE OF COMMON ADULT DISEASES IN THE UNITED STATES

DISEASE	NUMBER AFFECTED (APPROXIMATE)
Alcoholism	14 million
Alzheimer disease	4 million
Arthritis	43 million
Asthma	17 million
Cancer	8 million
Cardiovascular disease (all forms)	
Coronary artery disease	13 million
Congestive heart failure	5 million
Congenital defects	1 million
Hypertension	50 million
Stroke	5 million
Depression and bipolar disorder	17 million
Diabetes (type 1)	1 million
Diabetes (type 2)	15 million
Epilepsy	2.5 million
Multiple sclerosis	350,000
Obesity*	60 million
Parkinson disease	500,000
Psoriasis	3–5 million
Schizophrenia	2 million

*Body mass index >30.

Data from National Center for Chronic Disease Prevention and Health Promotion; American Heart Association (*2002 Heart and Stroke Statistical Update*); National Institute on Alcohol Abuse and Alcoholism; Office of the U.S. Surgeon General; American Academy of Allergy, Asthma and Immunology; Cown WM, Kandel ER: *JAMA* 285:594–600, 2001; Flegal et al: *JAMA* 288:1723–1727, 2002.

Coronary Heart Disease

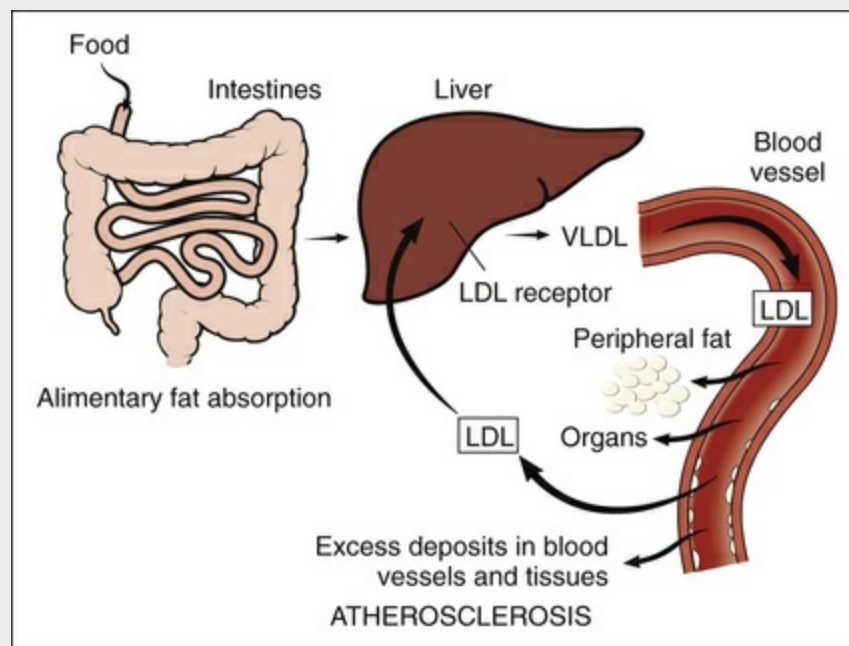

It is well known that coronary heart disease (CHD) is the leading killer of Americans, accounting for approximately 25% of all deaths in the United States. It is caused by *atherosclerosis* (narrowing as a result of the formation of lipid-laden lesions) of the coronary arteries. This narrowing impedes blood flow to the heart and can eventually result in a *myocardial infarction* (destruction of heart tissue caused by an inadequate supply of oxygen). When atherosclerosis occurs in arteries supplying blood to the brain, a *stroke* can result. Many risk factors for heart disease have been identified, including obesity, cigarette smoking, hypertension, elevated cholesterol level, and positive family history (usually defined as having one or more affected first-degree relatives). Many studies have examined the role of family history in CHD, and they show that an individual with a positive family history is two to seven times more likely to have heart disease than is an individual with no family history (this would be the relative risk of heart disease as a result of a positive family history). Generally, these studies also show that the risk increases if (1) there are more affected relatives; (2) the affected relative or relatives are female (the less commonly affected sex) rather than male; and (3) the age of onset in the affected relative is early (before 55 years). For example, one study showed that men between the ages of 20 and 39 years had a relative risk of 3 for CHD if they had one affected first-degree relative. The relative risk increased to 13 if two first-degree relatives were affected with CHD before 55 years of age.⁷

What part do genes play in the familial clustering of heart disease? Because of the key role of lipids in atherosclerosis, many studies are focusing on the genetic determination of various lipoproteins.⁸ An important advance in this area has been the identification of several

genes that encode the processing of low-density lipoproteins and that, when mutated, can cause *familial hypercholesterolemia* (Box 5.3). Many other genes involved in lipid variation, coagulation, and hypertension have been identified, including several genes encoding apolipoproteins (the protein components of lipoproteins) (Table 5.6).⁹ Functional analysis of these genes is leading to an increased understanding, and eventually more effective treatment, of CHD.

Box 5.3

Familial Hypercholesterolemia

Autosomal dominant familial hypercholesterolemia (FH) is an important cause of heart disease, accounting for approximately 5% of myocardial infarctions in individuals less than 60 years of age. FH is one of the most common autosomal dominant disorders: in most populations surveyed to date, about 1 in 500 people is a heterozygote. Plasma cholesterol levels are approximately twice as high as normal (i.e., about 300 to 400 mg/dL), resulting in

substantially accelerated atherosclerosis and distinctive cholesterol deposits in skin and tendons (*xanthomas* [Fig. 5.5]). Data compiled from five studies showed that approximately 75% of men with FH developed coronary disease, and 50% had a fatal myocardial infarction by 60 years. The corresponding percentages for women were lower (45% and 15%) because women generally develop heart disease at a later age than men.

FIGURE 5.5 Xanthoma. Fatty deposits, referred to as xanthomas as seen here on the knuckles, are often noted in individuals with familial hypercholesterolemia. (From Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

Consistent with Hardy-Weinberg predictions, about 1 in 1 million births is homozygous for the FH gene. Homozygotes are much more severely affected, with cholesterol levels ranging from 600 to 1200 mg/dL. Most experience myocardial infarctions before 20 years of age, and a myocardial infarction at 18 months of age has been reported. If untreated, most FH homozygotes die before 30 years of age.

All cells require cholesterol as a component of their plasma membrane. They can either synthesize their own cholesterol or, preferably, obtain it from the extracellular environment, where it is

carried primarily by low-density lipoprotein (LDL). In a process known as *endocytosis*, LDL-bound cholesterol is taken into the cell via LDL receptors on the cell's surface (Fig. 5.6). FH is most commonly caused by a reduction in the number of functional LDL receptors on cell surfaces. Lacking the normal number of LDL receptors, cellular cholesterol uptake is reduced and circulating cholesterol levels increase.

Much of what we know about endocytosis has been learned through the study of LDL receptors. The process of endocytosis and the processing of LDL in the cell are described in detail in Fig. 5.6 (endocytosis is discussed in Chapter 1). These processes result in a fine-tuned regulation of cholesterol levels within cells, and they influence the level of circulating cholesterol as well.

FIGURE 5.6 Process of Receptor-Mediated Endocytosis. Numbers in parentheses correspond to numbers shown in the figure. 1, The low-density lipoprotein (*LDL*) receptors, which are glycoproteins, are synthesized in the endoplasmic reticulum of the cell. 2, From here, they pass through the Golgi apparatus to the cell surface, where part of the receptor protrudes outside the cell. 3, The circulating *LDL* particle is bound by the *LDL* receptor and localized in cell surface depressions called *coated pits* (so named because they are coated with a protein called *clathrin*). 4, The coated pit invaginates, bringing the *LDL* particle inside the cell. 5, Once inside the cell, the *LDL* particle is separated from the receptor, taken into a lysosome, and broken down into its constituents by lysosomal enzymes. 6, The *LDL* receptor is recirculated to the cell surface to bind another *LDL* particle (each *LDL* receptor goes through this cycle approximately once every 10 minutes even if it is not occupied by an *LDL* particle). 7, Free cholesterol is released from the lysosome for incorporation into cell membranes or metabolism into bile acids or steroids. Excess cholesterol can be stored in the cell as a cholesterol ester or removed from the cell by associating with high-density lipoprotein (*HDL*). 8, As cholesterol levels in the cell rise, cellular cholesterol synthesis is reduced by inhibition of the rate-limiting enzyme 3-hydroxy-3-methylglutaryl coenzyme A (*HMG-CoA*) reductase. 9, Rising

cholesterol levels also increase the activity of acyl coenzyme A (acyl CoA):cholesterol acyltransferase (ACAT), an enzyme that modifies cholesterol for storage as cholesterol esters. 10, In addition, the number of LDL receptors is decreased by lowering the transcription rate of the LDL receptor gene itself. This decreases cholesterol uptake. (From Jorde LB et al: *Medical genetics*, ed 5, Philadelphia, 2016, Elsevier.)

The identification of the LDL receptor gene in 1984 was critical in understanding exactly how LDL receptor defects cause FH. More than 1000 different mutations, including missense and nonsense substitutions as well as insertions and deletions, have been identified in the LDL receptor gene. These can be grouped into five broad classes according to their effects on the activity of the receptor. Class 1 mutations result in no detectable protein product. Thus, heterozygotes would produce only half the normal number of LDL receptors. Class 2 mutations in the LDL receptor gene result in production of the LDL receptor, but it is altered such that it cannot leave the endoplasmic reticulum. It is eventually degraded. Class 3 mutations produce an LDL receptor that is capable of migrating to the cell surface but incapable of normal binding to LDL. Class 4 mutations, which are comparatively rare, produce receptors that are normal except that they do not migrate specifically to coated pits and thus cannot carry LDL into the cell. The final group of mutations, class 5, produces an LDL receptor that cannot dissociate from the LDL particle after entry into the cell. The receptor cannot return to the cell surface and is degraded. Each class of mutations reduces the number of effective LDL receptors, resulting in decreased LDL uptake and hence elevated levels of circulating cholesterol. The number of effective receptors is reduced by about half in FH heterozygotes, and homozygotes have virtually no functional LDL receptors.

Understanding the defects that lead to FH has helped to develop effective therapies for the disorder. Dietary reduction of cholesterol (primarily through the reduced intake of saturated fats) has only modest effects on cholesterol levels in FH heterozygotes. Because cholesterol is reabsorbed into the gut and then recycled through the liver (where most cholesterol synthesis takes place), serum cholesterol levels can be reduced by the administration of bile acid–

absorbing resins, such as cholestyramine. The absorbed cholesterol is then excreted. It is interesting that reduced recirculation from the gut causes the liver cells to form additional LDL receptors, lowering circulating cholesterol levels. However, the decrease in the concentration of intracellular cholesterol also stimulates cholesterol synthesis by liver cells, so the overall reduction in plasma LDL level is only about 15% to 20%. This treatment is much more effective when combined with agents that reduce cholesterol synthesis by inhibiting 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase (the “statin” class of drugs). Decreased synthesis leads to further production of LDL receptors. When these therapies are used in combination, serum cholesterol levels in FH heterozygotes can be reduced to approximately normal levels.

The picture is less encouraging for FH homozygotes. The therapies just discussed can enhance cholesterol elimination and reduce its synthesis, but they are largely ineffective because homozygotes have few or no LDL receptors. Liver transplants, which provide hepatocytes that have normal LDL receptors, have been successful in some cases, but this option is often limited by a lack of donors. Plasma exchange, carried out every 1 to 2 weeks, in combination with drug therapy, can reduce cholesterol levels by about 50%. However, this therapy is difficult to continue for long periods. Somatic cell gene therapy, in which hepatocytes carrying normal LDL receptor genes are introduced into the portal circulation, is now being tested. It may eventually prove to be an effective treatment for FH homozygotes.

FH also can be caused by inherited mutations in the gene that encodes apolipoprotein B. In addition, a small number of FH cases are caused by mutations in the gene that encodes PCSK9 (proprotein convertase subtilisin/kexin type 9), an enzyme that plays a key role in degrading LDL receptors. Gain-of-function mutations in the *PCSK9* gene reduce the number of LDL receptors, causing FH. Loss-of-function mutations in this gene can increase the number of LDL receptors, resulting in exceptionally low circulating LDL levels. These findings have led to the development of drugs

that inhibit PCSK9 activity, thus lowering LDL cholesterol levels. These drugs, which have been approved for clinical use, can reduce LDL cholesterol levels by approximately 50% in the general population of persons with hypercholesterolemia and produce significant effects even in those who are using statin drugs.

The FH story illustrates how medical research has made important contributions both to our understanding of basic cell biology and to our advances in clinical therapy. The process of receptor-mediated endocytosis, elucidated largely by research on the LDL receptor defects, is of fundamental significance for cellular processes throughout the body. Equally important is that this research, by clarifying how cholesterol synthesis and uptake can be modified, has led to significant improvements in therapy for this important cause of heart disease. The discovery of rare mutations in PCSK9 has led to PCSK9 inhibitor drugs that may benefit millions of persons with high cholesterol levels.

VLDL, very-low-density lipoprotein.

TABLE 5.6

LIPOPROTEIN GENES KNOWN TO CONTRIBUTE TO CORONARY ARTERY DISEASE RISK

GENE	CHROMOSOME LOCATION	FUNCTION OF PROTEIN PRODUCT
Apolipoprotein A-I	11q	HDL component; LCAT cofactor
Apolipoprotein A-IV	11q	Component of chylomicrons and HDL; may influence HDL metabolism
Apolipoprotein C-III	11q	Allelic variation associated with hypertriglyceridemia
Apolipoprotein B	2p	Ligand for LDL receptor; involved in formation of VLDL, LDL, IDL, and chylomicrons
Apolipoprotein D	2p	HDL component
Apolipoprotein C-I	19q	LCAT activation
Apolipoprotein C-II	19q	Lipoprotein lipase activation

Apolipoprotein E	19q	Ligand for LDL receptor
Apolipoprotein A-II	1p	HDL component
LDL receptor	19p	Uptake of circulating LDL particles
Lipoprotein(a)	6q	Cholesterol transport
Lipoprotein lipase	8p	Hydrolysis of lipoprotein lipids
Hepatic triglyceride lipase	15q	Hydrolysis of lipoprotein lipids
LCAT	16q	Cholesterol esterification
Cholesterol ester transfer protein	16q	Facilitates transfer of cholesterol esters and phospholipids between lipoproteins

HDL, High-density lipoprotein; *IDL*, intermediate-density lipoprotein; *LCAT*, lecithin cholesterol acyltransferase; *LDL*, low-density lipoprotein; *VLDL*, very-low-density lipoprotein.

Adapted in part from King RA, Rotter JI, editors: *The genetic basis of common diseases*, ed 2, New York, 2002, Oxford University Press.

Environmental factors, many of which are easily modified, are also important causes of CHD. Abundant epidemiologic evidence shows that cigarette smoking and obesity increase the risk of CHD, whereas exercise and a diet low in saturated fats decrease the risk. Indeed, the approximate 50% decline in CHD prevalence in the United States during the past 40 years is usually attributed to a decrease in the proportion of adults who smoke cigarettes, a decreased consumption of saturated fats, and an increased emphasis on exercise and a generally healthier lifestyle.

Hypertension

Systemic hypertension, which has a worldwide prevalence of approximately 25% to 30%, is a key risk factor for heart disease, stroke, and kidney disease. Studies of blood pressure correlations within families indicate that about 20% to 40% of the variation in both systolic and diastolic blood pressure is caused by genetic factors. The fact that this figure is substantially less than 100% indicates that environmental factors also must be important causes of blood pressure variation. The most important environmental risk factors for hypertension are increased sodium intake, decreased physical activity,

psychosocial stress, and obesity (but, as discussed later, the latter factor is itself influenced by both genes and environment).

Blood pressure regulation is a highly complex process that is influenced by many physiologic systems, including various aspects of kidney function, cellular ion transport, and heart function.¹⁰ Because of this complexity, much research is now focused on specific components that may influence blood pressure variation, such as the renin-angiotensin system (involved in sodium reabsorption and vasoconstriction), vasodilators such as nitric oxide and the kallikrein-kinin system, and ion-transport systems such as adducin and sodium-lithium countertransport (Fig. 5.7). These individual factors are more likely to be under the control of smaller numbers of genes than is blood pressure itself, simplifying the task of identifying these genes and their role in blood pressure regulation. For example, linkage and association studies have implicated several genes involved in the renin-angiotensin system (e.g., the genes that encode angiotensinogen, angiotensin-converting enzyme, angiotensin receptors) in the causation of hypertension.

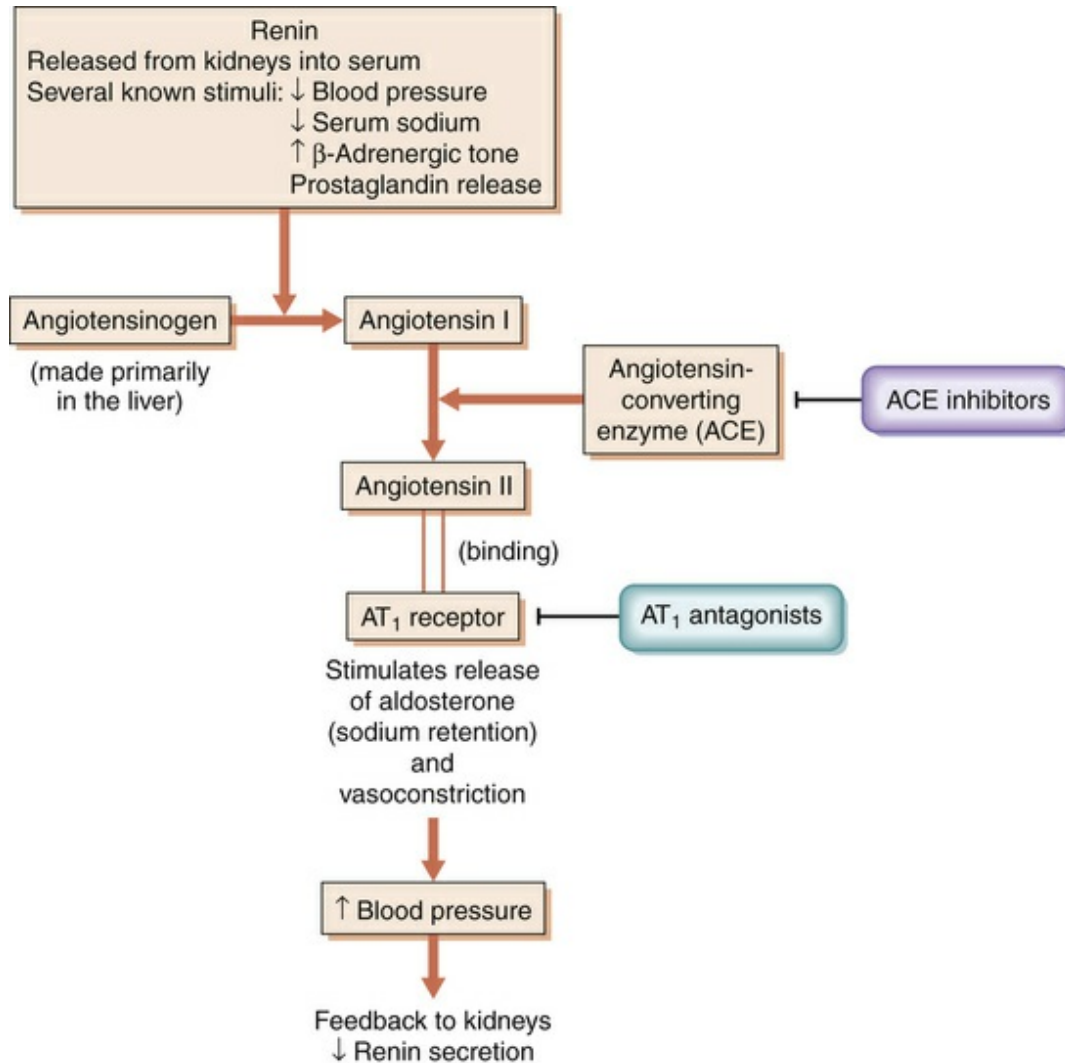

FIGURE 5.7 Renin-Angiotensin-Aldosterone System. (Modified from King RA, Rotter JI, Motulsky AG, editors: *The genetic basis of common diseases*, New York, 1992, Oxford University Press.)

Cancer

Cancer is the second leading cause of death in the United States. It is well established that many major types of cancer (e.g., breast, colon, prostate, ovarian) cluster strongly in families. This is caused by both inherited genes and shared environmental factors. Although numerous cancer-causing genes are being isolated,¹¹ environmental factors also play an important role in causing cancer. In particular, tobacco use is estimated to account for one-third of all cancer cases in the United States, making it the most important known cause of

cancer.¹² Typically, these environmental factors cause cancer by creating somatic mutations (see [Chapter 4](#)) in specific cell types. Thus, cancer can be caused both by inherited genetic variants and by noninherited somatic mutations acquired during an individual's lifetime.

Breast Cancer.

Breast cancer is the most common cancer among women, affecting approximately 12% of American women who live to 85 years or older. Formerly the leading cause of cancer death among women, it has been surpassed by lung cancer. Breast cancer aggregates strongly in families; for example, if a woman has one affected first-degree relative, her risk of developing breast cancer doubles. This risk increases further if the age of onset in the affected relative is early and if the cancer is bilateral (tumors in both breasts).

An autosomal dominant form of breast cancer accounts for approximately 5% to 10% of breast cancer cases in the United States. Genes responsible for this form of breast cancer have been identified on chromosomes 17 (*BRCA1*) and 13 (*BRCA2*), and these genes can be tested for inherited cancer-causing mutations.¹³ Women who inherit a mutation in *BRCA1* or *BRCA2* experience a 50% to 80% lifetime risk of developing breast cancer.¹⁴ *BRCA1* mutations also increase the risk of ovarian cancer among women (20% to 50% lifetime risk), and they confer a modestly increased risk of prostate and colon cancers. *BRCA2* mutations also confer an increased risk of ovarian cancer (10% to 20% lifetime prevalence). Approximately 6% of males who inherit a *BRCA2* mutation will develop breast cancer, representing a 100-fold increase over the risk in the general male population. Evaluation of the *BRCA1* and *BRCA2* gene products, which are both involved in deoxyribonucleic acid (DNA) repair, is yielding valuable evidence on the etiology of breast cancer in general.

Although *BRCA1* and *BRCA2* mutations are the most common known causes of inherited breast cancer, this disease also can be caused by inherited mutations in several other genes (e.g., *CHK2*, *ATM*, *PALB2*, and *TP53*). Germline mutations in a tumor-suppressor

gene called *PTEN* are responsible for Cowden disease, which is characterized by multiple benign tumors and an increased susceptibility to breast cancer. Despite the significance of these genes, it should be emphasized that more than 90% of breast cancer cases are not inherited as mendelian diseases.

Colorectal Cancer.

Colorectal cancer is second only to lung cancer in the number of cancer deaths occurring annually in the United States, with approximately 134,000 new cases (and 49,000 deaths) estimated in 2016.¹⁵ Approximately 1 in 21 Americans will develop colorectal cancer. Like breast cancer, it clusters in families (in fact, familial clustering of this form of cancer was reported in the medical literature as early as 1881). The risk of colorectal cancer in people with one affected first-degree relative is two to three times higher than that in the general population.

This familial aggregation is caused in part by subsets of colorectal cancer cases that are inherited as single-gene traits. For example, *familial adenomatous polyposis* occurs in approximately 1 in 8000 whites. The gene responsible for this disorder, *APC*, encodes a tumor suppressor.¹⁶ Importantly, somatic mutations of *APC* are found in at least 85% of all colon tumors. Thus although inherited *APC* mutations cause rare familial adenomatous polyposis, somatic mutations are involved in the great majority of all common colorectal cancers.

Hereditary nonpolyposis colorectal cancer, which may account for as many as 5% of colorectal cancer cases, is caused by mutations in any of six genes.¹⁷ Research has shown that all of these genes are involved in the vital process of DNA repair. When this function is compromised, cancer-causing mutations can persist in cells, leading eventually to growth of a tumor.

Other colorectal cancer cases are likely to be caused by a complex interaction of multiple genes. In addition, environmental factors, such as a high-fat, low-fiber diet, are thought to increase the risk of colorectal cancer.

Prostate Cancer.

Prostate cancer is the second most commonly diagnosed cancer in men (after skin cancer), with approximately 220,000 new cases annually in the United States. Prostate cancer is second only to lung cancer as a cause of cancer death in men, causing more than 27,000 deaths each year. Having an affected first-degree relative increases the risk of developing prostate cancer by a factor of two to three, and the heritability of prostate cancer is estimated to be approximately 40%.

The relatively late age of onset of most prostate cancer cases (median age 72 years) makes genetic analysis especially difficult. However, loss of heterozygosity (see [Chapter 12](#)) has been observed in a number of genomic regions in prostate tumor cells, possibly indicating the presence of genetic alterations in these regions. In addition, genome-wide association studies have identified several dozen polymorphisms associated with prostate cancer risk. Several of these are located in chromosome 8q24, which contains polymorphisms associated with several other cancers as well (colon, pancreas, and esophagus). Although the 8q24 region contains no protein-coding genes, it contains enhancer elements that affect expression of the *MYC* oncogene, located about 250 kilobytes (kb) from 8q24.

Nongenetic risk factors for prostate cancer may include a high-fat diet. Because prostate cancer usually progresses slowly and because it can be detected by digital examination and by the prostate-specific antigen (PSA) test, fatal metastasis can usually be prevented.

Cancer Gene Identification.

Recently developed techniques, including large-scale DNA sequencing, have identified hundreds of genes that are mutated in various cancers. Some of these genes contribute directly to a growth advantage in tumors and are considered primary causes of cancer. Approximately 150 such **driver genes** have been described.¹¹ A much larger number of genes undergo somatic mutations during tumorigenesis, but these genes do not directly confer a growth advantage to cells; these are termed **passenger genes**. The gene responsible for retinoblastoma (see [Chapter 4](#)), which normally acts as

a “brake” on cell division, is an example of a well-known driver gene. The *APC* gene, discussed previously, is another example.

Although many types of cancer, such as retinoblastoma or familial adenomatous polyposis, are relatively rare, study of the causative genes has provided many important insights into the nature of carcinogenesis in general. This can lead to more effective treatment and prevention of all cancers.

Diabetes Mellitus.

Like the other disorders discussed in this chapter, the etiology of diabetes mellitus is complex and not fully understood. Nevertheless, progress is being made in understanding the genetic basis of this disorder, which is a leading cause of blindness, heart disease, and kidney failure.^{18,19} An important advance has been the recognition that diabetes is actually a heterogeneous group of disorders, all characterized by elevated blood glucose level. The focus here is on the two major types of diabetes: type 1 (insulin-dependent diabetes mellitus [IDDM]) and type 2 (non-insulin-dependent diabetes mellitus [NIDDM]).

Type 1 Diabetes.

Type 1 diabetes, which is characterized by T-cell infiltration of the pancreas and destruction of the insulin-producing beta cells, usually (though not always) presents before age 40. Individuals with type 1 diabetes must receive exogenous insulin to survive. In addition to T-cell infiltration of the pancreas, autoantibodies are formed against pancreatic cells; the latter can be observed long before clinical symptoms occur. These findings, along with a strong association between type 1 diabetes and the presence of several major histocompatibility complex (MHC) class II alleles, indicate that this is an autoimmune disease. Over the past few decades, the incidence of type 1 diabetes has increased substantially.

Siblings of individuals with type 1 diabetes face a substantial elevation in risk: approximately 6%, as opposed to a risk of about 0.3% to 0.5% in the general population. The recurrence risk is also elevated

when there is a diabetic parent, although this risk varies with the sex of the affected parent. The risk for offspring of diabetic mothers is only 1% to 3%, whereas it is 4% to 6% for the offspring of diabetic fathers (because type 1 diabetes affects males and females in roughly equal proportions in the general population, this risk difference is inconsistent with the sex-specific threshold model for multifactorial traits). Twin studies show that the empirical risks for identical twins of people with type 1 diabetes range from 30% to 50%. In contrast, the concordance rates for dizygotic twins are 5% to 10%. The fact that type 1 diabetes is not 100% concordant among identical twins indicates that genetic factors are not solely responsible for the disorder. There is good evidence that specific viral infections contribute to the causation of type 1 diabetes in at least some individuals, possibly by activating an autoimmune response.

The association of specific MHC class II alleles (see [Chapter 22](#)) and type 1 diabetes has been studied extensively, and it is estimated that these alleles account for about 40% of the familial clustering of type 1 diabetes. Approximately 95% of whites with type 1 diabetes have the human leukocyte antigen (HLA) (part of the MHC), DR3, and/or DR4 alleles, whereas only about 50% of the general white population has either of these alleles. If an affected proband and a sibling are heterozygous for the DR3 and DR4 alleles, the sibling's risk of developing type 1 diabetes is nearly 20% (i.e., about 40 times higher than the risk in the general population). In addition, the presence of aspartic acid at position 57 of the HLA DQ chain is strongly associated with resistance to type 1 diabetes. In fact, those who do not have this amino acid at position 57 (and instead are homozygous for a different amino acid) are 100 times more likely to develop type 1 diabetes. The aspartic acid substitution alters the shape of the HLA class II molecule and thus its ability to bind and present peptides to T cells. Altered T-cell recognition may help protect individuals with the aspartic acid substitution from an autoimmune episode.

The insulin gene, which is located on the short arm of chromosome 11, is another logical candidate for type 1 diabetes susceptibility. Polymorphisms within and near this gene have been tested for

association with type 1 diabetes. It is estimated that inherited genetic variation in the insulin region accounts for approximately 10% of the familial clustering of type 1 diabetes.

Many additional genes have been shown to be associated with susceptibility to type 1 diabetes. The most significant of these are cytotoxic lymphocyte associated-4 (*CTLA4*), which encodes a protein involved in the regulation of T-cell proliferation, and *PTPN22*, which encodes a lymphoid-specific tyrosine phosphatase that negatively regulates T-cell activation. It is interesting that variation in the latter gene has been associated with several other autoimmune diseases, including systemic lupus erythematosus (SLE), rheumatoid arthritis, and autoimmune thyroid disease.

Type 2 Diabetes.

Type 2 diabetes accounts for more than 90% of all diabetes cases and affects 10% to 20% of the adult populations of many developed countries. A number of features distinguish it from type 1 diabetes. There is nearly always some endogenous insulin production in people with type 2 diabetes, and the disease can often be treated successfully with dietary modification and/or oral drugs. People with type 2 diabetes suffer from insulin resistance (i.e., their cells have difficulty in using insulin). This disease typically occurs among people older than age 40 and, in contrast to type 1 diabetes, is seen more commonly among the obese. The incidence of type 2 diabetes is rising dramatically among adolescents and young adults in developed countries, however, and is strongly correlated with an increased incidence of obesity. Neither MHC associations nor autoantibodies are commonly seen in this form of diabetes. Monozygotic twin concordance rates are substantially higher than those seen in type 1 diabetes, ranging from 70% to 90% (because of age dependence, the concordance rate increases if older subjects are studied). The empirical recurrence risks for first-degree relatives of type 2 diabetes cases are higher than those for type 1, generally ranging from 15% to 40%. The differences between type 1 and type 2 diabetes are summarized in [Table 5.7](#).

TABLE 5.7**COMPARISON OF MAJOR FEATURES OF TYPES 1 AND 2 DIABETES**

FEATURE	TYPE 1 DIABETES	TYPE 2 DIABETES
Age of onset	Usually <40 yr	Usually >40 yr (except maturity-onset diabetes of the young [MODY])
Insulin production	None	Partial
Insulin resistance	No	Yes
Autoimmunity	Yes	No
Obesity	Not common	Common
Monozygotic (MZ) twin concordance	0.55	0.90
Sibling recurrence risk	1–6%	10–15%

Hundreds of studies have been undertaken to identify genes that may contribute to type 2 diabetes susceptibility, and nearly 100 genes are now known to be associated with risk of this disease. An important risk factor is *TCF7L2*, which encodes a transcription factor involved in the secretion of insulin. A variant of *TCF7L2* is associated with a 50% increased risk of developing type 2 diabetes. A significant association has also been observed between type 2 diabetes and a common allele of the gene that encodes peroxisome proliferator-activated receptor-gamma (*PPAR- γ*), a nuclear receptor that is involved in adipocyte differentiation and glucose metabolism. This receptor is the target of thiazolidinediones (TZDs), a class of drugs commonly used to increase insulin sensitivity in those with type 2 diabetes. Although the disease-associated allele confers only a 25% increase in the risk of developing type 2 diabetes, it is found in more than 75% of individuals of European descent and thus helps to account for a significant proportion of type 2 diabetes cases. Variation in *KCNJ11*, which encodes a potassium channel necessary for glucose-stimulated insulin secretion, confers an additional 20% increase in type 2 diabetes susceptibility. The associations between diabetes susceptibility and each of these genes have been widely replicated in multiple populations.

The two most important risk factors for type 2 diabetes are positive family history and obesity; the latter increases insulin resistance. The disease tends to rise in prevalence when populations adopt a diet and exercise pattern typical of U.S. and European populations. Increases have been seen, for example, among Japanese immigrants to the United States and among some native populations of the South Pacific, Australia, and the Americas. Several studies, conducted on male and female subjects, have shown that regular exercise can substantially lower one's risk of developing type 2 diabetes, even among individuals with a family history of the disease. This is partly because exercise reduces obesity. However, even in the absence of weight loss, exercise increases insulin sensitivity and improves glucose tolerance.

Because of the dramatic increase in obesity in the United States and other developed countries, the prevalence of type 2 diabetes is also rising rapidly, and the average age of onset is decreasing. A small proportion of type 2 diabetes cases occurs early in life, often before 25 years of age, and typically exhibits autosomal dominant inheritance (unlike most type 2 diabetes cases). This subset is termed *maturity-onset diabetes of the young* (MODY). Studies of MODY pedigrees have shown that about half of cases of the disease are caused by mutations in the glucokinase gene. Glucokinase converts glucose to glucose-6-phosphate in the pancreas. In addition to the glucokinase gene, five other genes, all of which are involved in pancreatic development or regulation of insulin levels, have now been shown to be causes of MODY.

Obesity

Obesity is most commonly defined as a body mass index (BMI) greater than 30. (BMI is defined as W/H^2 , in which W is weight in kilograms and H is height in meters.) Using this criterion, more than one-third of American adults are obese, and an additional one-third are overweight (BMI greater than 25 but less than 30). The proportion of obese adults and children continues to increase rapidly. Although obesity itself is not a “disease,” it is an important risk factor for several

common diseases, including heart disease, stroke, type 2 diabetes, and cancers of the prostate, breast, and colon.

As one might expect, there is a strong correlation between obesity in parents and their children. This could easily be ascribed to common environmental effects: parents and children usually share similar dietary and exercise habits. However, there is good evidence for genetic components as well. Four adoption studies each showed that the body weights of adopted individuals correlated significantly with their natural parents' body weights but not with those of their adoptive parents. Twin studies also provide evidence for a genetic effect on body weight, with most studies yielding heritability estimates between 0.60 and 0.80.

Research, aided substantially by mouse models, has shown that many genes each play a role in human obesity. Important among these are the genes that encode leptin (Greek, "thin") and its receptor. The leptin hormone is secreted by adipocytes (fat storage cells) and binds to receptors in the hypothalamus, the site of the body's appetite control center. Cloning of the human leptin gene and its receptor led to optimistic predictions that leptin could be a key to weight loss in humans (without the perceived unpleasantness of dieting and exercise). Although mutations in the human leptin gene and its receptor have been identified in a few humans with severe obesity (BMI >40), they both appear to be extremely rare. Clinical trials using recombinant leptin have demonstrated moderate weight loss in a subset of obese individuals. In addition, leptin participates in important interactions with other components of appetite control, such as neuropeptide Y and α -melanocyte-stimulating hormone and its receptor, the melanocortin-4 receptor (MC4R). Mutations in the gene that encodes MC4R have been found in 3% to 5% of severely obese individuals. Homozygosity for a DNA variant in the *FTO* gene (which is seen in 16% of whites) has been associated with 40% and 70% increases in the risks of overweight and obesity, respectively. Recent evidence shows that the *FTO* variant is part of an enhancer that binds to the *IRX* gene, which is located 2 million base pairs away from *FTO* and is involved in regulation of fat mass. Identification of

these human genes is leading to a better understanding of natural weight control in the human, and it could eventually lead to effective treatments for some cases of obesity.

Alzheimer Disease

Alzheimer disease (AD), which is responsible for 60% to 70% of cases of progressive cognitive impairment among older adults, affects approximately 5% to 10% of the population older than 65 years of age and 40% of the population older than 85 years of age. Because of the aging of the population, the number of Americans with AD is predicted to increase substantially during the coming decade. AD is characterized by progressive dementia and memory loss and by the formation of amyloid plaques and neurofibrillary tangles in the brain, particularly in the cerebral cortex and hippocampus. The plaques and tangles lead to progressive neuronal loss, and death usually occurs within 7 to 10 years after the first appearance of symptoms.

The risk of developing AD doubles in individuals who have an affected first-degree relative. Although most cases do not appear to be caused by single loci, approximately 10% follow an autosomal dominant mode of transmission. About 3% to 5% of AD cases occur before age 65 and are considered early onset; these are much more likely to be inherited in autosomal dominant fashion.²⁰

AD is a genetically heterogeneous disorder. Approximately half of early-onset cases can be attributed to mutations in any of three genes, all of which affect amyloid- β deposition.²⁰

Two of the genes, presenilin 1 (*PS1*) and presenilin 2 (*PS2*), are very similar to one another, and their protein products are involved in cleavage of the amyloid- β precursor protein (APP). When APP is not cleaved normally, a long form of it accumulates excessively and is deposited in the brain. This is thought to be a primary cause of AD. Mutations in *PS1* typically result in early-onset AD, with the first occurrence of symptoms in the fifth decade of life.

A small number of cases of early-onset AD are caused by mutations of the gene that encodes APP itself, which is located on chromosome 21. These mutations disrupt normal cleavage sites in APP, again

leading to the accumulation of the longer protein product. It is interesting that this gene is present in three copies in trisomy 21 individuals, in which the extra gene copy leads to amyloid deposition and the occurrence of AD in those with Down syndrome (see [Chapter 4](#)). High-throughput DNA sequencing (techniques allowing the sequencing of massive amounts of DNA at once) studies have revealed an allele in APP that is protective against Alzheimer disease and may help to prevent cognitive decline.

An important risk factor for the more common late-onset form of AD is allelic variation in the apolipoprotein E (*APOE*) locus, which has three major alleles: $\epsilon 2$, $\epsilon 3$, and $\epsilon 4$. Studies conducted in diverse populations have shown that persons who have one copy of the $\epsilon 4$ allele are at least 2 to 5 times more likely to develop AD, whereas those with two copies of this allele are at least 5 to 10 times more likely to develop AD. The risk varies somewhat by population, with higher $\epsilon 4$ -associated risks in Europeans and Japanese and relatively lower risks in Hispanics and blacks. Despite the strong association between $\epsilon 4$ and AD, approximately half of individuals who develop late-onset AD do not have a copy of the $\epsilon 4$ allele, and many who are homozygous for $\epsilon 4$ remain free of AD even at advanced age. The apolipoprotein E protein product is not involved in cleavage of APP but instead appears to be associated with clearance of amyloid from the brain.

Alcoholism

At some point, alcoholism is diagnosed in approximately 10% of adult males and 3% to 5% of adult females in the United States. The national cost of alcoholism, in terms of lost productivity and direct medical costs, is approximately \$250 billion per year. More than 100 studies have shown that this disease clusters in families.²¹ The risk of developing alcoholism among individuals with one affected parent is three to five times higher than for those with unaffected parents.

Most twin studies have yielded concordance rates for DZ twins less than 30% and concordance rates for MZ twins in excess of 60%. Adoption studies have shown that the offspring of an alcoholic

parent, even when raised by nonalcoholic parents, have a fourfold increased risk of developing the disorder. To control for possible prenatal effects in an alcoholic mother, some studies have included only the offspring of alcoholic fathers. The results have remained the same. One study showed that the offspring of nonalcoholic parents, when reared by alcoholics, did *not* have an increased risk of developing alcoholism. These data argue that there may be genetic variants that predispose some people to alcoholism.

It has long been known that an individual's physiologic response to alcohol can be influenced by variation in the key enzymes responsible for alcohol metabolism: alcohol dehydrogenases (ADHs), which convert ethanol to acetaldehyde; and aldehyde dehydrogenases (ALDHs), which convert acetaldehyde to acetate. In particular, an allele of the *ALDH2* gene (*ALDH2*2*) results in excessive accumulation of acetaldehyde and thus in facial flushing, nausea, palpitations, and lightheadedness. Because of these unpleasant effects, individuals who have the *ALDH2*2* allele are much less likely to become alcoholics. This “protective” allele is common in some Asian populations but is rare in other populations.

A number of other genes are associated with susceptibility to alcohol addiction, including genes that encode components of gamma-aminobutyric acid (GABA) receptors. This finding is biologically plausible, because the GABA neurotransmitter system inhibits excitatory signals in neurons, exerting a calming effect. Alcohol has been shown to increase GABA release, and allelic variation in GABA receptor genes may modulate this effect.

It should be underscored that genes may increase one's *susceptibility* to alcoholism. Obviously this is a disease that requires an environmental component, regardless of genetic constitution.

Psychiatric Disorders

The major psychiatric diseases, schizophrenia and affective disorder, have been the subjects of numerous genetic studies.²² Twin, adoption, and family studies have shown that both disorders aggregate in families.

Schizophrenia.

Schizophrenia is a severe emotional disorder characterized by delusions, hallucinations, retreat from reality, and bizarre, withdrawn, or inappropriate behavior. (Contrary to popular belief, schizophrenia is not a “split personality” disorder.) The lifetime recurrence risk for schizophrenia among the offspring of one affected parent is approximately 8% to 10%, which is about 10 times higher than the risk in the general population.²³ As one might expect, the empirical risks increase when more relatives are affected. For example, an individual with an affected sibling and an affected parent has a risk approaching 20% and an individual with two affected parents has a risk of nearly 50%. The risks decrease when the affected family member is a second- or third-degree relative. Details are given in [Table 5.8](#). On inspection of [Table 5.8](#), it may seem puzzling that the proportion of schizophrenic probands who have a schizophrenic parent is only about 5%, which is substantially lower than the risk for other first-degree relatives (e.g., siblings, affected parents and their offspring). This can be explained by the fact that people with schizophrenia are less likely to marry and produce children than are other individuals. Thus substantial selection against schizophrenia occurs in the population.

TABLE 5.8

RECURRENCE RISKS FOR RELATIVES OF SCHIZOPHRENIC PROBANDS

RELATIONSHIP TO PROBAND	RECURRENCE RISK (%)
Monozygotic twin	44.3
Dizygotic twin	12.1
Offspring	9.4
Sibling	7.3
Niece/nephew	2.7
Grandchild	2.8
First cousin	1.6
Spouse	1

NOTE: Figures are based on multiple studies of Western European populations.

Data from McGue M, Gottesman II, Rao DC: *Behav Genet* 16(1):75–87, 1986.

Twin and adoption studies also indicate that genetic factors are likely to be involved in schizophrenia. Data pooled from five different twin studies show a 47% concordance rate for MZ twins, compared with a concordance rate of only 12% for DZ twins. When the offspring of a schizophrenic parent are adopted by normal parents, their risk of developing the disease is about 10%, which is approximately the same as the risk when raised by a schizophrenic biologic parent. Large-scale genetic studies have revealed more than 100 loci that are associated with risk of schizophrenia. Many of these genes encode components of the dopaminergic and glutamatergic neuronal signaling pathways. These findings are biologically plausible because the major therapeutic drugs used to treat schizophrenia block dopamine receptors.

Bipolar Disorder.

Bipolar disorder, also known as *manic-depressive disorder*, is a form of psychosis with extreme mood swings and emotional instability. The incidence of the disorder in the general population is approximately 0.5%, but it rises to 5% to 10% among those with an affected first-degree relative. Twin and family studies show that approximately 60% of the risk for bipolar disorder is attributable to genetic factors, whereas about 30% of the risk for unipolar disorder (major depression) is because of genetic factors.²⁴

As with schizophrenia, many large-scale studies have been undertaken to identify genes associated with susceptibility to bipolar disorder. Some of these loci were identified because their products are involved in neurotransmitter systems that are targets of drugs used to treat the disease (e.g., the serotonin, dopamine, and noradrenaline systems). Some of the best-replicated genetic studies implicate genes that encode voltage-gated calcium channels. Ion-channel modulating drugs are frequently used as mood stabilizers, lending the genetic results functional plausibility. Many of the genes associated with bipolar disorder also are associated with schizophrenia.

Genetic studies of psychiatric disorders are especially challenging

because these disorders are undoubtedly heterogeneous, reflecting the influence of numerous genetic and environmental factors. Also, definition of the phenotype is not always straightforward and it may change through time, significantly complicating genetic analysis.

Other Complex Disorders

The disorders discussed in this chapter represent some of the most common multifactorial disorders and those for which significant progress has been made in identifying genes. Many other multifactorial disorders are being studied as well, and in some cases specific susceptibility genes have been identified. These include, for example, Parkinson disease, hearing loss, multiple sclerosis, amyotrophic lateral sclerosis, epilepsy, asthma, inflammatory bowel disease, and some forms of blindness.

Some General Principles and Conclusions

Some general principles can be deduced from the results obtained thus far on the genetics of complex disorders. First, the more strongly inherited forms of complex disorders generally have an earlier age of onset (e.g., breast cancer, AD, heart disease). Often these represent subsets of cases in which there is single-gene inheritance. Second, when laterality is a component, the bilateral forms are more likely to cluster strongly in families (e.g., breast cancer, CL/P). Third, although the sex-specific threshold model fits some of the complex disorders (e.g., pyloric stenosis, CL/P, autism, heart disease), it fails to fit others (e.g., type 1 diabetes).

A tendency exists, particularly among the lay public, to assume that the presence of a genetic component means that the course of a disease cannot be altered. *This is incorrect.* Most of the diseases discussed in this chapter have both genetic and environmental components. Thus lifestyle modification (e.g., diet, exercise, stress reduction) often can reduce risk significantly. Such modification may be especially important for individuals with a family history of a disease because they are likely to develop the disease earlier in life.

Those with a family history of heart disease, for example, can often add many years of productive living with relatively minor lifestyle alterations. By targeting those who can benefit most from intervention, genetics helps to serve the goal of preventive medicine.

In addition, it should be stressed that the identification of a specific genetic lesion can lead to more effective prevention and treatment of the disease. Identification of mutations that cause autosomal dominant breast cancer may enable early screening and prevention of metastasis. Pinpointing a gene responsible for a neurotransmitter defect in a behavioral disorder such as schizophrenia could lead to the development of more effective drug treatments. In some cases, such as those with familial hypercholesterolemia, targeted drug therapy or gene therapy may prove to be useful in treating the disease. It is important for healthcare practitioners to help individuals understand these facts.

Although the genetics of common disorders is complex and often confusing, the community health effect of these diseases, together with the evidence for hereditary factors in their etiology, demands that genetic studies be pursued. Substantial progress is already being made. The next decade will undoubtedly witness many further advances in the understanding and treatment of these disorders.

Summary Review

Factors Influencing Incidence of Disease in Populations

1. The incidence rate is the number of new cases of a disease reported during a specific period (typically 1 year) divided by the number of individuals in the population.
2. The prevalence rate is the proportion of the population affected by a disease at a specific point in time. This rate, and the incidence rate, can be used to compare population variations in disease frequency.

3. Relative risk is a common measure of the effect of a specific risk factor. It is expressed as a ratio of the incidence rate of the disease among individuals exposed to a risk factor divided by the incidence of the disease among individuals *not* exposed to a risk factor.
4. Many factors can influence the risk of acquiring a common disease, such as cancer, diabetes, or hypertension. The factors can include age, gender, diet, exercise, and family history of the disease.

Principles of Multifactorial Inheritance

1. Traits in which variation is thought to be caused by the combined effects of multiple genes are polygenic.
2. The term *multifactorial* is used when environmental factors also are believed to cause variation in the trait.
3. Many quantitative traits (e.g., blood pressure) are multifactorial.
4. Because traits are caused by the additive effects of many genetic and environmental factors, they tend to follow a normal or bell-shaped distribution in populations.
5. Those diseases, however, that do not follow a bell-shaped distribution appear to be either present or absent in individuals. They do not follow the inheritance patterns of single-gene disease. Instead, such diseases may follow an underlying liability distribution. It is thought that a threshold of liability must be crossed before the disease is expressed.
6. Examples of diseases that correspond to the liability model include pyloric stenosis, neural tube defects, CL/P, and some forms of congenital heart disease.
7. Many of the common adult diseases, such as hypertension, coronary heart disease, stroke, diabetes mellitus (types 1 and 2), and some cancers, are caused by complex genetic and environmental factors and are thus multifactorial diseases.
8. For most multifactorial diseases, empirical risks (risks based on

direct observation of data) have been derived.

9. In contrast to most single-gene diseases, recurrence risks for multifactorial diseases can change significantly from one population to another because gene frequencies, as well as environmental factors, can differ among populations.
10. Several criteria are used to define multifactorial inheritance: (a) the recurrence risk becomes higher if more than one family member is affected; (b) if the expression of the disease in a proband is more severe, the recurrence risk is higher; (c) the recurrence risk is higher if the proband is of the less commonly affected sex; (d) the recurrence risk for the disease usually decreases rapidly in more remotely related relatives; and (e) if the prevalence of the disease in a population is f , the risk for offspring and siblings of probands is approximately \sqrt{f} .

Nature and Nurture: Disentangling the Effects of Genes and Environment

1. Family members share genes and a common environment; therefore, resemblance in traits, such as high blood pressure, reflects both genetic and environmental factors (nature and nurture, respectively).
2. Few traits are influenced *only* by genes or *only* by environment. Most are influenced by both.
3. When a disease has a relatively larger genetic component, as in breast cancer, examination of family history should be emphasized in addition to lifestyle modification.
4. Two research strategies often are used to estimate the relative influence of genes and environment-lifestyle: twin studies and adoption studies.
5. Monozygotic twins originate when the developing embryo divides to form two separate but identical embryos.
6. Dizygotic twins are the result of a double ovulation followed

- by the fertilization of each egg by a different sperm.
7. If both members of a twin pair share a trait, they are said to be *concordant*. If they do not share the same trait, they are *discordant*.
 8. Studies of adopted children also are used to estimate the genetic contribution to a multifactorial trait.
 9. A genetic predisposition may interact with an environmental-lifestyle factor to increase the risk of disease; this is called a *gene-environment interaction*.

Genetics of Common Diseases

1. Congenital diseases are those present at birth. Most of these diseases are multifactorial in etiology.
2. Multifactorial diseases in adults include coronary heart disease, hypertension, breast cancer, colon cancer, diabetes mellitus, obesity, AD, alcoholism, schizophrenia, and bipolar affective disorder.
3. It is incorrect to assume that the presence of a genetic component means that the course of a disease cannot be altered — most diseases have *both* genetic and environmental aspects.

Humans exhibit an impressive diversity of physical and behavioral traits. Much of this diversity is attributable to genetic variation. Another substantial contributor is epigenetic (“upon genetic”) modification. The specific definition of epigenetic remains a topic of discussion among biologists.^{1,2} Under one definition, the term is reserved for modifications that are not encoded in nucleotide sequence but are nevertheless transmitted when a somatic cell divides (mitotic inheritance), when gametes are produced (germline inheritance), or both.³ In this chapter, the term epigenetic is used to refer to processes that modulate how a given set of genomic information gives rise to phenotype. Under this definition, epigenetic mechanisms include chemical modifications to DNA and associated histones, the production of small regulatory RNA molecules, and, more generally, gene regulation by epigenetic processes at the level of either transcription or translation.

Epigenetic modification is essential to fundamental processes of human development, including the differentiation of embryonic stem cells into specific cell types, and the inactivation of one of the two X chromosomes in each cell of a genetic female. Some genes are said to be *imprinted*, meaning that they are inherited from the mother and the father in predictable and distinct epigenetic states. At imprinted loci, it is always either the allele from the mother or the allele from the father that is expressed in the offspring.⁴⁻⁶

A variety of diseases can result from abnormal epigenetic states. For example, metabolic disease can occur when there is abnormal expression from both alleles at a locus that is typically imprinted; exposure to environmental stressors can markedly increase the risk of abnormal epigenetic states and is strongly associated with some cancers. Because of their increasingly clear role in a wide range of pathologies, such epigenetic perturbations are currently a focus of both preventative efforts and pharmaceutical interventions.

Overview of Epigenetic Mechanisms

Epigenetic marks include DNA methylation and hydroxymethylation, chemical modifications that alter the charges of the histone proteins around which DNA is wound for compaction within the nucleus, and RNA-based mechanisms (Fig. 6.1).

FIGURE 6.1 Three Major Types of Epigenetic Processes. Investigators are studying the following epigenetic mechanisms: (1) DNA methylation, (2) histone modifications, and (3) RNA based-mechanisms. See text for discussion.

DNA Methylation

DNA methylation occurs through the attachment of a methyl group to the carbon-5 position of a cytosine. In the somatic cells of adults, DNA methylation occurs principally at cytosines that are followed by

a guanine base (sometimes known as cytosines in “CpG dinucleotides”); in human embryonic stem cells, methylation also can occur at cytosines outside of the CpG context.⁷

DNA methylation plays a prominent role in human health and disease. For example, in each cell of a normal human female, one of the two X chromosomes has dense methylation at most regions. Dense methylation is a key feature of **heterochromatin**, a structure consisting of DNA tightly wound around histones into a condensed state and not actively transcribed. The heterochromatization of the so-called “inactive X” accounts for the cytologic observations that each cell from a human female has a region of densely stained DNA. This region was later confirmed to be the highly condensed inactive X chromosome.^{8,9}

Most regions of the other X chromosome in a cell from a human female, the so-called *active X chromosome*, are largely devoid of DNA methylation. The active X chromosome is said to be a transcriptionally active *euchromatic* state. Epigenetic inactivation of one of the two X chromosomes occurs in each cell of a human female during gastrulation, a phase of early embryonic development. The determination of which chromosome is to be silenced, either the copy from the father or the copy from the mother, occurs at random and independently in each cell; the silent state of that chromosome and the active state of the other are inherited by descendant cells. If a woman's two X chromosomes carry different alleles at a given locus, random **X inactivation** in early development can lead to **somatic mosaicism**, wherein differences between the alleles active in two cells can confer two very different traits. Visually notable examples include the patchy coloration of calico cats and *anhidrotic ectodermal dysplasia*, the patchy presence and absence of sweat glands in the skin of human females with one X chromosome bearing a normal allele and one X chromosome bearing a mutant allele. It is important to note that somatic mosaicism because of random inactivation can arise for any X-encoded trait. As a result, females who inherit one normal allele and one disease allele at an X-encoded gene tend to have less severe disease phenotypes than do males whose lone X chromosome bears a disease allele. This pattern is reflected in the typically lower severity

in females as compared to males for color blindness, fragile X syndrome, and other phenotypes that arise from mutations on the X chromosome.

Aberrant DNA methylation, either the presence of dense methylation where it is typically absent or the absence of methylation where it is typically present, is associated with misregulation of **tumor-suppressor genes** and **oncogenes**. Specific alterations to DNA methylation states are a common feature of several human cancers, including those of the colon¹⁰ and breast;¹¹ the details of these alterations can be useful in assessing disease prognosis¹² (see [Figs. 6.1](#) and [6.4](#); also see [Chapter 12](#)).

DNA Hydroxymethylation

DNA hydroxymethylation is most common in cells that are undergoing epigenetic transition. DNA hydroxymethylation differs from DNA methylation in that it is a hydroxymethyl group, rather than methyl group, that is affixed to the C5 of cytosine. Discovery of this alternate DNA modification has helped to resolve long-standing uncertainties as to how genomic regions dense in DNA methylation undergo methylation loss, as observed, for example, in early embryonic development.¹³

In 2011, Wossidlo and colleagues¹⁴ found that genome-wide declines in DNA methylation in early murine zygotes occur in concert with genome-wide increases in DNA hydroxymethylation. They also found that this loss of methylation, as well as the parallel gain in hydroxymethylation, were obliterated in zygotes deficient in the Tet3 enzyme. These two findings helped to establish that Tet enzymes can convert DNA methylation into hydroxymethylation. The name *Tet* derives from the term “ten-eleven translocation,” a reference to the discovery of these enzymes through their association with a chromosomal translocation between chromosomes 10 and 11 that is commonly observed in some forms of leukemia.¹⁵ Though the specific functional impacts of hydroxymethylation remain an area of active investigation, one recent proposal is that it is associated with the activation of lineage-specific enhancers and so could play a role in

specifying cell lineages.¹⁶

Histone Modifications

Histones are the positively charged proteins around which negatively charged DNA molecules are wound, facilitating compaction of DNA into the cellular nuclei. When all of the DNA that comprises the human genome is wound around histones, it is only 1/40,000 as long as it would be in its uncondensed state. A set of histones and the segment of DNA wound around them are, together, known as individual **nucleosomes**. The total chromatin in a cell, a combination of DNA and its associated histones and RNA molecules, is made up of individual nucleosome units.

When a given segment of DNA is bound tightly to its associated histones it is said to be **heterochromatic**, such that, as noted previously in describing the inactive X chromosome, it is not accessible by **transcription factors** and so cannot be used to guide the production of mRNA. By contrast, if a given segment of DNA is only loosely bound to associated histones it is said to be **euchromatic**, such that, as noted previously in describing the active X chromosome, transcription factors are able to access it and use it as a template for production of mRNA. Whether a given segment of DNA is heterochromatic or euchromatic depends largely on chemical modifications to histone tails, parts of the histone-protein complex that extend away from the main part of the nucleosome.

Researchers are only beginning to understand the full diversity and complexity of these **histone modifications**.¹⁷ The two modifications best studied are histone acetylation and histone methylation. Histone acetylation tends to diminish the positive charge of histones, reducing the strength of their binding to negatively charged DNA and, ultimately, making DNA more accessible for transcription. Histone methylation can either increase or decrease the strength of bonding between DNA and histones, depending on the specific parts of the histones to which the methyl groups are added.

Whether individual segments of the genome are in heterochromatic or euchromatic states play a critical role in determining the

developmental potential of a given cell—that is, its capacity to give rise to a diverse set of differentiated cell types. For example, chromatin states differ substantially between embryonic stem cells, which are poised to give rise to all of the different cell types that comprise an individual, and terminally differentiated cells, which are committed to a specific developmental path. The fraction of DNA that is in the heterochromatic state typically increases as cells differentiate, in parallel to the reduction in the number of genes that are active as a cell lineage transitions from pluripotency, when they have the capacity to give rise to a large number of descendant cell types, to terminal differentiation, and when they are able to produce only a cell of a single specified type.¹⁸ Mutations in genes that encode histone-modifying proteins have been implicated in various pathologic states, including congenital heart disease,¹⁹ highlighting histone modification as critical to normal development.

In contrast to the vast majority of other cell types, including oocytes, sperm cells express not histones but **protamines**, which are evolutionarily derived from histones.²⁰ Protamines enable sperm DNA to achieve compaction even greater than for the histone-bound DNA in somatic cells. This tight compaction improves the hydrodynamic features of sperm cells, facilitating their movement.

Noncoding RNAs

Noncoding RNAs (ncRNAs) play an important role in regulating a wide variety of cellular processes, including RNA splicing and DNA replication. Of particular relevance to gene regulation are **microRNAs (miRNAs)**, which are encoded by DNA sequences approximately 22 nucleotides long and typically reside within the introns of genes or in noncoding intergenic regions. In contrast to DNA methylation and histone modification, both of which principally impact gene expression at the level of transcription, miRNAs typically modulate the stability and translational efficiency of messenger RNAs (mRNAs) encoded at other loci. Interaction between miRNAs and the mRNAs they target for degradation is typically mediated by regions of partial sequence complementarity. As a result, miRNAs can at once be

specific enough so that they do not bind to *all* of the mRNAs in a cell and general enough to regulate a large set of different mRNA sequences. miRNAs can also modulate translation by impairing ribosomal function. miRNAs regulate diverse signaling pathways; those that stimulate cancer development and progression are called **oncomirs**. For example, miRNAs have been linked to carcinogenesis because they alter the activity of oncogenes and tumor-suppressor genes (see [Chapter 12](#)). Like other classes of genomic elements, the sequences that encode miRNAs can be transcriptionally silenced by DNA methylation. Insofar as the expression of miRNAs can modulate the formation and growth of tumors, epigenetic modification of the sequences that encode them is a key area for exploration of strategies for characterizing and perhaps even treating cancer.²¹

Epigenetics and Human Development

Each of the cells in the early embryo has the potential to give rise to a somatic cell of any type. These **embryonic stem cells** are therefore said to be **totipotent** (“possessing all powers”). A key process in early development is the differential epigenetic modification of specific DNA nucleotide sequences in these embryonic stem cells, ultimately leading to the differential gene-expression profiles that characterize differentiated somatic cell types. Early modifications ensure that specific genes are expressed only in the cells and tissue types in which their gene products typically function (e.g., factor VIII expression primarily in hepatocytes, and dopamine-receptor expression in neurons).

Epigenetic modifications early in development processes also highlight a fundamental feature of genetic as compared to epigenetic information: all of the cells in a given individual contain almost exactly the same genetic information. It is the epigenetic information eventually placed “on top of” these sequences that enables them to achieve the diverse functions of differentiated somatic cells. A small percentage of genes, termed **housekeeping genes**, are necessary for the function and maintenance of all cells. These genes escape

epigenetic silencing and remain transcriptionally active in all or nearly all cells. Housekeeping genes include those encoding histones, DNA and RNA polymerases, and ribosomal RNA genes.

How do embryonic stem cells achieve epigenetic states typical of totipotency, whereby they can give rise to all of the diverse cell types that comprise a fully developed organism? One explanation is that early embryogenesis, which occurs during the 10 or so days just after fertilization, is characterized by rapid fluctuation in genome-wide DNA methylation densities. Fertilization triggers a global loss of DNA methylation at most loci in both the oocyte-contributed and the sperm-contributed genomes. This loss of methylation is accomplished in part by suppression of the **DNA methyltransferases**, the enzymes that add methyl groups to DNA. Methylation is not directly copied by the DNA replication process. Instead, immediately following replication, the methyltransferases read the pattern of methylation on the parent DNA strand and use that information to determine which daughter-strand cytosines should be methylated. As embryonic cell division proceeds in the absence of DNA methyltransferases, cell division continues, eventually yielding cells that have nearly all of their loci in unmethylated, transcriptionally active states. Around the time of implantation in the uterus, the DNA methyltransferases become active again, permitting establishment of the cell lineage-specific marks required for the establishment of organ systems.

Genomic Imprinting

A baby inherits two copies of each autosomal gene: one from its mother and one from its father. For a large subset of these genes, expression is **biallelic**, meaning that both the maternally and the paternally inherited copies contribute to offspring phenotype. As noted earlier, for another, smaller subset of these genes, expression is stochastically **monoallelic**,²² meaning that the maternal copy is randomly chosen for inactivation in some somatic cells and the paternal copy is randomly chosen for inactivation in other somatic cells. For a third and smaller subset of autosomes (about 1%), either

the maternal copy or the paternal copy is **imprinted**, meaning that either the copy inherited through the sperm or the copy inherited through the egg is inactivated and remains in this inactive state in all of the somatic cells of the individual.

The subset of genes that are subject to imprinting is highly enriched for loci relevant to organismal growth. The **genetic conflict hypothesis**²² was developed as a potential explanation for this pattern. The logic of this hypothesis is as follows. Although both the mother and the father benefit genetically from the birth and survival of offspring, their interests are not entirely aligned. Because mothers make a large physiologic investment in each child, it is in their evolutionary best interest to limit the flow of energetic resources to any given offspring so as to maintain their physiologic capacity to bear subsequent children. By contrast, except in cases of lifelong monogamy, it is in the best interest of the fathers for their child to extract maximum resources from its mother, since the fathers' reproductive success is tied to the survival of their own child but not to the mother's ability to bear additional offspring in the future. Therefore, imprinted genes expressed from the maternal genome are predicted to limit offspring size, whereas imprinted genes expressed from the paternal genome are predicted to result in larger offspring. Available data are broadly consistent with these predictions.

One hallmark of imprinting-associated disease is that the phenotype of affected individuals is critically dependent on whether the mutation is inherited from the mother or from the father. Some examples are included in the following.

Prader-Willi and Angelman Syndromes

A well-known disease example of imprinting is associated with a deletion of about 4 million base pairs of the long arm of chromosome 15. When this deletion is inherited from the father, the child manifests **Prader-Willi syndrome**, with features that include short stature, hypotonia, small hands and feet, obesity, mild to moderate intellectual disability, and hypogonadism^{23,24} (Fig. 6.2, A). The same deletion, when inherited from the mother, causes **Angelman syndrome**, which

is characterized by severe intellectual disability, seizures, and an ataxic gait (Fig. 6.2, B).²⁵ These diseases are each observed in about 1 of every 15,000 live births; chromosome deletions are responsible for about 70% of cases of both diseases. The deletions that cause Prader-Willi and Angelman syndromes are indistinguishable at the DNA sequence level and affect the same group of genes.

FIGURE 6.2 Prader-Willi and Angelman Syndromes. A, A child with Prader-Willi syndrome (truncal obesity, small hands and feet, inverted V-shaped upper lip). B, A child with Angelman syndrome (characteristic posture, ataxic gait, bouts of uncontrolled laughter). (From Jorde LB, Carey JC, Bamshad MJ: *Medical genetics*, ed 4, Philadelphia, 2010, Mosby.)

It was unclear for several decades how the same deletion could produce such disparate results in different individuals. Further analysis showed that the 4 million base-pairs deletion (the *critical*

region) contains several genes that are normally transcribed only on the copy of chromosome 15 that is inherited from the father.²⁶ These genes are imprinted on the copy of chromosome 15 inherited from the mother, meaning that they are transcriptionally silenced. Similarly, other genes in the critical region are transcriptionally active only on the chromosome copy inherited from the mother and are inactive, or imprinted, on the chromosome inherited from the father (Fig. 6.3). If the single active copy of one of these genes is lost because of a chromosome deletion, then no gene product is produced, resulting in disease.

FIGURE 6.3 Prader-Willi Syndrome (PWS) and Angelman Syndrome (AS) Pedigrees. These pedigrees illustrate the inheritance patterns of Prader-Willi syndrome, which can be caused by a 4 million base pair deletion of chromosome 15q when inherited from the father. In contrast, Angelman syndrome can be caused by the same deletion but only when it is inherited from the mother. The reason for this difference is that different genes in this region are normally imprinted (inactivated) in the copies of 15q transmitted by the mother and the father in Prader-Willi and Angelman syndromes, respectively. (From Jorde LB, Carey JC, Bamshad MJ: *Medical genetics*, ed 4, Philadelphia, 2010, Mosby.)

Molecular analysis has revealed a great deal about genes in this critical region of chromosome 15.²⁶ The gene responsible for Angelman syndrome encodes a ligase involved in protein degradation during brain development, an observation that may help to explain the intellectual disability and ataxia observed in this disorder. In the brain, this gene is active only on the chromosome copy inherited from the mother. Consequently, a maternally-transmitted deletion removes

the single active copy of this gene. Several genes in the critical region are associated with Prader-Willi syndrome and they are transcribed only on the chromosome transmitted by the father. A paternally-transmitted deletion removes the only active copies of these genes producing the features of Prader-Willi syndrome.

Beckwith-Wiedemann Syndrome

Another well-known example of imprinting is Beckwith-Wiedemann syndrome, an overgrowth condition accompanied by an elevated risk of cancer. **Beckwith-Wiedemann syndrome** is usually identifiable at birth because of the large size for gestational age, neonatal hypoglycemia, a large tongue, creases on the earlobe, and omphalocele (birth defect of infant's intestines).²⁷ Children with Beckwith-Wiedemann syndrome have an increased risk of developing Wilms tumor or hepatoblastoma. Both of these tumor types can be treated effectively if they are detected early; thus, screening at regular intervals is an important part of management. Some children with Beckwith-Wiedemann syndrome also develop asymmetrical overgrowth of a limb or one side of the face or trunk (hemihyperplasia).

As with Angelman syndrome, a minority of Beckwith-Wiedemann syndrome cases (about 20% to 30%) are caused by the inheritance of two copies of chromosome 11 from the father and no copy of the chromosome from the mother, in a process known as **uniparental disomy**. Several genes on the short arm of chromosome 11 are imprinted on either the paternally- or the maternally-transmitted chromosome. These genes are found in two separate, differentially methylated regions (DMRs). In DMR1, the gene that encodes insulin-like growth factor 2 (*IGF2*) is inactive on the maternally-transmitted chromosome but active on the paternally-transmitted chromosome, such that a normal individual has only one active copy of *IGF2*. When two copies of the paternal chromosome are inherited (i.e., paternal uniparental disomy) or there is loss of imprinting on the maternal copy of *IGF2*, an active *IGF2* gene is present in double dose. These changes produce increased levels of *IGF2* during fetal development,

contributing to the overgrowth features of Beckwith-Wiedemann syndrome. Thus, in contrast to Prader-Willi and Angelman syndromes, which are produced by a missing gene product, Beckwith-Wiedemann syndrome is caused, in part, by overexpression of a gene product.

Russell-Silver Syndrome

Russell-Silver syndrome is characterized by growth retardation; proportionate short stature; leg length discrepancy; and a small, triangular-shaped face. About one-third of Russell-Silver syndrome cases are caused by imprinting abnormalities of chromosome 11p15.5 that lead to down-regulation of *IGF2* and therefore diminished growth. Another 10% of cases of Russell-Silver syndrome are caused by maternal uniparental disomy. Thus, while it is upregulation, or extra copies, of active *IGF2* that causes overgrowth in Beckwith-Wiedemann syndrome, it is downregulation of *IGF2* that causes the diminished growth seen in Russell-Silver syndrome.

Epigenetics in Cognitive Development and Mental Health

Several lines of evidence suggest a role for epigenetic abnormalities in disorders of cognitive development.

Epigenetics and Ethanol Exposure in Utero

The impact of ethanol exposure *in utero* on skeletal and neural development was first reported in 1973,²⁸ and led to broad awareness of fetal alcohol syndrome. It was not until recently, however, that population-based and molecular-level studies began to clarify the **epigenetic** signals that are associated with these developmental abnormalities. Initially, researchers found that alcohol exposure in utero can impact the DNA methylation states of various genomic elements but without specific emphasis on loci directly relevant to

skeletal and neural development.²⁹ Later experiments revealed that treating cultured neural stem cells with ethanol impairs their ability to differentiate to functional neurons; this impairment seems to be correlated with aberrant, dense methylation at loci that are active in normal neuronal tissue.³⁰ One possible explanation for these effects is that ethanol exposure in utero modulates fetal expression of the DNA methyltransferases.³¹

Epigenetics and Mental Health

Several emerging lines of evidence suggest an association between altered epigenetic states and mental health. A recent study found that children who grow up under conditions of poverty have atypical methylation at a serotonin receptor, suggesting DNA methylation as a mechanistic link between early-life socioeconomic stress to an increased propensity to depression.³² Similarly, in individuals with posttraumatic stress disorder (PTSD), alterations in gene expression in key neural pathways are associated with atypical methylation in a large set of genes.³³ Among individuals with PTSD, specific changes in methylation are associated with suicidal ideation and behavior.³⁴ Autism-spectrum disorder also is associated with altered DNA methylation at some loci.³⁵ In these cases, as in the connection of epigenetic abnormality to depression and PTSD, it is not clear whether epigenetic alteration plays a mechanistic role in the etiology of cognitive syndromes, or whether information on this link is useful principally for suggesting biomarkers potentially useful for diagnosis.

Fragile X Syndrome: A Genetic/Epigenetic Syndrome

Fragile X syndrome can be described as a genetic and epigenetic disease, insofar as abnormalities of both sorts are observed at the fragile X locus, *FMR1*, in affected individuals. The most common *genetic* abnormality at *FMR1* involves expansion in the number of cytosine-guanine (CG) dinucleotide repeats in the gene promoter. Females who have CG repeats in excess of the ≈ 35 that are typical at

this locus are at risk for fragile X–associated primary ovarian insufficiency, characterized by an elevated risk of early menopause.³⁶ Males with moderate expansions are at risk of fragile X tremor ataxia syndrome (FXTAS), characterized by a late-onset intention tremor.³⁷ Both of these conditions seem to arise through accumulation of excess levels of *FMR1* mRNAs in nuclear inclusion bodies.^{38,39} Individuals with 200 repeats are at risk of fragile X syndrome, characterized by reduced IQ and a set of behavioral abnormalities.

Remarkably, while possession of a large CG repeat in the *FMR1* promoter dramatically increases the probability that an individual will have fragile X syndrome, the disease can be at once present in males who have the large repeat and absent in their brothers who have inherited an allele of very similar size.⁴⁰

This can be explained at least in part by the observation that acquisition of methylation-based silencing at *FMR1* is stochastic, meaning that the presence of a large repeat increases the probability of the dense promoter methylation that could lead to gene silencing, but does not guarantee it. It remains to be seen whether dietary or environmental features can modulate the probability that dense methylation at *FMR1* will accrue in individuals with the full-mutation allele.

Exploring the Possible Multigenerational Persistence of Epigenetic States That Arise in Response to Environmental Factors

Emerging data suggest that conditions encountered in utero, during childhood, and even during adolescence or later can have long-term impacts on epigenetic states. Some data have been interpreted to indicate that epigenetic changes arising during an individual's lifetime can be transmitted through the germline, with the potential to impact gene expression in future generations.

Some reports of transgenerational inheritance of environment-induced epigenetics have failed to be replicated in subsequent work by other researchers. For example, Iqbal and colleagues⁴¹ sought to follow up on an earlier report⁴² that the epigenetic impacts of endocrine disruptors can be transmitted, by an unknown mechanism, to the germline of the grandchildren of the mice exposed. Although they did confirm the capacity of endocrine disruptors to induce epigenetic changes in tissues and gametes directly exposed, they found no evidence that any differences can persist to the germline of exposed animals' grandchildren. Further investigation will be required to explain the disparity between these conflicting findings. A few examples of such apparent connections between environment and inheritance of epigenetic states are discussed below; all of the examples remain under active investigation.

Epigenetics and Nutrition

During the winter of 1943, millions of people in urban areas of the Netherlands suffered starvation conditions as a result of a Nazi blockade that prevented shipments of food from agricultural areas. When researchers sought to investigate how exposure to famine during this Dutch Hunger Winter had impacted individuals born in a historically prosperous country, they found that individuals who had been in utero during this interval of severe nutritional deprivation were more likely to suffer from obesity and diabetes as adults than were other individuals from the Netherlands. There also seemed to be a transgenerational impact, in that the children of individuals who were in utero during the Dutch Hunger Winter were found to be significantly smaller than were the children of those not impacted by the blockade. Other datasets reveal elevated risk of cardiovascular and metabolic disease for offspring of individuals exposed during early development to fluctuations in food availability.⁴³

The specific molecular mechanisms that may mediate these apparent relationships between nutritional deprivation and disease risk on one or more generations are largely unknown. From some animal models, it seems that the *IGF2* gene is a possible target of

epigenetic modifications arising through nutritional deprivation. Exposure in utero and through lactation to some chemicals (including bisphenol-A, a constituent of plastics sometimes used in food preparation and storage) seems to lead to epigenetic modifications similar to those that arise through nutritional deprivation in early life.⁴⁴

Epigenetics and Maternal Care

There is increasing evidence that parenting style can impact epigenetic states, and that this information can be transmitted from one generation to the next. Mice and other rodents can exhibit two alternate styles of nursing behavior. One style is characterized by frequent arched-back nursing, with a high level of licking and grooming behavior. An alternate style is characterized by infrequent arched-back nursing and less licking and grooming behavior. In one study,⁴⁵ pups of mothers that engaged in frequent arched-backed nursing were found to have significantly lower methylation levels and higher transcription activity of a glucocorticoid receptor–encoding locus. Because the glucocorticoid receptor is involved in a pathway that intensifies fearfulness and response to stress, these findings suggest that alteration to methylation states could help explain the finding that exposure to stress early in life can modulate behavior in adulthood. These findings also highlight the concept that epigenetic processes can help store information about the environment, and that the relevant epigenetic modifications can modulate behavior later in life.

Epigenetic Change Over the Life Span

Twin Studies Reveal Epigenetic Changes over Time

Identical (monozygotic) twins, whose DNA sequences are essentially the same, offer a unique opportunity to isolate and examine the trajectory of epigenetic change over the life span. A recent study

found that, as twins age, they exhibit increasingly substantial differences in methylation patterns of the DNA sequences of their somatic cells; these changes are often reflected in increasing numbers of phenotypic differences. Twins with significant lifestyle differences (e.g., smoking vs. nonsmoking) tend to accumulate larger numbers of differences in their methylation patterns. These results, along with findings generated in animal studies, suggest that changes in epigenetic states may be an important part of the aging process.⁴⁶

Epigenetics and Aging

The occurrence of epigenetic change over the life span, as suggested by studies in twins, is echoed by broader studies in both human and nonhuman systems. In yeast, a shift in histone modification, as well as an overall decline in histone abundance, is a marker of replicative aging and is associated with dysregulation of gene expression.⁴⁷ Chemical labeling techniques have revealed that the genome-wide abundance of hydroxymethylcytosine increases with time in the brains of adult mice.⁴⁸ In view of these and similar findings, some authors have proposed that senescence, itself, can be characterized as an epigenomic phenomenon.⁴⁹ From this perspective, while accrual of adverse exposures over the life span is to some degree unavoidable, understanding environmental impacts on epigenetic states could lead to a new paradigm for life span extension.

This apparent relationship between epigenetics and aging could help to explain the long-standing observation that metformin, a drug used to treat insulin resistance, also is effective in slowing senescence in yeast.⁵⁰ Studies in human populations suggest that long-term use of metformin may even extend mean life span in diabetic people beyond that expected for untreated, nondiabetic individuals.⁵¹ Initially, these effects, which echo the increase in life span occurring under caloric restriction in primate models,⁵² were thought to operate directly through the impact of metformin on metabolism. However, metformin has recently been found specifically to alter the expression of *SIRT1*, the gene encoding sirtuin, a protein that modulates the metabolic response to energy limitation. Therefore, it is possible that a

drug that has long been used to treat insulin resistance may modulate epigenetic pathways, with possible opportunities for life span extension in humans.⁴⁹

Molecular and Computational Tools for Exploring Epigenetic States

Epigenetic information is not encoded DNA sequence. Therefore, specialized methods must be used to detect and quantify it.

Detecting DNA Methylation in Populations of Molecules: Methyl-Sensitive Restriction Enzymes

Many restriction enzymes are sensitive to methylation, and so they cleave DNA only at unmethylated cytosines. Clues to the overall level of methylation in DNA isolated from a given individual can, therefore, be gathered by treating DNA with a methyl-sensitive enzyme, and then comparing banding patterns for enzyme-treated and nonenzyme-treated samples.⁵³

Detecting DNA Methylation in Single Molecules: Bisulfite Conversion

Sometimes it is of interest to gather information about methylation on individual molecules. For example, among males who inherit a full-mutation fragile X allele, there is a strong correlation between the severity of the syndrome and the number of cells in which the fragile X allele is densely methylated.⁴⁰ To collect information on the methylation states of individual molecules, DNA can be subjected to **bisulfite conversion** before sequencing. Bisulfite treatment does not alter most nucleotides, including methylated cytosines, but deaminates unmethylated cytosines to uracil.⁵⁴ Because uracil complements adenine, not guanine, in double-stranded DNA, methylated and unmethylated cytosines can be distinguished in conventional sequence data, provided that the original sequence of

that region is known and can be used to distinguish between true thymines and converted, unmethylated cytosines. Either subcloning followed by Sanger sequencing or single-molecule sequencing technologies can then be applied to ascertain the detailed methylation patterns of individual molecules.

Detecting DNA Hydroxymethylation: Fluorescence Resonance Energy Transfer

Following Wossidlo and colleagues'¹⁴ discovery that loss of DNA methylation and the gain of DNA hydroxymethylation during early development, there has been considerable interest in exploring the specific functional impacts and mechanisms of this transition. However, efforts in this area have been hampered by lack of a method to detect relative levels of DNA methylation and DNA hydroxymethylation within individual molecules. Recently, Song and colleagues⁵⁵ introduced a promising solution. Under their new method, DNAs are first treated with two different fluorophores. Of these, one binds methyl groups and the other binds hydroxymethyl groups. When samples are examined using fluorescence assays, the methylation and hydroxymethylation can be distinguished visually. This new method will undoubtedly enable critical insight into the basic biology of epigenetic transitions and, perhaps, into the mechanisms of epigenetic disease.

Identifying Histone-Modification States: Chromatin Immunoprecipitation

The identity of DNA-bound proteins can provide important clues as to the activity states of individual regions. The goal of **chromatin immunoprecipitation (ChIP)** is to ascertain the sequences bound by specific proteins of interest. Broadly, this is achieved in seven steps:

1. **Cross-link** DNA-bound proteins to the specific genomic regions to which they are attached. At this step, binding is not

specific, meaning that all proteins, regardless of identity, are cross-linked to DNA.

2. **Shear** DNA, lysing DNA regions that are not protein bound. Proteins prevent sheering of the DNA to which they are bound.
3. **Select** for proteins of interest, using a protein-specific antibody.
4. **Capture** protein-DNA complexes by using a secondary antibody that can bind to the first, and by washing away any remaining unbound DNA fragments.
5. **Remove** protein-DNA cross-links and wash away proteins.
6. **Sequence** DNA fragments to profile the portion of genome that was bound by the protein of interest.
7. **Repeat** to characterize DNAs bound to any other proteins of interest.

Detecting DNA Accessibility States: DNase Hypersensitivity Testing

DNase enzymes cleave uncondensed, transcriptionally active euchromatic DNA, but not condensed, transcriptionally silent heterochromatic DNA. Genomic regions that are euchromatic in a given cell type therefore can be identified through DNase treatment of bulk DNA samples. This approach can be readily applied at the genome scale,⁵⁶ opening opportunities to compare transcriptionally active states across cells under various differentiation states and culture conditions.

Detecting DNA Accessibility States in Single Molecules: Assay for Transposase-Accessible Chromatin

Like DNase hypersensitivity testing, the recently introduced **assay for transposase-accessible chromatin (ATAC-seq)** is focused on identifying genomic regions whose “open,” euchromatic states suggest that they could be transcriptionally active.⁵⁷ However, in

contrast to DNase assays under which transcriptionally active states are identified by their overall sensitivity to DNase enzyme cleavage, ATAC-seq uses a transposase for which cleavage of accessible sites is followed immediately by specific ligation of a linker that bears barcodes that differ among cells. Genomic regions that have been ligated to adapters can then be isolated, amplified, and sequenced. In contrast to earlier approaches, which collect population-level summaries of active and inactive states of individual genomic locations, the use of single-cell barcodes in ATAC-seq enables comparison of epigenomes across individual cells in a sample.⁵⁸ Using single-cell ATAC-seq, one group found that there is an unexpectedly high level of variation among the epigenetic states of individual intestinal lymphoid cells, and that this variation is shaped by the microbiome.⁵⁹

Publicly Available Resources Enable Exploration of Epigenetic States at Genome Scale

One of the great advances of the genomics era is the emergence of public, online data repositories for researchers to share their findings, enabling insights that might not be accessible from the work of any single research group. Such publicly available datasets have provided unprecedented opportunities to compare epigenomic profiles over developmental time and between tissues in disparate functional states.

The **Encyclopedia of DNA Elements (ENCODE)**, a project supported by the National Human Genome Research Institute (NHGRI), is providing great insights as a catalog of the epigenomic signatures of cells grown in culture.⁶⁰ The **Roadmap Epigenomics Project**, a cooperative venture of epigenomic biologists worldwide sponsored by the U.S. National Institutes of Health, is expanding this goal to provide information on freshly sampled cells and tissues.⁶¹

Although it is possible for users to browse data using a visual interface, the most efficient way to leverage these publicly available resources is to use a command-line approach to download, process,

and analyze available datasets. In just the past 3 years, data available through ROADMAP have provided insight into the genomic architecture underlying disorders of gonadal development,⁶² juvenile arthritis,⁶³ and attention-deficit/hyperactivity disorder (HDAD).⁶⁴

Epigenetics and Cancer

DNA Methylation and Cancer

Some of the most extensive evidence for the association of epigenetic modification with human disease comes from studies of cancer^{65,66} (Fig. 6.4). Tumor cells often exhibit decreased methylation genome-wide, relative to normal cells of the same type, which can increase the activity of oncogenes (see Chapter 12). Genome-wide loss of methylation tends to continue as tumors progress from benign neoplasms to malignancy. In addition, the promoter regions of tumor-suppressor genes are often hypermethylated, decreasing their rate of transcription and thus their ability to inhibit tumor formation. Hypermethylation of the promoter region of the *RB1* gene is often seen in retinoblastoma,⁶⁷ and hypermethylation of the *MLH1* locus is associated with colorectal cancer.⁶⁸ It is important to note that the observation of perturbed DNA methylation states in tumors is not, itself, an indication that perturbation in DNA methylation state is the proximate cause of cancer.⁶⁹ However, as described in the following, the finding that many tumors have epigenetic abnormalities hints at exciting new opportunities for minimally invasive cancer screening and diagnosis.

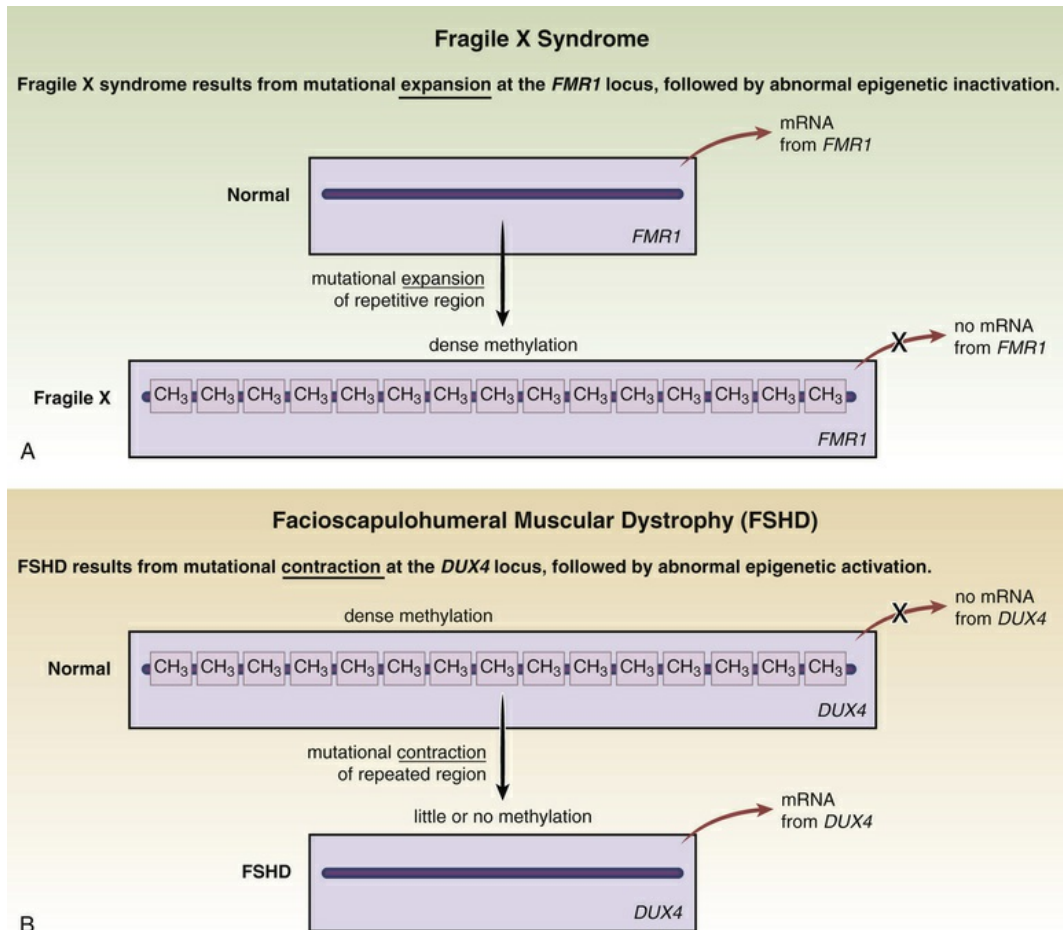

FIGURE 6.4 Comparing the Molecular Mechanisms of Fragile X and FSHD. **A**, *FMR1* in normal, expanded permutation, and full-mutation states. **B**, *DUX4* in normal and contracted states.

Global Epigenomic Alterations and Cancer

A major feature of one form of inherited colon cancer (hereditary nonpolyposis colorectal cancer [HNPCC]) is the methylation of the promoter region of a gene, *MLH1*, whose protein product repairs damaged DNA. Inactivation of *MLH1*, a DNA mismatch repair enzyme, is associated with accrual of DNA damage, another common feature of colon tumors (see Fig. 42.28). Abnormal methylation of tumor-suppressor genes also is common in the progression of Barrett's esophagus,⁷⁰ a condition in which the esophagus is lined with cells that have features typically associated with the lower intestinal tract.

Epigenetic Screening for Cancer

As noted previously, specific epigenetic abnormalities are often a defining feature of a tumor, but cannot necessarily be inferred to be the cause of disease. Regardless of the nature of the connection between epigenetic abnormality and any particular cancer, the ability to screen for abnormal epigenetic states raises the possibility that epigenetic screening approaches could complement or even replace existing early-detection methods. In some cases, epigenetic screening can be implemented using bodily fluids, such as urine or sputum, eliminating the need for the more invasive, costly, and risky strategies that are currently standard. For example, screening for epigenetic misregulation of miRNAs has shown promise as a tool for detecting and characterizing cancers of the colon,⁷¹ breast,⁷² and prostate.⁷³ Other epigenetics-based screening approaches have shown promise for detecting and characterizing cancers of the bladder,⁷⁴ lung,^{75,76} and prostate.⁷⁷

Screening for epigenetic abnormality to detect cancer may be especially powerful in conjunction with emerging methods for detecting tumors in blood and sputum samples.^{76,78} These “liquid-biopsy” methods are minimally invasive and so could be useful not only for characterizing abnormalities after diagnosis but also for performing routine, simultaneous screening for multiple types of cancers, even in individuals without signs of disease, and for detecting the emergence of drug-resistance mutations in individuals undergoing chemotherapy.

Misregulation of miRNAs in Cancer

Hypermethylation also is seen in microRNA genes, which encode small (22 base pair) RNA molecules that bind to the ends of mRNAs, degrading them and preventing their translation. More than 1000 microRNA sequences have been identified in humans, and hypermethylation of specific subgroups of microRNAs is associated with tumorigenesis.

Emerging Strategies for the Treatment of Epigenetic Disease

Epigenetic modifications are potentially reversible: DNA can be demethylated, histones can be modified to change the transcriptional state of nearby DNA, and miRNA-encoding loci can be up- or down-regulated. This raises the prospect for treating epigenetic disease with pharmaceutical agents that directly reverse the changes associated with the disease phenotype. In recent years, interventions involving all three types of epigenetic modulators (DNA methylation, histone modification, and miRNAs) have shown considerable promise for the treatment of disease.

DNA Demethylating Agents

5-Azacytidine has been used as a therapeutic drug in the treatment of leukemia and myelodysplastic syndrome.⁷⁹ A cytosine analog, 5-azacytidine, is incorporated into DNA opposite its complementary nucleotide, guanine. Chemical differences between 5-azacytidine and conventional cytosine (Fig. 6.5) cause it to achieve irreversible binding to the DNA methyltransferases. As a result, the administration of 5-azacytidine tends to reduce the density of DNA methylation,⁸⁰ offering prospects for reversing the aberrant accumulation of methylation at tumor-suppressor loci. Though associated with various side effects, including digestive disturbance, treatment with 5-azacytidine has shown promise in the treatment of diseases, including pancreatic cancer⁸¹ and myelodysplastic syndromes.⁸²

FIGURE 6.5 5-Azacytosine as Demethylating Agent. A, Unmethylated cytosines in DNA are typically subject to the addition of methyl groups by DNMT1, a DNA methyltransferase, using methyl groups supplied by the methyl donor S-adenosylmethionine. B, In 5-Azacytosine, the 5' carbon of cytosine is replaced with a nitrogen. This chemical difference is sufficient both to block the addition of a methyl group and to confer irreversible binding to DNMT1. Incorporation of 5-azacytosine into DNA is therefore sufficient to drive passive loss of methylation from replicating DNA, and thus to reactivate hypermethylated loci. 5-Azacytosine, bound to a sugar, can be integrated into DNA, and has been administered with some success in treating epigenetic diseases that arise through hypermethylation of individual loci.

Histone Deacetylase Inhibitors

The activity of the histone deacetylases (HDACs) increases chromatin compaction, decreasing transcriptional activity. In many cases, excessive activity of HDACs results in transcriptional inactivation of tumor-suppressor genes, leading ultimately to the development of tumors. Treatment with HDAC inhibitors, either alone or in combination with other drugs, has shown promise in reducing cell-division rates in culture cells of cancers of the breast,⁸³ prostate,⁸⁴ and pancreas.⁸⁵

Most recently, HDACs have been used to treat some forms of leukemia and lymphoma that are characterized by transcriptional repression. In those diseases, HDACs become overly active, removing

the acetyl groups that diminish the strength of bonds between DNA and histones, ultimately preventing transcription factors from accessing DNA regions whose activity is required for proper cellular function. A large number of drugs have proven useful in diminishing the removal of acetylation from histones. One drug in particular, abexinostat, is undergoing safety assessment to follow up on encouraging outcomes in a Phase II clinical trial.⁸⁶

miRNA Targeting

A major challenge in developing drugs that modify epigenetic alterations is to target only the genes responsible for a specific cancer. Therapeutic approaches that use microRNAs offer a potential solution to this problem because treatment can be targeted to individual loci that have aberrant expression using sequence characteristics of relevant RNA molecules.

Future Directions

Robust experimental observations are clarifying the roles of epigenetic states in determining cell fates and disease phenotypes. The well-documented involvement of epigenetic abnormalities in carcinogenesis and the mounting evidence for these epigenetic changes in other common diseases (discussed in other chapters) will likely elucidate possibilities for reversing the epigenetic abnormalities and possibly preventing their establishment in utero.

Summary Review

Overview of Epigenetic Mechanisms

1. Differences between the phenotypes of identical twins can provide novel insights into epigenetic phenomena.
2. To be both effective and safe, pharmaceutical strategies for treating epigenetic abnormalities must be targeted to affected

genomic regions.

3. Epigenetics modification alters gene expression without changes to DNA sequence.
4. Investigators are studying three major types of epigenetic processes: (a) DNA methylation, which results from attachment of a methyl group to a cytosine; in the somatic cells, all or nearly all methylation occurs at cytosines that are followed by guanines (“CpG dinucleotides”); (b) histone modification, through the addition of various chemical groups including methylation and acetylation; and (c) noncoding RNAs (ncRNAs or miRNAs), short nucleotides derived from introns of protein coding genes or transcribed as independent genes from regions of the genome whose functions, if any, remain poorly understood. MicroRNAs regulate diverse signaling pathways.
5. DNA methylation is, at present, the best-studied epigenetic process. When a gene becomes heavily methylated, the DNA is less likely to be transcribed into mRNA.
6. Methylation, along with histone hypoacetylation and condensation of chromatin, inhibits the binding of proteins that promote transcription, such that the gene becomes transcriptionally inactive.
7. Environmental factors, such as diet and exposure to certain chemicals, may cause epigenetic modifications.
8. The heritable transmission to future generations of epigenetic modifications is called *transgenerational inheritance*.
9. As twins age, they demonstrate increasing differences in methylation patterns of their DNA sequences, causing increasing numbers of phenotypic differences.
10. In studies of twins with significant lifestyle differences (e.g., smoking vs. nonsmoking) large numbers of differences in their methylation patterns are observed to accrue over time.

Genomic Imprinting

1. For some human genes, a given gene is transcriptionally active on only one copy of a chromosome (e.g., the copy inherited from the father). On the other copy of the chromosome (the one inherited from the mother), the gene is transcriptionally inactive. This process of gene silencing, in which genes are silenced depending on which parent transmits them, is known as *imprinting*; the transcriptionally silenced genes are said to be “imprinted.”
2. When an allele is imprinted, it typically has dense DNA methylation; the nonimprinted allele is typically not methylated.
3. A well-known disease example of imprinting is associated with a deletion of about 4 million base pairs (Mb) of the long arm of chromosome 15. When this deletion is inherited from the father, the child manifests Prader-Willi syndrome.
4. The same 4-Mb deletion, when inherited from the mother, causes Angelman syndrome.
5. Another well-known example of imprinting is Beckwith-Wiedemann syndrome, an overgrowth condition accompanied by an increased predisposition to cancer.
6. Whereas upregulation, or extra copies, of active *IGF2* causes overgrowth in Beckwith-Wiedemann syndrome, downregulation of *IGF2* causes the diminished growth seen in Russell-Silver syndrome.

Epigenetics in Cognitive Development and Mental Health

1. Consumption of alcohol during pregnancy has long been associated with the cognitive abnormalities of fetal alcohol syndrome. Recent findings suggest that alcohol may affect these changes through altered methylation of genes involved in neuronal differentiation.
2. Individuals with autism and with PTSD have altered DNA methylation profiles; current work is investigating the

- potential functional relevance of these alterations.
3. Fragile X syndrome results from a complex interaction of genetic and epigenetic abnormalities.
 4. Fetal alcohol syndrome, which results from ethanol exposure in utero, may be mediated by the repressive impact of ethanol on the DNA methyltransferases.
 5. Both abnormal gain of methylation, as in the case of fragile X syndrome, and abnormal loss of methylation, as in the case of FSHD, can produce disease phenotypes.

Exploring the Possible Multigenerational Persistence of Epigenetic States That Arise in Response to Environmental Factors

1. Events encountered in utero, in childhood, and in adolescence can result in specific epigenetic changes that yield a wide range of phenotypic abnormalities, including metabolic syndromes.

Epigenetic Change over the Life Span

1. Identical twins diverge in their epigenetic states over time at rates potentially modulated by environmental factors, such as tobacco use.
2. Metformin, a drug useful in treating insulin resistance, also may prolong life through epigenetic mechanisms.

Molecular and Computational Tools for Exploring Epigenetic States

1. Bisulfite conversion induces chemical changes in the binding properties of cytosine and methylcytosine, such that they can be distinguished in sequence data.

2. **Assay for transposase-accessible chromatin (ATAC-seq)** uses a transposase to introduce DNA cell-specific barcodes into euchromatic DNA regions, permitting comparison of chromatin states across cells.

Epigenetics and Cancer

1. The best evidence for epigenetic effects on disease risk comes from studies of human cancer.
2. Methylation densities decline as tumors progress, which can increase the activity of oncogenes, causing tumors to progress from benign neoplasms to malignancy. Additionally, the promoter regions of tumor-suppressor genes are often hypermethylated. These elevated methylation levels decrease their rate of transcription at these critical genes, thus reducing the ability to inhibit tumor formation.
3. Hypermethylation also is seen in microRNA genes and is associated with tumorigenesis.
4. 5-Azacytidine, a demethylating agent, has been used as a therapeutic drug in the treatment of leukemia and myelodysplastic syndrome.

Emerging Strategies for the Treatment of Epigenetic Disease

1. In diseases associated with aberrant, dense methylation of individual loci, treatment with 5-azacytidine, a cytosine analog that is refractory to the addition of methyl groups, can lead to clinically beneficial reduction in methylation densities.
2. miRNAs can be used to regulate the expression of loci whose altered epigenetic states are associated with disease.
3. Histone-deacetylase inhibitors have shown promise in treating cancers of the breast, prostate, and pancreas.

Future Directions

1. Robust experimental observations are defining the roles of epigenetic states in shaping cell fates.
2. The well-documented involvement of epigenetic abnormalities in carcinogenesis and the mounting evidence for these epigenetic changes in other common diseases (discussed throughout the text) will likely elucidate new therapies with the possibilities of reversing the epigenetic abnormalities.

People are exposed daily to an environment containing a large variety of toxic substances and potentially infectious and disease-causing microorganisms. Without an efficient system of protection most individuals would succumb to these hazards early in life. That system consists of multiple complementary and interdependent layers. An outer layer of specialized epithelium, including the skin and mucosal surfaces, is relatively resistant to most environmental hazards and resists infection with disease-causing microorganisms.¹ If the epithelial barrier is damaged, a highly efficient local and systemic response (**inflammation**) is mobilized to limit the extent of damage, protect against infection, and initiate repair of the damaged tissue. The natural epithelial barrier and inflammation confer innate resistance and protection, commonly referred to as **innate immunity**, also known as **natural** or **native immunity**. Inflammation associated with infection usually initiates an adaptive process that results in a long-term and very effective immunity to the infecting microorganism, referred to as **adaptive immunity**, also known as **acquired** or **specific immunity**. Adaptive immunity is relatively slow to develop but has memory and more rapidly targets and eradicates a second infection with a particular disease-causing microorganism.

The information presented in this chapter introduces the components and processes of innate immunity and sets the stage for

[Chapter 8](#), which discusses adaptive immunity. Although inflammation and adaptive immunity provide protection, either genetic or acquired aberrations in these processes can lead to disease. Diminution of innate or adaptive immunity may lead to critically decreased resistance to infection. Excessive inflammation or adaptive immunity may lead to damage to normal tissue or organs. Both may result in severe and potentially fatal disease, examples of which are discussed in [Chapter 9](#). Many microorganisms that cause disease have developed methods of bypassing our protective systems. These are discussed in [Chapter 10](#). Each chapter is designed to render an overview and is not intended to be all-inclusive. Protective mechanisms consist of a very large number of soluble factors and cells and would require many more pages to discuss in adequate detail. Different classes or groups of molecules and cells will be discussed, but only a few examples will be described in detail. Some components directly participate in the protective response, whereas others are designed to limit the extent of the response.

Human Defense Mechanisms

Innate immunity includes two lines of defense: natural barriers and inflammation ([Table 7.1](#)). **Natural barriers** are physical, mechanical, and biochemical barriers at the body's surfaces and are in place at birth to prevent damage by substances in the environment and thwart infection by pathogenic microorganisms. If the surface barriers are breached, the second line of defense, the **inflammatory response**, is activated to protect the body from further injury, prevent infection of the injured tissue, and promote healing. The inflammatory response is a rapid activation of biochemical and cellular processes that is relatively nonspecific, with similar responses being initiated against a wide variety of causes of tissue damage.

TABLE 7.1

OVERVIEW OF HUMAN DEFENSES

CHARACTERISTICS	INNATE IMMUNITY		ADAPTIVE (ACQUIRED) IMMUNITY
	BARRIERS	INFLAMMATORY RESPONSE	
Level of defense	First line of defense against infection and tissue injury	Second line of defense; occurs as a response to tissue injury or infection	Third line of defense; initiated when innate immune system signals the cells of adaptive immunity
Timing of defense	Constant	Immediate response	Delay between primary exposure to antigen and maximum response; immediate against secondary exposure to antigen
Specificity	Broadly specific	Broadly specific	Response is very specific toward "antigen"
Cells	Epithelial cells	Mast cells, granulocytes (neutrophils, eosinophils, basophils), monocytes/macrophages, natural killer (NK) cells, platelets, endothelial cells	T lymphocytes, B lymphocytes, macrophages, dendritic cells
Memory	No memory involved	No memory involved	Specific immunologic memory by T and B lymphocytes
Peptides	Defensins, cathelicidins, collectins, lactoferrin, bacterial toxins	Complement, clotting factors, kinins	Antibodies, complement
Protection	Protection includes anatomic barriers (i.e., skin and mucous	Protection includes vascular responses, cellular components (e.g., mast	Protection includes activated T

	membranes), cells and secretory molecules or cytokines (e.g., lysozymes, low pH of stomach and urine), and ciliary activity	cells, neutrophils, macrophages), secretory molecules or cytokines, and activation of plasma protein systems	and B lymphocytes, cytokines, and antibodies
--	---	--	--

First Line of Defense: Physical, Mechanical, and Biochemical Barriers and Normal Microbiome

Physical and Mechanical Barriers

The physical barriers that protect against damage and infection are composed of tightly associated epithelial cells including those of the skin and of the membranous sheets lining the gastrointestinal, genitourinary, and respiratory tracts (Fig. 7.1). The mucosal epithelial cells are highly interconnected junctions that prohibit the passage of microorganisms into the underlying tissue. The normal turnover of the cells in these sites as well as mechanisms for “washing” the surfaces may mechanically remove many infectious microorganisms and prevent their residence on the epithelial surfaces. For instance, the routine sloughing off and replacement of dead skin cells also removes adherent bacteria. Mechanical cleansing of the surfaces includes vomiting and urination. Goblet cells of the upper respiratory tract produce mucus that coats the epithelial surface and traps microorganisms that are removed by hairlike cilia that mechanically move the mucus upward to be expelled by coughing or sneezing. Additionally, the low temperature on the skin and low pH of the skin and stomach generally inhibit microorganisms, most of which prefer temperatures near 37°C (98.6°F) and a pH near neutral for more efficient growth.

G.J. Wassilchenko

FIGURE 7.1 The Closed Barrier. The digestive, respiratory, and genitourinary tracts and the skin form closed barriers between the internal organs and the environment. (From Grimes DE: *Infectious diseases*, St Louis, 1991, Mosby.)

Biochemical Barriers

Epithelial surfaces also provide biochemical barriers by synthesizing and secreting substances meant to trap or destroy microorganisms (**epithelial-derived chemicals**).² Mucus, perspiration (or sweat),

saliva, tears, and earwax are all examples of biochemical secretions that can trap and kill potential disease-causing microorganisms. Sebaceous glands in the skin secrete antibacterial and antifungal fatty acids and lactic acid. Perspiration, tears, and saliva contain an enzyme (lysozyme) that attacks the cell walls of gram-positive bacteria. These glandular secretions result in an acidic skin surface (pH 3 to 5), which is an inhospitable environment for most bacteria.

Epithelial cells secrete a complex array of proteins that destroy potential pathogens. Small-molecular-weight **antimicrobial peptides** are generally positively charged polypeptides of approximately 15 to 95 amino acids and can be divided into two classes—cathelicidins and defensins—based on their three-dimensional chemical structures. Both classes are in very high local concentrations and are toxic to several bacteria, fungi, and viruses. **Cathelicidins** have a linear α -helical shape, and only one is currently known to function in humans. In contrast, about 50 different defensins have been identified thus far. All are triple-stranded β -sheet structures. **Defensin** molecules contain 3 intrachain disulfide bonds and can be further subdivided into α (at least 6 identified in humans) and β types (at least 10 identified, but perhaps up to 40 different molecules), depending on how the cysteine residues are connected during formation of the disulfide linkages.³ The α -defensins often require activation by proteolytic enzymes, whereas the β -defensins are synthesized in active forms. Bacteria have cholesterol-free cell membranes, which may allow cathelicidins to insert into and disrupt their membranes. Given the similarity in their chemical charges, defensins may kill bacteria in the same way. These same chemicals also may contribute to other means of protection because they are also produced by monocytes, macrophages, and neutrophils, which are components of the inflammatory response. Cathelicidin is stored in neutrophils, mast cells, and a variety of epithelial cells. The α -defensins are particularly rich in the granules of neutrophils and may contribute to the killing of bacteria by those cells. They are also found in Paneth cells lining the small intestine, where they protect against a variety of disease-causing microorganisms. The β -defensins are found in epithelial cells lining the respiratory, urinary,

and intestinal tracts, as well as in the skin. In addition to antibacterial properties, β -defensins may also help protect epithelial surfaces from human immunodeficiency virus (HIV) infection. Both classes of antimicrobial peptides also can activate cells of innate and adaptive immunity.

The lung also produces and secretes a family of glycoproteins, **collectins**, which includes surfactant proteins A through D and mannose-binding lectin.⁴ Collectins react with different affinities to carbohydrates and lipids on the surfaces of a wide array of pathogenic microorganisms. Collectin binding facilitates recognition of the microorganism by macrophages, enhancing macrophage attachment, phagocytosis, and killing. **Mannose-binding lectin (MBL)** recognizes a sugar commonly found on the surface of microbes and is a powerful activator of a plasma protein system (complement) resulting in damage to bacteria or increased recognition by macrophages.

Other *epithelial antimicrobials* include resistin-like molecule β , bactericidal/permeability-inducing protein, and antimicrobial lectins. **Resistin-like molecule β** is found in the intestinal goblet cells, where it appears to protect against helminth infections. **Bactericidal/permeability-inducing (BPI) protein** is stored in neutrophils and intestinal epithelium. BPI protein specifically reacts with lipopolysaccharide on the surface of gram-negative bacteria, resulting in bacterial lysis. **Antimicrobial lectins** are carbohydrates that are found in intestinal epithelium and have activity against gram-positive bacteria.

Normal Microbiome

The body's surfaces are colonized with a spectrum of microorganisms, the **normal microbiome**. Each surface, including the skin and the mucous membranes of the eyes, upper and lower gastrointestinal tracts, urethra, and vagina, is colonized by a combination of bacteria and fungi that is unique to the particular location and individual (Fig. 7.2).⁵ The microorganisms in the microbiome do not normally cause disease, although several are opportunistic in that they can cause disease if the integrity of the body surface is compromised or the

individual's immune or inflammatory systems are defective. The relationship of the microbiome with humans has been referred to as *commensal* (to the benefit of one organism without affecting the other); however, the relationship may be more *mutualistic* (to the benefit of both organisms). Using the colon for an example, at birth the lower gut is relatively sterile but colonization with bacteria begins quickly, with the number, diversity, and concentration increasing progressively during the first year of life. To the benefit of humans, many of these microorganisms help digest fatty acids, large polysaccharides, and other dietary substances; produce biotin and vitamin K; and assist in the absorption of ions, such as calcium, iron, and magnesium.

FIGURE 7.2 The Human Microbiome. Typical phylum-level composition of the human microbiota that vary at each site. (From Cho I, Blaser MJ: *Nat Rev Genet* 13:260–270, 2012.)

These bacteria contribute to the human body's innate protection against pathogenic microorganisms in the colon. They compete with pathogens for nutrients and block attachment to the epithelium. Members of the normal microbiome also produce chemicals (ammonia, phenols, indoles, and other toxic materials) and toxic proteins (*bacteriocins*) that inhibit colonization by pathogenic microorganisms. Prolonged treatment with broad-spectrum

antibiotics can alter the normal intestinal microbiome, decreasing its protective activity, and lead to an overgrowth of opportunistic pathogenic microorganisms, such as the yeast *Candida albicans* or the bacteria *Clostridium difficile* (overgrowth can cause pseudomembranous colitis, an infection of the colon). Additionally, the normal microbiome of the gut helps train the adaptive immune system by inducing the growth of gut-associated lymphoid tissue (where cells of the adaptive immune system reside) and the development of both local and systemic adaptive immune systems.⁶

The bacterium *Lactobacillus* is a major constituent of the normal vaginal microbiome in healthy women: at least 22 different species of *Lactobacillus* have been identified in the vaginal microbiome, with 4 of those being predominantly represented.⁷ This microorganism produces a variety of chemicals (e.g., hydrogen peroxide, lactic acid, bacteriocins) that help prevent infections of the vagina and urinary tract by other bacteria and yeast. Prolonged antibiotic treatment can diminish colonization with *Lactobacillus* and increase the risk for urologic or vaginal infections, such as vaginosis.

Opportunistic microorganisms are normally controlled by the innate and adaptive immune systems and contribute to the human body's defenses. For example, *Pseudomonas aeruginosa* is a member of the normal microbiome of the skin and produces a toxin that protects against infections with staphylococcal and other bacteria. However, severe burns compromise the integrity of the skin and may lead to life-threatening systemic pseudomonal infections.

Second Line of Defense: Inflammation

Whereas the physical and chemical barriers of the innate immune system are relatively static, **inflammation** is programmed to respond to cellular or tissue damage, whether the damaged tissue is septic (contaminated with microorganisms) or sterile. The **inflammatory response** is a rapid initiation and interactive system of humoral (soluble in the blood) and cellular systems designed to limit the extent of tissue damage, destroy contaminating infectious microorganisms,

initiate the adaptive immune response, and begin the healing process (Fig. 7.3). The inflammatory response (1) occurs in tissues with a blood supply (vascularized); (2) is activated rapidly (within seconds) after damage occurs; (3) depends on the activity of both *cellular and chemical components*, including plasma proteins; and (4) is *nonspecific*, meaning that it takes place in approximately the same way regardless of the type of stimulus or whether exposure to the same stimulus has occurred in the past.

FIGURE 7.3 Acute Inflammatory Response. Inflammation is usually initiated by cellular injury, which results in mast cell degranulation, the activation of three plasma systems, and the release of subcellular components from the damaged cells. These systems are interdependent, so that induction of one (e.g., mast cell degranulation) can result in activation of the other two. The result is the development of microscopic changes in the inflamed site, as well as characteristic clinical manifestations. The figure numbers refer to those in which more detailed information may be found on that portion of the response.

Vascular Response

Virtually any injury to vascularized tissue will activate inflammation. Injury may result from a variety of causes including infection or

necrosis (e.g., trauma, oxygen deprivation [ischemia], nutrient deprivation, genetic or immune defects, chemical injury, foreign bodies, temperature extremes, ionizing radiation). The classic symptoms of acute inflammation include *redness* (erythema), *heat*, *swelling* (edema), and *pain*. This tetrad represents the “cardinal signs of inflammation” and was identified in the first century by a Roman writer, Celsus. A fifth sign was added later: *loss of function*. Microscopically, inflammatory changes can be seen at the vascular level (Fig. 7.4). The three characteristic changes in the microcirculation (arterioles, capillaries, and venules) near the site of an injury include the following:

FIGURE 7.4 Sequence of Events in the Acute Inflammatory Response. See text for details.

1. Vasodilation (increased size of the blood vessels) causes slower blood velocity and increases blood flow to the injured site.

2. Increased vascular permeability (the blood vessels become porous from contraction of endothelial cells) and leakage of fluid out of the vessel (exudation) cause swelling (edema) at the site of injury; as plasma moves outward, blood in the microcirculation becomes more viscous and flows more slowly, and the increased blood flow and increasing concentration of red cells at the site of inflammation cause locally increased redness (erythema) and warmth.
3. White blood cells adhere to the inner walls of vessels, and they migrate through enlarged junctions between the endothelial cells lining the vessels into the surrounding tissue (diapedesis).

The effects of inflammation are visible within seconds. First, arterioles near the site of infection or injury constrict briefly. Vasodilation then causes slower blood velocity and increases local blood flow to the injured site. The increased flow and capillary permeability result in leakage of plasma from the vessels, causing edema in the surrounding tissue. As plasma moves outward, blood remaining in the microcirculation flows more slowly and becomes more viscous. The increased blood flow and increasing concentration of red cells at the site of inflammation cause locally increased warmth and redness. Leukocytes adhere to vessel walls. At the same time, biochemical mediators (e.g., histamine, bradykinins, leukotrienes, prostaglandins) stimulate the endothelial cells that line capillaries and venules to retract, creating spaces at junctions between the cells, allowing leukocytes and plasma to enter the surrounding tissue (intercellular junctions are described in [Chapter 1](#)).

Each of the characteristic changes associated with inflammation is the direct result of the activities and interactions of a host of chemicals and cellular components found in the blood and tissues. The vascular changes deliver leukocytes (particularly neutrophils), plasma proteins, and other biochemical mediators to the site of injury where they act in concert.

Benefits of inflammation include:

1. Prevention of infection and further damage by contaminating microorganisms through the influx of fluid to dilute toxins produced by bacteria and released from dying cells, the influx and activation of plasma protein systems that help destroy and contain bacteria (e.g., complement system, clotting system), and the influx of cells (e.g., neutrophils, macrophages) that “eat” and destroy cellular debris and infectious agents.
2. Limitation and control of the inflammatory process through the influx of plasma protein systems (e.g., clotting system), plasma enzymes, and cells (e.g., eosinophils) that prevent the inflammatory response from spreading to areas of healthy tissue.
3. Interaction with components of the adaptive immune system to elicit a more specific response to contaminating pathogen(s) through the influx of macrophages and lymphocytes.
4. Preparation of the area of injury for healing through removal of bacterial products, dead cells, and other products of inflammation (e.g., by way of channels through the epithelium or drainage by lymphatic vessels) and initiation of mechanisms of healing and repair.

Extravascular fluid and debris that accumulate at an inflamed site are drained by lymphatic vessels. This process also facilitates the development of adaptive immunity because microbial antigens in lymphatic fluid pass through the lymph nodes, where they activate both B and T lymphocytes. (This process is discussed in [Chapter 8](#), and the lymphatic system is described in [Chapter 28](#).) The lymphatic vessels may, themselves, become secondarily inflamed. Lymphangitis of the lymph vessels and lymphadenitis of the nodes, which become hyperplastic, enlarge and frequently become painful.

Inflammation and repair can be divided into several phases ([Fig. 7.5](#)). The characteristics of the early (i.e., acute) inflammatory response differ from those of the later (i.e., chronic) response, and each phase involves different biochemical mediators and cells that function together. The acute inflammatory response is of short duration; that is,

it continues only until the immediate threat to the host is eliminated. This usually takes 8 to 10 days from onset to healing. (Mechanisms of cellular injury are described in [Chapter 2](#).)

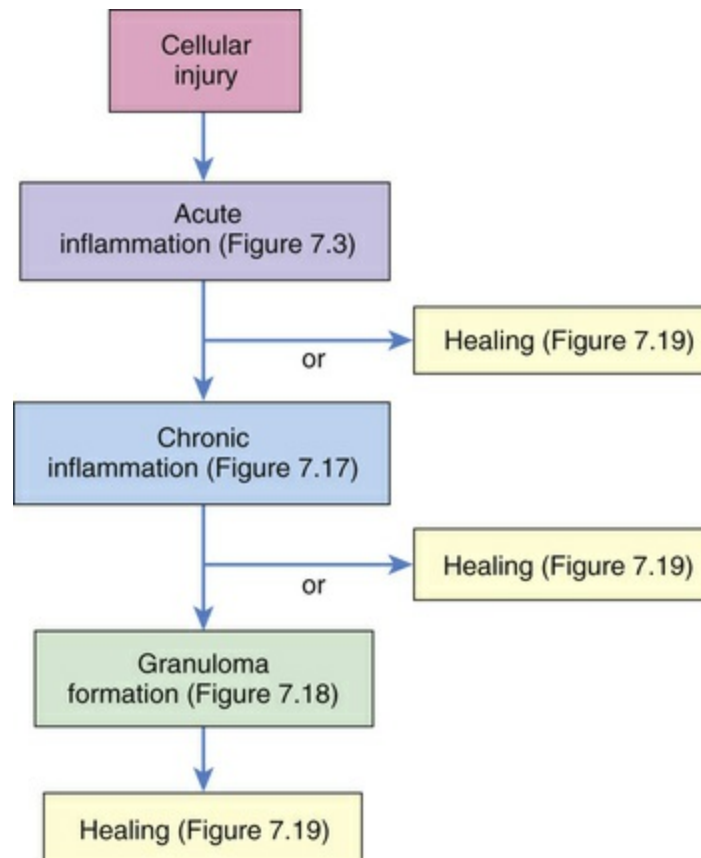

FIGURE 7.5 Inflammatory Phases. Cellular injury leads to acute inflammation and may result in resolution and healing of the injured site or may progress into chronic inflammation. Chronic inflammation in turn may result in healing or progress to development of a granuloma. The final step of the inflammatory process is usually healing and reconstruction of the damaged tissue. The figure numbers refer to those in which more detailed information on that portion of the process may be found.

Plasma Protein Systems

Three key **plasma protein systems** are essential to an effective inflammatory response. These are the complement system, the clotting system, and the kinin system ([Figs. 7.6, 7.7, and 7.8](#), respectively). Although each system has a unique role in inflammation, they also

have many similarities. Each system consists of multiple proteins in the blood. To prevent activation in unnecessary situations, each protein is normally in an inactive form. Several of the proteins are enzymes that circulate in inactive forms as **proenzymes**. Each system contains a few proteins that can be activated early in inflammation. Activation of the first component of a system results in sequential activation of other components, leading to a biologic function that helps protect the individual. This sequential activation is referred to as a *cascade*. Thus, we refer to the complement cascade, the clotting cascade, or the kinin cascade. In some cases, activation of a protein may require that it be enzymatically cut into two pieces or fragments of different size. Usually the larger fragment continues the cascade by activating the next component, and the smaller fragment frequently has potent biologic activities to promote inflammation.

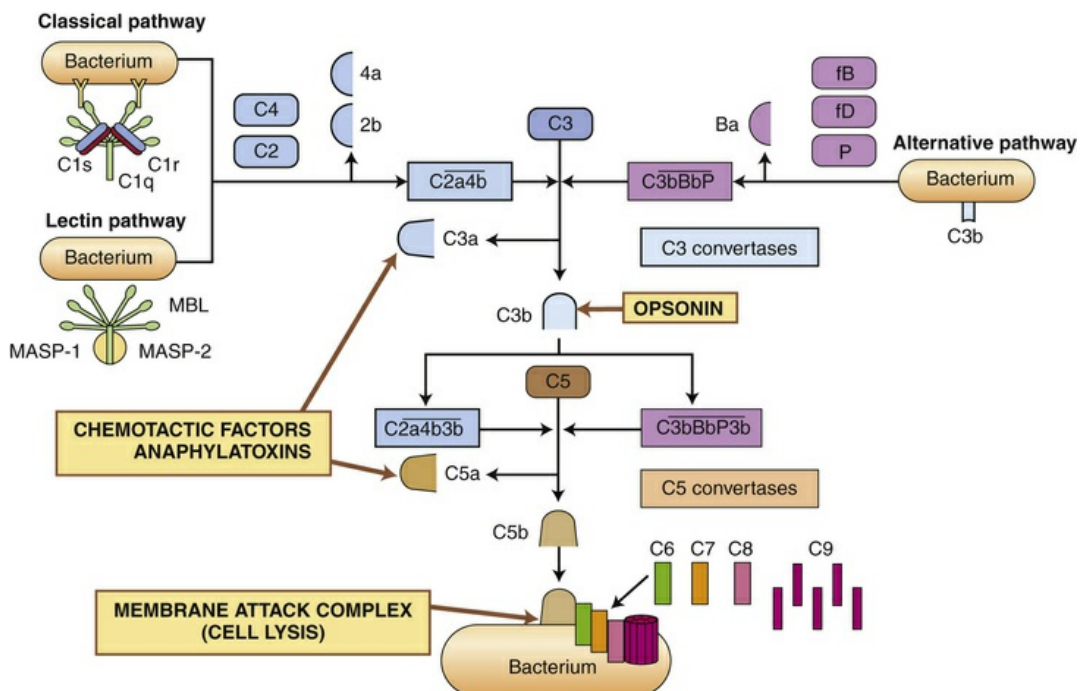

FIGURE 7.6 Pathways of Complement Cascade Activation. The complement system is activated by three pathways: the classical pathway, the lectin pathway, and the alternative pathway. During activation, many complement components are cleaved into fragments (2b, 4a, Ba, C3a, and C5a). The smaller fragments frequently have potent biologic activities and may serve as chemotactic factors and anaphylatoxins. The larger activated fragments are usually converted into active enzymes (indicated by the bar above the names) and form complexes with additional components in the

cascade. The classical pathway is usually activated by antigen-antibody complexes through component C1, which consists of C1q and two C1r and C1s molecules. As indicated, the C1q must simultaneously bind to two antibody molecules (indicated by Y-shaped structures). The lectin pathway is activated by mannose-binding lectin (*MBL*), which binds to two mannose-rich pathogen-associated molecular patterns on the surface of a bacterium. MBL contains two associated enzymes, MASP-1 and MASP-2, and functions in a manner similar to C1. C1 and MBL each activate complement components C4 and C2. The alternative pathway is activated by many agents, such as bacterial polysaccharides, which bind and stabilize C3b, which is produced by normal breakdown of C3 in the blood. The C3b forms the site of binding of factor B (*fB*), which is activated by factor D (*fD*) into Bb and the small fragment Ba. Properdin (*P*) helps stabilize the complex. Each pathway produces C3 and C5 convertases, which are enzymatically active complexes that activate C3 and C5, respectively. C3b produced by the C3 convertase can function as an opsonin. C5b initiates assemblage of the membrane attack complex (MAC), which results in multiple C9 molecules forming a pore in the bacterial membrane.

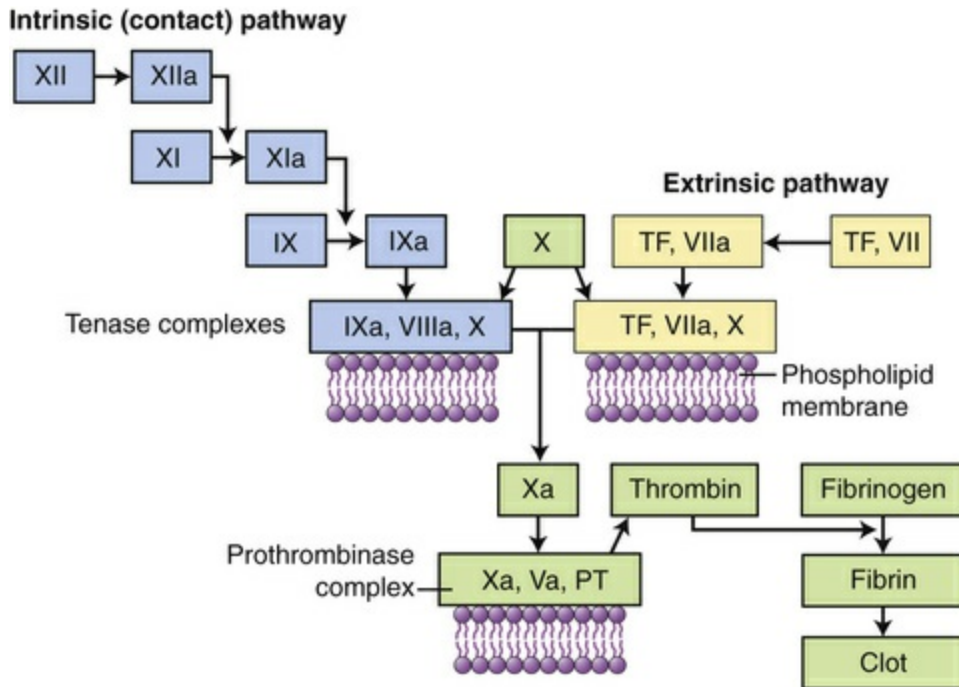

FIGURE 7.7 Coagulation Cascade. Clotting is activated through two pathways: the intrinsic (contact) pathway and the extrinsic pathway. The intrinsic pathway is initiated by the activation of Hageman factor (*XII*) into *XIIa* (activated factors are enzymes and are indicated by a lowercase *a*). The sequential activation of other intrinsic pathway components results in formation of a complex of *IXa*, *VIIIa*, and *X*. The extrinsic pathway is activated by exposure of tissue factor (*TF*) during tissue damage. *TF* complexes with factor *VII*, which is activated (*VIIa*) and forms a complex with factor *X* (*TF, VIIa, X*). Both the intrinsic and the extrinsic pathway complexes are dependent on calcium, form on phospholipid membranes

that are rich in phosphatidylserine, and have “tenase” activity (can activate factor X into Xa). Factor X begins a common pathway in which Xa complexes with Va and prothrombin (*PT*), with calcium and phospholipid membranes, to form an active prothrombinase (activates prothrombin into thrombin). Thrombin is an enzyme that cuts high-molecular-weight fibrinogen into fibrin molecules. Fibrin polymerizes to form a clot.

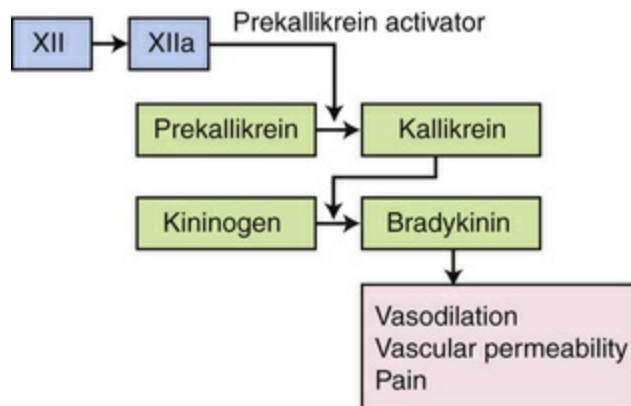

FIGURE 7.8 Plasma Kinin Cascade. The kinin pathway is activated by factor XIIa from the clotting system, which functions as an enzyme (prekallikrein activator) to convert prekallikrein into kallikrein. Enzymatically active kallikrein converts kininogen into bradykinin.

Complement System

The **complement system** consists of several plasma proteins (sometimes called *complement components*) that together constitute about 10% of the total circulating serum protein. Activation of the complement system produces several factors that can destroy pathogens directly and can activate or collaborate with other components of the innate and adaptive immune responses. Factors produced during activation of the complement system are among the body's most potent defenders, particularly against bacterial infection.⁸

Activation of the complement system can be accomplished in three different pathways, all of which converge at the third component (C3) of the pathway:

1. **Classical pathway:** activated by proteins of the adaptive immune system (antibodies) bound to their specific targets

(antigen)

2. **Lectin pathway:** activated by mannose-containing bacterial carbohydrates
3. **Alternative pathway:** activated by gram-negative bacterial and fungal cell wall polysaccharides

The principal routes by which the **complement cascade** may be activated are shown in [Fig. 7.6](#).

Activation of the *classical pathway* begins with the activation of complement protein C1 and is preceded by formation of a complex between an antigen and an antibody to form an **antigen-antibody complex (immune complex)** (discussed in [Chapter 8](#)). The antigen may be a unique chemical component of the surface of a bacterium or other microorganism. Most pathogens express multiple antigens; therefore, multiple antibodies are usually bound in the complex. The first component of the classical complement cascade, C1, has six sites that can bind to antibodies, and efficient activation of the complement cascade usually requires concurrent binding of C1 to at least two antibody molecules. The complex formed by antigen-antibody-complement binding is shown in [Fig. 7.6](#). C1 is a macromolecular complex consisting of C1q and two molecules each of C1r and C1s. A conformational change in C1 results in an enzymatically active molecule whose substrates are C4 and C2. The resultant complex formed by the interaction of C1, C4, and C2 uses C3 as a substrate, resulting in the production of C3a and C3b. A complex that has C3 as a substrate is generally referred to as a **C3 convertase**. The addition of C3b to the complex changes the substrate specificity to C5, resulting in the conversion of C5 to C5a and C5b. A complex that has C5 as a substrate is generally called a **C5 convertase**. Thus activation of C1 initiates the sequential enzymatic activation of all other components of the classical pathway, ultimately resulting in the activation of C5. The classical pathway also can be activated to a lesser degree by biologic molecules other than antibody, including heparin (a charged molecule that prevents clotting), deoxyribonucleic acid (DNA) or ribonucleic acid (RNA), and C-reactive protein, which is increased in the blood

during inflammation.

Even under normal conditions small amounts of circulating C3 are spontaneously broken down into C3b and C3a by a number of naturally occurring enzymes in the blood. The rate of C3 spontaneous activation is generally very low, and C3b is readily inactivated by complement regulator proteins in the blood (e.g., factor H and factor I). However, materials produced by some infectious microorganisms (e.g., lipopolysaccharides [endotoxins] on the bacterial surface, yeast cell wall carbohydrates [zymosans]) can bind the naturally produced C3b and protect it from inactivation. This will initiate activation of the *alternative complement pathway*. The C3b bound to bacterial products can react with another normally occurring component, factor B. The complex of C3b and factor B is recognized by an enzyme, factor D, which activates factor B, producing factor Bb. The resultant C3b/Bb complex is very unstable unless it binds to properdin (P). The C3b/Bb/P complex is a C3 convertase that produces further C3b, resulting in a C3b/Bb/P/C3b complex that is a C5 convertase, which activates C5.

The *lectin pathway* is similar to the classical pathway but is antibody independent. It is activated by a plasma protein called *mannose-binding lectin (MBL)*. MBL is similar to C1q and binds to bacterial polysaccharides containing the carbohydrate mannose and activates complement through two MBL-associated serine proteases (MASP-1 and MASP-2) that substitute for C1r and C1s and activate C4 and C2 to create a C3 convertase.⁹ Thus, infectious agents that do not activate the alternative pathway may be susceptible to complement through the lectin pathway.

After activation of C5, the cascade continues through the terminal components C6, C7, C8, and C9. Components C5b through C9 assemble to form complexes (*membrane attack complex, or MAC*) capable of creating pores in cell membranes and permitting the influx of water and ions and may ultimately result in **cell lysis**.

The most important result of complement activation is the production of fragments during the activation of C4, C2, C3, and C5. The fragments C4a, C2b, C3a, and C5a are soluble and of low-

molecular-weight that contribute in other ways to the inflammatory response. C2b affects smooth muscle, causing vasodilation and increased vascular permeability. C3a and C5a, and to a limited extent C4a, are **anaphylatoxins**; that is, they induce rapid **mast cell degranulation** (release of granular contents) and the release of histamine (see Fig. 7.12), causing vasodilation and increased capillary permeability.¹⁰ C5a is the major chemotactic factor for neutrophils. C3a is approximately 100 times less potent in chemotactic and anaphylatoxic activity. A **chemotactic factor** is a biochemical substance that attracts leukocytes to the site of inflammation.

The dual functions of a chemotactic factor and an anaphylatoxin are not needed simultaneously or to the same degree. Anaphylatoxic activity is necessary early in inflammation and occurs close to the inflammatory site to induce local mast cell degranulation and to increase the number of soluble mediators available to enhance vascular permeability and vasodilation. Chemotactic activity, on the other hand, is required for a much longer period and occurs distal to the inflammatory site to attract leukocytes from the circulation. Thus it is beneficial to an effective inflammatory response to limit the range of anaphylatoxic activity while allowing widespread chemotactic activity. A plasma enzyme, a **carboxypeptidase**, removes a terminal arginine on both C3a and C5a peptides, thereby producing “C3a desArg” and “C5a desArg,” respectively, which are inactive as anaphylatoxins but retain chemotactic activity. Thus chemotactic activity is retained, while not inducing distal mast cell degranulation that would result in considerable enlargement of the inflammatory response to the detriment of surrounding healthy tissue.

C3b adheres to the surface of a pathogenic microorganism and serves as an efficient opsonin. **Opsonins** are molecules that “tag” microorganisms for destruction by cells of the inflammatory system (primarily neutrophils and macrophages). C3b on the cell surface also can be broken down by several enzymes in the blood into inactive fragments (e.g., iC3b), which retain opsonic activity.

In summary, the complement cascade can be activated by at least three different means, and its products have four functions: (1)

anaphylatoxic activity resulting in mast cell degranulation (C3a, C3b), (2) leukocyte chemotaxis (C5a), (3) opsonization (C3b), and (4) cell lysis (C5b-C9, MAC).

Clotting System

The clotting (coagulation) system is a group of plasma proteins that, when activated sequentially, forms a blood clot at an injured or inflamed site. A blood clot is a meshwork of protein (fibrin) strands that contains platelets (the primary cellular initiator of clotting) and traps other cells, such as erythrocytes, phagocytes, and microorganisms. This (1) prevents the spread of infection to adjacent tissues, (2) traps microorganisms and foreign bodies at the site of inflammation for removal by infiltrating cells (e.g., neutrophils and macrophages), (3) forms a clot that stops bleeding, and (4) provides a framework for future repair and healing. The main substance in this fibrinous mesh is an insoluble protein called *fibrin* that is the end product of the **coagulation cascade**.

The clotting system can be activated by many substances that are released during tissue injury and infection, including collagen, proteinases, kallikrein, and plasmin, as well as by bacterial products such as endotoxins. Like the complement cascade, the coagulation cascade can be activated through different convergent pathways (see [Fig. 7.7](#)). The tissue factor (extrinsic) pathway is activated by tissue factor (TF) (also called *tissue thromboplastin*) that is released by damaged endothelial cells in blood vessels and reacts with activated factor VII (VIIa).¹¹ The intrinsic (contact) pathway is activated when the vessel wall is damaged and **Hageman factor (factor XII)** in plasma contacts negatively charged subendothelial substances. The pathways converge at factor X. Activation of factor X begins a common pathway leading to activation of fibrin that polymerizes to form a fibrin clot. The coagulation system is discussed in more detail and illustrated again in [Chapter 28](#).

As with the complement system, activation of the clotting system produces protein fragments that enhance the inflammatory response. Two low-molecular-weight fibrinopeptides, A and B, are released

from fibrinogen when fibrin is produced. Both fibrinopeptides (especially fibrinopeptide B) are chemotactic for neutrophils and increase vascular permeability of endothelial cells by enhancing the effects of bradykinin (formed from the kinin system).

Kinin System

The third plasma protein system, the **kinin system**, augments inflammation in several ways. The primary product from the kinin system is **bradykinin**, which causes dilation of blood vessels, acts with prostaglandins to stimulate nerve endings and induce pain, causes smooth muscle cell contraction, increases vascular permeability, and may increase leukocyte chemotaxis (see Fig. 7.3). Bradykinin induces smooth muscle contraction more slowly than histamine and, along with prostaglandins of the E series, is probably responsible for endothelial cell retraction and increased vascular permeability in the later phases of inflammation (endothelial cell retraction is shown in Figs. 7.4 and 7.16).

The kinin system is activated by stimulation of the **plasma kinin cascade** (see Fig. 7.8). The conversion of plasma prekallikrein to kallikrein is induced by *prekallikrein activator*, which is identical to factor XIIa (the product that results from activation of Hageman factor—factor XII) of the clotting cascade. Kallikrein then converts kininogen to bradykinin. Although the plasma kinin cascade is one pathway that leads to the production of bradykinin, tissue kallikreins in saliva, sweat, tears, urine, and feces provide other sources for this inflammatory mediator. These tissue kallikreins convert serum kininogens to kallidin, also known as *Lys-bradykinin*, which may be converted to bradykinin by plasma aminopeptidase. In order to limit the extent of inflammation, kinins are rapidly degraded by **kininase** enzymes present in plasma and tissues.

Control and Interactions of Plasma Protein Systems

The three plasma protein systems are highly interactive so that

activation of one system results in the production of a large number of very potent, biologically active substances that further activate the other systems (Fig. 7.9). Very tight control of these processes is essential for two reasons:

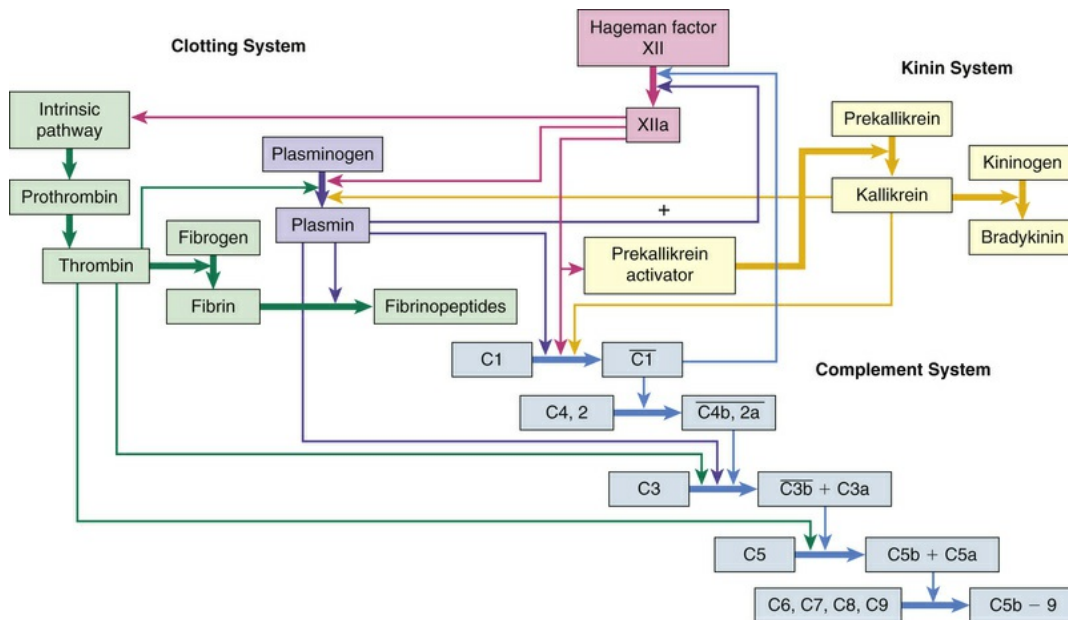

FIGURE 7.9 Interactions between the Complement, Clotting, and Kinin Systems. *Thick colored arrows* denote the activation of factors within a system. *Thin colored arrows* denote the interaction between systems.

1. The inflammatory process is critical for an individual's survival; thus, efficient activation must be guaranteed regardless of the cause of tissue injury.
2. The biochemical mediators generated during these processes are so potent and potentially detrimental to the individual, and their actions must be strictly confined to injured or infected tissues.

Multiple mechanisms are available to either *activate* or *inactivate* (regulate) these plasma protein systems. For instance, the plasma that enters the tissues during inflammation (edema) contains enzymes that destroy mediators of inflammation. **Carboxypeptidase** inactivates the

anaphylatoxic activities of C3a and C5a, and kininases degrade kinins. **Histaminase** degrades histamine and kallikrein and down-regulates the inflammatory response.

The formation of clots also activates a **fibrinolytic system** that is designed to limit the size of the clot and remove the clot after bleeding has ceased. Thrombin activates **plasminogen** in the blood to form the enzyme plasmin. The primary activity of **plasmin** is to degrade fibrin polymers in clots. However, plasmin also can activate the complement cascade through components C1, C3, and C5 and the kinin cascade by activating factor XII and producing prekallikrein activator. Activation of Hageman factor has four effects that impact all three of the plasma protein systems:

1. Activation of the clotting cascade through factor XI
2. Control of clotting through conversion of plasminogen proactivator to plasminogen activator, resulting in the generation of plasmin
3. Activation of the kinin system by activated Hageman factor (prekallikrein activator)
4. Activation of C1 in the complement cascade

The activity of plasmin itself is also regulated because it is synthesized as a proenzyme, plasminogen. Plasminogen is converted to plasmin by several factors, including plasminogen activator generated from the kallikrein system, thrombin generated from the clotting system, bacterial factors such as streptokinase produced by hemolytic streptococci, plasminogen activators produced by endothelial cells, and several cellular enzymes released during tissue destruction.

Another example of a common regulator is **C1-esterase inhibitor (C1-inh)**.¹² C1-inh inhibits complement activation through reactivity with C1 (classical pathway), MASP-2 (lectin pathway), and C3b (alternative pathway). It is also a major inhibitor of clotting and kinin pathway components (e.g., kallikrein, XIIa). A genetic defect in C1-inh (C1-inh deficiency) results in **hereditary angioedema**, which is a self-

limiting edema of cutaneous and mucosal layers resulting from stress, illness, or relative minor or unapparent trauma. The disease is characterized by hyperactivation of all three plasma protein systems, although excessive production of bradykinin appears to be the principal cause of increased vascular permeability.

Cellular Mediators of Inflammation

Inflammation is a process in vascular tissue; thus, the cellular components are found in the blood and in the tissue surrounding the blood vessels. The vessels are lined with endothelial cells, which under normal conditions actively maintain normal blood flow. During inflammation the vascular endothelium becomes a principal coordinator of blood clotting and the passage of cells and fluid into the tissue. The tissue close to the vessels contains mast cells, which are probably the most important activators of inflammation, and dendritic cells, which connect the innate and adaptive immune responses. The blood contains a complex mixture of cells (see [Fig. 7.4](#)). Blood cells are divided into erythrocytes (red blood cells), platelets, and leukocytes (white blood cells). Erythrocytes carry oxygen to the tissues, and platelets are small cell fragments involved in blood clotting. Leukocytes are subdivided into **granulocytes** (containing many enzyme-filled cytoplasmic granules), monocytes, and lymphocytes. Granulocytes are the most common leukocytes and are classified by the type of stains needed to visualize their granules (basophils, eosinophils, and neutrophils). Monocytes in the blood are precursors of macrophages that are found in the tissues. Various forms of lymphocytes participate in the innate (e.g., natural killer [NK] cells) and the adaptive immune response (B and T cells).

Cells of both innate and acquired immune systems are recruited and activated by biochemical mediators produced at the site of cellular damage. These molecules originate from destroyed or damaged cells, contaminating microbes, activation of the plasma protein systems, or secretions by other cells of the innate or acquired immune systems. Activation may result in the cell gaining a function critical to the inflammatory response or induction of the release of

additional cellular products that increase inflammation, or both. These inflammatory cells and protein systems, along with the substances they produce, act at the site of tissue injury to confine the extent of damage, kill microorganisms, and remove the debris of “battle” in preparation for healing: tissue regeneration or repair (processes known as *resolution*).

Cellular Receptors

Cells of both innate and adaptive immunity must recognize and respond to their environment, whether to products of damaged cells or to potential pathogenic microorganisms. Each cell has receptors on the cell surface that specifically bind soluble substances (ligands) produced during tissue damage or infection. The binding of a ligand to its receptor results in activation of intracellular signaling pathways and activation of the cell. As will be discussed in [Chapter 8](#), B and T lymphocytes of the adaptive immune system have evolved surface receptors (i.e., the T-cell receptor, or TCR, and the B-cell receptor, or BCR) that bind a large spectrum of antigens. Cells involved in innate resistance have evolved a different set of receptors that recognize a much more limited array of specific molecules. These are referred to as **pattern recognition receptors (PRRs)**, and they recognize molecular “patterns” on infectious agents or their products (**pathogen-associated molecular patterns, or PAMPs**), or products of cellular damage (necrosis or apoptosis; **damage-associated molecular patterns, or DAMPs**).¹³ PRRs are generally found on cells at the interface of the host and environment (i.e., skin, respiratory tract, gastrointestinal tract, genitourinary tract), where they monitor for products of cellular damage and potentially infectious microorganisms. Although most PRRs are on the cell surface, some are secreted or intracellular.¹⁴ An example of a secreted PRR is mannose-binding lectin of the lectin pathway of complement activation. Cellular PRRs include Toll-like receptors, complement receptors (CRs), scavenger receptors, glucan receptors, and mannose receptors.

In humans, at least 11 different **Toll-like receptors (TLRs)** have

been described, 10 of which are functional.¹⁵ They are expressed on the surface of many cells that have direct and early contact with potential pathogenic microorganisms. These include mucosal epithelial cells, mast cells, neutrophils, macrophages, dendritic cells, and some subpopulations of lymphocytes. (Dendritic cells are found in the skin, mucosa, and lymphoid tissues, where they have developed from Langerhans cells and function as highly specialized initiators of the adaptive immune response.) TLRs recognize a large variety of PAMPs located on the microorganism's cell wall or surface (e.g., bacterial lipopolysaccharide [LPS], peptidoglycans, lipoproteins, yeast zymosan, viral coat proteins), other surface structures (e.g., bacterial flagellin), or microbial nucleic acid (e.g., bacterial DNA, viral double-stranded RNA). Some TLRs recognize host factors that are produced by “stressed” or damaged cells (e.g., breakdown products of extracellular matrix proteins, chromatin). Interactions between PAMPs and TLRs, with the collaboration of other cellular receptors (e.g., CD14), can result in activation of the cell and the release of soluble products (e.g., cytokines) that increase local resistance to the pathogenic microorganism. TLRs are also one of the bridges between innate resistance and the adaptive immune response through the induction of cytokines that increase the response of lymphocytes to foreign antigens on the pathogens. Genetic polymorphisms in TLRs may explain some observed differences among individuals' resistance and susceptibility to infections. Information on each of the TLRs found in humans is shown in [Table 7.2](#).

TABLE 7.2

CELLULAR SOURCE AND MICROBIAL TARGET FOR EACH TOLL-LIKE RECEPTOR (TLR)

RECEPTOR	CELLULAR EXPRESSION PATTERN	PAMP RECOGNITION
TLR1	Cell surface (ubiquitous): neutrophils, monocytes/macrophages, dendritic cells, T cells, B cells, NK cells	Fungal, bacterial, viral; forms heterodimer with TLR2 (TLR2 recognition)
TLR2	Cell surface: neutrophils,	Fungal (yeast zymosan), bacterial (gram-

	monocytes/macrophages, dendritic cells	positive bacterial peptidoglycan, lipoproteins), viral (lipoproteins)
TLR3	Intracellular: monocytes/macrophages, dendritic cells, T cells, NK cells, epithelial cells	Double-stranded RNA produced by many viruses
TLR4	Cell surface: granulocytes, monocytes/macrophages, dendritic cells, T cells, B cells, epithelial cells	Bacterial (primarily gram-negative bacterial LPS, lipoteichoic acids), viral (RSV F protein, hepatitis C)
TLR5	Cell surface: granulocytes, monocytes/macrophages, dendritic cells, NK cells, epithelial cells	Bacterial (flagellin); forms heterodimer with TLR4
TLR6	Cell surface: monocytes/macrophages, dendritic cells, B cells, NK cells	Fungal, bacterial, viral; forms heterodimer with TLR2 (TLR2 recognition)
TLR7	Intracellular: monocytes/macrophages, dendritic cells, B cells	Natural ligand uncertain; may bind viral single-strand RNA
TLR8	Cell surface: monocytes/macrophages, dendritic cells, NK cells	Natural ligand uncertain; may bind fungal PAMPs or viral single-stranded RNA
TLR9	Intracellular: monocytes/macrophages, dendritic cells, B cells	Bacterial (unmethylated DNA [CpG dinucleotides])
TLR10	Cell surface: monocytes/macrophages, dendritic cells, B cells	Natural ligand uncertain; may form heterodimers with TLR2
TLR11	TLR11 gene does not code a full-length protein in humans	No known immune response

DNA, Deoxyribonucleic acid; *LPS*, lipopolysaccharide; *NK*, natural killer; *PAMPs*, pathogen-associated molecular patterns; *RNA*, ribonucleic acid; *RSV*, respiratory syncytial virus.

Complement receptors are found on many cells of the innate and adaptive immune responses (e.g., granulocytes, monocytes/macrophages, lymphocytes, mast cells, erythrocytes, platelets), as well as some epithelial cells. They recognize several fragments produced through activation of the complement system.¹⁶ Under a variety of normal and disease-related conditions, immune complexes of antibody, antigen, and complement form in the blood and are removed by cells expressing surface complement receptor-1 (CR1), which binds to C4b, C3b, and C3b breakdown products (e.g., iC3b). CR2 is found on B lymphocytes, as well as dendritic cells and some epithelial cells, and recognizes C3b breakdown products (particularly iC3b). CR2 appears to facilitate B-cell function and

antibody production. Both CR3 and CR4 are integrins that primarily recognize C3b breakdown products (particularly iC3b). CR3 (integrin $\alpha M\beta 2$, also called CD11b/CD18) facilitates phagocytosis by neutrophils and monocytes/macrophages. CR4 ($\alpha X\beta 2$, also called CD11c/CD18) is found primarily on platelets. (**Integrins** are cell surface receptors that have a role in cell adhesion and attachment and mediate intracellular signaling within the extracellular matrix [see Fig. 1.17].)

Scavenger receptors are primarily expressed on macrophages and facilitate recognition and phagocytosis of bacterial pathogens, as well as damaged cells and altered soluble lipoproteins associated with vascular damage (e.g., high-density lipoprotein [HDL], acetylated low-density lipoprotein [LDL], oxidized LDL).¹⁷ More than eight receptors have been identified. Some scavenger receptors (e.g., SR-PSOX) recognize the cell membrane phospholipid phosphatidylserine (PS). PS is normally sequestered on the cytoplasmic surface of the cell membrane, but it is externalized under a very limited variety of conditions, including erythrocyte senescence and cellular apoptosis. Thus, macrophages, through this receptor, can identify and remove old red blood cells and cells undergoing apoptosis. Another important scavenger receptor is CD14, which recognizes the complex of LPS and LPS-binding protein. LPS-binding protein is up-regulated during inflammation by the cytokines interleukin-6 (IL-6) and IL-1 and helps remove bacterial LPS (endotoxin) from the circulation.

NOD-like receptors (NLRs) are cytoplasmic receptors that recognize products of microbes and damaged cells.¹⁸ At least 22 NLRs have been identified in humans. NOD-1 and NOD-2 are cytoplasmic and recognize fragments of peptidoglycans from intracellular bacteria and initiate production of proinflammatory mediators, such as tumor necrosis factor (TNF) and IL-6. Some NLRs associate with intracellular multiprotein complexes called **inflammasomes**. Inflammasomes primarily bind cellular stress-related molecules, a type of DAMP, and through the activation of caspases-1 control the activation and secretion of inflammatory cytokines, such as IL-1 β .¹⁹

Cellular Products

To elicit an effective inflammatory (or adaptive immune) response, intercellular communication and cooperation are necessary. **Cytokines** constitute a large family of small-molecular-weight soluble intercellular-signaling molecules that are secreted, bind to specific cell membrane receptors, and regulate innate or adaptive immunity (Fig. 7.10). Cytokines may be either *proinflammatory* or *antiinflammatory* in nature, depending on whether they tend to induce or inhibit the inflammatory response. These molecules usually diffuse over short distances, but some effects occur over long distances, such as the systemic induction of fever by some cytokines (i.e., endogenous pyrogens) that are produced at an inflammatory site. Binding of cytokines to a target cell often induces synthesis of additional cellular products. For example, binding of the cytokine TNF- α to a cell may result in synthesis and release of IL-1.

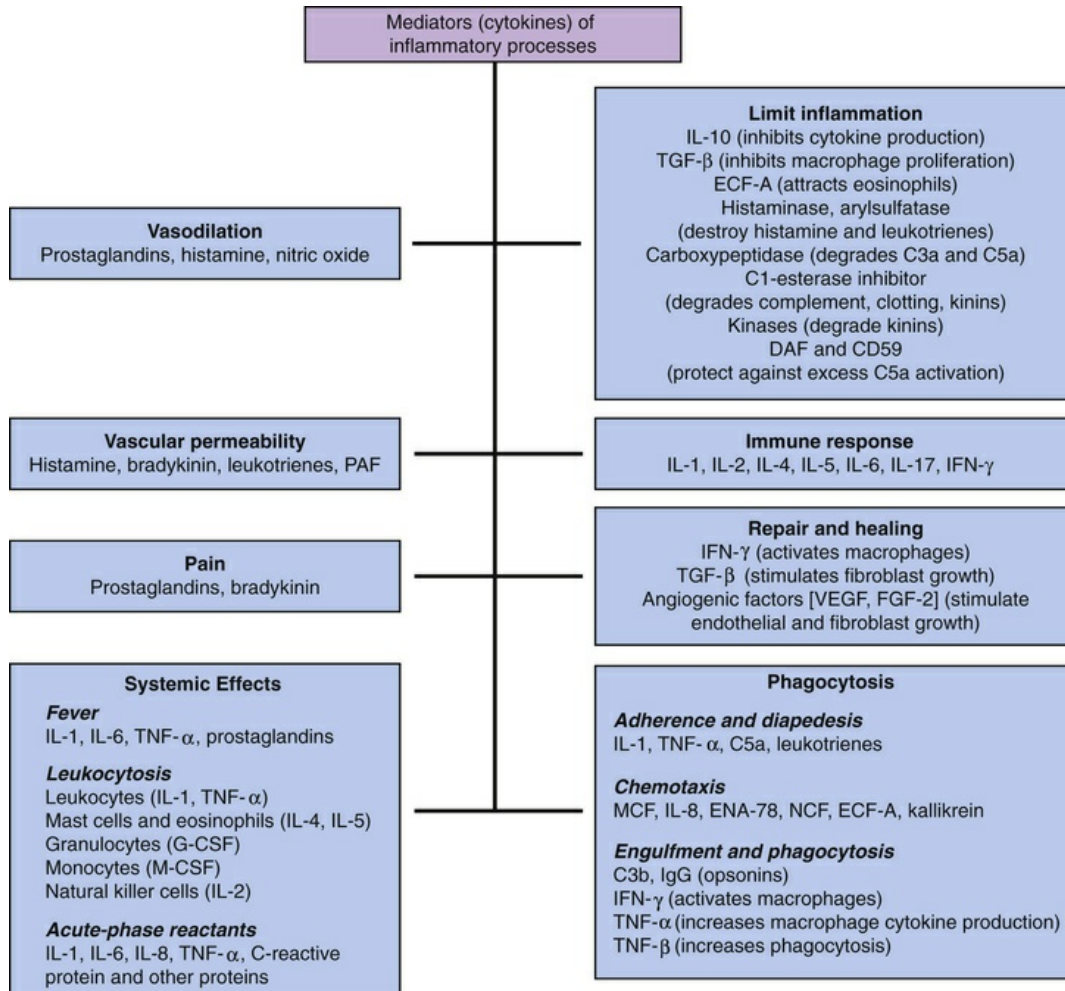

FIGURE 7.10 Principal Mediators of Inflammation. *C3b*, Large fragment produced from complement component C3; *C5a*, small fragment produced from complement component C5; *ECF-A*, eosinophil chemotactic factor of anaphylaxis; *ENA*, epithelial-dermoid neutrophil attractant; *FGF*, fibroblast growth factor; *G-CSF*, granulocyte colony–stimulating factor; *IFN*, interferon; *IgG*, immunoglobulin G (predominant class of antibody in the blood); *IL*, interleukin; *MCF*, monocyte chemotactic factor; *M-CSF*, monocyte colony–stimulating factor; *NCF*, neutrophil chemotactic factor; *PAF*, platelet-activating factor; *TGF*, T-cell growth factor; *TNF*, tumor necrosis factor; *VEGF*, vascular endothelial growth factor.

The actions of chemokines and cytokines are *pleiotropic*, indicating that the same molecule may have a large variety of different biologic activities depending on the particular target cell to which it binds. In addition, the same molecule may be produced by a large spectrum of cells, many of which are not part of inflammation or the immune system. These molecules may be *synergistic*, so that their combined activity exceeds the sum of their individual activities, or have

antagonistic properties that cause them to inhibit each other. (A partial list cytokines that are particularly relevant to the acquired immune response is provided in [Chapter 8, Table 8.4.](#))

A large number of cytokines have been described and are classified into several families. The terms lymphokines and monokines refer respectively to cytokines secreted from lymphocytes or monocytes, although cytokines are secreted by many different types of cells. **Chemokines** are members of a special family of cytokines that are chemotactic and primarily attract leukocytes to sites of inflammation. Chemokines are synthesized by many cell types, including macrophages, fibroblasts, and endothelial cells, in response to proinflammatory cytokines, such as TNF- α . To date, more than 50 different human chemokines have been described. Examples include those that primarily attract macrophages (e.g., monocyte/macrophage chemotactic proteins [MCP-1, MCP-2, and MCP-3], macrophage inflammatory proteins [MIP-1 α and MIP-1 β]) or neutrophils (e.g., IL-8).

Cytokines.

The majority of important cytokines are classified as interleukins or interferons. Other critical cytokines, however, are not classified as either. Many of these same cytokines are produced by cells of the acquired immune system in response to specific antigens and are discussed further in [Chapter 8](#).

The **interleukins (ILs)** are biochemical messengers produced predominantly by macrophages and lymphocytes in response to stimulation of PRRs or by other cytokines. More than 30 interleukins have been identified. Their effects include the following:

1. Alteration of adhesion molecule expression on many types of cells
2. Attraction of leukocytes to a site of inflammation (chemotaxis)
3. Induction of proliferation and maturation of leukocytes in the bone marrow
4. General enhancement or suppression of inflammation

5. Mediation of development of the acquired immune response

Two major proinflammatory interleukins are IL-1 and IL-6, which cooperate closely with another cytokine, tumor necrosis factor-alpha (TNF- α). **Interleukin-1 (IL-1)** is produced in two forms (IL-1 α and IL-1 β) mainly by macrophages. IL-1 activates monocytes, other macrophages, and lymphocytes, thereby enhancing both innate and acquired immunity, and acts as a growth factor for many cells.²⁰ It has several effects on neutrophils, including induction of proliferation (resulting in an increase in the number of circulating neutrophils), attraction to an inflammatory site (chemotaxis), and an increase in cellular respiration and lysosomal enzyme activity (both effects resulting in increased cellular killing of bacteria). IL-1 is an endogenous pyrogen (i.e., fever-causing cytokine) that reacts with receptors on cells of the hypothalamus and affects the body's thermostat, resulting in fever.

Interleukin-6 (IL-6) is produced by macrophages, lymphocytes, fibroblasts, and other cells. IL-6 directly induces hepatocytes (liver cells) to produce many of the proteins needed in inflammation (acute-phase reactants, discussed later in this chapter).²¹ IL-6 also stimulates growth and differentiation of blood cells in the bone marrow and the growth of fibroblasts (required for wound healing).

Although not classified as an interleukin, **tumor necrosis factor-alpha (TNF- α)** is secreted by macrophages and other cells (e.g., mast cells) in response to recognition of PAMPs by TLRs.²² Macrophages secrete TNF- α in response to recognition of PAMPs by TLRs. TNF- α is initially synthesized as a membrane-anchored protein, which is cleaved into a soluble form by a membrane-associated protease, TNF-converting enzyme (TACE). Soluble TNF- α induces a multitude of proinflammatory effects, including enhancement of endothelial cell **adhesion molecule** expression and induction of chemokine production by both endothelial cells and macrophages. When secreted in large amounts, TNF- α has systemic effects as well:

1. Induces fever by acting as an endogenous pyrogen

2. Causes increased synthesis of proinflammatory serum proteins by the liver
3. Causes muscle wasting (cachexia) and intravascular thrombosis as a consequence of prolonged production in cases of severe infection or cancer
4. Probably responsible for fatalities from shock caused by gram-negative bacterial infections

Some cytokines are antiinflammatory and diminish the inflammatory response. The most important are IL-10 and transforming growth factor-beta (TGF- β). **Interleukin-10 (IL-10)** is primarily produced by lymphocytes and suppresses the growth of other lymphocytes and the production of proinflammatory cytokines by macrophages, leading to the downregulation of both inflammation and the adaptive immune response. **Transforming growth factors**, including **transforming growth factor-beta (TGF- β)**, are produced by many types of cells in response to inflammation and induce cell division and differentiation of other cell types, such as immature blood cells.

Interferons (IFNs) are members of a family of low-molecular-weight proteins that primarily protect against viral infections and modulate the inflammatory response. (Mechanisms of viral infection are described in [Chapter 10](#).) Type I interferons (primarily IFN- α , IFN- β) are produced and released by virally infected cells in response to viral double-stranded RNA and other viral PAMPs.²³ Type I IFNs do not kill viruses directly but instead are secreted from virally infected cells, attach to a receptor on neighboring cells, and, if the neighboring cells are uninfected, stimulate the production of a variety of antiviral proteins that will interfere with transcription of viral nucleic acids or with viral replication. Interferons are species specific, meaning that human interferon is effective only in humans; however, these cytokines are not virus specific, meaning that they are effective against almost all viruses.

Type II interferon (IFN- γ) is produced primarily by lymphocytes; it activates macrophages, resulting in increased capacity to kill

infectious agents (including viruses and bacteria), and it enhances the development of acquired immune responses against viruses.

Chemokines.

Chemokines are members of a family of low-molecular-weight (8 to 10 kDa) peptides that function primarily to induce leukocyte chemotaxis.²⁴ This response can be elicited either by soluble chemokines or by chemokines that are bound to extracellular glycosaminoglycan carbohydrates. Chemokines can be synthesized by multiple cell types, including macrophages, fibroblasts, and endothelial cells, in response to proinflammatory cytokines. Macrophages can be stimulated to produce chemokines by recognition of either infectious microorganisms or a β -defensin (both through TLR4). To date, more than 40 different human chemokines have been described, the vast majority of which are classified as either CC-chemokines (β -chemokines) or CXC-chemokines (α -chemokines), depending on the arrangement of cysteine amino acids in the protein. This amino acid arrangement also determines which target cell(s) will respond to a given chemokine. CC-chemokines affect mainly monocytes, lymphocytes, and eosinophils, whereas CXC-chemokines generally affect neutrophils. Examples of CC-chemokines include RANTES (regulated on activation, normal T expressed and secreted), monocyte/macrophage chemotactic proteins (MCP-1, MCP-2, and MCP-3), and macrophage inflammatory proteins (MIP-1 α and MIP-1 β). CXC-chemokines include IL-8 and epithelial-dermoid neutrophil attractant (ENA-78).

Mast Cells and Basophils

The mast cell is probably the most important cellular activator of the inflammatory response. **Mast cells**, first described by Paul Ehrlich²⁵ in 1877, are cellular bags of granules located in the loose connective tissues close to blood vessels near the body's outer surfaces (i.e., in the skin and lining the gastrointestinal and respiratory tracts) (Fig. 7.11). **Basophils** are found in the blood and probably function in the same way as tissue mast cells. A great number of stimuli activate mast cells

to release potent soluble inducers of inflammation. These are released by (1) *degranulation* (the release of the contents of mast cell granules) and (2) *synthesis* (the new production and release of mediators in response to a stimulus). Typical causes of mast cell activation include (1) physical injury (e.g., heat, mechanical trauma, ultraviolet light, and x-rays), (2) chemical agents (e.g., toxins, snake and bee venoms, proteolytic enzymes, and antimicrobial peptides), (3) immunologic means (e.g., anaphylatoxins released during activation of complement components or particular types of antibody [e.g., immunoglobulin E (IgE)] produced by cells of the adaptive immune response [see [Chapter 8](#)]), and (4) activation of TLRs by bacteria and viruses. Soluble and extremely potent chemicals from the mast cell are responsible for its effects on inflammation. Mast cells are also involved in initiating many allergic responses (discussed in [Chapter 9](#)).

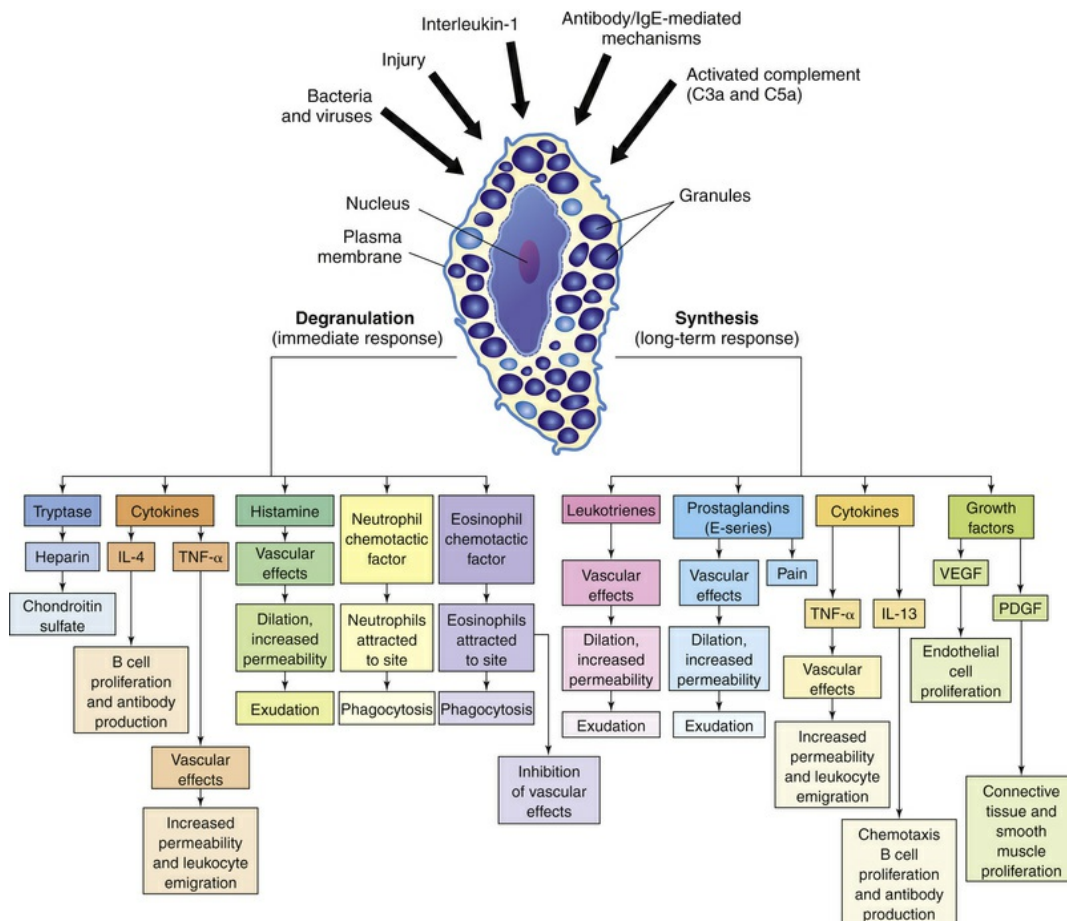

FIGURE 7.11 Effects of Degranulation (*left*) and Synthesis (*right*) by Mast Cells. The depiction of a tissue mast cell shows darkly stained granules in the cytoplasm. *IgE*, Immunoglobulin E; *IL-4*, interleukin-4; *IL-13*, interleukin-13; *PDGF*, platelet-derived growth factor; *TNF- α* , tumor necrosis factor-alpha; *VEGF*, vascular endothelial growth factor.

Degranulation.

In response to a stimulus, biochemical mediators in the mast cell granules, including histamine, chemotactic factors (e.g., neutrophil chemotactic factor, **eosinophil chemotactic factor of anaphylaxis** or **ECF-A**), and cytokines (e.g., $TNF-\alpha$, IL-4), are released within seconds and exert their effects immediately (see Fig. 7.11).

Histamine is a small-molecular-weight molecule with potent effects on many other cells, particularly those that control the circulation. Histamine, along with serotonin (found in many cells, but not human mast cells), is called a *vasoactive amine*. Histamine causes temporary, rapid constriction of smooth muscle and dilation of the postcapillary venules, both of which result in increased blood flow into the microcirculation. Histamine also causes increased vascular permeability resulting from retraction of endothelial cells lining the capillaries and increased adherence of leukocytes to the endothelium (see Fig. 7.4). The pharmacologic effects of histamine are partially determined by histamine receptors on the person's target cells. Two main histamine receptors are the H1 and H2 receptors (Fig. 7.12), and two other receptors, H3 and H4, have been described.²⁶ Binding of histamine to the *H1 receptor* is essentially proinflammatory; that is, it promotes inflammation. On the other hand, binding to the *H2 receptor* is generally antiinflammatory because it results in suppression of leukocyte function. The H1 receptor is present on smooth muscle cells, especially those of the bronchi, and causes bronchial smooth muscle to contract (bronchoconstriction) when stimulated. Both types of receptors are distributed among many different cells and are often present on the same cells and may act in an antagonistic fashion. For instance, neutrophils express both types of receptors, with stimulation of H1 receptors resulting in the augmentation of neutrophil chemotaxis, and H2 stimulation resulting in its inhibition. The H2

receptor is especially abundant on parietal cells of the stomach mucosa and induces the secretion of gastric acid as part of the normal physiology of the stomach. The role of H1 and H2 receptors is discussed further in [Chapter 9](#).

FIGURE 7.12 Effects of Histamine through H1 and H2 Receptors. Effects depend on (1) density and affinity of H1 or H2 receptors on the target cell, and (2) the identity of the target cell. *ATP*, Adenosine triphosphate; *cAMP*, cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; *GTP*, guanosine triphosphate.

Mast cell granules also contain chemotactic factors, two of which are **neutrophil chemotactic factor (NCF)** and **eosinophil chemotactic factor of anaphylaxis (ECF-A)**. **Chemotaxis** is directional movement of cells along a chemical gradient formed by a chemotactic factor (see [Fig. 7.4](#)). Neutrophils (attracted by NCF) are the predominant leukocytes at work during the early phases of acute inflammation, and eosinophils (attracted by ECF-A) have several functions in the inflammatory process; both of these important inflammatory cells are discussed in more detail later in this chapter.

Synthesis of Mediators.

Activated mast cells initiate synthesis of other mediators of inflammation, including those derived from plasma membrane lipids (leukotrienes, prostaglandins, platelet-activating factor),²⁷ cytokines (TNF- α , various interleukins), and factors that stimulate cell growth

and angiogenesis. **Leukotrienes** (also known as **slow-reacting substances of anaphylaxis [SRS-A]**) are products of arachidonic acid, which is released from mast cell membranes by an intracellular phospholipase that acts on membrane phospholipids (Fig. 7.13). Leukotrienes are acidic, sulfur-containing lipids produced by *lipoxygenase* that produce effects similar to those of histamine: smooth muscle contraction, increased vascular permeability, and perhaps neutrophil and eosinophil chemotaxis. Leukotrienes appear to be important in the later stages of the inflammatory response because they stimulate slower and more prolonged responses than do histamines.

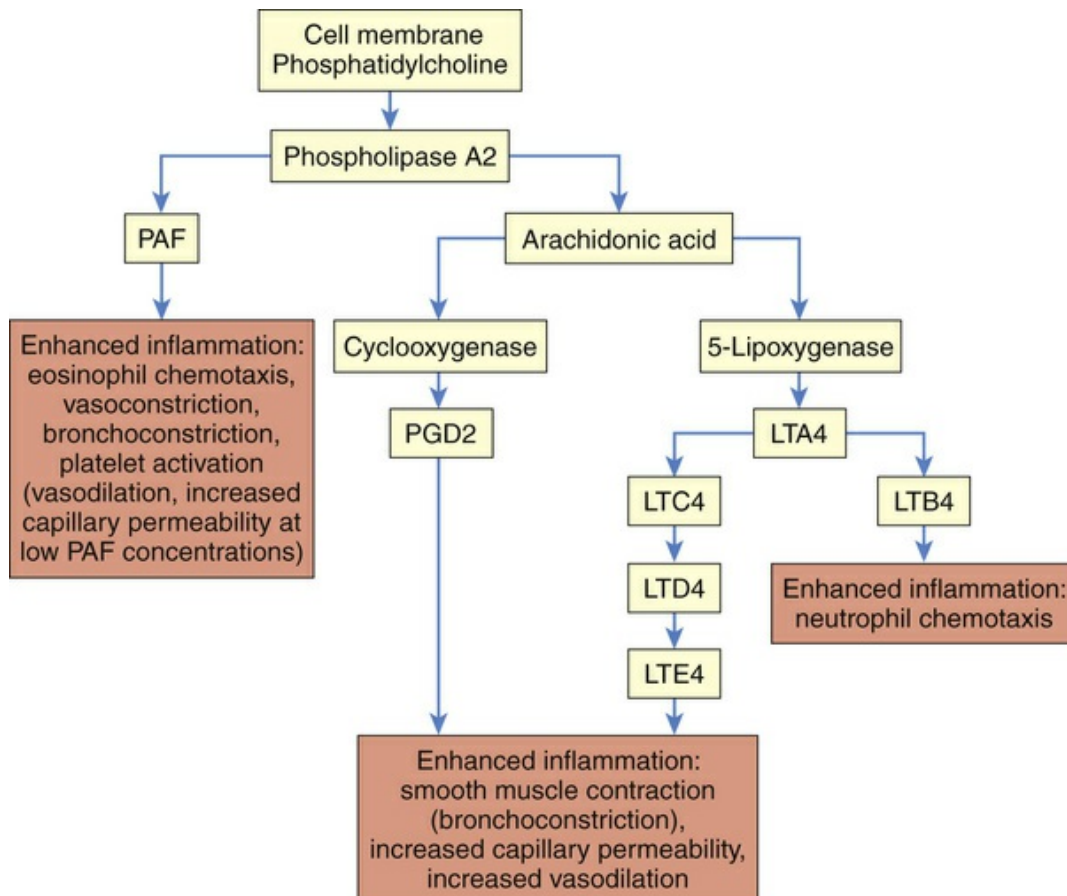

FIGURE 7.13 Production of Lipid Vasoactive Substances by Mast Cells. *LTA4*, *LTC4*, *LTD4*, *LTE4*, *LTB4*, Various leukotriene molecules; *PAF*, platelet-activating factor; *PGD2*, prostaglandin D₂.

Prostaglandins are long-chain unsaturated fatty acids produced from arachidonic acid by the action of the enzyme *cyclooxygenase* (COX) and are classified into groups (E, D, A, F, and B) according to their structure. Prostaglandins E₁ and E₂ cause increased vascular permeability and smooth muscle contraction, apparently acting directly on postcapillary venules. They can inhibit some aspects of inflammation by suppressing both the release of histamine from mast cells and the release of lysosomal enzymes (enzymes responsible for killing and digesting microorganisms) from neutrophils. Enhancement or suppression of the inflammatory response may be related to the concentration of prostaglandins. Cyclooxygenase exists in two different forms: COX-1 is found in most tissues and COX-2 is associated with inflammation. Aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) inhibit both COX-1 and COX-2, blocking synthesis of prostaglandins of the E series, but inhibition of COX-1 causes complications, such as gastrointestinal toxicity. Selective COX-2 inhibitors are now available. Dietary free fatty acids also promote antiinflammatory effects (see [Nutrition & Disease: Essential Fatty Acids and Inflammation](#)).

Nutrition & Disease

Essential Fatty Acids and Inflammation

Both omega-3 and omega-6 polyunsaturated fatty acids are essential fatty acids available only in the diet. They are essential because human physiologic processes cannot add the necessary double bonds to the carbon chains. Omega-6 fatty acids are contained in vegetable oils, and most are linolenic acid. Omega-3 essential fatty acids, which are mostly alpha-linolenic acid, are found in green leafy vegetables, walnuts, flaxseed, and canola oil. The metabolic products of alpha-linolenic acid are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), and the richest source of these acids is in the oils of deep-sea cold-water fish. Both the omega-3 and the omega-6 fatty acids use the same enzymes to

produce their metabolic products, and they compete for this enzyme, delta-5-desaturase. *Delta-5-desaturase* converts EPA into antiinflammatory prostaglandins (PGs) of the PGE₃ series. The omega-6 fatty acid dihomo-gamma-linolenic acid (DGLA) can be converted to either antiinflammatory PG₁ or arachidonic acid (AA), a precursor of inflammatory PG₂ and leukotrienes. Conversion of DGLA into PG₁ does not require any enzymes, but conversion of DGLA into AA requires the enzymes delta-6- and delta-5-desaturase. When the diet is high in omega-3 fatty acids, most of the delta-5-desaturase will be used in the omega-3 pathway and the production of antiinflammatory prostaglandins. Little delta-5-desaturase will be available to convert DGLA into arachidonic acid and subsequent inflammatory mediators. DGLA ends up being converted into the antiinflammatory PG₁, and, overall, inflammation is decreased. The resulting antiinflammatory effects of omega-3 essential fatty acids decrease the risk for cardiovascular disease, cancer, and other conditions associated with inflammation. Omega-3 fatty acids have been shown to decrease blood triglyceride concentrations; decrease production of chemoattractants, growth factors, and adhesion molecules; lower blood pressure; increase nitric oxide production, endothelial relaxation, and vascular compliance; decrease thrombosis and cardiac dysrhythmias; and stabilize or reverse atherosclerotic plaque. The American diet tends to be high in saturated and omega-6 fatty acids and deficient in omega-3 fatty acids, with a ratio estimated at about 15:1. The Mediterranean-style diet has more whole grains, fish, olive oil, fresh fruits, and vegetables, and a more balanced ratio of omega-6 to omega-3 fatty acids estimated at about (3–4):1. Increasing omega-3 fatty acids in the diet may significantly improve health and reduce the risk of cardiovascular disease, cancer, and other diseases associated with chronic inflammation.

From Backes J et al: *Lipids Health Dis* 15(1):118, 2016; Sears B: *J Am Coll Nutr* 34(Suppl 1):14–21, 2015.

Platelet-activating factor (PAF) is produced by removal of a fatty acid from the plasma membrane phospholipid phosphatidylcholine by phospholipase A₂. Although mast cells are a major source of PAF, this molecule also can be produced during inflammation by neutrophils, monocytes, endothelial cells, and platelets. The biologic activity of PAF is virtually identical to that of leukotrienes: causing endothelial cell retraction to increase vascular permeability, leukocyte adhesion to endothelial cells, and platelet activation.

Endothelium

The blood vessel walls consist of a layer of endothelial cells that adhere to an underlying matrix of connective tissue that contains a variety of proteins, including collagen, fibronectin, and laminins. Circulating cells and platelets and components of plasma protein systems continually contact **endothelial cells**, which contribute to regulation of normal blood flow by preventing spontaneous activation of platelets and members of the clotting system.²⁸ **Nitric oxide (NO)** produced from arginine and prostacyclin (PGI₂) from arachidonic acid maintain blood flow and pressure and inhibit platelet activation. PGI₂ and NO are synergistic. NO is released continually to relax vascular smooth muscle and suppress the effects of low levels of cytokines, thus maintaining vascular tone. PGI₂ production varies a great deal and is increased when additional regulation is needed.

Damage to the endothelial cell lining of the vessel exposes the subendothelial connective tissue matrix, which is prothrombogenic and initiates platelet activation and formation of clots (the contact activation [intrinsic] clotting pathway). Proinflammatory mediators (e.g., histamine, prostacyclin, and many others) affect the endothelium, resulting in adherence of leukocytes to the vessel surface, invasion of leukocytes into the tissue, and efflux of plasma from the vessel.

Platelets

Platelets (thrombocytes) are anucleate cytoplasmic fragments formed

from megakaryocytes. They circulate in the bloodstream until vascular injury occurs, resulting in platelet activation. Platelets can be activated by many products of both the innate and the adaptive immune responses, including collagen, thrombin, thromboxane, PAF, and antigen-antibody complexes.²⁹ Activated platelets (1) relocate plasma membrane phosphatidylserine to the cell surface, which provides a foundation for interaction with components of the coagulation cascade to stop bleeding; (2) degranulate to release biochemical mediators such as serotonin (a vasoactive amine with histamine-like vasoactive effects); and (3) synthesize thromboxane A₂ (TXA₂) from prostaglandin H₂. Platelets contain alpha (α) granules and dense granules. *Alpha granules* generally contain polypeptides that affect inflammation, including coagulation proteins (e.g., fibrinogen, factor V), soluble adhesion molecules (e.g., von Willebrand factor, vitronectin), growth factors that promote wound healing (e.g., platelet-derived growth factor, epidermal growth factor), protease inhibitors (e.g., plasminogen activator inhibitor-1, α_2 -antiplasmin), and membrane adhesion molecules (e.g., P-selectin, α IIb β 3).³⁰ *Dense granules* contain several small molecules, including adenosine diphosphate (ADP), serotonin, calcium, and magnesium. TXA₂ is a potent vasoconstrictor and inducer of platelet aggregation. Prolonged use of low-dose aspirin preferentially suppresses production of TXA₂ without interfering with the production of antiinflammatory PGI₂ by endothelium. (Platelet function is described in detail in [Chapter 28](#).)

Phagocytes

The primary role of most granulocytes (neutrophils, eosinophils, basophils) and monocytes/macrophages is **phagocytosis**, the process by which a cell ingests and disposes of damaged cells and foreign material, including microorganisms.

Neutrophil.

The **neutrophil**, or **polymorphonuclear neutrophil (PMN)**, is a member of the granulocytic series of white blood cells and is named

for the characteristic staining pattern of its granules, as well as its multilobed nucleus. Neutrophils are the predominant **phagocytes** in the early inflammatory site, arriving within 6 to 12 hours after the initial injury, where they ingest (phagocytose) bacteria, dead cells, and cellular debris. Several inflammatory mediators (e.g., some bacterial proteins, complement fragments C3a and C5a, and mast cell neutrophil chemotactic factor) specifically attract neutrophils from the circulation and activate them. Macrophages and lymphocytes, on the other hand, enter the site later, usually after 24 hours, and gradually replace the neutrophils.

Because the neutrophil is a mature cell incapable of division and sensitive to the acidic environment it is short-lived at the inflammatory site and becomes a component of the purulent exudate, or *pus*, which is removed from the body through the epithelium or through the lymphatic system. (The lymphatic system is described in [Chapter 28](#).) The primary roles of the neutrophil are removal of debris in sterile lesions, such as burns, and phagocytosis of bacteria in nonsterile lesions.

Eosinophil.

Another population of granulocytes is the **eosinophil**. Although eosinophils are only mildly phagocytic, they have two specific functions: (1) to serve as the body's primary defense against parasites and (2) to help regulate vascular mediators released from mast cells. Their role in resistance to parasites occurs in collaboration with specific antibodies produced by the adaptive immune system and will be discussed in [Chapter 8](#).

Regulation of mast cell–derived inflammatory mediators is critical for control of inflammation. The acute inflammatory response is needed only in a circumscribed area and for a limited time. Therefore, control mechanisms are necessary to prevent biochemical mediators from evoking more inflammation than necessary. Mast cells' ECF-A attracts eosinophils to the site of inflammation. Eosinophil lysosomal granules contain enzymes that degrade vasoactive molecules, thereby controlling the vascular effects of inflammation.³¹ Histaminase

degrades histamine, and arylsulfatase B degrades leukotrienes.

Basophil.

The **basophil** is the least prevalent granulocyte in the blood. It is very similar to mast cells in the content of its granules and, in addition, is an important source of the cytokine IL-4, which is a key regulator of the adaptive immune response.³² Although often associated with allergies and asthma, its primary role is yet unknown.

Dendritic Cells.

Dendritic cells provide one of the major links between the innate and acquired immune responses. They are the primary phagocytic cells located in the peripheral organs and skin, where molecules released from infectious agents are encountered, recognized through PRRs, and internalized through phagocytosis. Dendritic cells then migrate through the lymphatic vessels to lymphoid tissue, such as lymph nodes, and interact with T lymphocytes to generate an acquired immune response.³³ Through the production of a family of cytokines, they guide development of a subset of T cells (helper cells) that coordinate the development of functional B and T cells (discussed in [Chapter 8](#)).

Monocyte and Macrophage.

Monocytes are the largest normal blood cells (14 to 20 μm in diameter) and have a nucleus that is often indented, or horseshoe shaped. Monocytes are produced in the bone marrow, enter the circulation, and migrate to the inflammatory site where they develop into macrophages. Monocytes also appear to be the precursors of macrophages that are found in tissues (tissue macrophages, discussed in [Chapter 8](#)), including Kupffer cells in the liver, alveolar macrophages in the lungs, and microglia in the brain. **Macrophages** are generally larger (20 to 40 μm) and are more active as phagocytes than their monocytic precursors. Macrophages, particularly those residing in the tissues, are often important cellular initiators of the inflammatory response ([Fig. 7.14](#)).

FIGURE 7.14 Scanning Electron Micrograph of Lymphocytes and Macrophages. The lymphocytes are small and spherical; the macrophages are larger and more irregular in shape. (From Raven PH, Johnson GB: *Biology*, St Louis, 1992, Mosby.)

Monocyte-derived macrophages from the circulation may appear at the inflammatory site as soon as 24 hours after the initial neutrophil infiltration, but usually arrive 3 to 7 days later. Neutrophils and monocytes/macrophages are cooperative but differ chiefly in the following ways:

1. *Speed*: Neutrophils arrive at the injury site first, whereas macrophages move more sluggishly.
2. *Active life span*: Macrophages survive and divide in the acidic inflammatory site, whereas neutrophils cannot.
3. *Chemotactic factors*: Neutrophils and macrophages are not attracted by the same factors, such as macrophage chemotactic factor, which is released by neutrophils.
4. *Content of their lysosomes, or digestive vacuoles*: Neutrophils produce large amounts of reactive oxygen species, myeloperoxidase, and antimicrobial proteins compared to macrophages.
5. *Role in the immune response*: Macrophages, but not neutrophils, are involved in activation of the adaptive immune system.
6. *Role in wound repair*: Macrophages are the primary cells that infiltrate tissue in wounds, remove cells and cellular debris, promote angiogenesis, and produce cytokines and growth factors that suppress further inflammation and initiate healing

by promoting epithelial cell division, activating fibroblasts, and promoting synthesis of extracellular matrix and collagen.

Phagocytosis.

The two most important phagocytes are neutrophils and macrophages. Both cells are circulating in the blood and must first leave the circulation and migrate to the site of inflammation before initiating phagocytosis (Fig. 7.15). Under normal conditions, the circulation in the capillaries and venules is rapidly moving with red blood cells in the main stream and neutrophils and other leukocytes tending to flow more slowly along the vessel's periphery. Many of the biochemical products produced early at inflammatory sites (e.g., histamine, TNF- α , bradykinin, leukotrienes, prostaglandins) diffuse to the vessels and affect both leukocytes and endothelial cells.

FIGURE 7.15 Process of Phagocytosis. The process that results in phagocytosis is characterized by three interrelated steps: adherence and diapedesis, tissue invasion by chemotaxis, and phagocytosis. A, Tissue

damage. **Adherence, margination, and diapedesis:** The primary phagocyte in the blood is the neutrophil, which usually moves freely within the vessel (1). At sites of inflammation, the neutrophil progressively develops increased adherence to the endothelium, leading to accumulation along the vessel wall (margination or pavementing) (2). At sites of endothelial cell retraction, the neutrophil exits the blood by means of diapedesis (3). **Chemotaxis:** In the tissues, the neutrophil detects chemotactic factor gradients through surface receptors (1) and migrates toward higher concentrations of the factors (2). The high concentration of chemotactic factors at the site of inflammation immobilizes the neutrophil (3). **B, Recognition and attachment. Specific receptors and ligands for recognition and attachment. C, Phagocytosis.** (1) Opsonized microorganisms are recognized and bind to the surface of a phagocyte through specific receptors. (2) The microorganism is engulfed (ingested) into a phagocytic vacuole, or phagosome. (3) Lysosomes fuse with the phagosome, resulting in the formation of a phagolysosome. During this process the microorganism is exposed to products of the lysosomes, including a variety of enzymes and products of the hexose-monophosphate shunt (e.g., H_2O_2 , O_2^-). (4) The microorganism is killed and digested. *Ab*, Antibody; *AbR*, antibody receptor; *Ag*, antigen; *C3b*, complement component C3b; *C3bR*, complement C3b receptor; *PAMP*, pathogen-associated molecular pattern; *PRR*, pattern recognition receptor.

Both cell populations respond by expressing new **cell adhesion molecules (CAMs)** on their surfaces. CAMs are a family of transmembrane proteins that provide adhesion between cells or between a cell and components of extracellular matrix (e.g., fibronectin, collagen, fibrinogen). The most important CAMs related to vascular inflammation are selectins and integrins. **Selectins** are CAMs that bind carbohydrate ligands on transmembrane glycoproteins: E-selectins are found on endothelial cells, L-selectins on leukocytes, and P-selectins on platelets and endothelial cells. **Integrins** are proteins consisting of alpha (α) and beta (β) chains that primarily provide cell-to-cell adhesion by binding to ligands on another cell. Their affinity for a ligand is dependent on conformational changes of the integrin molecule. The reciprocal change in adhesion molecules on leukocytes (from low-affinity integrins to high-affinity integrins), as well as platelets, promotes their interaction with the endothelial cells.³⁴ The initial change of surface molecules increases the adhesion, or stickiness, between leukocytes and endothelial cells, causing the leukocytes to adhere more avidly to the walls of the capillaries and postcapillary venules in a process called **margination**, or **pavementing** (see Fig. 7.15). Adhesion molecules, such as platelet

endothelial cell adhesion molecules (PCAMs), that are expressed later lead to **diapedesis** or emigration of the cells through the endothelial junctions that have retracted in response to the same mediators.³⁵ The leukocytes digest the basement membrane and migrate into the surrounding tissues.

Additionally, **endothelial cells** release NO, a gas that under normal conditions maintains vascular tone. Inflammation induces additional endothelial nitric oxide synthase, increasing the amount of NO production. Effects of NO on inflammation include vasodilation by inducing relaxation of vascular smooth muscle, a response that is local and short-lived, and suppression of mast cell function as well as platelet adhesion and aggregation.

Once inside the connective tissue in the perivascular space, leukocytes migrate to the inflammatory site by means of chemotaxis. They detect chemotactic factors in the environment through chemoreceptors at multiple locations on their plasma membranes and migrate in the direction of highest concentration (see [Fig. 7.15](#)). The primary chemotactic factors include many bacterial products, complement fragments C3a and C5a, kallikrein, plasminogen activator, products of fibrin degradation (fibrinopeptides), and chemokines, such as IL-8. Eosinophils and neutrophils also respond to chemotactic factors released from mast cells (ECF-A, neutrophil chemotactic factor [NCF]). Monocytes are attracted toward a factor (monocyte chemotactic factor) that has been released by neutrophils already at the site of injury. And although histamine is not itself chemotactic, it may facilitate the chemotactic effects of other factors.

Once the phagocytic cell enters the inflammatory site, the process of phagocytosis involves four steps: (1) *opsonization* (*recognition* of the target and *adherence* of the phagocyte to it); (2) *engulfment* (ingestion or endocytosis) and *formation of phagosome*; (3) *fusion of the phagosome* with lysosomal granules within the phagocyte to form a phagolysosome; and (4) *destruction* of the target (see [Fig. 7.15, C](#)) (lysosomes are described in [Chapter 1](#)). Throughout the process, both the ingested material and the digestive enzymes are isolated within membrane-bound vesicles. Isolation protects the phagocyte itself from the

harmful effects of a microorganism, as well as its own enzymes.

Most phagocytes can trap and engulf bacteria using cellular PRRs and PAMPs normally expressed on the bacterial surface (see Fig. 7.15, B). However, that process is slow and inefficient. **Opsonization**, usually by antibody or complement component C3b, greatly enhances both recognition and adherence. Phagocytosis of a red blood cell is illustrated in Fig. 7.16. Opsonins function as “glue” between the phagocyte and the target cell because receptors on the phagocyte are specific for sites on the opsonin (**Fc receptors** for antibody, **C3b receptors** for C3b). This enables the phagocyte to bind an opsonized target very tightly to its surface. Antibody forms a stronger attachment, but the signal through the C3b receptor activates the phagocytic process to a greater extent.

FIGURE 7.16 Steps in Phagocytosis. This scanning electron micrograph shows the progressive steps in phagocytosis. A, Red blood cells (*R*) attach to the surface of a macrophage (*M*). B, Part of the macrophage (*M*) membrane starts to enclose the red cell (*R*). C, The red blood cells are

almost totally engulfed by the macrophage. (From King DW, Fenoglio CM, Lefwitsch JH: *General pathology: principles and dynamics*, Philadelphia, 1983, Lea & Febiger.)

Although the inflammatory response is considered to be nonspecific, opsonins and other recognition molecules add a degree of specificity to efficient phagocytosis. Antibodies on the surface of bacteria are directed against antigens that are highly specific to that particular microorganism. Certain bacterial and fungal polysaccharide coatings activate the alternative and lectin pathways of complement activation resulting in C3b deposition.

Engulfment (endocytosis) is carried out by small pseudopods that extend from the plasma membrane and surround the adherent microorganism, forming an intracellular phagocytic vacuole, or **phagosome** (see [Figs. 7.15](#) and [7.16](#)). The membrane that surrounds the phagosome consists of inverted plasma membrane. Lysosomes converge on and fuse with the phagosome, creating a **phagolysosome**. The **primary lysosomal granules** (*azurophilic granules*) contain a variety of bactericidal molecules, including myeloperoxidase, lysozyme, defensins, acid hydrolases, elastase, and others. Most phagocytes also contain **secondary granules** (*specific granules*) with molecules that are bactericidal and involved in remodeling the surrounding tissue, including lysozyme, collagenase, lactoferrin, and other proteases. Destruction of the bacterium takes place within the phagolysosome and is accomplished by both oxygen-dependent and oxygen-independent mechanisms.

Oxygen-dependent killing mechanisms result from the production of toxic oxygen species. Phagocytosis is accompanied by a burst of oxygen uptake by the phagocyte, termed the “respiratory burst,” which results from a shift in much of the cell's glucose metabolism to the **hexose-monophosphate shunt**. The nicotinamide adenine dinucleotide phosphate (NADPH) that is produced because of this shift is used by a membrane-associated enzyme, NADPH oxidase, to generate superoxide, a reactive oxygen intermediate that is converted to hydrogen peroxide and other reactive oxygen species. Many of the reactive oxygen species are directly toxic to the microorganism. Hydrogen peroxide also can collaborate with the lysosomal enzyme

myeloperoxidase and halide anions (Cl^- and Br^-) to form acids, such as hypochlorous (HClO) and hypobromous (HBrO) acids. These acids probably kill bacteria and fungi by adding Cl^- or Br^- to the surface of these cells.

Oxygen-independent mechanisms of microbial killing include (1) the acidic pH (3.5 to 4.0) of the phagolysosome caused by lactic acid production; (2) cationic proteins, such as defensins and cathelicidins, that bind to and damage cell membranes; (3) enzymatic attack of the microorganism's cell wall by lysozyme and other enzymes; and (4) inhibition of bacterial growth by lactoferrin that binds iron.

When a phagocyte dies at an inflammatory site, it frequently lyses (breaks open) and releases its cytoplasmic contents into the tissue. Although released lysosomal products may contribute to inflammation by increasing vascular permeability, attracting additional monocytes, and activating the complement and kinin systems, they also may increase the tissue destruction associated with inflammation. For instance, the contents of neutrophil primary granules (e.g., lysozyme, hydrolases, neutral proteases) and secondary granules (e.g., lysozyme, collagenase, gelatinase) can digest the connective tissue matrix. The destructive effects of many enzymes and reactive oxygen molecules released by dying phagocytes are minimized by natural inhibitors found in the blood, such as superoxide dismutase (breaks down superoxide), catalase (breaks down hydrogen peroxide), and the antiproteases α_1 -**antitrypsin** and α_2 -**macroglobulin** (both produced by the liver). An inherited deficiency of α_1 -antitrypsin often results in chronic lung damage and emphysema as a result of inflammation. (The pulmonary effects of α_1 -antitrypsin deficiency are described in [Chapter 36](#).)

Macrophage Activation.

Several bacteria are resistant to killing by granulocytes and can even survive inside macrophages. Microorganisms such as *Mycobacterium tuberculosis* (tuberculosis), *Mycobacterium leprae* (leprosy), *Salmonella typhi* (typhoid fever), *Brucella abortus* (brucellosis), and *Listeria monocytogenes* (listeriosis) can remain dormant or even multiply inside

the phagolysosomes of macrophages.

The bactericidal activity of macrophages can be markedly increased by activation. Macrophage activation results in two subpopulations of cells. *M1 macrophages* are activated through TLRs by substances found in sites of inflammation (e.g., microbial products, endotoxin, or interferon- γ [IFN- γ]) and produce NO and cytokines, release lysosomal granules, and have greater bacterial killing capacity. *M2 macrophages* are activated by cytokines produced by subsets of T lymphocytes of the adaptive immune system (e.g., IL-4, IL-13) and are primarily involved in healing and repair. Activated macrophages have increased (1) phagocytic activity, (2) size, (3) ruffling of the plasma membrane to increase surface area, (4) glucose metabolism, and (5) number of lysosomes.³⁶ Activated macrophages also secrete factors that stimulate the growth, differentiation, and activation of other inflammatory cells as well as control the initiation of healing processes. These include granulocyte colony-stimulating factor (G-CSF), IFN- γ , IL-1 β , angiogenic factor, fibroblast activating factor, and growth factors that promote regeneration of damaged tissues. Macrophages are also the primary cells that infiltrate wounds to remove cellular debris and initiate the regenerative process. In some cases, inadequate macrophage activation results from defects in the adaptive immune responses and deficits in the production of appropriate cytokines. For example, a form of leprosy called *lepomatous leprosy* is characterized by the survival of phagocytosed *M. leprae* bacteria in macrophage phagolysosomes. In individuals with lepomatous leprosy, cells of the adaptive immune system have failed to secrete the cytokines necessary to transform macrophages into highly efficient killing cells.

Natural Killer Cells and Lymphocytes

The main function of **natural killer (NK) cells** is recognition and elimination of cells infected with viruses, although they are also somewhat effective at elimination of other abnormal cells, specifically cancer cells. NK cells seem to be more efficient in this role when they encounter abnormal cells within the circulatory system as opposed to

within tissues. Along with TLRs, NK cells have additional inhibitory and activating receptors that allow differentiation between infected or tumor cells and normal cells. If the NK cell binds to a target cell through activating receptors, it produces several cytokines and toxic molecules that can kill the target. NK cells and lymphocytes, which are the principal cells of the adaptive immune response, will be discussed in much more detail in [Chapter 8](#).

Local Manifestations of Inflammation

The cells and plasma protein systems described previously interact to produce all the characteristics of inflammation, whether local or systemic, as well as determine the duration of inflammation, either acute or chronic. Local inflammation accompanies all types of cellular and tissue injury, whether infected or sterile, from fractures or strains of the musculoskeletal system to burn injuries (see [Chapters 2](#) and [49](#)), and is responsible for initiating healing.

All the *local* manifestations of acute inflammation (i.e., swelling, pain, heat, and redness) result from vascular changes and the subsequent leakage of circulating components into the tissue. **Heat** and **redness** are the result of vasodilation and increased blood flow through the injured site. **Swelling** occurs as exudate (fluid and cells) accumulates. Swelling is usually accompanied by **pain** caused by pressure exerted by exudate accumulation, as well as the presence of soluble biochemical mediators such as prostaglandins and bradykinin.³⁷ Loss of function at the cellular, tissue, or organ level is associated with these manifestations.

Exudate varies in composition, depending on the stage of the inflammatory response and, to some extent, the injurious stimulus. In early or mild inflammation, the exudate is watery (**serous**) with very few plasma proteins or leukocytes. An example of serous exudate is the fluid in a blister. In more severe or advanced inflammation, the exudate may be thick and clotted (**fibrinous exudate**), such as in the lungs of individuals with pneumonia. If a large number of leukocytes accumulate, as in persistent bacterial infections, the exudate consists

of pus and is called a **purulent (suppurative) exudate**. Purulent exudate is characteristic of walled-off lesions (**cysts** or **abscesses**). If bleeding occurs, the exudate is filled with erythrocytes and is described as a **hemorrhagic exudate**.

Although the local manifestations of inflammation can affect all vascularized tissues, lesions vary depending on the organ or tissue involved. The lesion resulting from widespread cellular death (necrosis), for example, differs in myocardial (heart muscle), brain, and hepatic (liver) tissues. Cellular death resulting from myocardial infarction (deprivation of oxygen caused by cessation of blood flow) causes a response that proceeds to replacement of the dead tissue with a fibrinous scar. The same injury to brain tissue is more likely to result in the formation of an abscess filled with necrotic tissue (types of necrosis are described in [Chapter 2](#)). Destruction of liver tissue stimulates the regrowth, or regeneration, of liver cells.

Systemic Manifestations of Acute Inflammation

The three primary *systemic* changes associated with the acute inflammatory response are fever, leukocytosis (a transient increase in the levels of circulating leukocytes), and plasma protein synthesis (increased levels of circulating plasma proteins).

Fever

Fever is an early systemic response, which is partially induced by specific cytokines, for example, IL-1 released from neutrophils and macrophages. These fever-causing cytokines are known as **endogenous pyrogens** to differentiate them from pathogen-produced *exogenous pyrogens*. Pyrogens act directly on the hypothalamus, the portion of the brain that controls the body's thermostat. The release of endogenous pyrogens by inflammatory cells occurs after phagocytosis, after exposure to bacterial endotoxins, or after exposure to antigen-antibody complexes. (Mechanisms of temperature

regulation are discussed in [Chapter 16](#).)

A febrile response can be beneficial because the microorganisms that cause some conditions (e.g., those that cause syphilis or gonococcal urethritis) are highly sensitive to small increases in body temperature. On the other hand, fever may have some harmful side effects because it may enhance the person's susceptibility to the effects of endotoxins associated with gram-negative bacterial infections (bacterial toxins are described in [Chapter 10](#)).

Leukocytosis

Leukocytosis is an increase in the number of circulating white blood cells (greater than $11,000/\text{mL}^3$ in adults). During many infections, leukocytosis may be accompanied by a *left shift* in the ratio of immature to mature neutrophils, so that the more immature forms of neutrophils, such as band cells, metamyelocytes, and occasionally myelocytes, are present in relatively greater than normal proportions. ([Chapter 28](#) discusses the development and maturation of blood cells.) Production of immature leukocytes increases primarily from proliferation and release of granulocyte and monocyte precursors in the bone marrow, which is stimulated by several products of inflammation, including complement product C3a and G-CSF.

Plasma Protein Synthesis

The synthesis of many plasma proteins, mostly products of the liver, is increased during inflammation. These proteins, which can be either proinflammatory or antiinflammatory in nature, are referred to as **acute-phase reactants** ([Table 7.3](#)). Acute-phase reactants reach maximal circulating levels within 10 to 40 hours of initial infection. IL-1 is indirectly responsible for the synthesis of acute-phase reactants through the induction of IL-6, which directly stimulates liver cells to synthesize most of the acute-phase reactants.

TABLE 7.3

CIRCULATING LEVELS OF ACUTE-PHASE REACTANTS DURING INFLAMMATION

FUNCTION	INCREASED	DECREASED
Coagulation components	Fibrinogen Prothrombin Factor VIII Plasminogen	None
Protease inhibitors	α_1 -Antitrypsin α_1 -Antichymotrypsin	Inter- α -antitrypsin
Transport proteins	Haptoglobin Hemopexin Ceruloplasmin Ferritin	Transferrin
Complement components	C1s, C2, C3, C4, C5, C9, factor B, C1 inhibitor	Properdin
Miscellaneous proteins	α_1 -Acid glycoprotein Fibronectin Serum amyloid A (SAA) C-reactive protein (CRP)	Albumin Prealbumin α_1 -Lipoprotein β -Lipoprotein

Common laboratory tests for inflammation measure levels of acute-phase reactants. For example, an increase in blood levels of acute-phase reactants, primarily fibrinogen, is associated with an increased adhesion among erythrocytes and a corresponding increase in the sedimentation rate. The alteration in plasma proteins probably leads to an enhanced erythrocyte rouleaux formation (stacking of erythrocytes, as in a stack of coins) and thereby an increased rate of sedimentation. Although increased erythrocyte sedimentation is a nonspecific reaction, it is considered a good indicator of an acute inflammatory response. Other symptoms of acute inflammation include somnolence (drowsiness), malaise (generalized feeling of discomfort or illness), anorexia (lack of desire to eat), and muscle aching.

Chronic Inflammation

Superficially, the difference between acute and chronic inflammation is purely one of duration, in that chronic inflammation lasts 2 weeks or longer regardless of cause. Characteristic histologic and mechanistic differences also may be present (Fig. 7.17). Chronic

inflammation is sometimes preceded by an unsuccessful acute inflammatory response. For example, if bacterial contamination or foreign objects (e.g., dirt, wood splinters, glass) persist in a traumatic wound, an acute response may be prolonged beyond 2 weeks. Pus formation, suppuration (purulent discharge), and incomplete wound healing may characterize this type of chronic inflammation.

FIGURE 7.17 The Chronic Inflammatory Response. Inflammation usually becomes chronic because of the persistence of an infection, an antibody, or a foreign body in the wound. Chronic inflammation is characterized by the persistence of many of the processes of acute inflammation. In addition, the presence of large amounts of neutrophil degranulation and death, the activation of lymphocytes, and the concurrent activation of fibroblasts result in the release of mediators that induce the infiltration of more lymphocytes and monocytes/macrophages and the beginning of wound healing and tissue repair.

Chronic inflammation can occur also as a distinct process without much previous acute inflammation. Some microorganisms (e.g., mycobacteria that cause tuberculosis) have cell walls with a very high lipid and wax content, making them relatively insensitive to degradation by phagocytes and therefore relatively resistant to clearance in an acute inflammatory response. Other microorganisms, such as those that cause leprosy, syphilis, and brucellosis, can survive within the macrophage and thereby also avoid clearance by the acute inflammatory response. Other microorganisms produce toxins that damage tissue and cause persistent inflammation even after the microorganism is killed. Finally, chemicals, particulate matter, or physical irritants (e.g., inhaled dusts, wood splinters, and suture

material) also can cause a prolonged inflammatory response.

Chronic inflammation is characterized by a dense infiltration of lymphocytes and macrophages. If macrophages are unable to limit the tissue damage or infection, the body attempts to wall off and isolate the infected area, thus forming a **granuloma** (Fig. 7.18). Granulomas may form if neutrophils and macrophages are unable to destroy microorganisms during the acute inflammatory response. For example, infections caused by some bacteria (*Listeria* sp., *Brucella* sp.), fungi (histoplasmosis, coccidioidomycosis), and parasites (leishmaniasis, schistosomiasis, toxoplasmosis) can result in granuloma formation. Large antigen-antibody complexes such as those present in rheumatoid arthritis also can result in the formation of these structures. TNF- α primarily drives granuloma formation. Some macrophages differentiate into large **epithelioid cells**, cells that are incapable of phagocytosing large bacteria but are capable of taking up debris and other small particles. Other macrophages fuse into multinucleated **giant cells**, which are active phagocytes that can engulf very large particles—larger than those that can be engulfed by a single macrophage. These two types of specialized cells form the center of the granuloma, which is surrounded by a wall of lymphocytes. The granuloma itself is also often encapsulated by fibrous deposits of collagen and may become cartilaginous or possibly calcified by deposits of calcium carbonate and calcium phosphate.

FIGURE 7.18 Tuberculous Granuloma. A central area of amorphous caseous necrosis (*C*) is surrounded by a zone of lymphocytes (*L*) and enlarged epithelioid cells (*E*). Activated macrophages frequently fuse to form multinucleated cells (Langhans giant cells). In tuberculoid granulomas the nuclei of the giant cells move to the cellular margins in a horseshoe-like formation.

The classic granuloma associated with tuberculosis is characterized by a wall of epithelioid cells surrounding a cheeselike proteinaceous center derived from dead and decaying tissue (caseous necrosis, see [Chapter 2](#)) and mycobacteria. Decay of cells within the granuloma results in the release of acids and the enzymatic contents of lysosomes from dead phagocytes. In this inhospitable environment, the cellular debris is broken down and a clear fluid may remain (liquefaction necrosis, see [Chapter 2](#)). Eventually this fluid diffuses out and leaves a hollow, thick-walled structure that has replaced normal tissue and reduces organ function.

Wound Healing

The conclusion of inflammation is healing and repair. The most favorable outcome of healing is tissue **regeneration** (replacement of damaged tissue with healthy tissue, such as occurs in the epithelia of

the skin and intestines, and in some organs, such as liver) with complete return to normal structure and function (Fig. 7.19). This restoration is called **resolution**, may take up to 2 years, and local production of IL-10 appears to play a critical role. Resolution may not be possible if extensive damage is present, the tissue is not capable of regeneration, infection results in abscess or granuloma formation, or fibrin persists in the lesion. In those cases, repair takes place instead of resolution. **Repair** is the replacement of destroyed tissue with scar tissue. **Scar tissue** is composed primarily of collagen that fills in the lesion and restores strength but cannot carry out the physiologic functions of destroyed tissue, resulting in loss of function.

FIGURE 7.19 Wound Repair by Primary or Secondary Intention. A–D, Healing by primary intention. E–I, Healing by secondary intention.

Wound healing involves processes that (1) fill in, (2) seal, and (3) shrink the wound. These characteristics of healing vary in importance and duration among different types of wounds. A clean incision, such as a paper cut or a sutured surgical wound, heals primarily through the process of collagen synthesis. Because this type of wound has

minimal tissue loss and close apposition of the wound edges, very little sealing (**epithelialization**) and shrinkage (**contraction**) are required. Wounds that heal under conditions of minimal tissue loss are said to heal by **primary intention** (see Fig. 7.19).

Other wounds do not heal as easily. Healing of an open wound, such as a stage IV pressure injury (bedsore), requires a great deal of tissue replacement so that epithelialization, scar formation, and contraction take longer and healing occurs through **secondary intention** (see Fig. 7.19). Healing by either primary or secondary intention may occur at different rates for different types of tissue injury.

Epidermal wounds that heal by secondary intention and unsutured internal lesions are not completely restored by healing. At best, repaired tissue regains 80% of its original tensile strength. Only epithelial, hepatic (liver), and bone marrow cells are capable of the complete mitotic regeneration of the normal tissue known as *compensatory hyperplasia*. In fibrous connective tissue, such as joints and ligaments, normal healing results in replacement of the original tissue with new tissue that does not have exactly the same structure or function as that of the original. Some tissues heal without replacement of cells. For example, damage resulting from myocardial infarction heals with a scar composed of fibrous tissue rather than with cardiac muscle. Wound healing occurs in three overlapping phases: inflammation, proliferation and new tissue formation, and remodeling and maturation.^{37a}

Phase I: Inflammation

The early phase of wound healing, the transition from acute inflammation to healing, begins almost immediately. The **inflammatory phase** includes coagulation and the infiltration of cells that participate in wound healing, including platelets, neutrophils, and macrophages.³⁸ The fibrin mesh of the blood clot acts as a scaffold for cells that participate in healing. Platelets contribute to clot formation and, as they degranulate, release growth factors that initiate proliferation of undamaged cells. Neutrophils and macrophages clear

the wound of debris (fibrin from dissolved clots, microorganisms, erythrocytes, and dead tissue cells). This cleanup of the lesion, which also involves dissolution of fibrin clots (or scabs) by fibrinolytic enzymes, is called **débridement**. After débridement the remaining debris is drained away by blood vessels and lymphatics, and the vascular dilation and permeability associated with inflammation are reversed, thus preparing the lesion for either regeneration or repair.

Phase II: Proliferation and New Tissue Formation (Reconstruction)

The proliferative phase begins 3 to 4 days after the injury and continues for as long as 2 weeks. The wound is sealed and the fibrin clot is replaced by normal tissue or scar tissue during this phase. The **proliferative phase** is characterized by macrophage invasion of the dissolving clot and recruitment and proliferation of fibroblasts (connective tissue cells), followed by fibroblast collagen synthesis, epithelialization, contraction of the wound, and cellular differentiation.³⁹ Macrophages secrete a variety of biochemical mediators that promote healing, including the following:

1. **Transforming growth factor-beta (TGF- β)** stimulates fibroblasts entering the lesion to synthesize and secrete the collagen precursor procollagen.
2. **Angiogenesis factors**, such as vascular endothelial growth factor (VEGF) and fibroblast growth factor-2 (FGF-2), stimulate vascular endothelial cells to form capillary buds that grow into the lesion; decreased pH and decreased wound oxygen tension also promote angiogenesis.
3. **Matrix metalloproteinases (MMPs)** degrade and remodel extracellular matrix proteins (e.g., collagen and fibrin) at the site of injury.⁴⁰

Granulation tissue grows into the wound from surrounding healthy connective tissue and consists of invasive cells, new lymphatic

vessels, and new capillaries derived from capillaries in the surrounding tissue, giving the granulation tissue a red, granular appearance. Capillary buds sprout from vascular endothelial cells around the wound and extend into the débrided areas. Loops form when the young capillaries join (*anastomose*). The loops are more fragile and permeable than mature vessels, resulting in leakage of erythrocytes and neutrophils. The erythrocytes are phagocytosed by macrophages, and the neutrophils assist in further débridement of the inflammatory lesion. Many of the new capillaries differentiate into larger vessels as repair continues, promoting influx of nutrients and removal of metabolic wastes. New lymphatic vessels also grow into the granulation tissue by a similar process.

The healing wound must be protected during this process. Epithelialization is the process by which epithelial cells grow into the wound from surrounding healthy tissue. Epithelial cells migrate under the clot or scab using MMPs to unravel collagen. Migrating epithelial cells contact similar cells from all sides of the wound and seal it. The epithelial cells remain active, undergoing differentiation to give rise to the various epidermal layers. Epithelialization of a skin wound can be hastened if the wound is kept moist, preventing the fibrin clot from becoming a scab.

Fibroblasts are important cells during healing because they secrete collagen and other connective tissue proteins. Fibroblasts are stimulated by macrophage-derived TGF- β to proliferate, enter the lesion, and deposit connective tissue proteins in débrided areas about 6 days after the fibroblasts have entered the lesion. **Collagen** is the most abundant protein in the body. It contains high concentrations of the amino acids glycine, proline, and lysine, many of which are enzymatically modified. Modification of proline and lysine requires several cofactors that are absolutely necessary for proper collagen polymerization and function. These include iron, ascorbic acid (vitamin C), and molecular oxygen (O₂); absence of any of these results in impaired wound healing.

Immature collagen (i.e., procollagen) is secreted by fibroblasts as a complex of three polypeptide chains cross-linked by intermolecular

bonds. Procollagen is converted to mature collagen by the proteolytic removal of small polypeptide sequences at both ends of the trimer. As healing progresses, collagen molecules are cross-linked by intramolecular covalent bonds to form collagen fibrils that are further cross-linked to form collagen fibers. The process of complete collagen matrix assembly takes several months because collagen is initially deposited randomly but then is remodeled by repeated dissolution (by MMPs) and reassembly. During this remodeling period, collagen fibers orient along the lines of mechanical stress; further cross-linking adds strength to the final collagen matrix.

Wound contraction is the final process of the reconstruction of new tissue. It is necessary for closure of all wounds, but especially those that heal by secondary intention. Contraction is noticeable 6 to 12 days after injury and may amount to inward movement of the wound edge by approximately 0.5 mm/day in normal healing. In granulation tissue, TGF- β induces some fibroblasts to transition into **myofibroblasts**, specialized cells responsible for wound contraction.⁴¹ Myofibroblasts have features of both smooth muscle cells and fibroblasts. They appear microscopically similar to fibroblasts but differ in that their cytoplasm contains bundles of parallel fibers similar to those found in smooth muscle cells. Wound contraction occurs as extensions from the plasma membrane of myofibroblasts establish connections between neighboring cells, contract their fibers, and exert tension on the neighboring cells while anchoring themselves to the wound bed.

Phase III: Remodeling and Maturation

Tissue remodeling and maturation begins several weeks after injury and is normally complete within 2 years. During this phase, there is continuation of cellular differentiation, scar formation, and scar remodeling. The fibroblast is the major cell of tissue remodeling with the deposition of collagen into an organized matrix. Tissue regeneration and wound contraction continue in the remodeling and **maturation phase**—a phase for recovering normal tissue structure that can persist for years. For wounds that heal by scarring, scar tissue

is remodeled and capillaries disappear, leaving the scar avascular. Within 2 to 3 weeks after maturation has begun, the scar tissue has gained about two-thirds of its eventual maximal strength.

Dysfunctional Wound Healing

Dysfunctional wound healing and impaired epithelialization may occur during any phase of the healing process. The causes of dysfunctional wound healing include ischemia; excessive bleeding; excessive fibrin deposition; a predisposing disorder, such as diabetes mellitus; obesity; wound infection; inadequate nutrients; numerous drugs; and tobacco smoke.

Dysfunction during the Inflammatory Response

Oxygen-deprived (ischemic) is susceptible to cellular death and infection, which prolongs inflammation and delays healing. *Ischemia* reduces energy production and impairs collagen synthesis and the tensile strength of regenerating connective tissue.

Healing may be prolonged if bleeding is not stopped during acute inflammation. *Hemorrhage* in a damaged area delays healing for several reasons. Initially the excess blood cells that accumulate at the site of injury must be cleared—a process that requires additional time. Formation of a clot increases the amount of space that granulation tissue must fill and serves as a mechanical barrier to oxygen diffusion. *Hypovolemia*—decreased blood volume—hinders inflammation. The physiologic response to hypovolemia is vessel constriction rather than the dilation required to deliver inflammatory cells to the site of injury. The great amount of fibrin that is deposited during hemorrhage also must eventually be reabsorbed in order to prevent its organization into *fibrous adhesions*. **Adhesions** formed in the pleural, pericardial, or abdominal cavities, can bind organs together by fibrous bands and distort or strangulate the affected organ.

Accumulated blood also serves as an excellent culture medium for bacteria, promoting continued infection and prolonging inflammation by increasing purulent exudate formation. Prolonged infection can

promote *excess scar formation* or even prevent healing completely. Continued infection of a wound, termed *wound sepsis*, can be clinically treated in several ways. Most important is the débridement of necrotic tissue and foreign bodies. This removal is accomplished either through surgery or through the use of absorbent dressings. Wound irrigation and antibiotic therapy also may assist in combating continued infection.

Optimal nutrition is important during all phases of healing because metabolic needs are increased. The most essential nutrients for healing are glucose, oxygen, and amino acids. Leukocytes need glucose to produce the adenosine triphosphate (5'-ATP) needed for chemotaxis, phagocytosis, intercellular killing, and initiation of healing; therefore, the wounds of persons with diabetes who receive insufficient insulin heal poorly. Persons with diabetes also are at risk for ischemic wounds because they are likely to have both small-vessel diseases that impair the microcirculation and altered (glycosylated) hemoglobin, which has an increased affinity for oxygen and thus does not readily release oxygen in tissues. Oxygen delivery is also compromised by hypoxemic states because ischemic tissue is susceptible to infection. *Hypoproteinemia* prolongs inflammation because the associated decrease in available amino acids is an impediment to fibroblast proliferation and collagen synthesis. Other nutrients, including iron, zinc, manganese, copper, and vitamins A and C, also are required as cofactors for collagen synthesis. Malnutrition increases risk for wound infection, delays healing, and reduces wound tensile strength.

Medications, including antineoplastic (anticancer) agents, nonsteroidal antiinflammatory drugs (NSAIDs), and steroids, delay wound healing. Antineoplastic agents slow cell division and inhibit angiogenesis. Although NSAIDs inhibit prostaglandin production and suppress acute inflammation and relieve pain, they also can delay wound healing, particularly bone formation, and may contribute to the formation of excessive scarring. Antiinflammatory steroids prevent macrophages from migrating to the site of injury and inhibit release of collagenase and plasminogen activator. Steroids also inhibit fibroblast migration into the wound during the proliferative phase

and delay epithelialization. Toxic agents in tobacco smoke (i.e., nicotine, carbon monoxide, and hydrogen cyanide) delay wound healing and increase the risk for wound infection.

Dysfunction during the Reconstructive Phase of Healing

Three of the essential processes that occur during the **reconstructive phase** are assembly and remodeling of the collagen matrix, epithelialization of the wound bed, and contraction of the wound. Dysfunctional wound healing can result from the impairment of any of these processes.

Impaired Collagen Matrix Assembly.

A number of factors may interfere with the production of collagen in healing tissues, most being nutritional. Scurvy, for example, is a condition caused by a deficiency in ascorbic acid, one of the cofactors required for the amino acid modification that is necessary for proper collagen matrix assembly. The complication of scurvy is a poorly formed collagen matrix and, therefore, greatly impaired wound healing. Other nutrients, including iron, copper, and calcium, play additional roles in the enzymatic reactions required for collagen modification and assembly. Usually, however, such minute amounts of these substances are required that deficiencies are not clinically significant. Nutritionally, appropriate protein intake is also essential for collagen synthesis. The amino acid methionine that is found in proteins is converted to cysteine, the role of which in collagen synthesis is twofold: (1) it functions as an important cofactor in the enzymatic reactions required for collagen synthesis; and (2) it contains sulfur, which contributes to formation of the strong covalent bonds in cross-linked collagen fibrils.

Dysfunctional collagen synthesis may involve excessive production of collagen, causing surface “overhealing,” leading to a hypertrophic scar or keloid. A hypertrophic scar is raised but remains within the original boundaries of the wound and tends to regress over time (Fig.

7.20, A). A **keloid** is a raised scar that extends beyond the original boundaries of the wound, invades surrounding tissue, and is likely to recur after surgical removal (Fig. 7.20, B). A familial tendency to keloid formation has been observed, with a greater incidence in blacks than whites.

FIGURE 7.20 Hypertrophic Scar and Keloid Scar Formation. Hypertrophic scar (A) and keloid scar (B) caused by excessive synthesis of collagen at suture sites. (A from Flint PW et al: *Cummings otolaryngology: head & neck surgery*, ed 6, Philadelphia, 2015, Mosby; B from Damjanov I, Linder J: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Similar to a keloid, a **hypertrophic scar** is also raised but differs in that it remains within the original boundaries of the wound.

Hypertrophic scars tend to regress over time, whereas keloids do not. Both keloids and hypertrophic scars are caused by an imbalance between collagen synthesis and collagen degradation in which synthesis is increased relative to degradation. Although the precise mechanism of this imbalance is unknown, recent evidence suggests that keloid fibroblasts have lower rates of apoptosis and an inability to respond to normal suppressive feedback.

Impaired Epithelialization.

The process of epithelialization is suppressed by antiinflammatory steroids, hypoxemia, and nutritional deficiencies. Antiinflammatory steroids inhibit phagocyte production of the biochemical mediators required for epithelialization, hypoxemia deprives cells of the energy required for the process, and dietary zinc is necessary for the MMP activity that is crucial to cellular migration.

Wound care techniques also may greatly influence epithelial cell migration. External wounds that are draining or healing by secondary intention often are clinically débrided and protected with dressings. The ideal dressing is one that absorbs some drainage without being incorporated into the clot or granulation tissue. Because epithelial cells must migrate across the wound during healing, dressings that débride healthy epithelial cells along with necrotic tissue prolong epithelialization. Many solutions that traditionally have been used to clean or irrigate wounds are now known to be deleterious to the fragile new cells in the wound bed. Normal saline is the most innocuous solution that can be used to cleanse or irrigate a wound that is healing primarily by epithelialization. Solutions such as povidone-iodine and hydrogen peroxide are desiccating (drying) and, as such, inhibit rather than promote epithelial cell migration.

Impaired Contraction.

Excessive wound contraction may result in a deformity or **contracture**. Burn wounds are especially susceptible to the development of contractures. Internal contractures may occur as well, and are common in cirrhosis of the liver. Internally, scar tissue that becomes

contracted constricts blood flow that may contribute to the development of portal hypertension and esophageal varices. Other types of internal contraction deformity include duodenal strictures caused by dysfunctional healing of an ulcer and esophageal strictures caused by chemical burns.

Proper positioning and range-of-motion exercises, as well as surgery, are among the physical means used to overcome the excessive myofibroblast-derived tension that results in contractures. Clinical use of pharmacologic methods for control of wound contracture is still largely experimental, but includes control of myofibroblast contraction by the administration of smooth muscle cell inhibitors such as colchicine and inhibition of proper collagen matrix assembly with drugs that prevent either collagen cross-linking or MMP activity. These latter treatments are based on the knowledge that myofibroblast binding to collagen can “lock” contracted cells into position.

Wound Disruption

Finally, a potential complication in the healing of wounds that are sutured closed is **dehiscence**, in which the wound pulls apart at the suture line. The greatest incidence of dehiscence occurs 5 to 12 days after suturing, paradoxically at the time when collagen synthesis is at its peak. Approximately 50% of dehiscence occurrences are associated with wound sepsis, although dehiscence also may occur when sutures break as a result of excessive strain. Obesity increases the risk of suture breakage because adipose tissue is difficult to suture. Wound dehiscence usually is heralded by an increase in serous drainage from the wound. In addition, patients may report a feeling that “something gave way.” Prompt surgical attention is required.

Pediatrics: Innate Immunity in the Newborn Child

Neonates commonly have transiently depressed inflammatory and

immune function since they are being born from a sterile environment. For example, neutrophils and perhaps monocytes may not be capable of efficient chemotaxis. Insufficient response to chemotactic factors appears to be caused by lack of fluidity in the phagocyte's plasma membrane so that pseudopod formation and migration are impaired. Neonates are prone to infections associated with chemotactic defects, including cutaneous abscesses caused by staphylococci and cutaneous candidiasis. Further, neutrophils in neonates who were stressed by in utero infection or respiratory insufficiency have diminished oxidative and bacterial responses. (Acquired phagocytic defects, which may be induced by a variety of infections, metabolic disorders, nutrition deficiencies, or drugs, are described in [Chapter 9](#).)

Neonates also are partially deficient in complement, especially components of the alternative pathway. They tend to have a relative deficiency of factor B and to develop severe, overwhelming sepsis and meningitis when infected with bacteria against which there is no transferred maternal antibody. Low levels of mannose-binding lectin increase the risk for neonatal hospital-acquired sepsis. Neonates also may be deficient in some of the collectins and collectin-like proteins. This is especially true of preterm neonates. Some preterm infants with respiratory distress syndrome are deficient in at least one collectin, which provides innate defense against respiratory tract infections.

Aging: Innate Immunity in the Older Adult Population

The older adult population is also at risk for impaired inflammation and wound healing. In some cases, impaired healing is not directly associated with aging in general but can instead be linked to a chronic illness, such as cardiovascular disease or diabetes mellitus.⁴² Aging also alters the tissue microenvironment and macrophage function with changes in wound healing neoangiogenesis and fibrosis.⁴³ In addition, many older adults require medications such as

antiinflammatory steroids that can interfere with the healing process.

Older adults have increased susceptibility to bacterial infections of the lungs, urinary tract, and skin. Because of impaired sensation or mobility and physiologic changes in the skin, older adults are at increased risk for sustaining various wounds. With aging, subcutaneous fat is lost, diminishing a layer of protection. Collagen fibers become thicker and a certain percentage of elastin is lost, further contributing to loss of protection. The regenerative capability of the skin is maintained with aging, but the epidermis undergoes age-associated changes that include atrophy of the underlying capillaries. The consequent decrease of perfusion makes older adults more susceptible than younger people to the adverse effects of hypoxia in the wound bed. In addition, aging fibroblasts may have a slower rate of proliferation, and therefore wound healing is attenuated.

Immunosenescence affects both innate and adaptive immune systems, limiting responses to both infections and vaccines. Several cellular components of innate resistance are deficient in number (e.g., alveolar macrophages) or have diminished activity (e.g., neutrophil chemotaxis, degranulation, and phagocytosis). One explanation for this diminished inflammatory cellular activity is an age-related decrease in expression and function of several, if not all, TLRs. Alterations in T cells and NK cells also occur. The levels of proinflammatory cytokines (e.g., IL-6, TNF- α , and IL-1 β) are elevated with aging and can contribute to systemic disease.^{44,45}

Summary Review

Human Defense Mechanisms

1. There are three layers of human defense: barriers; innate immunity, which includes the inflammatory response; and adaptive (acquired) immunity.

First Line of Defense: Physical, Mechanical, and

Biochemical Barriers and Normal Microbiome

1. Physical and mechanical barriers are the first lines of defense that prevent damage to the individual and prevent invasion by pathogens; these include the skin and mucous membranes.
2. Antibacterial peptides in mucous secretions, perspiration, saliva, tears, and other secretions provide a biochemical barrier against pathogenic microorganisms.
3. The normal bacterial flora provides protection by releasing chemicals that prevent colonization by pathogens.

Second Line of Defense: Inflammation

1. Inflammation is a rapid and nonspecific protective response to cellular injury from any cause. It can occur only in vascularized tissue.
2. The macroscopic hallmarks of inflammation are redness, swelling, heat, pain, and loss of function of the inflamed tissues.
3. The microscopic hallmark of inflammation is an accumulation of fluid and cells at the inflammatory site.
4. Inflammation is mediated by three key plasma protein systems: the complement system, the clotting system, and the kinin system. The components of all three systems are a series of inactive proteins that are activated sequentially.
5. The complement system can be activated by antigen-antibody reactions (through the classical pathway) or by other products, especially bacterial polysaccharides (through the lectin pathway or the alternative pathway), resulting in the production of biologically active fragments and the destruction of cells.
6. The most biologically potent products of the complement system are C3b (opsonin), C3a (anaphylatoxin), and C5a (anaphylatoxin, chemotactic factor).
7. The clotting system stops bleeding, localizes microorganisms,

and provides a meshwork for repair and healing.

8. Bradykinin is the most important product of the kinin system and causes vascular permeability, smooth muscle contraction, and pain.
9. Many different types of cells are involved in the inflammatory process including mast cells, endothelial cells, platelets, phagocytes (neutrophils, eosinophils, monocytes and macrophages, dendritic cells), natural killer (NK) cells, and lymphocytes.
10. Most cells express plasma membrane pattern recognition receptors (PRRs) that recognize molecules produced by infectious microorganisms (pathogen-associated molecular patterns, or PAMPs), or products of cellular damage (damage-associated molecular patterns, or DAMPs).
11. The cells of the innate immune system secrete many biochemical mediators (cytokines) that are responsible for activating other cells; these cytokines include interleukins, chemokines, interferons, and other molecules.
12. The most important proinflammatory cytokines are IL-1, IL-6, and tumor necrosis factor-alpha (TNF- α).
13. Interferons are produced by cells that are infected by viruses. Once released from infected cells, interferons can stimulate neighboring healthy cells to produce substances that prevent viral infection.
14. Chemokines are synthesized by a number of different cells and induce leukocyte chemotaxis.
15. The most important activator of the inflammatory response is the mast cell, which initiates inflammation by releasing biochemical mediators (histamine, chemotactic factors) from preformed cytoplasmic granules and synthesizing other mediators (prostaglandins, leukotrienes) in response to a stimulus.
16. Histamine is the major vasoactive amine released from mast cells. It causes dilation of capillaries and retraction of endothelial cells lining the capillaries, which increases

vascular permeability.

17. The endothelial cells lining the circulatory system (vascular endothelium) normally regulate circulating components of the inflammatory system and maintain normal blood flow by preventing spontaneous activation of platelets and members of the clotting system.
18. During inflammation the endothelium expresses receptors that help leukocytes leave the vessel and retract to allow fluid to pass into the tissues.
19. Platelets interact with the coagulation cascade to stop bleeding and release a number of mediators that promote and control inflammation.
20. The polymorphonuclear neutrophil (PMN), the predominant phagocytic cell in the early inflammatory response, exits the circulation by diapedesis through the retracted endothelial cell junctions and moves to the inflammatory site by chemotaxis.
21. Eosinophils release products that control the inflammatory response and are the principal cell that kills parasitic organisms.
22. The macrophage, the predominant phagocytic cell in the late inflammatory response, is highly phagocytic, is responsive to cytokines, and promotes wound healing.
23. Dendritic cells connect the innate and acquired immune systems by collecting antigens at the site of inflammation and transporting them to sites, such as the lymph nodes, where immunocompetent B and T cells reside.
24. Phagocytosis is a multistep cellular process for the elimination of pathogens and foreign debris. The steps include recognition and attachment, engulfment, formation of a phagosome and phagolysosome, and destruction of pathogens or foreign debris. Phagocytic cells engulf microorganisms and enclose them in phagocytic vacuoles (phagolysosomes), within which toxic products (especially metabolites of oxygen) and degradative lysosomal enzymes kill and digest the microorganisms.

25. Opsonins, such as antibody and complement component C3b, coat microorganisms and make them more susceptible to phagocytosis by binding them more tightly to the phagocyte.

Local Manifestations of Inflammation

1. Local manifestations of inflammation are the result of the vascular changes associated with the inflammatory process, including vasodilation and increased capillary permeability. The symptoms include redness, heat, swelling, and pain.

Systemic Manifestations of Acute Inflammation

1. The principal systemic effects of inflammation are fever and increases in levels of circulating leukocytes (leukocytosis) and plasma proteins (acute-phase reactants).

Chronic Inflammation

1. Chronic inflammation can be a continuation of acute inflammation that lasts 2 weeks or longer. It also can occur as a distinct process without much preceding acute inflammation.
2. Chronic inflammation is characterized by a dense infiltration of lymphocytes and macrophages. The body may wall off and isolate the infection to protect against tissue damage by formation of a granuloma.

Wound Healing

1. Resolution (regeneration) is the return of tissue to nearly normal structure and function. Repair is healing by scar tissue formation.
2. Damaged tissue proceeds to resolution (restoration of the original tissue structure and function) if little tissue has been

lost or injured tissue is capable of regeneration. This is called healing by primary intention.

3. Tissues that sustained extensive damage or those incapable of regeneration heal by the process of repair, resulting in the formation of a scar. This is called healing by secondary intention.
4. Resolution and repair occur in two separate phases: the reconstructive phase in which the wound begins to heal and the maturation phase in which the healed wound is remodeled.
5. Dysfunctional wound healing can be related to ischemia, excessive bleeding, excessive fibrin deposition, a predisposing disorder (such as diabetes mellitus), wound infection, inadequate nutrients, numerous drugs, or altered collagen synthesis.
6. Dehiscence is a disruption in which the wound pulls apart at the suture line.
7. A contracture is a deformity caused by the excessive shortening of collagen in scar tissue.

Pediatrics: Innate Immunity in the Newborn Child

1. Neonates often have transiently depressed inflammatory function, particularly neutrophil chemotaxis and alternative complement pathway activity.

Aging: Innate Immunity in the Older Adult Population

1. Older adults are at risk for impaired wound healing, usually because of chronic illnesses.
2. Alterations in both the innate and the adaptive immune systems occur with aging and affect responses to inflammation, infection, and vaccination.

AGING and Immune Function, 251

The third line of defense in the human body is **adaptive (acquired) immunity**, often called the immune response or **immunity**, and consists of **lymphocytes** (Fig. 8.1) and serum proteins called *antibodies*. Once constitutive protective mechanisms at external barriers (first line of defense) have been compromised and inflammation (see Chapter 7) has been activated (second line of defense), the adaptive immune response is called into action. Thus inflammation is the “first responder” that contains the initial injury and slows spread of infection, whereas adaptive immunity is the “secondary responder” that augments the initial defenses against infection and provides long-term security against reinfection. Innate immunity, especially inflammation, and adaptive immunity are highly interactive and complementary. Components of innate resistance are necessary for the development of the adaptive immune response. Conversely, products of the adaptive immune response activate components of the innate immune system. Thus both systems are essential for complete protection against infectious disease.

FIGURE 8.1 Scanning Electron Micrograph Showing Lymphocytes (Yellow), Red Blood Cells, and Platelets. (Copyright Dennis Kunkel Microscopy, Inc.)

Inflammation and adaptive immunity differ in several key ways. First, adaptive immunity develops more slowly than inflammation. The components of inflammation preexist in the blood and tissues and are activated immediately after and as a result of tissue damage. Adaptive immunity is *inducible*. The effectors of the immune response, lymphocytes and antibodies, do not preexist but must be produced in response to infection. Second, each inflammatory response is similar (although not identical) regardless of differences in the cause of tissue damage or whether the inflammatory site is sterile or contaminated with microorganisms. The adaptive immune response is exquisitely *specific*. The lymphocytes and antibodies induced in response to a particular infectious agent are extremely specific to that agent. A different infectious agent will induce a different battery of lymphocytes and antibodies. Third, the residual mediators of inflammation must be removed quickly to limit damage to surrounding healthy tissue and allow healing. The effectors of the adaptive immune response are *long-lived* and systemic, providing long-term protection against a specific infectious agent. Fourth, activation of the inflammatory response to recurrent tissue damage or repeated infection with the same microorganism is generally identical.

The adaptive immune response has *memory*. If reinfected with the same microorganism, protective lymphocytes and antibody are produced rapidly, thus providing permanent long-term protection. Thus the adaptive immune response is distinguished by being inducible, specific, and long-lived, and by having memory.

The collaborative and beneficial nature of inflammation and adaptive immunity can, on occasion, fail. [Chapter 9](#) discusses these medically relevant aberrations in both inflammation and immunity, including allergies, diseases that involve unwanted immunologic destruction of healthy tissue, and diseases that are caused by a deficiency in the normal immune or inflammatory responses. [Chapter 10](#) presents an overview of infection and [Chapter 11](#) discusses the connection between stress and disease and the interrelatedness of the immune, nervous, and endocrine systems.

General Characteristics of Adaptive Immunity

The adaptive immune system has its own vocabulary ([Fig. 8.2](#)). The immune system of the normal adult is continually challenged by a spectrum of substances that it may recognize as foreign, or “nonself.” These substances, called *foreign antigens*, are often associated with pathogens such as viruses, bacteria, fungi, or parasites, although they are also found on noninfectious environmental agents such as pollens, foods, and bee venom, and still others are associated with clinically derived drugs, vaccines, transfusions, and transplanted tissues ([Table 8.1](#)). The products (i.e., effectors) of the adaptive immune response include antibodies (sometimes called **immunoglobulins**) and lymphocytes that are specific for particular antigens.

FIGURE 8.2 Overview of Immune Response. The immune response can be separated into two phases: the *generation of clonal diversity* and *clonal selection*. During the generation of clonal diversity, lymphoid stem cells from the bone marrow migrate to the central lymphoid organs (the thymus or regions of the bone marrow), where they undergo a series of cellular division and differentiation stages resulting in either immunocompetent T cells from the thymus or immunocompetent B cells from the bone marrow. (This process is outlined in more detail in Figs. 8.9 and 8.12.) These cells are still naïve in that they have never encountered foreign antigen. The immunocompetent cells enter the circulation and migrate to the secondary lymphoid organs (e.g., spleen and lymph nodes), where they take up residence in B- and T-cell-rich areas. The clonal selection phase is initiated by exposure to foreign antigen. The antigen is usually processed by antigen-presenting cells (APCs) for presentation to helper T cells (Th cells) (more detail in Fig. 8.16). The intercellular cooperation among APCs, Th cells, and immunocompetent T and B cells results in a second stage of cellular proliferation and differentiation (more details in Figs. 8.18 and 8.21). Because antigen has “selected” those T and B cells with compatible antigen receptors, only a small population of T and B cells undergoes this process at one time. The result is an active cellular immunity or humoral immunity, or both. Cellular immunity is mediated by a population of “effector” T cells that can kill targets (cytotoxic T cells) or regulate the immune response (T-regulatory cells), as well as a population of memory cells (memory T cells) that can respond more quickly to a second challenge with the same antigen. Humoral immunity is mediated by a population of soluble proteins (antibodies) produced by plasma cells and by a population of memory B cells that can produce more antibody rapidly to a second challenge with the same antigen.

TABLE 8.1

CLONAL SELECTION OF ANTIGEN OR ANTIBODY

CLINICAL USE OF ANTIGEN OR ANTIBODY

ANTIGEN SOURCE	PROTECTION: COMBAT ACTIVE DISEASE	PROTECTION: VACCINATION	DIAGNOSIS	THERAPY
Infectious agents	Neutralize or destroy pathogenic microorganisms (e.g., antibody response against viral infections)	Induce safe and protective immune response (e.g., recommended childhood vaccines)	Measure circulating antigen from infectious agent or antibody (e.g., diagnosis of hepatitis B infection)	Passive treatment with antibody to treat or prevent infection (e.g., administration of antibody against hepatitis A)
Cancers	Prevent tumor growth or spread (e.g., immune surveillance to prevent early cancers)	Prevent cancer growth or spread (e.g., vaccination with cancer antigens)	Measure circulating antigen (e.g., circulating PSA for diagnosis of prostate cancer)	Immunotherapy (e.g., treatment of cancer with antibodies against cancer antigens)
Environmental substances	Prevent entrance into body (e.g., secretory IgA limits systemic exposure to potential allergens)	No clear example	Measure circulating antigen or antibody (e.g., diagnosis of allergy by measuring circulating IgE)	Immunotherapy (e.g., administration of antigen for desensitization of individuals with severe allergies)
Self-antigens	Immune system tolerance to self-antigens, which may be altered by an infectious agent leading to autoimmune disease (see Chapter 9)	Some cases of vaccination alter tolerance to self-antigens leading to autoimmune disease	Measure circulating antibody against self-antigen for diagnosis of autoimmune disease (see Chapter 9)	No clear example

IgA, Immunoglobulin A; *PSA*, prostate-specific antigen.

Specificity and memory are primary characteristics that differentiate

the immune response from other protective mechanisms. This chapter first discusses the nature of that specificity by defining the various types of antigens recognized by the immune system, the ways in which they are recognized by antibodies and lymphocytes, and the specific intercellular recognition molecules that are necessary for effective immune responses. After the recognition molecules are defined, the development of the immune response is discussed. An immune response can be divided into two phases (see [Fig. 8.2](#)). In the fetus, well before being exposed to any infectious microorganisms, lymphocytes undergo extensive differentiation and proliferation. These events occur in the primary lymphoid organs (thymus and bone marrow). Some lymphoid stem cells in humans enter the thymus and differentiate into **T lymphocytes (T cells**, T indicating thymus derived) and others enter specific regions in the bone marrow and differentiate into **B lymphocytes (B cells**, B indicating bone marrow derived). Each type of cell develops origin-specific cell surface proteins that identify them as T or B cells. Both B and T cells also develop cell surface antigen receptors. The receptors are remarkable because an individual B or T cell is programmed to recognize only one specific antigen before having encountered that antigen. It is estimated that each person has produced a population of B and T cells with an extensive diversity of antigen receptors capable of recognizing at least 10^8 different antigens. This process is called **generation of clonal diversity** (see [Fig. 8.2](#)).

Lymphocytes leave the primary lymphoid organs as immunocompetent but naïve B and T cells. They are **immunocompetent** in that they have the capacity to respond to antigen, but naïve in that they have not yet encountered antigen. These cells enter the blood and lymphatic vessels and migrate to the secondary lymphoid organs (e.g., lymph nodes, spleen) of the systemic immune system ([Fig. 8.3](#)). Some take up residence in B-cell- and T-cell-rich areas of those organs and others reenter the circulation. Approximately 60% to 70% of circulating lymphocytes are immunocompetent T cells, and 10% to 20% are immunocompetent B cells.

FIGURE 8.3 Lymphoid Tissues: Sites of B-Cell and T-Cell Differentiation. Immature lymphocytes migrate through central (primary) lymphoid tissues: the bone marrow (central lymphoid tissue for B lymphocytes) and the thymus (central lymphoid tissue for T lymphocytes). Mature lymphocytes later reside in the T- and B-lymphocyte-rich areas of the peripheral (secondary) lymphoid tissues.

The second phase, called **clonal selection**, is initiated by exposure to foreign antigen usually related to infection (see Fig. 8.2). Antigen reacts with, or selects, clones of B and T cells with surface receptors against that specific antigen and initiates a process of further differentiation and proliferation into mature effector cells. The process requires the cooperation among a variety of cells in the secondary lymphoid organs; most antigens need to be processed (antigen processing) by phagocytic cells, primarily dendritic cells, that also present the processed antigen on their surfaces and present (**antigen presentation**) the antigen to lymphocytes. These cells are generally called antigen-processing or **antigen-presenting cells (APCs)**. Thus

begins a symphony of cellular interactions that define clonal selection, involving APCs and several subsets of B and T cells, intercellular adhesion through antigen receptors and specific intercellular adhesion molecules, the production and response to multiple cytokines, and eventual differentiation of immunocompetent B and T cells into highly specialized effector cells. B cells develop into plasma cells that become factories for the production of antibody. T cells develop into several subsets that identify and kill a target cell (**T-cytotoxic cell [Tc cell]**), regulate the immune response by helping the clonal selection process (**T-helper cell [Th cell]**), or suppress or limit the immune response (**T-regulatory cell [Treg cell]**). Both B and T cells also differentiate into very long-lived **memory cells** that exist for decades or, in some cases, the life of the individual. Memory cells “remember” the initial antigen and are rapidly activated if a second exposure occurs to the same microorganism.

Humoral and Cell-Mediated Immunity

The immune response has two arms: antibody and T cells, both of which protect against infection. Antibody circulates in the blood and in secretions and defends against extracellular microbes found in those fluids and microbial toxins. This interaction can result in direct inactivation of the microorganism or activation of a variety of inflammatory mediators (e.g., complement, phagocytes) that will destroy the pathogen. Antibody is primarily responsible for protection against many bacteria and viruses. This arm of the immune response is termed the humoral immune response, or **humoral immunity**.

Effector T cells are found in the blood and in tissues and organs and defend against intracellular pathogens (e.g., some viruses) and cancer cells. T cells may produce cytokines that stimulate the protective response of other leukocytes. Others develop into Tc cells that attack and kill cellular targets directly. This arm of the immune response is termed the cellular immune response, or **cellular immunity**. The humoral and cellular immune responses are interdependent at many levels. In the end, the success of an acquired immune response depends on the functions of both the humoral and the cellular

responses, as well as the appropriate interactions between them.

Active vs. Passive Immunity

Adaptive immunity can be either active or passive, depending on whether the antibodies or T cells are produced by the individual in response to antigen or are administered directly. **Active immunity (active acquired immunity)** is produced by an individual either after natural exposure to an antigen or after immunization, whereas **passive immunity (passive acquired immunity)** does not involve the host's immune response at all. Rather, passive immunity occurs when preformed antibodies or T lymphocytes are transferred from a donor to the recipient. This can occur naturally, as in the passage of maternal antibodies across the placenta to the fetus, or artificially, as in a clinic using immunotherapy for a specific disease. Unvaccinated individuals who are exposed to particular infectious agents (e.g., hepatitis A virus, rabies virus) often will be given immunoglobulins that are prepared from individuals who already have antibodies against that particular pathogen (see [Table 8.1](#)). Whereas active acquired immunity is long-lived, passive immunity is only temporary because the donor's antibodies or T cells are eventually destroyed.

Recognition and Response

The foundation of any successful immune response is the specific recognition of antigen by antibody or receptors on the surface of B or T cells, followed by a set of complex intercellular communications among a variety of APCs and lymphocytes. To fully understand the immune response, it is necessary to initially understand the basis for that recognition. Many of the molecules discussed in this chapter are part of a nomenclature that uses the prefix “CD” followed by a number (e.g., CD1 or CD2) ([Table 8.2](#)). The definition of the **CD (cluster of differentiation)** format has changed over time. It was originally used to describe proteins found on the surface of lymphocytes. Currently, CD is the accepted format for labeling a very

large family of proteins found on the surface of many cells. Many have alternative names related to their function, which may be used in this chapter. The list of identified molecules is constantly increasing (the number of molecules with a CD designation is probably in excess of 370). In a similar fashion, the list of known cytokines is continually growing, with more than 70 having been identified so far. A large number of CD molecules and cytokines contribute to the acquired immune response. This book attempts to focus on a small number of highly important examples to illustrate the immensely complicated, but highly effective, interactions that take place to produce a protective immune response.

TABLE 8.2

SELECT CD MOLECULES AND THEIR FUNCTIONS

CD MOLECULES	PRIMARY LOCATION	FUNCTIONS
CD1	APCs	Presents lipid antigens
CD2	All T cells, NK cells	T-cell marker; adhesion molecule that binds to CD58 (LFA-3) and provides a costimulatory signal
CD3	All T cells	Associated with TCR and provides intracellular signaling
CD4	Th cells	Binds to MHC class II as co-receptor with the TCR
CD8	Tc cells	Binds to MHC class I as co-receptor with the TCR
CD19	B cells	Complexes with CD21 to form a co-receptor for B cells
CD20	B cells	Major regulator of B-cell function
CD21	B cells	Receptor for complement that complexes with CD19 to form a co-receptor for B cells
CD25	Activated T cells	α chain of IL-2 receptor
CD28	T cells	Adhesion molecule that binds to CD80 to provide costimulatory signal for Tc cells
CD40	B cells, macrophages	Adhesion molecule that binds to CD154 to provide costimulatory signal for B cells
CD45	All lymphocytes	Has multiple types; augments antigen signal
CD58 (LFA-3)	Most cells	Adhesion molecule that binds to CD2 to provide a costimulatory signal
CD80 (B7-1)	APCs	Adhesion molecule that binds to CD28 to provide a costimulatory

		signal
CD154 (CD40L)	Th2 cells	Adhesion molecule that binds to CD40 to provide a costimulatory signal

APCs, Antigen-presenting cells; *IL*, interleukin; *MHC*, major histocompatibility complex; *NK*, natural killer; *Tc*, cytotoxic; *TCR*, T-cell receptor; *Th*, T-helper.

Antigens and Immunogens

Initially, we need to understand the molecules against which an immune response is directed. Although the terms antigen and immunogen are commonly used as synonyms, there are clinically important differences between the two. **Antigen** is a commonly used term to describe a molecule that can *react with* binding sites on antibodies or antigen receptors on B and T cells. Most, but not all, antigens are also **immunogens**. An antigen that is **immunogenic** will *induce* an immune response, resulting in the production of antibodies or functional T cells. Thus a substance may be antigenic yet not be immunogenic.

The precise portion of the antigen that is configured for recognition and binding is called its **antigenic determinant**, or **epitope**. The matching portion on the antibody or the lymphocyte receptor is sometimes referred to as the *antigen-binding site*, or **paratope**. The size of an antigenic determinant is relatively small, perhaps just a few amino acids or carbohydrate residues on the surface of a large molecule (Fig. 8.4). Antigenic determinants may be linear or conformational. For instance, linear antigenic determinants consist of amino acids (or other chemicals) that are adjacent in the molecule's primary structure; thus they are stable when the molecule is denatured. Conformational antigenic determinants consist of amino acids that are only adjacent when the molecule is folded appropriately. When the molecule is denatured or processed, that antigenic determinant is destroyed. Therefore macromolecules (e.g., proteins, polysaccharides, nucleic acids) usually contain multiple and diverse antigenic determinants, and the immune response against the macromolecule will usually consist of a mixture of specific antibodies against several of these determinants.

FIGURE 8.4 Antigenic Determinants (Epitopes). Shown are generic examples of linear epitopes on protein (A) and polysaccharide (B) molecules and conformational epitopes on protein (C). In A, an antigenic protein may have multiple different epitopes (epitopes 1 and 2) that react with different antibodies. Each sphere represents an amino acid, with the yellow spheres representing epitope 1 and the red spheres representing epitope 2. Individual epitopes may consist of eight or nine amino acids. In B, a polysaccharide is constructed of a backbone with branched side chains. Each sphere represents an individual carbohydrate, with the yellow spheres representing the carbohydrates that form the epitope. In this example, two identical epitopes are shown that would bind two identical antibodies. In C, an epitope consists of amino acids from different portions of the primary sequence that are placed near each other during folding of the molecule. When the molecule is denatured, the epitope is destroyed.

Certain criteria influence the degree to which an antigen is

immunogenic. These include (1) being foreign to the host, (2) being appropriate in size, (3) having an adequate chemical complexity, and (4) being present in a sufficient quantity.

Foremost among the criteria for immunogenicity is the antigen's foreignness. A **self-antigen** is part of the individual's makeup that fulfills all these criteria *except* foreignness and does not normally elicit an immune response. Thus most individuals are *tolerant* to their own antigens. The immune system has an exquisite ability to distinguish self (self-antigens) from nonself (foreign antigens). Tolerance was once thought to be a state of nonresponsiveness in which the immune system passively allowed self-antigens to persist, but tolerance is now known to have a variety of mechanisms. In some cases, a state of central tolerance exists, in which lymphocytes with receptors against self-antigens have been eliminated during generation of clonal diversity. In other cases, tolerance is peripheral tolerance that is mediated by Treg cells (see [Fig. 8.2](#)). Rather than merely tolerating some self-antigens, the immune system actively prevents or limits their recognition by lymphocytes and antibodies. Some pathogens have developed a survival advantage by their capacity to mimic self-antigens and avoid inducing an immune response.

Molecular size also contributes to an antigen's immunogenicity. In general, large molecules (those bigger than 10,000 daltons), such as proteins, polysaccharides, and nucleic acids, are most immunogenic. Low-molecular-weight molecules, such as amino acids, monosaccharides, fatty acids, and the purine and pyrimidine bases, tend to be unable to induce an immune response. Many small molecules can function as **haptens**: antigens that are too small to be immunogenic by themselves but become immunogenic after binding with larger molecules that function as **carriers** for the hapten. For example, the antigens of penicillin (a β -lactam antibiotic of about 243 daltons) and poison ivy (which contains urushiol, an oily sap of about 1500 daltons) are haptens, but they initiate allergic responses only after binding to large-molecular-weight proteins in the allergic individual's blood or skin. Antigens that induce an allergic response are also called **allergens**. Allergic conditions are discussed in [Chapter](#)

9.

Chemical complexity affects immunogenicity. The best immunogens contain a diversity of chemically different components. For instance, a large synthetic protein consisting only of the amino acid alanine would not be very immunogenic despite its size and foreignness. However, if other amino acids, such as tyrosine, tryptophan, or phenylalanine, were inserted into the structure, the degree of immunogenicity would increase greatly.

Finally, antigens that are present in extremely small or large quantities may be unable to elicit an immune response and therefore by definition are also nonimmunogenic. In many cases, exposure to high or low extremes of antigen quantities may induce a state of tolerance rather than immunity.

Even if an antigen fulfills all these criteria, the quality and intensity of the immune response may still be affected by a variety of additional factors. For example, the route and vehicle of antigenic entry or administration are critical to the immunogenicity of some antigens. This has important clinical implications. The most common routes for clinical administration of antigen, such as vaccines, are intravenous, intraperitoneal, subcutaneous, intranasal, and oral. Each route preferentially stimulates a different set of lymphocyte-containing (lymphoid) tissues and therefore results in the induction of different types of cell-mediated or humoral immune responses. For some vaccines, the route may affect the protectiveness of the immune response so that the individual is protected if immunized by one route, but may remain susceptible to infection if administered through a different route. Immunogenicity of an antigen also may be altered by being delivered along with substances that stimulate the immune response; these substances are known as *adjuvants*. Finally, the genetic makeup of a host can play a critical role in the immune system's ability to respond to many antigens; some individuals appear to be unable to respond to immunization with a particular antigen, whereas they respond well to other antigens. For instance, a small percentage of the population may fail to produce a measurable immune response to a common vaccine, despite multiple injections, whereas they will

respond well to a different vaccine. Many other factors can modulate the immune response. These include the individual's age, nutritional status, and reproductive status, as well as the exposure to traumatic injury, the presence of concurrent disease, or the use of immunosuppressive medications. These are discussed further in [Chapter 9](#).

Molecules That Recognize Antigen

Antigen is directly recognized by three molecules: circulating antibody and antigen receptors on the surface of B lymphocytes (**B-cell receptor**, or **BCR**) and T lymphocytes (**T-cell receptor**, or **TCR**) ([Fig. 8.5](#)).

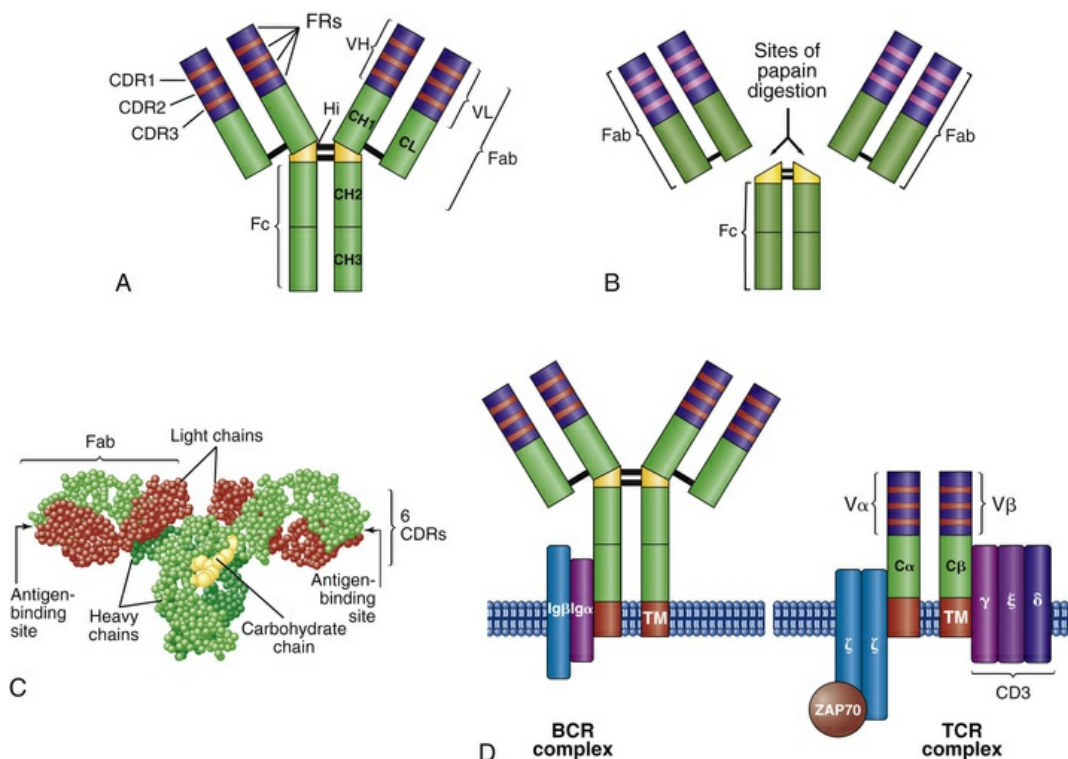

FIGURE 8.5 Antigen-Binding Molecules. Antigen-binding molecules include soluble antibody (A, B, C) and cell surface receptors (D). A, The typical antibody molecule consists of two identical heavy chains and two identical light chains connected by interchain disulfide bonds (– between chains in the figure). Each heavy chain is divided into three regions with relatively constant amino acid sequences (*CH1*, *CH2*, and *CH3*) and a region with a variable amino acid sequence (*VH*). Each light chain is divided into a constant region (*CL*) and a variable region (*VL*). The hinge

region (*Hi*) provides flexibility in some classes of antibody. Within each variable region are three highly variable complementary-determining regions (*CDR1*, *CDR2*, *CDR3*) separated by relatively constant framework regions (*FRs*). B, Fragmentation of the antibody molecule by limited digestion with the enzyme papain has identified three important portions of the molecule: a fragment crystallizable (*Fc*) and two identical fragment antigen binding (*Fab*) fragments. Both *Fab* fragments bind antigen. As the antibody folds (*C*), the *CDRs* are placed in proximity to form the antigen-binding site. D, The antigen receptor on the surface of B cells (*BCR complex*) is a monomeric antibody with a structure similar to that of circulating antibody, with an additional hydrophobic transmembrane region (*TM*) that anchors the molecule to the cell surface. The active *BCR* complex contains molecules (*Igα* and *Igβ*) that are responsible for intracellular signaling after the receptor has bound antigen. The T-cell receptor (*TCR*) consists of an α chain and a β chain joined by a disulfide bond. Each chain consists of a constant region (*Cα* and *Cβ*) and a variable region (*Vα* and *Vβ*). Each variable region contains *CDRs* and *FRs* in a structure similar to that of antibody. The active *TCR* is associated with several molecules that are responsible for intracellular signaling. These include *CD3*, which is a complex of γ (gamma), ϵ (epsilon), and δ (delta) subunits, and a complex of two ζ (zeta) molecules. The ζ molecules are attached to a cytoplasmic protein kinase (*ZAP70*) that is critical to intracellular signaling. (C adapted from Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

Antibody

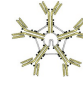

An understanding of antibodies and how they react with antigen will provide a foundation for more complex topics, such as the B-cell and T-cell receptors for antigen. An **antibody**, or immunoglobulin, is a serum glycoprotein produced by plasma cells in response to a challenge by an immunogen. The term *immunoglobulin* is used as a generic description of a general group of antibodies, whereas the term *antibody* commonly denotes one particular set of immunoglobulins known to have specificity for a specific antigen.

Classes.

There are five molecular classes of immunoglobulins (*IgG*, *IgA*, *IgM*, *IgE*, and *IgD*) that are characterized by differences in antigenicity, structure, and function. Within two of the immunoglobulin classes are several distinct subclasses including four subclasses of *IgG* and two subclasses of *IgA* (Table 8.3).

TABLE 8.3

PROPERTIES OF IMMUNOGLOBULINS

	IgG	IgM	IgA	sIgA
				
Physiochemical Properties of Immunoglobulins				
Subclasses	IgG1, IgG2, IgG3, IgG4	IgM	IgA1, IgA2	IgA1,
Heavy chain	$\gamma_1, \gamma_2, \gamma_3, \gamma_4$	μ	α_1, α_2	α_1, α_2
MW	146,000	970,000	160,000	385,000
Serum levels*	850, 290, 95, 50	135	290, 50	5
Biologic Properties of Immunoglobulins				
Complement activation	Yes IgG3 > IgG1 > IgG2	Yes	No	No
Fc binds to phagocytes	Yes IgG1, IgG3	No	No	No
Fc binds to mast cells	Yes IgG4	No	No	No
Fc binds to platelets	Yes	No	No	No
Placental transfer	Yes IgG1 = IgG3 > IgG4 > IgG2	No	No	No
Biologic Function				
	Toxin neutralization, complement activation, opsonization, long-term immunity	Initial antibody produced, agglutination, complement fixation, B-cell receptor	Neutralization	In secretions, neonatal

* Average adult levels (mg/dL) arranged by subclass.

Fc, Fragment crystallizable; *MW*, molecular weight in daltons.

IgG is the most abundant class of immunoglobulins, constituting 80% to 85% of those circulating in the body and accounting for most of the protective activity against infections (see [Table 8.3](#)). Maternal IgG is transported across the placenta during pregnancy and protects the newborn child during the first 6 months of life. Four subclasses of IgG

have been described: IgG1, IgG2, IgG3, and IgG4.

IgA can be divided into two subclasses, IgA1 and IgA2. IgA1 molecules are found predominantly in the blood, whereas IgA2 is the predominant class of antibody found in normal body secretions (**secretory IgA [sIgA]**). sIgA molecules are dimers anchored together through a J chain and “secretory piece.” This secretory piece is attached to the IgA dimer inside mucosal epithelial cells and protects these immunoglobulins against degradation by enzymes also found in the secretions.

IgM is the largest of the immunoglobulins and usually exists as a pentamer (a molecule consisting of five identical smaller molecules) that is stabilized by a J (joining) chain. It is the first antibody produced during the initial, or primary, response to antigen. IgM is usually synthesized early in neonatal life, but may be increased as a response to infection in utero.

Information on the role of IgD is limited. This class of immunoglobulins is found in very low concentrations in the blood. IgD functions as an antigen receptor on the surface of early B lymphocytes.

IgE is normally at low concentrations in the circulation. It functions as a mediator of many common allergic responses (see [Chapter 9](#)) and in the defense against parasitic infections.

Molecular Structure.

Structural analysis of immunoglobulins began with Porter's early studies on the effects of the enzyme papain to digest IgG.¹ IgG was cleaved into three fragments, two of which were identical. The two identical fragments retained the ability to bind antigen, and each was termed an **antigen-binding fragment (Fab)**.² The third fragment crystallized when separated from the Fab portions and was termed the **crystalline fragment (Fc)** (see [Fig. 8.5](#)).

The Fab portions contain identical recognition sites (receptors) for antigenic determinants and confer the molecule's specificity toward a particular antigen. The Fc portion is responsible for most of the biologic functions of antibodies that have bound antigen, including

activation of the complement cascade and **opsonization** by binding to Fc receptors on the surface of the cells of the innate immune system.

The basic structure of an antibody molecule consists of four polypeptide chains—two identical light (L) chains and two identical heavy (H) chains (see Fig. 8.5). The class of antibody is determined by which heavy chain is used: gamma (IgG), mu (IgM), alpha (IgA), epsilon (IgE), or delta (IgD). The light chains of an antibody molecule are of either the kappa (κ) or the lambda (λ) type. The light and heavy chains are held together by two major forces: noncovalent bonds and disulfide linkages. A set of disulfide bridges between the heavy chains occurs in the **hinge region** and in some instances lends a degree of molecular flexibility at that site so that the Fab regions can move. An individual plasma cell produces only one type of H chain and one type of L chain at a time; for instance, one plasma cell may produce only IgG κ , whereas other plasma cells will be producing other antibody classes with either κ or λ light chains.

Light and heavy chains are further subdivided into constant (C) and variable (V) regions. The constant regions have relatively stable amino acid sequences within a particular immunoglobulin class or subclass or a particular light chain type. Thus the amino acid sequence of the constant region of one IgG1 heavy chain should be almost identical with the sequence of the same region of another IgG1 heavy chain, even if they react with different antigens. This holds true for light chains also; all λ chains possess highly similar constant regions that differ from those in κ chains. The amino acid sequences of the variable regions in heavy and light chains, however, differ greatly and determine the antigen-binding specificity of the molecule. Therefore two IgG1 molecules against different antigens may have similar constant regions but have many differences in the amino acid sequence of their variable regions. The diversity of amino acid sequences in the variable region is localized into three regions of the variable region. These three areas were once called *hypervariable regions*, but are now called **complementary-determining regions (CDRs)**. The four regions separating the CDRs have relatively stable amino acid sequences and are called **framework regions (FRs)**.

Antigen Binding

The antigen-binding site is formed by folding an antibody molecule so that the CDRs of the variable regions of both the heavy (V_H) and the light (V_L) chains are moved into close proximity, resulting in a binding site that is lined by the three CDRs of the heavy chain and the three CDRs of the light chain (see Fig. 8.5). Most proteins will naturally fold and take on secondary or tertiary structures. The FRs control the accuracy of folding in the variable regions of antibodies so that the CDRs in both variable regions are placed into accurate positions to bind antigen.³ The specificity of an antibody toward a particular antigen is determined by the chemical nature of the particular amino acids in the six CDRs and the shape of the binding site. The antigen that will bind most strongly must have complementary chemistry and topography with the binding site formed by the antibody.⁴ The antigen fits into this binding site with the specificity of a key into a lock and is held there by noncovalent chemical interactions (Fig. 8.6). In some cases the substitution of a single critical amino acid in a CDR may have a significant effect on the shape of the binding site and the specificity of the antibody molecule.

FIGURE 8.6 Antigen-Antibody Binding. The specificity required for

antibody binding with an antigen is determined by the shape and chemistry of the six complementary-determining regions (*CDRs*) in the combining site on the variable region of the antibody. This figure indicates two different antibodies (Fab portions of antibody 1 and antibody 2) that have different sets of *CDRs* and therefore different specificities. As indicated, the antigenic determinant that reacts well with antibody 1 is unable to react with antibody 2 because of differences in the antibody combining site. *CH*, Constant region of the heavy chain; *CL*, constant region of the light chain; *Fab*, antigen-binding fragment; *V*, variable; *VH*, variable heavy chain; *VL*, variable light chain.

Because the heavy and light chains are identical within the same antibody molecule, the two binding sites are also identical and have specificity for the same antigen. The number of functional antigen-binding sites is called the antibody's **valence**. Most antibody classes (i.e., IgG, IgE, IgD, and circulating IgA) have a valence of 2, but secretory IgA has a valence of 4. IgM, being a pentamer, has a theoretical valence of 10, but can simultaneously use only about 5 binding sites because a large antigenic molecule binding to 1 site blocks antigen binding to other sites.

B-Cell Receptor Complex

The **B-cell receptor (BCR)** is a **complex** of antibody bound to the cell surface and other molecules involved in intracellular signaling (see [Fig. 8.5](#)). Its role is to recognize antigen and communicate that information to the cell's nucleus. Therefore the BCR complex consists of antigen-recognition molecules and accessory molecules involved in intracellular signaling (Ig α and Ig β). BCRs on the surface of immunocompetent B cells are membrane-associated IgM (mIgM) with or without IgD (mIgD) immunoglobulins. The immunoglobulin portion of the BCR is produced from the same genes used by plasma cells for soluble antibodies and has the same antigen specificity as circulating antibodies produced from the same cell after clonal selection. As a BCR, however, mIgM is a monomer rather than the pentamer, and both mIgM and mIgD express an extra hydrophobic transmembrane region that anchors to the hydrophobic regions of the plasma membrane.

The BCR signaling complex consists of two Ig α and Ig β heterodimers that are closely associated with the BCR and contain

tyrosine kinase signaling activity. The antibody portion of the BCR complex is responsible for recognition and binding to an antigen, but by itself cannot provide the intracellular signals required to activate the B cell and complete its maturation into antibody-producing plasma cells. That message is conveyed by the $Ig\alpha$ and $Ig\beta$ heterodimers.

T-Cell Receptor Complex

T lymphocytes use a similar but distinct array of proteins in their recognition and response to antigens. The **T-cell receptor (TCR) complex** is composed of an antibody-like transmembrane protein (TCR) and a group of accessory proteins (collectively referred to as **CD3**) that are involved in intracellular signaling (see [Fig. 8.5](#)). The most common TCR resembles an antibody Fab region and consists of two protein chains, α and β chains, each of which has a variable and constant region and is encoded from genes located independently of the antibody heavy and light chains. Similar to the BCR, the TCR is responsible for recognition and binding to the antigen, whereas the accessory proteins are responsible for the intracellular signaling necessary for activation and differentiation of the T cell. Each of the individual components of the TCR complex is important, and several severe defects in the T-cell immune response have been related to mutations in individual components of the complex (see [Chapter 9](#)).

Molecules That Present Antigen

For an effective immune response, most antigens must be processed by APCs and presented on the cell surface by specialized molecules, molecules of the **major histocompatibility complex (MHC)** ([Fig. 8.7](#)). MHC molecules in humans also are called *human leukocyte antigens* (HLAs) (discussed in greater detail in [Chapter 9](#) related to their role in transplantation). Some types of antigen are processed only by highly specialized cells: APCs. Other types of antigen can be processed and presented by almost any type of cell. Several sets of cell surface molecules have the responsibility for appropriately presenting

antigen. These molecules are described next.

FIGURE 8.7 Genetics and Structure of Antigen-Presenting Molecules. Three sets of molecules are primarily responsible for antigen presentation: MHC class I, MHC class II, and CD1. The major histocompatibility complex (MHC) molecules are encoded from the MHC region on chromosome 6, which contains information for class I and class II molecules, as well as for several other molecules that participate in the innate or immune responses. These include several complement proteins (*C'*) and cytokines (*Cyto*), which are referred to as *MHC class III molecules*. Three principal class I molecules, HLA-A, HLA-B, and HLA-C, are presented here, but this region contains information for the α chains of several other molecules, including HLA-E, HLA-F, and HLA-G. The MHC class I products complex with β 2-microglobulin, which is encoded by a gene on chromosome 15. The MHC class I molecules present small peptide antigens in a pocket formed by the α 1 and α 2 domains of the α chain. The conformation of the molecule is stabilized by β 2-microglobulin (β 2M) as well as by intrachain disulfide

bonds (-S-S-). The α and β chains of class II molecules are also encoded in this region: HLA-DR, HLA-DP, and HLA-DQ. In some cases, multiple genes for α and β chains are available. The MHC class II molecules present peptide antigens in a pocket formed by the $\alpha 1$ domain of the α chain and the $\beta 1$ domain of the β chain. The genes for CD1 molecules are encoded on chromosome 1, which contains genes for five α chains (CD1A-E), and the α chains complex with β_2 -microglobulin to present lipid antigens in a pocket formed by the $\alpha 1$ and $\alpha 2$ domains. All three sets of antigen-presenting molecules are anchored to the plasma membrane by hydrophobic regions on the ends of the α and β chains. APCs, antigen-presenting cells; Tc, T cytotoxic; Th, T-helper.

Major Histocompatibility Complex

MHC molecules are glycoproteins found on the surface of all human cells except red blood cells. They are divided into two general classes, class I and class II, based on their molecular structure, distribution among cell populations, and function in antigen presentation. MHC class I molecules are heterodimers composed of a large alpha (α) chain and a smaller chain called β_2 -microglobulin. MHC class II molecules are also heterodimers composed of α and β chains. The α and β chains of the MHC molecules are encoded from different genetic loci in a large complex of genes on the short arm of human chromosome 6 (β_2 -microglobulin is found on chromosome 15). The MHC also contains other genes that control the quality and quantity of an immune response, which are commonly referred to as *class III MHC genes*. The general properties of each of the MHC classes are summarized in [Fig. 8.7](#).

The primary **MHC class I genes** consist of three closely linked loci labeled A, B, and C. The primary **MHC class II genes** are located within an area called the *D region*, which actually consists of three separate and independent loci: DR, DP, and DQ.

MHC loci are the most genetically diverse (polymorphic) of any human genetic loci. Within the human population, the number of possible different alleles (i.e., forms of the gene) expressed by each locus is astounding: approximately 700 at the A locus, 1000 at the B locus, 350 at the C locus, 600 at the DR locus (α and β), 125 at the DQ locus (α and β), and 150 at the DP locus (α and β). These numbers are based on the polymorphism of observed DNA sequences and may not

reflect differences in function. Clearly, not every allele is expressed in the same individual. Humans have two copies of each MHC locus (one inherited from each parent) that are codominant so that molecules encoded by each parent's genes are expressed on the cell surface. Within an individual, each locus will be expressing only one allele. For instance, each person will have only two different A proteins (one from each parent).

Transplantation.

The diversity of MHC molecules is clinically relevant during organ transplantation. Cells in transplanted tissue or organs from one individual will have a different set of MHC surface antigens than those of the recipient; therefore the recipient can mount an immune response against the foreign MHC antigens, resulting in rejection of the transplanted tissue. As a result of studies of transplantation, the human MHC molecule is also referred to as **human leukocyte antigen (HLA)**, and the different MHC genetic loci are commonly called HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ, and HLA-DP. To minimize the chance of tissue rejection, the donor and recipient are often *tissue typed* beforehand to identify differences in HLA antigens. The more similar two individuals are in their HLA tissue type, the more likely a transplant from one to the other will be successful. Because of the large number of different alleles, it is highly unlikely that a perfect "match" can be found in the general population between a potential donor and the recipient.

The specific combination of alleles at the six major HLA loci on one chromosome (A, B, C, DR, DQ, and DP) is termed a **haplotype**. Each individual has two HLA haplotypes, one from the paternal chromosome 6 and another from the maternal chromosome. Because the different HLA loci within the MHC are in such close proximity to one another, haplotypes are not *usually* disrupted by recombination and are thus inherited intact. One HLA haplotype from each parent is passed to each of the offspring, meaning that children usually share one haplotype with each parent (Fig. 8.8). Odds dictate that children of the same parents will share one haplotype with half of their siblings

and either no haplotypes or both haplotypes with a quarter of their siblings. Thus the chance of finding a match among siblings is much higher (25%) than that from the general population. Identical twins, originating from the same egg and sperm, will have a complete set of identical genes, including HLA molecules.

FIGURE 8.8 Inheritance of Human Leukocyte Antigen. Human leukocyte antigen (HLA) alleles are inherited in a codominant fashion so that both maternal and paternal antigens are expressed. Specific HLA alleles are commonly given numbers to indicate different antigens. In this example, the mother has linked genes for HLA-A3 and HLA-B12 on one chromosome 6 and genes for HLA-A10 and HLA-B5 on the second chromosome 6. The father has HLA-A28 and HLA-B7 on one chromosome and HLA-A1 and HLA-B35 on the second chromosome. On one particular chromosome, the HLA antigens are firmly linked, with crossovers occurring in only 1% of individuals. The children from this pairing may have one of four possible combinations of maternal and paternal HLA.

It should be noted, however, that although HLA alleles are the primary contributor to rejection of a transplant, a number of other antigens also have a role in determining tissue compatibility. Some of these are encoded on other chromosomes and are inherited independently of HLA antigens. This means that although two people have the same HLA makeup, a graft or transplant still may be rejected because of differences between other antigens. It is preferable to obtain a graft or transplant from a closely related individual, such as a sibling, because the chance of sharing both the same HLA antigens and other undetermined antigenic differences encoded outside the

MHC is much greater.

CD1

Another set of antigen-presenting molecules are members of the CD1 group. CD1 molecules have very low genetic polymorphism and a structure similar to that of MHC class I, and they are found primarily on APCs and cells in the thymus.⁵ Unlike MHC molecules that present proteins, the CD1 molecules appear to specialize in presenting lipid antigens contained in lipoproteins, glycolipids, and other molecules. These antigens are commonly important factors in infections with bacteria of the *Mycobacterium* spp. (e.g., *Mycobacterium tuberculosis* that causes tuberculosis and *Mycobacterium leprae* that causes leprosy), which have a very large amount of lipid in their cell membranes.

Molecules That Hold Cells Together

The efficient development of an immune response requires several antigen-independent interactions between cells. The interactions between specific cellular receptors and their ligands result in intracellular signaling events that are independent of the TCR or BCR complexes but are necessary complements to the antigen-specific signal. Several of these molecules are listed in [Box 8.1](#).

Box 8.1

Important Adhesion Molecule Pairings

Th-cell CD4	⇔	MHC class II on APC
Tc-cell CD8	⇔	MHC class I on APC
Tc-cell CD2	⇔	CD58 (LFA-3) on APC
Tc-cell CD28	⇔	CD80 (B7-1) on APC
Tc-cell LFA-1	⇔	ICAM-1 on APC
Th-cell CD40L (CD154)	⇔	CD40 on B cell
Th-cell CD40L (CD154)	⇔	CD40 on APC

APC, Antigen-presenting cell; *ICAM*, intercellular adhesion molecule; *LFA*, lymphocyte function associated antigen; *MHC*, major histocompatibility complex; *Tc*, T-cytotoxic; *Th*, T-helper.

Cytokines and Their Receptors

As discussed in [Chapter 7](#), cytokines are low-molecular-weight proteins or glycoproteins that function as chemical signals between cells. A large number of cytokines are secreted by APCs and lymphocytes and provide both positive and negative regulation of the immune response. The effects of particular cytokines depend on binding to specific cellular receptors, which are linked to intracellular signaling pathways. The lymphocyte may respond in many ways. One of the most common responses is an increase in the production of proteins, many of which are other cytokines or cytokine receptors. Many cytokines also cause a lymphocyte to proliferate and differentiate. The participation of cytokines is essential to the development of an adequate immune response, and in general the precise combination of cytokines influences the ultimate response of a given cell. Specific deficiencies in the immune response that result from genetic mutations that lead to defective cytokine production or defective cytokine receptors are discussed in [Chapter 9](#). [Table 8.4](#) provides information about key cytokines and receptors that are known to influence the immune response.

TABLE 8.4

KEY CYTOKINES AND RECEPTORS THAT INFLUENCE THE IMMUNE RESPONSE

CYTOKINE	PRIMARY SOURCE	PRIMARY FUNCTION
Interleukin (IL)		
IL-1	APCs	Stimulates proliferation and differentiation of T cells; induces acute-phase proteins in inflammatory response; endogenous pyrogen
IL-2	Th1 cells, NK cells	Stimulates proliferation and differentiation of T cells and NK cells

IL-4	Th2 cells, mast cells	Induces B-cell proliferation and differentiation; up-regulates MHC class II expression; induces class-switch to IgE
IL-5	Th2 cells, mast cells	Induces eosinophil proliferation and differentiation; induces B-cell proliferation and differentiation
IL-6	Th2 cells, APCs	Induces B-cell proliferation and differentiation into plasma cells; induces acute-phase proteins in inflammatory response
IL-7	Thymic epithelial cells, bone marrow stromal cells	Major cytokine for induction of B- and T-cell proliferation and differentiation in central lymphoid organs
IL-8	Macrophages	Chemotactic factor for neutrophils
IL-10	Th cells, B cells	Inhibits cytokine production; activator of B cells
IL-12	B cells, APCs	Induces NK-cell proliferation; increases production of IFN- γ
IL-13	Th2 cells	IL-4-like properties; decreases inflammatory responses
IL-17	Th17 cells	Increases inflammation; increased influx of neutrophils and macrophages; increased epithelial cell chemokine production
IL-22	Th17 cells	Increases inflammation; increased epithelial cell production of antimicrobial peptides
Interferon (IFN)		
IFN- α , IFN- β	Macrophages, some virally infected cells	Antiviral; increases expression of MHC class I; activates NK cells
IFN- γ	Th1 cells, NK cells, Tc cells	Increases expression of MHC class II; activates macrophages and NK cells
Tumor Necrosis Factor (TNF)		
TNF- α (cachectin)	Macrophages	IL-1-like properties; induces cellular proliferation
TNF- β (lymphotoxin)	Tc cells	Kills some cells; increases phagocytosis by macrophages and neutrophils
Transforming Growth Factor (TGF)		
TGF- β	Lymphocytes, macrophages, fibroblasts	Chemotactic for macrophages; increases macrophage IL-1 production; stimulates wound healing
CYTOKINE RECEPTORS	LIGAND	ADDITIONAL INFORMATION
Class I receptor dimers (α and β)	IL-3, IL-5, IL-6, IL-11, IL-12, IL-13	IL-3 and IL-5 share a common α chain; IL-6 and IL-11 share a common β chain

chains)		
Trimers (α , β , and γ chains)	IL-2, IL-4, IL-7, IL-9, IL-15	All share a common γ chain
Class II receptors	IFN- α , - β , and - γ	Two chains
TNF receptors	TNF- α , TNF- β , CD40, Fas	Single chain
Immunoglobulin-like receptors	IL-1	Single chain with immunoglobulin-like characteristics

APCs, Antigen-presenting cells; *Fas*, death receptor; *MHC*, major histocompatibility complex; *NK*, natural killer; *Tc*, T-cytotoxic; *Th*, T-helper.

Generation of Clonal Diversity

The immune response occurs in two phases: generation of clonal diversity and clonal selection (Table 8.5 and see Fig. 8.2).^{6,7} During generation of clonal diversity, a large population of T cells and B cells is produced before birth. These lymphocytes have the capacity to recognize almost any foreign antigen found in the environment. This process occurs mostly in specialized lymphoid organs (the **primary [central] lymphoid organs**): the **thymus** for T cells and the **bone marrow** for B cells. The result is differentiation of lymphoid stem cells into B and T lymphocytes. **Lymphoid stem cells** are precursor cells formed in the liver (in the fetus) or in the bone marrow (of a child or adult) that do not have antigen-specific receptors (BCR and TCR) or other B-cell-specific and T-cell-specific surface proteins. After maturation in the central lymphoid organs, these stem cells develop into immunocompetent cells with antigen-specific receptors without encountering foreign antigen. Although each B or T cell expresses receptors against a single specific antigen, the total population of immunocompetent cells may have receptors that can react with more than 10^8 different antigenic determinants. Thus before the individual is exposed to any foreign antigen, millions of different T- and B-cell antigen receptors must be constructed to recognize *any* potential antigenic determinant. Immunocompetent lymphocytes are released to the circulation and many reside in **secondary (peripheral)**

lymphoid organs (e.g., spleen, lymph nodes, adenoids, tonsils, Peyer patches).

TABLE 8.5

GENERATION OF CLONAL DIVERSITY VS. CLONAL SELECTION

	GENERATION OF CLONAL DIVERSITY	CLONAL SELECTION
Purpose?	To produce large numbers of T and B lymphocytes with the maximum diversity of antigen receptors	Select, expand, and differentiate clones of T and B cells against a specific antigen
When does it occur?	Primarily in the fetus	Primarily after birth and throughout life
Where does it occur?	Central lymphoid organs: thymus for T cells, bone marrow for B cells	Peripheral lymphoid organs, including lymph nodes, spleen, and other lymphoid tissues
Is foreign antigen involved?	No	Yes; antigen determines which clones of cells will be selected
What hormones/cytokines are involved?	Thymic hormones, IL-7, others	Many cytokines produced by Th cells and APCs
Is tolerance induced?	Central tolerance induced as autoreactive cells are deleted	Peripheral tolerance induced as autoreactive cells are regulated
Final product?	Immunocompetent T and B cells that can react with antigen but have not seen antigen, and migrate to the secondary lymphoid organs	Plasma cells that produce antibody, effector T cells that help (Th), kill targets (Tc), or regulate immune responses (Treg); memory B and T cells

APCs, Antigen-presenting cells; *IL*, interleukin; *Tc*, T-cytotoxic; *Th*, T-helper; *Treg*, regulatory T cells.

Although generation of clonal diversity primarily occurs in the fetus, it probably continues to a low degree throughout most of adult life. The endless array of possible antibodies and TCRs certainly cannot be constructed from the amount of deoxyribonucleic acid (DNA) that is in the nucleus of a human lymphocyte. The enormous repertoire of specificities with appropriate conservation of DNA is made possible by rearrangement of smaller regions of existing DNA during T- and B-cell development in the primary lymphoid organs. Loci in the DNA that encode parts of the variable regions of

immunoglobulins and TCRs are rearranged, a process known as **somatic recombination**, in a unique way to generate receptors that collectively can recognize and bind to any possible antigen.

B-Cell Maturation

Central Lymphoid Organ

Lymphoid stem cells destined to become B cells percolate through specialized regions of the bone marrow, where they are exposed to hormones and cytokines that induce proliferation and differentiation into immunocompetent B cells (Fig. 8.9).⁸ They interact with stromal cells through a variety of intercellular adhesion molecules (e.g., stem cell factor [a cytokine bound to the membrane of stromal cells and sometimes known as steel factor]). As the stem cell begins to mature, it progressively develops a variety of necessary surface markers, one of the earliest being the interleukin-7 (IL-7) receptor. IL-7, produced by the stromal cells, is critical in driving the further differentiation and proliferation of the B cell.⁹ The next stage in development is formation of the B-cell receptor.

FIGURE 8.9 B-Cell Development in the Bone Marrow. During the generation of clonal diversity, lymphoid stem cells enter portions of the bone marrow that serve as the central lymph organ for B-cell development. Interactions with a series of bone marrow stromal cells guide the proliferation and differentiation process through direct cell-to-cell contact and the production of cytokines and hormones by the stromal cells, but without the presence of foreign antigen. A simplified scheme for that process is presented here. The differentiation process of B cells is characterized by the upregulation of many important surface molecules (only some of which are shown) and the random development of a huge number of different B-cell receptors. The early B cell (pro-B cell) binds to a membrane-bound cytokine (stem cell factor) on the stromal cell and initiates expression of the surface molecule CD45R and begins to rearrange the *DJ* regions of the antibody heavy-chain gene. As the cell progresses to the pre-B-cell stage, it concludes DNA rearrangement of the heavy chain (*VDJ*) and begins expressing cytoplasmic mu (μ) heavy chain. The μ chain is incorporated into a pre-B-cell receptor (*pBCR*) using a surrogate protein in place of the light chain. The cell also up-regulates the IL-7 receptor (*IL-7R*), which interacts with IL-7 produced by the stromal cells to drive the remaining steps in differentiation. Some pBCRs have specificities toward self-antigen. Many of these encounter self-antigen

expressed on the stromal cells and undergo negative selection (clonal deletion). The surviving cells (immature B cells) rearrange the light-chain DNA (*VJ*) and express a BCR consisting of light chain and the μ heavy chain (membrane-bound IgM [mIgM]). In the mature B cell, changes in processing of the heavy-chain precursor RNA result in coexpression of mIgM and mIgD (see Fig. 8.11 for more details).

Production of the B-Cell Receptor (BCR)

The BCR is a complex of antibody that is anchored to the plasma membrane and other molecules involved in intracellular signaling. Its role is to recognize an antigen and communicate that information to the cell nucleus. BCRs on immunocompetent B cells are membrane-associated IgM (mIgM) with or without concurrent mIgD that have identical specificities for antigen.

The enormous repertoire of specificities is related to the sum of diversities of CDRs in the heavy and light chain variable regions. The CDRs are encoded by multiple sets of genes that undergo somatic recombination. The process of recombination is simplest for the antibody light chains (Fig. 8.10). The segments of DNA that encode either kappa (κ) (chromosome 2) or lambda (λ) (chromosome 22) light chain are clustered in *V*, *J*, and *C* genes. Diversity is accomplished by random rearrangement of *V* and *J* gene regions encoding the *V* region. The *V* genes encode the first two CDRs and intervening FR regions of the *V* region. The *J* genes (joining genes) encode the third CDR (CDR3) and FR4. To create the *V* region of the light chain, one *V* gene and one *J* gene are randomly selected and rearranged so that the *V* and *J* are moved to adjacent positions, and the intervening DNA is excised and spliced, resulting in a *VJ* region that encodes the *V* region of the light chain. Somatic recombination is controlled by enzymes encoded by *recombination activating genes* (*RAG-1*, *RAG-2*) that cut and remove intervening DNA between the selected *V* and *J* gene regions and splice the *VJ* together.¹⁰

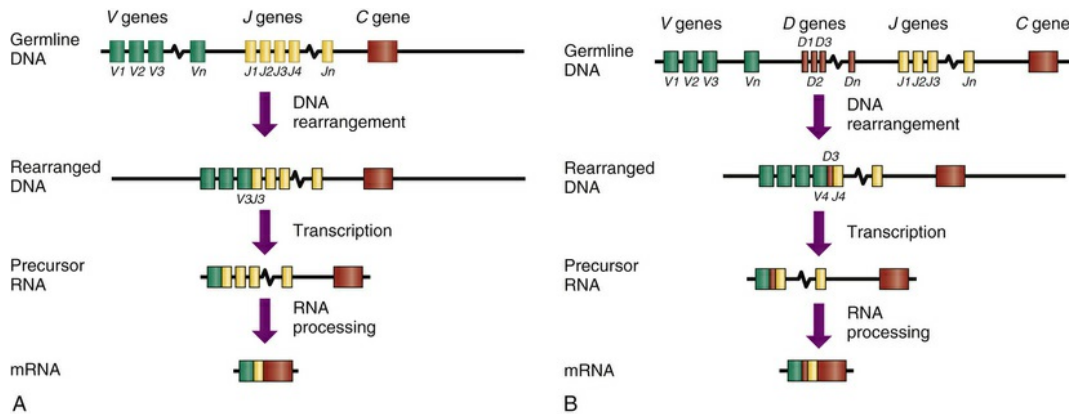

FIGURE 8.10 DNA Rearrangement of Genes for Antigen-Binding Molecules. During the generation of clonal diversity, a tremendous number of different antigen-binding molecules are produced. These include the B-cell receptor (BCR), which consists of a membrane-bound antibody molecule, and the T-cell receptor (TCR). The process by which receptor diversity is created is identical for all antigen-binding molecules and is summarized in this figure. Maximum diversity with minimum use of DNA is accomplished by random rearrangement of sets of genes that encode different portions of the variable regions. **A**, The variable regions of the light chain of antibody and the α chain of the TCR independently rearrange two sets of genes: *V* region genes and *J* region genes. The light chain uses its own set of genes, and the α chain uses a completely different set. In either case is the exact number of *V* or *J* region genes known; therefore in this figure they are numbered from 1 to an unknown value (n). In a particular cell's DNA, one *V* gene is randomly selected and moved to a position immediately adjacent to a randomly selected *J* gene. In this example, *V3* and *J3* were selected. The DNA between the selected genes is enzymatically removed and the DNA repaired, so that the rearranged DNA in this example is missing the portion found in the germline DNA between *V3* and *J3*. This product is transcribed into a precursor ribonucleic acid (RNA) that contains information for the rearranged *VJ* pair, a span containing other unselected *J* regions, and information for the appropriate constant region (*C gene*) of the molecule. The RNA between the *VJ* and the *C* regions is not translated; therefore it is removed by RNA processing to produce a messenger RNA (*mRNA*) that is translated. **B**, The variable region of the antibody heavy chain and the TCR β chain result from a similar DNA rearrangement, with the added diversity contributed by a group of *D* region genes. The joining of *D* and *J* occurs first, with the removal of intervening DNA. In this example, *D3* and *J4* were chosen. This is followed by rearrangement of the *V* gene (e.g., *V4*) and formation of a *VDJ* region in the rearranged DNA. The precursor RNA contains information for the *VDJ*, the intervening portion of DNA, and the appropriate constant region. After RNA processing, an mRNA is formed for the intact antibody heavy chain or the TCR β chain. Once the DNA is rearranged and spliced in a given B or T cell, all of the antigen receptors produced by that cell employ the same *V*, *D*, and *J* segments and have the same specificity.

Some *V* gene regions are defective; however, estimates of functional gene regions range from 40 to 70. About 5 *J* gene regions appear to be available. Thus recombination of a light chain may result in as many

as 350 *VJ* possible recombinants. Within a particular differentiating B cell, a precise order of light chain rearrangement exists so that a successful *VJ* rearrangement prevents any attempts to any rearrangement of light chain genes on other chromosomes, and each B cell only produces one light chain. The primary mRNA transcript contains information for the *VJ* region, an intervening intron, and the *C* region gene. Processing of the mRNA (RNA splicing) removes the intron, resulting in a mRNA with contiguous *VJC* regions that is transcribed into an intact light chain.

The gene for the heavy chain on chromosome 14 undergoes similar somatic recombination. Unlike the light chain organization of *V*, *J*, and *C* gene regions, the heavy chain loci consist of approximately 50 *V*, 30 *D*, and 6 *J* gene regions and 9 *C* regions, with the gene for the mu (μ) constant region being closest to the *VDJ* region, and the delta (δ) constant region gene being next in sequence (see Fig. 8.10). Somatic rearrangement of the *V* region genes is a two-step process with rearrangement to a contiguous *DJ* followed by formation of *VDJ*. During both rearrangements, intervening sequences of DNA are excised and repaired. The *V* gene region encodes the CDR1 and CDR2 regions and intervening *FR* regions. The genetic information for the CDR3 is a composite of a small amount of DNA from the *V* gene region, the entire *D* region, and a portion of the *J* gene region. Somatic recombination may result in more than 13,500 different heavy chain variable regions.

The primary mRNA contains five exons: *VDJ*, μ constant region ($C\mu$), a μ transmembrane region ($TM\mu$), δ constant region ($C\delta$), and a $TM\mu$ region (Fig. 8.11). There are no stop signals between the $C\mu$ and $C\delta$ so that both will be transcribed in the same mRNA.¹¹ A stop signal is present after the information for $C\delta$ so that other constant regions will not be transcribed. During RNA splicing all introns will be excised and all mRNA molecules will retain the same *VDJ* region. All cells will produce a population of mRNA containing the $C\mu$ and its *TM* region. Through alternative splicing, many cells also will produce concurrently a second group of mRNA containing the $C\delta$ and its *TM* region. Within a single developing immunocompetent B cell,

alternatively spliced mRNA may be translated into μ and δ heavy chains that have identical *V* regions and have *TM* regions for anchoring to the cell membrane. The light chains are assembled with two μ chains to form monomeric IgM or with two δ chains to form IgD antibody. Initially, the developing B cell rearranges and expresses heavy chain that is followed by the rearrangement of either the κ or the λ light chain so that only one type is produced. The hydrophobic *TM* regions will result in insertion into the plasma membrane and simultaneous expression of mIgM and mIgD with identical CDRs and antigen specificities. A very rough calculation of the diversity resulting from this process would be the diversity of the H chain (13,500) \times the diversity of the κ light chain (350) + the H chain diversity (13,500) \times the λ light chain (350) = 9.45×10^6 combinations of H and L chain CDRs.

FIGURE 8.11 Coexpression of IgM and IgD B-Cell Receptors. Most mature immunocompetent B cells express both membrane-bound IgM and IgD as the B-cell receptor. In the germline DNA, the heavy-chain gene complex consists of a series of *V*, *D*, *J*, and constant region genes. In humans, each class and subclass of antibody has a unique constant region gene arranged in the indicated order. Switch regions occur preceding every constant region gene, except mu (μ) (IgM) and delta (δ) (IgD). After successful DNA rearrangement of the *VDJ* regions, a ribonucleic acid (RNA) molecule is transcribed that contains the information from the *VDJ*, intervening DNA, the μ constant region, and the δ constant region. Precursor RNA molecules are alternatively processed to produce messenger RNAs (mRNAs) containing either μ or δ . Initially, RNA

processing favors the μ chain and production of membrane-bound IgM (see Fig. 8.10), but as the B cell matures, both mRNA molecules are produced. *IgD*, immunoglobulin D; *IgM*, immunoglobulin M.

The BCR signaling complex is further constructed by the addition of two $Ig\alpha$ and $Ig\beta$ heterodimers that are closely associated with the BCR and contain tyrosine kinase signaling activity. The antibody portion of the BCR complex is responsible for recognition and binding to an antigen but, by itself, cannot provide the intracellular signals required to activate the B cell and complete its later maturation into plasma cells. That message is conveyed by the $Ig\alpha$ and $Ig\beta$ heterodimers.

Changes in Characteristic Surface Markers

B-cell differentiation is also characterized by the development of a variety of important surface molecules. These include CD21 (a complement receptor) and CD40 (adhesion molecule required for later interactions with Th cells).

Central Tolerance

Because assembly of the *VJ* and *VDJ* regions is random, B-cell receptors will be produced that react with self-antigens (*autoreactive B cells*). Further development and release of these autoreactive cells into the circulation would result in a catastrophic immune attack against the individual's own tissues. One stage at which **immune tolerance** (suppression or limitation of immune responses against self-antigens) occurs is the deletion of autoreactive B cells in the bone marrow, which is referred to as **central tolerance** (induction of tolerance within the central lymphoid organs). During the very earliest stages of formation of the BCR in the bone marrow, a large number of autoreactive B cells undergo apoptosis (*clonal deletion*) if exposed to self-antigen. This process of *negative selection* induces the death of more than 90% of developing B cells. Some autoreactive clones persist and must be controlled by other means in the lymphoid organs (**peripheral tolerance**).

T-Cell Maturation

Central Lymphoid Organ

The process of T-cell generation of clonal diversity is similar to that for B cells. The primary lymphoid organ for T-cell development is the thymus, which is an organ located near the heart. Lymphoid stem cells migrate to the thymus and enter the subcapsular region. As the cells journey through the thymic cortex to the medulla, they are instructed by interactions with various thymic cells (epithelial cells, macrophages, and dendritic cells), thymic hormones (e.g., thymosin, thymopoietin, thymostimulin, and others produced by the thymic epithelium), and the cytokine IL-7 to undergo proliferation and progressive development of the characteristics of immunocompetent T cells (Fig. 8.12). Changes include development of the T-cell receptor complex and expression of characteristic surface molecules. The final immunocompetent T cells are released into the blood vessels and lymphatic vessels to establish residence in the secondary lymphoid organs to await antigen.

FIGURE 8.12 T-Cell Development in the Thymus. During the generation of clonal diversity in the fetus, lymphoid stem cells undergo several stages of cellular division and differentiation in a central lymphoid organ (the thymus) under the control of hormones but without the influence of foreign antigen. A simplified scheme for that process is presented here. The differentiation process is characterized by the upregulation of many important surface molecules (only some of which are shown) and the random development of a huge number of different T-cell receptors against all possible antigens that the adult may encounter. The lymphoid stem cell enters the subcapsular region of the thymus, where it begins to undergo differentiation. One of the first surface changes is the appearance of the molecule CD2, which is a marker for all T cells. In the cortex of the thymus, the developing cell encounters epithelial cells that guide most of the early differentiation process. The pre-T cell begins expressing the surface receptor for the cytokine IL-7, which is produced by the epithelial cell along with other thymic hormones to drive the T-cell differentiation process. At this stage the T cell begins constructing the T-cell receptor (TCR) by first rearranging and expressing the TCR β chain (more detail is provided in Fig. 8.10) and expressing CD3 molecules. Although the TCR α chain has not yet been produced, the β chain is expressed on the surface as a pre-TCR (pTCR) using a protein that acts as a surrogate for the α chain. Because of the randomness of the process, some pTCRs are produced with specificities toward self-antigens. Many of these undergo negative selection and are deleted (clonal deletion) by apoptosis induced through interactions with self-antigens presented by the epithelial cells. Survivors of negative selection move toward the thymic cortex and begin expressing the TCR α chain, the normal TCR, and both CD4 and CD8 on their surfaces. These CD4+, CD8+ “double-positive” cells encounter medullary epithelial cells that express both MHC class I and MHC class II molecules. The phenotype of the developing T cell is positively selected so that interaction between CD4 and MHC class II selects for retention of CD4 expression,

whereas interaction between CD8 and MHC class I favors the CD8 phenotype. Thus two populations of “single-positive” immunocompetent T cells leave the thymus: one cell is CD4+, CD8- (destined to be a helper T [Th] cell) and the other is CD4-, CD8+ (destined to be a cytotoxic T [Tc] cell).

Production of the T-Cell Receptor

Within the thymic cortex, the cells begin rearranging the variable region genes necessary for forming a functional T-cell receptor. The basic process of TCR rearrangement is essentially identical with formation of the BCR and, although the structure of the TCR closely resembles a Fab portion of antibody, the TCR uses different genes than are used for antibody (see Fig. 8.5). The most common TCR contains α and β chains, each of which has a variable region and a constant region.

The variable regions of the TCR α and β chains also undergo somatic recombination: the α chain gene (chromosome 14) rearranges V and J regions and the β chain gene (chromosome 7) rearranges V , D , and J regions. Somatic recombination of the α chain proceeds as described for the antibody light chain using a set of at least 70 V region genes and at least 50 J region genes (see Fig. 8.10). Thus potentially 3500 different α chains may be generated. Rearrangement of the β chain occurs similarly as described for antibody heavy chain rearrangement. A major difference, however, is the option of using two separate C gene regions ($C\beta_1$ and $C\beta_2$) each of which is adjacent to its own set of D and J gene regions. Somatic rearrangement of the β chain gene segments uses at least 60 V gene regions and 2 $C\beta$ regions (each containing at least 1 D and 6 or 7 J gene regions). As many as 720 different β chains may be produced. As with the generation of antibody diversity, the primary mRNA for α and β chains contains V region and C region exons with an intervening intron that is removed by RNA processing. Assembly of the α and β chains results in TCR diversity that potentially represents 2.5×10^6 (3500 α chains \times 720 β chains) antigenic specificities.

For both α and β chains, the V region genes encode the amino acid sequences that include CDR1 and CDR2 and their appropriate FR

regions. The *J* regions contain information for CDR3 and FR4. The TCR β chain *D* regions encode a short amino acid sequence found in the CDR3 and greatly increase the diversity of the β chain CDR3.

As with somatic rearrangement of antibody light and heavy gene regions, the level of diversity, especially for the CDR3 regions, may be increased further by other factors. Imprecise joining increases the diversity of the CDR3 regions. For example, the sites of *VJ* and *VDJ* joining may shift slightly, resulting in an amino acid being inserted or deleted from the protein.

Although the $\alpha\beta$ TCR is the preferred antigen receptor, some T cells (about 5% of the total T-cell population) use alternative genes: gamma (γ) (chromosome 7) and delta (δ) (chromosome 14, in the middle of α chain genes). T cells with $\gamma\delta$ TCRs appear to migrate to unique areas of the body (the epithelial areas in the skin, reproductive tract, intestine, respiratory tract) and have different and less well understood functions than the T cells with $\alpha\beta$ TCRs.

A functional TCR requires intracellular signaling molecules. Insertion of the TCR into the plasma membrane is associated with expression and association with TCR accessory molecules (collectively called *CD3*) that provide signaling to the nucleus after the binding of antigen to the TCR. *CD3* is a marker for T cells that successfully form a TCR complex and are immunocompetent.

Changes in Characteristic Surface Markers

Differentiation of T cells in the thymus also results in changes in a variety of important surface molecules. Much of T-cell development is controlled by hormones and cytokines in the thymus, and an early step in maturation is expression of the receptor for interleukin-7 (IL-7R), which is a major cytokine that drives the differentiation process.¹² Transit through the thymic cortex initiates expression of the molecule *CD2* on the cell surface. *CD2* is expressed on virtually every subpopulation of cells that have undergone development in the thymus and is thus a T-cell marker.

The developing T cell also begins making two other important surface proteins, **CD4** and **CD8**, which are concurrently expressed on

the developing cell's surface at this stage.¹³ CD4+, CD8+ cells are often called “double-positive” cells. After entering the medulla of the thymus, the double-positive cells become “single-positive.” That is, some of the cells suppress production of the CD8 molecule and remain only CD4+, whereas others suppress CD4 production and remain CD8+. The phenotypic change to single-positive cells is driven by exposure of CD4+, CD8+ cells to MHC antigen expressed on cells of thymus. The CD4 and CD8 molecules react specifically with MHC class II molecules or MHC class I molecules, respectively. For instance, if a double-positive cell initially comes into contact with MHC class II molecules on the thymic cells, the T cell will suppress expression of CD8 and become CD4 single-positive. However, if initial reactivity occurs between the CD8 and MHC class I molecules, the cells will become CD8 single-positive. Thus this *positive selection* process results in two groups of immunocompetent cells with different functional characteristics: CD4 cells develop into T-helper cells (Th cells) in the clonal selection process, whereas CD8 cells become mediators of cell-mediated immunity and kill other cells directly (e.g., Tc cells). Approximately 60% of immunocompetent T cells in the circulation express CD4 and 40% express CD8.

Central Tolerance

During the random rearrangement of *VJ* and *VDJ* genes to produce the T-cell receptor, some combinations result in specificities that recognize self-antigens. If some of these *autoreactive* T cells were allowed to progress further in development and leave the thymus, a severe immunologic reaction against the individual's own tissues could result. One stage at which tolerance for self-antigens is maintained is the deletion of autoreactive T cells in the thymus, which is referred to as central tolerance.

A large spectrum of self-antigens is expressed on the surface of thymic macrophages, dendritic cells, and especially epithelial cells.¹⁴ If a developing T-cell's TCR binds strongly with a self-antigen, it will undergo apoptosis (*clonal deletion*). Although this process of *negative selection* induces more than 95% of T cells to undergo apoptosis in the

thymus, a limited number of autoreactive clones persist and must be controlled by other means in the peripheral lymphoid organs (peripheral tolerance, discussed in the section titled [Antigens and Immunogens](#)).

Induction of an Immune Response: Clonal Selection

Antigens initiate the second phase of the immune response, clonal selection. The process proceeds through three finely tuned sets of intercellular collaborations that result in the production of effector cells (Th cells, plasma cells, Tc cells) and memory cells that provide long-term specific protection against infectious microorganisms. Step 1 is antigen processing and presentation. This is the “selection” component of clonal selection in that the particular antigen is selective for maturing those B and T cells with related TCR and BCR specificities. Step 2 is induction of a population of Th cells. Immunocompetent CD4⁺ T cells respond to presented antigen and proliferate and differentiate into populations of effector Th cells (e.g., Th1, Th2, Th17 cells). Step 3 is induction of immunocompetent B cells into plasma cells and immunocompetent CD8⁺ T cells into Tc cells. This step requires the presence of antigen presentation and effector Th cells. Steps 2 and 3 are dependent on highly regulated interactions among cells: APCs and immunocompetent Th cells in step 2 and APCs, effector Th cells, and immunocompetent B or CD8⁺ T cells in step 3. Successful intercellular collaborations depend on three complementary signaling events: antigen-specific recognition through the TCR complex, intercellular adhesion between specific cell surface receptors/ligands, and secretion of and response to specific groups of cytokines. Without all of these signaling events, a protective immune response would not be produced.

Clonal selection usually begins at birth and proceeds throughout the life of the individual as new antigens are encountered, although it can begin as early as the eighth week of gestation in humans if foreign

antigens are encountered in utero. Most commonly, foreign antigens encountered in utero are related to fetal infection during the last third of gestation.

Secondary Lymphoid Organs

Most aspects of clonal selection begin in the secondary lymphoid organs: the spleen, lymph nodes, adenoids, tonsils, Peyer patches (intestines), and the appendix (see Fig. 8.3). Immunocompetent lymphocytes enter the secondary lymphoid organs through the blood and enter specialized small veins, called **high endothelial venules (HEVs)**, where they bind to the endothelium through a family of adhesion molecules. The lymphocytes migrate from the vessels into the lymphoid tissues, which contain B- and T-cell-rich areas. B lymphocytes that encounter antigen in the secondary lymph organs usually undergo a process of differentiation and proliferation that results in the formation of specialized germinal centers in these organs (Fig. 8.13).¹⁵

FIGURE 8.13 Histology of a Secondary Lymphoid Organ. A, The lymph node contains areas (primary follicles) that are rich in immunocompetent B cells (stained green), and T cells (stained red) in the paracortex. B, A lymph node is organized into an outer cortex and an inner medulla. C, In response to antigen, B cells undergo proliferation, resulting in the formation of secondary follicles with germinal centers. (Modified from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.)

Antigen Processing and Presentation

Most antigens do not react directly with T or B cells, but require processing and presentation in the appropriate fashion. This is the duty of APCs. Most cells have the capacity to present antigen to some degree, but dendritic cells, macrophages, and B lymphocytes are so efficient at antigen presentation that they are considered “professional” APCs. Each is responsible for the presentation of antigens of different types and from different sources. B cells can process soluble antigens and present them to Th cells that facilitate development of the humoral immune response. Macrophages are effective APCs for the development of immune responses against antigenic components of infectious agents (e.g., bacteria). Contamination of tissue by infectious microbes usually initiates an inflammatory response and the infiltration of macrophages into the site. Macrophages also are very effective in presenting antigen to memory Th cells in order to initiate a rapid response to antigens that have been previously encountered by the immune system.

The dendritic cells are perhaps the most effective in presenting antigen to naïve immunocompetent Th cells.¹⁶ Dendritic cells develop from bone marrow precursor cells, either of myeloid or of lymphoid lineage (at least two populations of dendritic cells have been described). They migrate to the peripheral tissues (e.g., skin, intestinal tract) and to the secondary lymphoid organs. Immature dendritic cells at a site of inflammation function as phagocytes, and the process of phagocytosis can initiate differentiation and directed migration of dendritic cells to the secondary lymphoid organs, particularly the lymph nodes (Fig. 8.14). Thus dendritic cells can carry processed antigen from a site of inflammation to the T-cell-rich areas of the lymph nodes.

FIGURE 8.14 The Role of the Dendritic Cell in Capturing Antigen. Immature dendritic cells in the tissues encounter and phagocytose antigen, which results in the production of inflammatory cytokines and a loss of adhesive interactions with neighboring cells. The maturing dendritic cell migrates through the lymphatic vessels to a regional lymph node, where it presents the antigen to immunocompetent T cells to initiate the clonal selection process. (Redrawn from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.)

Additionally, infectious microbes or fragments of the microbe may be drained by lymphatic vessels to lymph nodes. The lymph nodes are extremely rich in dendritic cells and macrophages. Pathogens entering the bloodstream may be removed by phagocytic cells in the spleen and other lymphoid tissues. In either case, the phagocytic cells that engulf foreign microbes or their fragments are also responsible for processing antigens from the pathogen and displaying or presenting those antigens on the phagocyte's surface to neighboring lymphocytes in order to initiate the adaptive immune response against that specific pathogen.

Pathways of Antigen Processing and Presentation

In general, the immune system responds to two types of antigens: exogenous and endogenous. Using infection as a model, *exogenous antigens* are carried on microorganisms that are trapped and killed by phagocytic cells; therefore they come from outside the cell. *Endogenous antigens* are synthesized within a cell. These include viral antigens because viruses infect cells and use the normal cellular protein-synthesizing machinery to translate the viral genes into viral proteins. Endogenous antigens also may include those uniquely produced by cancerous cells. When many cells undergo malignant change, they begin producing unique proteins that are specific to cancer cells and are presented as foreign antigens on the cell surface.

Exogenous and endogenous antigens are preferentially presented by different classes of MHC molecules: class I MHC molecules generally present endogenous antigens, and class II molecules prefer exogenous antigens (Fig. 8.15). Because class I MHC molecules are expressed on all cells, except red blood cells, any change in that cell attributable to viral infection or malignancy may result in foreign antigen being presented by MHC class I. Class II MHC molecules are coexpressed with MHC class I molecules on a more limited number of cells that have APC function, including macrophages, dendritic cells, B lymphocytes, activated T lymphocytes, and some endothelial cells.

FIGURE 8.15 Antigen Processing and Presentation. Antigen processing and presentation are required for initiation of most immune responses. Foreign antigen may be either endogenous (cytosolic protein) or exogenous (e.g., bacterium). Endogenous antigenic determinants (antigenic peptides) are produced by cellular proteasomes and transported by transporter associated with antigen processing (TAP) proteins into the endoplasmic reticulum (ER) where the major histocompatibility complex (MHC) and CD1 molecules are being assembled. In the ER, antigenic peptides bind to the α chains of the MHC class I molecule, and the complex is transported to the cell surface. In the ER, the α and β chains of the MHC class II molecules are also being assembled, but the antigen-binding site is blocked by a small molecule (invariant chain) to prevent interactions with endogenous antigenic peptides. The MHC class II–invariant chain complex is transported to lysosomes, where exogenous antigenic fragments have been generated as a result of phagocytosis. In the lysosomes, the invariant chain is digested and replaced by exogenous antigenic peptides, after which the MHC class II–antigen complex is inserted into the cell membrane. CD1 is also assembled in the ER, but its antigen-binding site is specific for lipid antigenic determinants and does not bind endogenous antigenic peptides. The CD1 molecule is transported to the lysosomes and may encounter and bind antigenic lipids produced by phagocytic digestion of engulfed bacteria. The CD1–antigen complex is transported to the cell membrane and presents lipid antigens.

Thus the term **antigen processing** relates to the process by which exogenous and endogenous antigens are linked with the appropriate MHC molecules. Endogenous antigens are usually components of proteins synthesized in the cytosol.¹⁷ They are degraded into small peptides in the cytosol by proteasomes and transported by TAP

(transporter associated with antigen processing) proteins (TAP-1 and TAP-2) into the endoplasmic reticulum, where MHC class I and class II molecules are assembled.¹⁸ The class I MHC molecules have open antigen-binding sites so that antigen, the class I MHC α chain, and a β_2 -microglobulin molecule form a stable complex that is transported through the Golgi apparatus to the plasma membrane. The antigenic peptides presented by class I MHC molecules are usually very small, 8 to 10 amino acids in length.

MHC class II molecules are also assembled in the endoplasmic reticulum but do not bind with endogenous antigen because the antigen-binding site is blocked by a small protein called **invariant chain**.¹⁹ Exogenous antigens are internalized by phagocytosis and small antigenic molecules produced by digestion in the lysosomes. The MHC class II complexes of the class II α and β chains, with invariant chain, are transported to the lysosomes where the invariant chain is digested and replaced by antigenic molecules that are usually slightly larger (in excess of 12 amino acids in length) than those presented by MHC class I molecules.²⁰

CD1 is a third antigen-presenting molecule that presents a variety of lipid-containing antigens that are usually derived from phagocytosis and digestion of infectious microorganisms with very high lipid content in their cell membranes. Therefore CD1 complexes with antigen in the lysosomes, in a fashion similar to MHC class II. The “pocket” that holds antigen for presentation by CD1 is generally more narrow and deeper than that described for MHC molecules, and it is lined with many hydrophobic amino acids that interact with lipid.

T-Helper Lymphocytes

Formation of a robust immune response depends on generation of a spectrum of highly specialized effector cells, Th cells. A group of immunocompetent CD4+ cells (Th precursor cells) responds to antigen presentation by undergoing proliferation and maturation into a phenotypically diverse population of cells that will (1) help immunocompetent CD8+ T cells differentiate into Tc cells and **T-memory cells (Th1 cells)**, (2) help immunocompetent B cells

differentiate into plasma cells and B-memory cells (Th2 cells), (3) increase the capacity of phagocytes to defend against infection with chronic microorganisms that are relatively resistant to normal levels of inflammation (e.g., organisms that cause tuberculosis or leprosy) (Th17 cells), and (4) limit the immune response to control excessive damage to normal tissue (Treg cells). These subpopulations of Th cells are critical to most immune responses, and a variety of major Th-cell defects that lead to severely diminished immune responses are discussed in [Chapter 9](#).

APC-Th Cooperation

Cells that are destined to become Th cells emerge from the thymus with characteristic cell surface markers. They have a functional $\alpha\beta$ TCR complex and express the surface molecule CD4 and lack CD8. These are generally referred to as *precursor Th cells*, or sometimes Thp cells ([Fig. 8.16](#)). Three critical and concurrent signals between APCs and Thp cells are necessary to initiate the Th-cell differentiation process. The first is an antigen-specific signal. The APC presents antigen held by the polymorphic regions ($\alpha 1$ and $\beta 1$) of the α and β chains of MHC class II molecules.²⁰ The antigen also binds to the TCR complex on the Th cell. The strength of the intercellular antigen binding is increased by CD4 on the Th cell, which binds to a nonpolymorphic (a region of amino acids shared by all MHC class II molecules) sequence of the $\beta 2$ region of the MHC class II molecule. As a result of collaborative binding of the TCR to the MHC class II/antigen complex, the cytoplasmic portions of CD3 (the TCR signaling complex) and the CD4 molecule interact and initiate a series of enzymatic interactions that send a signal to the nucleus.

FIGURE 8.16 Development of T-Cell Subsets. The most important step in clonal selection is the production of populations of T helper (Th) cells (Th1, Th2, and Th17) and regulatory T (Treg) cells that are necessary for the development of cellular and humoral immune responses. In this model, APCs (probably multiple populations) may influence whether a precursor Th cell (Thp cell) will differentiate into a Th1, Th2, Th17, or Treg cell. Differentiation of the Thp cell is initiated by three signaling events. (1) The antigen signal is produced by the interaction of the T-cell receptor (TCR) and CD4 with antigen presented by MHC class II molecules. A set of costimulatory signals is produced from interactions between adhesion molecules (e.g., CD80 and CD28) (not shown). A third signal is produced by the interactions of cytokines (particularly interleukin-1 [IL-1]) with appropriate cytokine receptors (IL-1R) on the Thp cell. (2) The Thp cell up-regulates IL-2 production and expression of the IL-2 receptor (IL-2R), which act in an autocrine fashion to accelerate Thp-cell differentiation and proliferation. (3) Commitment to a particular phenotype results from the relative concentrations of other cytokines. IL-12 and IFN- γ produced by some populations of APCs favor differentiation into the Th1-cell phenotype; IL-4, which is produced by a variety of cells, favors differentiation into the Th2-cell phenotype; IL-6 and TGF- β (T-cell growth factor) facilitate differentiation into Th17 cells; IL-2 and TGF- β induce differentiation into Treg cells. The Th1 cell is characterized by the production of cytokines that assist in the differentiation of cytotoxic T (Tc) cells, leading to cellular immunity, whereas the Th2 cell produces cytokines that favor B-cell differentiation and humoral immunity. Th1 and Th2 cells affect each other through the production of inhibitory cytokines: IFN- γ will inhibit the development of Th2 cells, and IL-4 will inhibit the development of Th1 cells. Th17 cells produce cytokines that affect phagocytes and increase inflammation. Treg cells produce immunosuppressive cytokines that prevent the immune response from being excessive. APC, Antigen-presenting cell; IFN, interferon; MHC, major histocompatibility complex; TGF, transforming growth factor; TNF- β , tumor necrosis factor-beta.

A second costimulatory signal results from the interactions of a variety of adhesion molecules. The antigenic signal alone is inadequate and may even inactivate the Th cell if costimulatory signals are not present.²¹ The most critical interaction is between B7 on the APC and CD28 on the Th cell, which activates the enzymatic activity of the cytoplasmic portion of CD28 and initiation of additional intracellular signaling pathways.

The third signal occurs through Th-cell cytokine receptors. In the early stages of Th-cell differentiation, IL-1 secreted by the APC provides this signal through the IL-1 receptor on the Th cell (see Fig. 8.16). Initially, the Th cell responds by producing the cytokine IL-2 and upregulation of IL-2 receptors. IL-2 is secreted and acts in an autocrine (self-stimulating) fashion to induce further maturation and proliferation of the Th cell. Without IL-2 production, the Th cell cannot efficiently mature into a functional helper cell.

Th Subsets

At this point and depending on the predominant cytokines in the immediate environment, Th cells undergo differentiation into one of several subsets: Th1, Th2, Th17, or Treg cells. These subsets have different primary functions: **Th1 cells** preferentially provide help in developing Tc cells (cell-mediated immunity), **Th2 cells** provide help for developing B cells (humoral immunity), **Th17 cells** are cytokine-secreting cells that activate macrophages, and Treg cells limit the immune response (these functions are discussed in the sections on cellular interactions). The Th subsets are cytokine-secreting (lymphokine-secreting) T cells but differ considerably in the spectrum of molecules they produce, their cytokine receptors, and intercellular adhesion molecules. Th1 cells produce IL-2, tumor necrosis factor-beta (TNF- β), and interferon-gamma (IFN- γ);²² Th2 cells produce IL-4, IL-5, IL-6, and IL-13,²³ and Th17 cells produce IL-17, IL-21, and IL-22.²⁴

Th1 and Th2 cells have different cytokine receptors and may suppress each other (Th1 cell IFN- γ will inhibit development of Th2 cells and Th2 cell IL-4 will inhibit development of Th1 cells) so that

the immune response may favor either antibody formation with suppression of a cell-mediated response, or the opposite.²⁵ For example, antigens derived from viral or bacterial pathogens and those derived from cancer cells seem to induce a greater number of Th1 cells relative to Th2 cells, whereas antigens derived from multicellular parasites and allergens may result in production of more Th2 cells. Many antigens (e.g., tetanus vaccine), however, will produce excellent humoral- and cell-mediated responses simultaneously.

How a Th cell is guided into becoming a Th1, Th2, or Th17 cell is not fully known. Some evidence indicates that different subpopulations of APCs influence the choice by secreting different profiles of cytokines that may favor one route of differentiation over another (see [Fig. 8.16](#)).

B-Cell Clonal Selection: The Humoral Immune Response

When an immunocompetent B cell encounters an antigen for the first time, only those cells with specific BCRs complementary to that antigen's determinant sites are stimulated to proliferate and differentiate (clonal selection), resulting in multiple copies of that particular B cell. The differentiated B cell becomes a **plasma cell** and can be found in the blood, secondary lymphoid organs (primarily spleen and lymph nodes), and some inflammatory sites. Each plasma cell is a factory for antibody production and is dedicated to the secretion of a single class or subclass of antibody with one variable region and therefore specificity against one antigenic determinant.

Primary and Secondary Immune Responses

The immune response to antigenic challenge has classically been divided into two phases—the primary and secondary responses. These phases occur for development of both humoral and cellular immunity but can be most easily demonstrated by serologic tests that measure plasma concentrations of antibody over time ([Fig. 8.17](#)). On initial or primary exposure to most antigens, there is a latent period,

or lag phase. After approximately 5 to 7 days, IgM antibody specific for that antigen can be detected in the circulation followed by the production of IgG against the same antigen. The quantity of IgG produced may be about equal to or less than the amount of IgM production. The amount of antibody in a serum sample is frequently referred to as the *titer*; a higher titer indicates more antibodies. This is the **primary immune response**. The lag phase is a result of the time necessary for clonal selection, including processing and presentation of antigens, induction of Th cells, interactions between immunocompetent B cells and Th cells, and maturation and proliferation of the B cells into plasma cells and memory cells. If no further exposure to the antigen occurs, the circulating antibody is catabolized (broken down) and measurable quantities fall. The individual's immune system, however, has been primed.

FIGURE 8.17 Primary and Secondary Immune Responses. Antigen responses are dominated by two classes of immunoglobulins, IgM and IgG. IgM predominates on initial exposure to the antigen in the primary response, with IgG appearing later. After the host's immune system is primed, another challenge by the same antigen induces the secondary response in which some IgM and larger amounts of IgG are produced.

A second challenge by the same antigen results in the **secondary (anamnestic) immune response**, which is characterized by a very

rapid production of a larger amount of antibody than that produced by the primary response. The rapidity of the secondary immune response is the result of the presence of memory cells that require little further differentiation into plasma cells. IgM may be transiently produced in the secondary response, and the quantity may be about the same as that produced in the primary response. IgG production is increased considerably, making it the predominant antibody class of the secondary response. It is often present in concentrations severalfold larger than those of IgM, and levels of circulating IgG specific for that antigen may remain elevated for an extended period of time. Natural infection (e.g., the virus rubella) may result in measurable levels of protective IgG for the life of the individual. Some vaccines (e.g., polio) also may produce extremely long-lived protection, although most vaccines require boosters at specified intervals.

The existence of a prolonged and protective secondary immune response explains how vaccinations provide protection against certain pathogenic microorganisms. Edward Jenner, an English physician of the late eighteenth century, performed the first well-documented vaccine trial.^{26,27} Although some of the stories about Jenner's experiments are fanciful, it is known that Jenner recognized that milkmaids were protected from the deadly smallpox virus if they had previously developed cowpox, a bovine equivalent of smallpox that causes only mild disease in humans. Jenner took material from a cowpox pustule on the hand of an infected milkmaid and injected it into the arm of an 8-year-old boy. After the boy's initial inflammatory reaction to the injection subsided, Jenner injected the boy again, this time with material from a smallpox pustule. Fortunately, the experiment was a success because Jenner is reported to have injected smallpox virus into the boy at least 20 times without the child becoming ill. In Jenner's experiment, the antigens on the cowpox virus and the smallpox virus were sufficiently similar that the cowpox antigen functioned as an altered or attenuated smallpox antigen. The antibodies and lymphocytes that recognized and destroyed cowpox also were able to recognize the smallpox virus, thereby protecting the

immunized child against smallpox. In 1798, Jenner used the term *vaccination* (*vacca* = cow) to describe his technique.

Cellular Interactions

A further sequence of cellular interactions is required to produce an effective antibody response (Fig. 8.18). The immunocompetent B cell is also an APC and expresses surface mIgM and mIgD BCRs. Unlike the T-cell receptor that can only “see” processed and presented antigen, the BCR can react with soluble antigen that has not been processed.²⁸ B cells also express surface CD21, which is a receptor for **opsonins** produced by the complement system. Circulating antigen released from the surface of a microbial pathogen will have activated the complement system through the alternative or lectin pathways. Thus complement receptors on the B cell, such as CD21 and CD19, act as co-receptors to bind antigen. Antigen binding through the BCR complex and CD21 activates the B cell to internalize, process, and present a complex of antigenic molecules and MHC class II molecules to neighboring Th2 cells. The Th2 cell binds to the presented antigen through its TCR and CD4. The intercellular bridge created through antigen induces the Th2 cell to up-regulate additional surface receptors and secrete cytokines. Interactions between CD40 on the B-cell surface and the CD40 ligand (CD40L, also called *CD154*) on the Th2 cell, as well as between B7 on the B cell and CD28 on the Th cell, provide necessary costimulatory signals. The cytokine signal is provided by Th2-cell cytokines (particularly IL-4) binding to the appropriate cytokine receptors (e.g., IL-4R) on the B cell and initiating B-cell proliferation and maturation into a plasma cell.

FIGURE 8.18 B-Cell Clonal Selection. Immunocompetent B cells undergo proliferation and differentiation into antibody-secreting plasma cells. Three signals are necessary. The antigen signal is provided by the B cell itself. A B cell can recognize soluble antigen directly through the B-cell receptor and co-receptors, such as complement receptors (*CD21*), which usually involve accessory molecules such as *CD19* (not shown). Antigen is internalized and processed for presentation by major histocompatibility complex (MHC) class II molecules, which interact with the T-cell receptor (*TCR*) and *CD4* on Th2 cells. Costimulatory signals are provided through adhesion molecules, particularly *CD40* and *CD40L* (*CD154*). The cytokine signal is provided by Th2 cytokines (particularly interleukin [*IL*]-4) binding to appropriate cytokine receptors (*IL-4R*) on the B cell. Additional cytokines influence switch to particular classes or subclasses of antibody.

Class-Switch

A major component of maturation is antibody **class-switch**, the process that results in the change in antibody production from one class to another during the primary immune response.¹¹ The immunocompetent B cell produces mIgM and mIgD before clonal selection. After encountering antigen, however, each B cell has the option of changing the class of antibody to a secreted form of one of the four IgG subclasses, one of the two IgA subclasses, or IgE, or continuing to produce IgM but changing to a secreted form, usually a pentamer. This process is called class- or **isotype-switch**. During this

process the variable region of the antibody heavy chain is conserved, and the light chain remains unchanged from that used in the BCR; therefore the antigenic specificity of new classes of antibody also remains unchanged.

The mechanism of class-switch involves another round of somatic recombination, during which the *VDJ* region encoding the heavy chain's variable region is moved to another site on the DNA that is adjacent to the gene for a different constant region. This step is under the control of activation-induced cytidine deaminase (AICD) (Fig. 8.19). The intervening DNA is cut and mended with removal of the DNA that was between the *VDJ* site and the new constant region. Specific recognition sites (switch regions) precede each constant region gene, and the particular constant region chosen for class-switch appears to be, at least partially, under the control of specific Th2 cytokines. For instance, IL-4 and IL-13 appear to preferentially stimulate switch to IgE secretion, and transforming growth factor-beta (TGF- β) and IL-5 appear to play major roles in class-switch to IgA secretion.²⁹ Thus during clonal selection a B cell may produce a population of plasma cells that are capable of producing many different classes and subclasses of antibodies against the same antigen.

FIGURE 8.19 Genetics of Class-Switch. During clonal selection, most B cells switch from expression of surface IgM and IgD to a different class or subclass of antibody. A first set of DNA rearrangements during the generation of clonal diversity resulted in formation of the *VDJ* region. The

class-switch process involves a second DNA rearrangement during which the *VDJ* region is moved to a switch region (*orange ovals*) immediately preceding the new class/subclass of antibody. In this example, the B cell undergoes class-switch to a $\gamma 1$ heavy chain and secretion of an IgG1 antibody. The intervening DNA between the *VDJ* and the selected switch region is excised, and the DNA is repaired (DNA after second rearrangement) and transcribed into a precursor ribonucleic acid (RNA). The RNA is processed to a messenger RNA (mRNA) with information for the new heavy chain.

A few antigens can bypass the need for Th cells and can directly stimulate B-cell maturation and proliferation. These are called *T cell-independent antigens* (Fig. 8.20). They are mostly bacterial products that are large and are likely to have repeating antigenic determinants (multiple identical antigenic determinant sites) that bind and cross-link several B-cell receptors. The accumulated intracellular signal is adequate to induce differentiation to a plasma cell but is not adequate to induce class-switch. The CD40-CD40L interaction is a necessary component of the signal that leads to class-switch. T cell-independent antigens usually induce a relatively pure IgM primary and secondary immune response.

FIGURE 8.20 Activation of a B Cell by a T-Cell-Independent Antigen. Molecules containing repeating identical antigenic determinants may interact simultaneously with several receptors on the surface of the B cell and induce the proliferation and production of immunoglobulins, mainly IgM.

During the differentiation of B cells into plasma cells, the CDR portions of the antibody variable region are prone to somatic point

mutations that lead to changes in single amino acids. Some of these changes produce better antibodies that bind more strongly (higher affinity) to the antigen. The presence of antigen creates a positive selective pressure toward the developing B cells that express the higher-affinity antibody, which results in a process called *affinity maturation* and an improved quality of circulating antibody over time. Plasma cells may migrate to special regions of the spleen, lymph nodes, and mucosal-associated lymphoid tissues that support the plasma cell's long-term survival and function so that an adequate level of protective antibody may be available in the circulation for decades after vaccination or resolution of infection.

B Memory Cells

During the clonal selection process, B cells differentiate into antibody-producing plasma cells and into a set of long-lived memory cells. Memory cells remain inactive until subsequent exposure to the same antigen. Upon reexposure, these memory cells do not require much further differentiation and will therefore differentiate rapidly into new plasma cells and produce larger amounts of antibody (secondary immune response).

T-Cell Activation: The Cellular Immune Response

The clonal selection process produces several subsets of effector T cells (different phenotypes of Th cells have been discussed in the section on [Th subsets](#)). Clonal selection of other T-cell phenotypes is dependent on help by the Th1 cell phenotype. Other effector cells include Tc cells that attack and destroy cells expressing antigens of intracellular (endogenous) origins (virus-infected cells, cancer cells), T-regulatory cells (Treg cells) that limit (suppress) the immune response, and T-memory cells that provide a rapid cell-mediated immune reaction to repeated exposure to the same antigen (secondary immune response).

Cellular Interactions

During the clonal selection phase of the cell-mediated immune response, immunocompetent CD8⁺ T cells in the peripheral lymphoid organs must recognize antigen that has been processed and presented by MHC class I molecules (Fig. 8.21). The antigen is usually an endogenous antigen expressed on the surface of cells infected with a virus or cells that have become malignant. The antigen-driven signal for Tc-cell clonal selection is recognition of the presented antigen by the TCR combined with CD8 binding to a constant region of the MHC class I molecule α chain. The presence of the CD8 molecule confines antigen recognition to MHC class I molecules; therefore CD8⁺ T cells are *class I restricted*. The co-recognition of the MHC-antigen complex by the TCR and CD8 brings the CD8 cytoplasmic region into proximity with the CD3 components of the TCR complex, which initiates a series of enzymatic interactions among other molecules associated with the cytoplasmic portions of CD3 and CD4, as was described for Th-cell activation.³⁰ These molecules activate a signaling pathway from the TCR to the T-cell nucleus.

FIGURE 8.21 Tc-Cell Clonal Selection. The development of effector T-cytotoxic (Tc) cells during clonal selection results from three cooperative

signaling events provided by antigen, costimulatory adhesion molecules, and cytokines. The immunocompetent Tc cell “sees” antigen presented by major histocompatibility complex (MHC) class I molecules on the surface of a virally infected or cancerous “abnormal” cell. The antigen–MHC class I complex is recognized simultaneously by the T-cell receptor (TCR), which binds to antigen, and CD8, which binds to the MHC class I molecule. The proximity of signaling molecules associated with the cytoplasmic portions of CD8 and the TCR results in intracellular signaling. A separate signal results from the interaction of several groups of adhesion molecules (e.g., CD80 and CD28 in this example). The third signal is provided by the interaction of cytokine, particularly IL-2 from type 1 T-helper (Th1) cells, and the appropriate receptor.

Interactions of costimulatory adhesion molecules and cytokines are also necessary for proliferation and maturation of Tc cells. The costimulatory signals for Tc-cell maturation are virtually the same as has been described for Th-cell maturation: B7 on the cell-presenting antigen and CD28 on the T cell, CD48 on the antigen-presenting cell and CD2 on the T cell, and a variety of other adhesion molecules. Development of Tc cells also requires cytokines, especially IL-2, produced by the Th1 cell. As with B cells, some of the Tc cells that become activated in response to antigen presentation will not become effectors that destroy infected targets, but instead develop into a population of T-memory cells.³¹ These cells have the capacity to rapidly respond to further exposure to the same antigen.

Superantigens

Several pathogenic viruses and bacteria manipulate the normal interaction between APCs and Th1 cells to the detriment of the individual and the benefit of the microbe. A group of microbial molecules called **superantigens (SAGs)** binds to a portion of the TCR outside its normal antigen-specific binding site (usually to the V region of the β chain) and to MHC class II molecules outside their antigen-presentation sites (either to the α or to the β chain, depending on the particular SAG) (Fig. 8.22). These molecules are not digested and processed by an APC to be presented to an immune cell. Binding results in adherence of the TCR and MHC class II molecules, independent of antigen recognition, and provides a signal for Th-cell activation and proliferation. Other SAGs may bind to costimulatory

molecules, such as CD28, and induce similar polyclonal Th-cell activation.

FIGURE 8.22 Superantigens. The T-cell receptor (TCR) and a major histocompatibility complex (MHC) class II molecule normally simultaneously interact with a processed antigen to induce T-cell differentiation. Superantigens, such as some bacterial toxins, bind directly to the TCR and the MHC class II molecules. Superantigens activate Th cells independently of TCR antigen specificity. V, Variable; V α , variable region of the α chain; V β , variable region of the β chain.

The normal antigen-specific recognition between Th cells and APCs results in activation of relatively few cells (fewer than 0.1% of Th cells): only those cells with specific TCRs against that antigen. SAg induce polyclonal Th-cell activation (up to 25% of Th cells) regardless of the antigen specificity of the TCRs. SAg-activated T cells overproduce cytokines, especially IFN- γ , which is an activator of phenotype macrophage 1 (M1) macrophages. Extensive M1 macrophage activation leads to secretion of IL-1, IL-6, and TNF- α , which are primary mediators of systemic inflammatory responses.

The overproduction of inflammatory cytokines results in symptoms of a systemic inflammatory reaction, including fever, low blood pressure, and, potentially, fatal shock. Some examples of SAGs are the bacterial toxins produced by *Staphylococcus aureus* and *Streptococcus pyogenes* (including the superantigens that cause toxic shock syndrome and food poisoning).³²

Effector Mechanisms

Antibody Function

Protection Against Infection

The chief function of circulating antibodies is to protect against infection. Protection can be afforded by antibody in several ways, either directly or indirectly (Fig. 8.23). Directly, antibody can cause **neutralization** (inactivating or blocking the binding of an antigen to a receptor), **agglutination** (clumping insoluble particles that are in suspension), or **precipitation** (making a soluble antigen into an insoluble precipitate) of infectious agents or their toxic products. Indirectly, antibodies activate several components of innate immunity, including complement and phagocytes.

FIGURE 8.23 Direct and Indirect Functions of Antibody. Protective activities of antibodies can be direct (through the action of antibody alone) or indirect (requiring activation of other components of the innate immune response, usually through the Fc region). Direct means include neutralization of viruses or bacterial toxins before they bind to receptors on the surface of the host's cells. Indirect means include activation of the classical complement pathway through C1, resulting in formation of the membrane attack complex (MAC), or by increased phagocytosis of bacteria opsonized with antibody and complement components bound to appropriate surface receptors (FcR and C3bR).

Direct Effects.

Many pathogens initiate infection by attaching to specific receptors on cells. Viruses that cause the common cold or influenza must attach to specific receptors on respiratory epithelial cells. Some bacteria, such as *Neisseria gonorrhoeae* that causes gonorrhea, must attach to specific sites on urogenital epithelial cells. Antibodies may protect against infection by covering sites on the microorganism that are needed for attachment. Neutralization, or prevention of attachment to the host cell, thereby prevents infection of the host. Many viral infections can be prevented by vaccination with inactivated or **attenuated**

(weakened) **viruses** designed to induce neutralizing antibody production at the site of the entrance of the virus into the body. Vaccination against influenza using an inhaled vaccine particularly induces protective IgA in the respiratory tract. Viruses found in the bloodstream also may be agglutinated by antibody, rendering them unable to infect cells.

Some bacteria secrete toxins that harm individuals. For instance, specific bacterial toxins cause the symptoms of tetanus or diphtheria. Most toxins are proteins that bind to surface molecules on cells and damage those cells. Protective antibodies produced against the toxin (referred to as *antitoxins*) can bind to the toxins, prevent their interaction with cells, and neutralize their biologic effects. Additionally, antibody may precipitate soluble toxins and prevent binding to cells. Detection of the presence of an antibody response against a specific toxin can aid in the diagnosis of diseases. Group A streptococcal bacteria produce a toxin, streptolysin O, that destroys cells, particularly erythrocytes and leukocytes. The infected individual produces an antibody that can neutralize this toxin (antistreptolysin O) and can be detected in laboratory tests as a useful diagnostic tool for infections with group A streptococci.

Vaccines that induce protective antibody against toxins are commonly used. To prevent harming the recipient of immunization, bacterial toxins are chemically inactivated to destroy their harmful properties but still retain immunogenicity. These are referred to as *toxoids*. Examples of bacterial pathogens for which immunization with toxoids can provide immunologic protection include those that cause diphtheria and tetanus (others are discussed in [Chapter 10](#)).

Indirect effects.

Indirectly, through the Fc portion, antibodies activate components of innate immunity, including complement and phagocytes (see [Fig. 8.23](#)). Through the classical pathway, complement component C1 will be activated by binding simultaneously to the Fc regions of two adjacent antibodies bound to a microbe, resulting in activation of the entire cascade (see [Chapter 7](#)). Phagocytic cells express receptors that

bind the Fc portion of antibody and components of the complement cascade (e.g., C3b); thus antibody and complement are opsonins that facilitate phagocytosis of bacteria. Additionally, activation of the complement cascade may damage or destroy some infectious microbes. IgM is the best complement-activating antibody, and IgG is the best opsonin.

Because bacteria are coated with several proteins and carbohydrates, each of which has multiple antigenic determinants, a normal antibody response usually consists of a mixed population of classes, specificities, and capacity to provide the functions previously listed. Some of these antibodies are more protective than others. It is now a common procedure to clone the “best” antibodies (monoclonal antibodies) for use in diagnostic tests and for therapy (see Box E 8.1 on Evolve).

Secretory Immune Response

Immunocompetent lymphocytes migrate among secondary lymphoid organs and tissues as part of the **systemic immune system**. A distinct set of lymphoid tissues makes up another, partially independent, immune system that protects the external surfaces of the body through lacrimal and salivary glands and a network of lymphoid tissues residing in the breast, bronchi, intestines, and genitourinary tract. This system is called the **secretory (mucosal) immune system** (Fig. 8.24). Immunocompetent lymphocytes of the systemic immune system travel through the spleen and lymph nodes where they undergo clonal selection and mature into plasma cells. Lymphocytes destined for the secretory immune system undergo a different pattern of migration to mucosal areas where they undergo clonal selection and maturation. Plasma cells in those sites secrete antibodies (secretory immunoglobulins) into bodily secretions, such as tears, sweat, saliva, mucus, and breast milk, to prevent pathogenic microorganism from infecting the body's surfaces and possibly penetrating to cause systemic disease.

FIGURE 8.24 Secretory Immune System. Lymphocytes from the mucosal-associated lymphoid tissues circulate throughout the body in a pattern separate from other lymphocytes. For example, lymphocytes from the gut-associated lymphoid tissue circulate through the regional lymph nodes, the thoracic duct, and the blood and return to other mucosal-associated lymphoid tissues rather than to lymphoid tissue of the systemic immune system.

IgA is the dominant secretory immunoglobulin, although IgM and IgG also are present in secretions. The primary role of IgA is to prevent the attachment and invasion of pathogens through mucosal membranes, such as those of the gastrointestinal, pulmonary, and genitourinary tracts.³³ Dimeric IgA antibodies containing the J chain are produced by plasma cells of the mucosa. Mucosal epithelium expresses a cell surface immunoglobulin receptor that binds and internalizes IgA. The IgA, along with the epithelial receptor (secretory piece), is secreted as secretory IgA (sIgA).

The lymphoid tissues of the secretory immune system are connected; thus many foreign antigens in a mother's gastrointestinal tract (e.g., poliovirus) induce secretion of specific antibodies into the breast milk (colostral antibodies). Colostral antibodies may protect the nursing newborn against infectious disease agents that enter through

the gastrointestinal tract. Although colostral antibodies provide the newborn with passive immunity against gastrointestinal infections, they do not provide systemic immunity because transport across the newborn's gut into the bloodstream shuts down after the first 24 hours of life. Maternal antibodies that pass across the placenta into the fetus before birth provide passive systemic immunity.

Local protection is a distinct advantage to combat infectious microorganisms that are inhaled, swallowed, or otherwise come into contact with external body surfaces. Once they have taken up residence in the external layers of the body, harmful microorganisms can cause local disease or possibly penetrate the barriers described in [Chapter 7](#) to cause systemic disease. Alternatively, the microorganisms may reside in the mucosal membranes without causing disease, and may be shed and cause infection in other individuals. For instance, in the 1950s two different vaccines were developed to prevent infection with poliovirus, which enters through the gastrointestinal tract. The Sabin vaccine was administered orally as an attenuated (i.e., inactivated so as to render the virus relatively harmless) live virus. This route caused a transient, limited infection and induced effective systemic and secretory immunity, preventing both the disease and the establishment of a carrier state. The Salk vaccine, on the other hand, consisted of killed viruses that were administered by injection into the skin. It induced adequate systemic protection but did not generally prevent an intestinal carrier state. Thus recipients of the Salk vaccine were protected from disease but could still shed the virus and infect others.

The mechanisms and functions of antigen-antibody binding are the same in the secretory immune system as they are in the systemic immune systems; that is, binding neutralizes or opsonizes the antigen, preventing it from harming the host. The major differences between the two systems include (1) the order of utilization—the secretory immune response is incorporated as part of the body's first-line defense, whereas the systemic response is the body's final defense to prevent spread of infection to internal organs; (2) the lymphocytes of each system follow different paths of migration and pass through

different secondary lymphoid tissues; and (3) the secretory response occurs locally and externally (in body secretions), whereas the systemic response occurs systemically and internally (in blood and tissues).

IgE

IgE is a special class of antibody that is designed to help protect the individual from infection with large parasitic worms (helminths).³⁴ However, when IgE is produced against relatively innocuous environmental antigens, it is also the primary cause of common allergies (e.g., hay fever, dust allergies, bee stings). The role of IgE in allergies is discussed in [Chapter 9](#).

Large multicellular parasites usually invade mucosal tissues ([Fig. 8.25](#)). In response to parasitic antigens, a variety of different antibody classes are produced with many B cells class-switching to IgE-secreting plasma cells under the direction of Th2 cells primarily producing IL-4 and IL-13. IgG, IgM, and IgA bind to the surface of parasites, activate complement, generate chemotactic factors for neutrophils and macrophages, and serve as opsonins for those phagocytic cells. The influx of neutrophils and macrophages progressively leads to development of a granulomatous response around the parasite. Unique to parasitic infections, the eosinophil is a primary cell in the granuloma and the only cell that can adequately damage the parasite because of the special contents of its granules: major basic protein (binds to heparin sulfate proteoglycans), eosinophil cationic protein (a member of the RNase A family), eosinophil peroxidase, and eosinophil neurotoxin. The influx of eosinophils results from IgE-triggered mast cell degranulation.

FIGURE 8.25 IgE Function. Soluble antigens from a parasitic infection are processed by local antigen-presenting cells (APCs) and presented to Th2 cells (1), which respond by producing cytokines that favor class-switch to IgE production (2). B cells bind soluble parasite antigen, and some switch to producing IgG, whereas others switch to IgE. The secreted IgE molecules bind to IgE-specific receptors (*FcεR*) on the mast cell surface (3). Additional soluble parasite antigen cross-links IgE-*FcεR* complexes on the mast cell surface (4), leading to mast cell degranulation and release of many proinflammatory products, including eosinophil chemotactic factor of anaphylaxis (*ECF-A*) (5). Eosinophils have receptors for *ECF-A* (*ECFR*) and are stimulated to increase adherence to the vessel walls and initiate diapedesis (6) and invasion of the surrounding tissue. The eosinophil also responds by increasing the density of surface receptors for IgG (*FcγR*) and complement component C3b (*C3bR*) (7). IgG had previously attached to the antigens on the parasite's surface and activated the complement cascade (*C' activation*) in a failed attempt to damage the parasite. The eosinophil attaches to the parasite's surface through Fc and C3b receptors (8). Once bound to the parasite, the eosinophil releases its lysosomal enzymes onto the parasite, damaging its outer membrane (9). *Th2*, Type 2 T-helper cell.

Mast cells in the tissues have very high affinity Fc receptors for IgE. IgE antibody against antigens of the parasite are rapidly bound to the mast cell surface. Soluble parasite molecules with multiple antigenic determinants diffuse to neighboring mast cells and bind to multiple IgE-Fc receptors and initiate mast cell degranulation (see [Chapter 7](#)).

Eosinophil chemotactic factor of anaphylaxis (ECF-A) is released from mast cell granules and attracts eosinophils to the site of infection, as well as up-regulates surface receptors for IgG and complement component C3b. Eosinophil attachment to the parasite through these opsonins results in degranulation, releasing a variety of very toxic proteins at the eosinophil/parasite interface. These can cause extensive and lethal damage to the parasite if an adequate number of eosinophils are involved.

T-Lymphocyte Function

Killing Abnormal Cells

T-Cytotoxic Lymphocytes.

T-cytotoxic lymphocytes (Tc cells) are responsible for the cell-mediated destruction of tumor cells or cells infected with viruses. In a fashion similar to intercellular recognition during the clonal selection process, the Tc cell must directly adhere to the target cell through TCR/CD8 recognition of antigen presented by MHC class I molecules (Fig. 8.26). Because of the broad cellular distribution of MHC class I molecules, Tc cells can recognize antigen on the surface of almost any type of cell that has been infected by a virus or has become cancerous. Unlike clonal selection, the roles of costimulatory signals through adhesion molecules and cytokines are of less importance here.

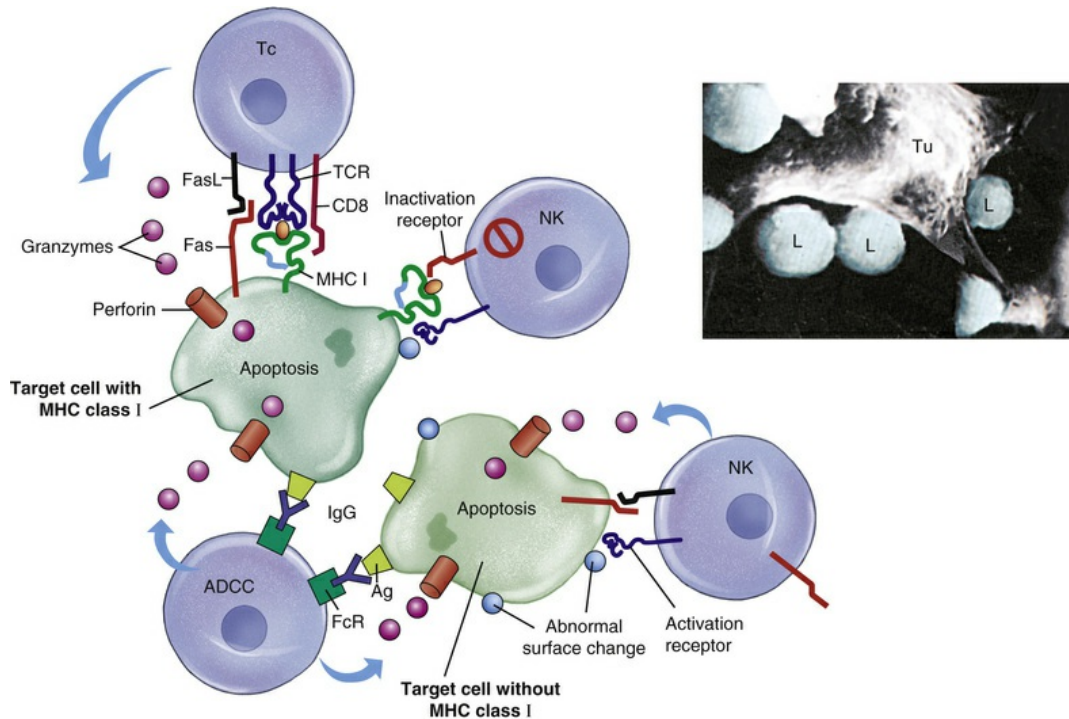

FIGURE 8.26 Cell Killing Mechanisms. Several cells have the capacity to kill abnormal (e.g., virally infected, cancerous) target cells. T-cytotoxic (*Tc*) cells recognized endogenous antigen presented by major histocompatibility complex (*MHC*) class I molecules (*cell on upper left*). The intercellular interaction is enhanced through a variety of costimulatory adhesion molecules (not shown). The *Tc* cell mobilizes multiple killing mechanisms that induce apoptosis of the target cell, including the secretion of perforin that creates pores for the entrance of granzymes into the target cell and stimulation of Fas molecules on the target cell surface by Fas ligand (*FasL*) on the *Tc* cell. Natural killer (*NK*) cells (*cells on right*) use the same mechanisms to kill target cells through activation receptors that recognize “abnormal surface changes.” *NK* cells specifically kill targets that have down-regulated expression of surface *MHC* class I molecules. Targets expressing *MHC* class I molecules inactivate *NK* cells through a variety of inactivation receptors (*cell on upper right*). Several cells, including macrophages and *NK* cells, can kill by antibody-dependent cell-mediated cytotoxicity (*ADCC*). *IgG* antibody binds to foreign antigen on the target cell. Cells involved in *ADCC* (*cell on lower left*) bind *IgG* through *Fc* receptors (*FcRs*) and initiate killing. The insert is a scanning electron microscopic view of *Tc* cells (*L*) attacking a much larger tumor cell (*Tu*). (Insert from Abbas A, Lichtman A: *Cellular and molecular immunology*, ed 5, Philadelphia, 2003, Saunders.)

After attachment to a target cell, killing can occur by at least two different mechanisms that induce apoptosis: through the actions of perforin and granzyme or by direct receptor interactions. Perforins and granzymes are contained in *Tc*-cell lysosomal granules, which are released onto the surface of the target cell. Perforin acts in a fashion similar to *C9* of the complement cascade and penetrates, polymerizes,

and forms pores in the target cell's plasma membrane. The granzymes enter the target cell through the perforin-lined pores and activate cellular enzymes (caspases) that initiate apoptosis and death of the target. Additionally, target cell apoptosis can be induced directly through the stimulation of specific receptors on the cell surface. For instance, Tc cells express a surface molecule called *Fas ligand*, which is very similar to TNF- α and reacts with a protein called *Fas* (CD95) on the target cell surface. Activation of Fas signals the target cell to undergo apoptosis.

Other Cells That Kill Abnormal Cells.

Various other cells kill targets in a fashion similar to Tc lymphocytes. Prominent among these cells are natural killer (NK) cells (see [Chapter 7](#)). NK cells are a special group of lymphoid cells that are similar to Tc cells.³⁵ NK cells are not selected in the thymus and lack antigen-specific receptors. Instead, they express a variety of cell surface activation receptors (similar to pattern recognition receptors, see [Chapter 7](#)) that identify protein changes on the surface of cells infected with viruses or that have become cancerous. After attachment, the NK cell kills its target in a manner similar to that of Tc cells. NK cells also have receptors for MHC class I. However, NK cells lack CD8 so that binding to MHC class I molecules results in an inactivation signal in the NK cell.

NK cells complement the target cell specificity of Tc cells; Tc cells kill targets that express MHC class I, and NK cells kill targets that do not express MHC class I (see [Fig. 8.26](#)). In some instances, a virus infected or cancerous cell will “protect” itself by down-regulating MHC class I molecule expression. Without surface MHC class I molecules a cell becomes resistant to Tc-cell recognition and killing. However, suppression of MHC class I results in vulnerability to NK cells. Thus Tc cells kill abnormal cells that continue to express MHC class I, whereas NK cells kill abnormal cells that have suppressed MHC class I expression.

NK cells, as well as some macrophages, can specifically kill targets through the use of antibodies. NK cells express Fc receptors for IgG

(CD16, a marker for NK cells). If antigens on the cell are infected with virus or a cancerous cell binds IgG, the NK cell can attach through the Fc receptors and activate its normal killing mechanisms. This is referred to as **antibody-dependent cell-mediated cytotoxicity (ADCC)** (see [Fig. 8.26](#)).

Another population of NK-like cells has been identified, NK-T cells. NK-T cells are produced in the thymus and more closely resemble Tc cells. However, they express TCRs that have very limited variability and recognize antigens presented by CD1.

T Cells That Activate Macrophages

Th1, Th2, and Th17 cells produce cytokines that amplify inflammation. Th1 cells secrete cytokines that activate M1 macrophages to increase phagocytosis and microbial killing³⁶ (see [Fig. 8.27](#) and described in [Chapter 7](#)). The most important Th1-cell cytokine for M1 macrophage activation is interferon- γ (IFN- γ). IFN- γ -induced macrophage activation is also achieved by NK cells and CD8+ Tc cells. Additional signals (e.g., the CXC chemokine macrophage migration inhibitory factor) retain macrophages at inflammatory sites and increase intercellular adhesion between the Th1 cell (CD40L) and the macrophage (CD40). Th2 cells secrete cytokines (e.g., IL-4, IL-13) that activate M2 macrophages for healing and repair of damaged tissue (described in [Chapter 7](#)). Th17 cells secrete a set of cytokines (e.g., IL-17, IL-21, IL-22) that recruit phagocytic cells, particularly neutrophils and macrophages, to a site of inflammation.³⁷ Th17 cell cytokines also may activate cells, particularly epithelial cells, to produce antimicrobial proteins in defense against certain bacterial and fungal pathogens. IL-17 cytokines induce epithelial cell chemokines and neutrophil infiltration, and IL-22 affects production of antimicrobial protein by epithelial cells. Thus Th17 cells control many aspects of inflammation, including chronic inflammation.

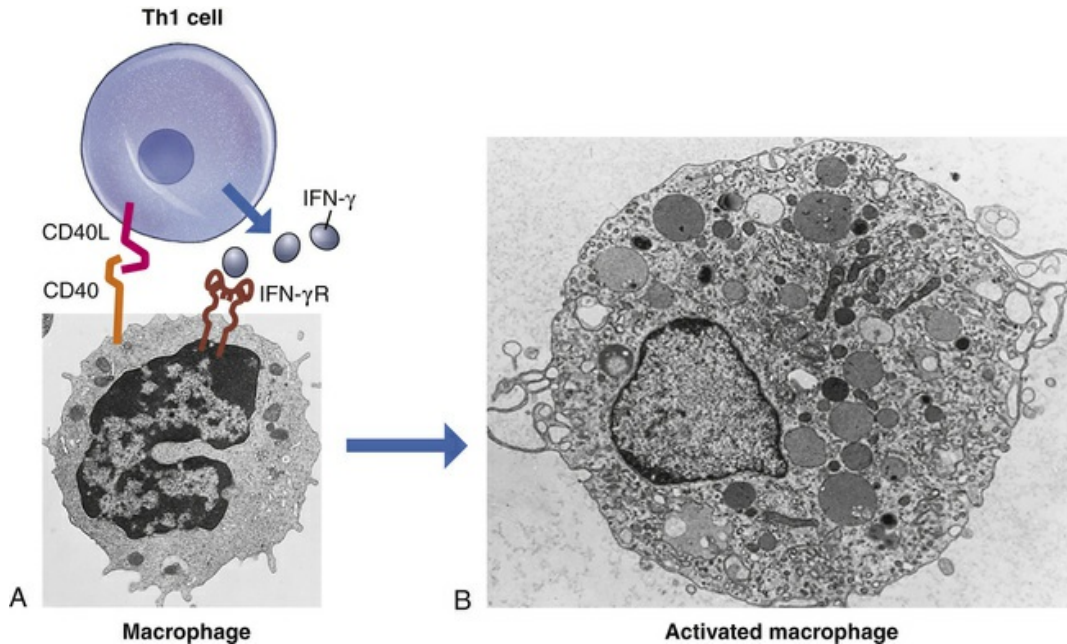

FIGURE 8.27 Activation of a Macrophage by a T Cell. A population of T cells that helps immune and inflammatory responses (T-helper cells or Th1 cells) produces cytokines that activate macrophages. Optimal macrophage activation also requires close contact among the cells, which is mediated by a variety of adhesion molecules expressed on the surface of each cell (CD40L and CD40 shown here). *CD40L*, CD40 ligand; *IFN- γ* , interferon-gamma; *IFN- γ R*, receptor for interferon-gamma. (Micrograph in A courtesy Dr. Noel Weidner, Department of Pathology, University of California, San Diego. B from Fawcett DW: *Bloom and Fawcett: a textbook of histology*, ed 12, New York, 1994, Chapman & Hall. With kind permission of Springer Science and Business Media.)

T-Regulatory Lymphocytes

T-regulatory (Treg) cells are a diverse group of T cells that control the immune response, usually suppressing the response and maintaining tolerance against self-antigens. This process occurs in the secondary lymphoid organs and other tissues; therefore it is referred to as *peripheral tolerance*,³⁸ in contrast to the process of central tolerance described earlier. This population of Treg cells that differentiates from the Th-cell population expresses CD4 and binds to antigens presented by MHC class II molecules (see Fig. 8.16). Unlike other Th cells, however, Treg cells express consistently high levels of CD25 (the α chain of the IL-2 receptor) and are frequently designated CD4+, CD25+ Treg cells. Differentiation from the Th precursor cell is controlled

primarily by TGF- β and IL-2. Treg cells produce very high levels of the immunosuppressive cytokines TGF- β and IL-10, which generally decrease Th1 and Th2 activity by suppressing antigen recognition and Th-cell proliferation.

B-regulatory (Breg) cells contain a population of B cells that functions in a similar fashion to Treg cells. Breg cells control peripheral tolerance through the production of immunosuppressive cytokines (IL-10, IL-35, TGF- β) that suppress proliferation of autoreactive Th cells.³⁹

Fetal and Neonatal Immune Function

The normal human infant is immunologically immature at birth. Although cell-mediated immunologic capabilities begin developing early in gestation and probably are completely functional at birth, phagocytic activity, antibody production, and complement activity are clearly deficient. In the last trimester, the fetus appears capable of producing a primary immune response (almost entirely IgM) to in utero infections (e.g., cytomegalovirus, rubella virus, and *Toxoplasma gondii*) but is unable to produce a significant IgG response. Although some IgA can be detected, the capacity to produce IgA is underdeveloped.

To protect the child against infectious agents both in utero and during the first few postnatal months, a system of active transport facilitates the passage of maternal antibodies into the fetal circulation (Fig. 8.28). In the placenta, maternal and fetal blood is separated by a layer of specialized multinucleate cells termed *syncytiotrophoblasts*. Immunoglobulins are too large to diffuse across this cellular layer so the trophoblastic cells actively transport immunoglobulins from the maternal to the fetal circulation. Active transport of maternal IgG is mediated by surface receptors that are specific for the Fc portion of free IgG but not for IgM, IgE, or IgA. Active transport sometimes results in higher **antibody titers** in umbilical cord blood than in maternal blood. (Active transport mechanisms are discussed in [Chapter 1](#).)

FIGURE 8.28 Transport of IgG Across the Syncytiotrophoblast. The human placenta is covered with a specialized multinucleated cell, the syncytiotrophoblast. Transport of maternal IgG across the syncytiotrophoblast and into the fetal circulation is an active process. Maternal IgG binds to Fc receptors on the surface of the syncytiotrophoblast and is internalized by the process of endocytosis. Receptors on the syncytiotrophoblast are specific for the Fc portion of IgG and do not bind other classes of immunoglobulins. Interaction of IgG with Fc receptors protects the antibody from lysosomal digestion during transport of the vacuole across the cell (i.e., transcytosis). On the fetal side of the syncytiotrophoblast, IgG is released by exocytosis (see [Chapter 1](#)).

At birth, total IgG levels in the umbilical cord are near adult levels ([Fig. 8.29](#)). When the source of maternal antibodies is severed at birth, antibody titers in the newborn begin to drop as maternal antibody is catabolized. Thus antibody titers drop rapidly as the neonate's production of IgG is beginning to rise. The rate of catabolism is usually more rapid than the rate of production so that the total immunoglobulin levels reach a minimum at 5 to 6 months in the normal child, occasionally causing transient hypogammaglobulinemia (insufficient quantities of circulating immunoglobulins). Many normal infants experience recurrent mild respiratory tract infections at this age.

FIGURE 8.29 Antibody Levels in Umbilical Cord Blood and in Neonatal Circulation. Early in gestation, maternal IgG begins crossing the placenta and enters the fetal circulation. At birth, the fetal circulation may contain nearly adult levels of IgG, which is almost exclusively from the maternal source. The fetal immune system has the capacity to produce IgM and small amounts of IgA before birth (not shown). After delivery, maternal IgG is rapidly catabolized and neonatal IgG production increases.

Aging and Immune Function

Immune function decreases with age as a result of changes in both lymphocyte function and relative lymphocyte populations. Individuals older than 60 years of age generally exhibit decreased T-cell activity as demonstrated by laboratory assays of T-cell function, as well as in vivo reductions in cell-mediated responses to infections. The thymus, where T cells begin their development, reaches its maximum size at sexual maturity and then undergoes involution until the thymus is only 15% of its maximum size by middle age.⁴⁰ Decrease in thymic activity is accompanied by decreased production of thymic hormones, and the capacity to mediate T-cell differentiation decreases with this atrophy. Although the total number of circulating T cells does not decrease with age, there is a shift in the populations of T-cell subtypes.

B-cell function is also altered with age as shown by decreases in specific antibody production in response to antigenic challenge, with concomitant increases in circulating immune complexes and in circulating autoantibodies (antibodies against self-antigens). A decrease in the number of circulating memory B cells is also observed.

Summary Review

General Characteristics of Adaptive Immunity

1. The third line of defense is adaptive immunity, often called the immune response. It consists of lymphocytes and serum proteins called antibodies. The adaptive immune response develops more slowly than inflammation and is exquisitely specific in response to a particular infectious agent.
2. Compared with the innate inflammatory response, the adaptive immune response is slower, is specific (rather than nonspecific or general), and has “memory” that makes it much longer lived.
3. The adaptive immune response is most often initiated by cells of the innate system. These cells process and present portions of invading pathogens (i.e., antigens) to lymphocytes in peripheral lymphoid tissue.
4. The adaptive immune response is mediated by two different types of lymphocytes—B lymphocytes and T lymphocytes. Each has distinct functions. B cells are responsible for humoral immunity that is mediated by circulating antibodies, whereas T cells are responsible for cell-mediated immunity, in which they kill targets directly or stimulate the activity of other leukocytes.
5. Both T cells and B cells are programmed to recognize only one specific antigen before having encountered that antigen. B and T cells have an extensive diversity of antigen receptors capable of recognizing different antigens. This process is called clonal diversity. Clonal selection is initiated by exposure to foreign

antigen usually related to infection.

6. Most antigens need to be processed (antigen processing) by phagocytic cells, primarily dendritic cells. These cells also present processed antigen on their surfaces and present (antigen presentation) the antigen to lymphocytes. These antigen-presenting cells (APCs) define clonal selection involving APCs and subsets of B and T cells. B cells develop into plasma cells and become factories for the production of antibody.
7. T cells develop into subsets that identify and kill a target cell (T-cytotoxic [Tc cell]), regulate the immune response (T-helper cell [Th cell]), or suppress or limit the immune response (T-regulatory [Treg cell]). Both B and T cells also differentiate into very long-lived memory cells.
8. Antibodies and T cells both protect against infection. Antibody is primarily responsible for protection against many bacteria and viruses. This arm of the immune response is termed the humoral immune response, or humoral immunity.
9. Effector T cells are found in the blood and in tissues and organs and defend against intracellular pathogens (e.g., some viruses) and cancer cells. This arm of the immune response is termed the cellular immune response, or cellular immunity.
10. Active immunity (active acquired immunity) is produced by an individual either after natural exposure to an antigen or after immunization, whereas passive immunity (passive acquired immunity) does not involve the host's immune response at all. Rather, passive immunity occurs when preformed antibodies or T lymphocytes are transferred from a donor to the recipient.
11. Passive immunity can occur naturally, as in the passage of maternal antibodies across the placenta to the fetus, or artificially, as in a clinic using immunotherapy for a specific disease.

Recognition and Response

1. Antigens are the molecules that can react with components of the adaptive immune system, including antibodies and lymphocyte surface receptors. Immunogens are antigens that can initiate the adaptive immune response. To be immunogenic, an antigen must be of the correct type, size, and complexity and be present in sufficient quantities. Haptens are small-molecular-weight antigens that are not themselves immunogenic.
2. Both B and T lymphocytes bind antigen through cognate receptor complexes on their surfaces. These receptor complexes (i.e., the BCR and TCR complexes, respectively) work in conjunction with accessory proteins to produce lymphocyte activation.
3. The antigen-binding molecule of the BCR is antibody. Antibodies are composed of four polypeptide chains—two identical heavy chains and two identical light chains—held together by disulfide bonds. Each heavy chain has a variable region and a large constant region. Each light chain has a variable region and a short constant region. The class of antibody is determined by which constant regions make up their heavy chains, giving each class a slightly different molecular structure. The classes include IgG (the most prevalent), IgA (mostly in secretions), IgE (the most rare), IgD, and IgM (the first and largest immunoglobulin produced). The parts of antibody that bind antigen are called the Fab, and the part that reacts with cells and molecules of the innate system is called the Fc. Antigen binds to hypervariable regions (complementary-determining regions, or CDRs) of both the heavy and the light chains.
4. For most antigens to elicit an immune response, they must be presented to lymphocytes by molecules on the surface of antigen-presenting cells. Endogenous protein antigens are presented by class I molecules of MHC. Exogenous protein antigens are presented by class II MHC molecules. Lipid antigens are presented by CD1.

5. The MHC is a cluster of genes found on human chromosome 6. The products of these genes are also called *HLA antigens*. The MHC genes are highly polymorphic, having many different possible alleles. An individual will carry only two alleles at each locus, one from each parent. The particular combination of alleles given individuals carry define their MHC haplotype.
6. For an immune response to develop, a variety of cells must interact through surface adhesion molecules.
7. During their interactions, cells must communicate with each other through soluble cytokines. In addition to their roles in the innate immune response, cytokines have multiple functions in the adaptive immune response including both positive and negative regulation of B-cell and T-cell maturation. In general, it is the precise combination of cytokines influencing a given cell that ultimately determines that cell's response.

Generation of Clonal Diversity

1. The generation of clonal diversity occurs in the primary lymphoid organs (thymus for T cells, bone marrow for B cells) in the fetus.
2. An individual's population of T cells and B cells has the collective ability to respond to virtually any antigen. This ability results from genetic rearrangement of various genes to form the variable regions for the TCR and BCR. Rearrangement of *V* and *J* genes results in the variable regions of the TCR α chain and the BCR light chain, and rearrangement of *V*, *D*, and *J* genes results in the variable regions of the TCR β chain and the BCR heavy chain.
3. Differentiation of B cells and T cells in the primary lymphoid organs results in expression of several characteristic surface markers, such as CD4 on helper T cells, CD8 on cytotoxic T cells, and CD21 and CD40 on B cells.
4. During generation of clonal diversity, B cells and T cells that

produce receptors against self-antigens are eliminated by a process of central tolerance.

5. Cells leaving the primary lymphoid organs are immunocompetent (capable of reacting to antigen) and enter the circulation and secondary lymphoid organs.

Induction of an Immune Response: Clonal Selection

1. Clonal selection is the process by which antigen selects lymphocytes with complementary TCRs or BCRs and induces an immune response with the production of specific antibody or cytotoxic T cells, or both.
2. For lymphocyte activation, most antigens must be processed and presented by an APC in the context of the appropriate molecule, either MHC class I, MHC class II, or CD1 molecules.
3. Most immune responses require T-helper cells (Th cells). Precursor Th cells interact with APCs through the TCR-CD4 complex, a variety of adhesion molecules, and cytokines, especially IL-1, and develop into either Th1 or Th2 subsets. Th1 cells are responsible for helping to activate macrophages and cytotoxic T cells, whereas Th2 cells are responsible for helping to activate B cells.
4. Another set of Th cells, Th17 cells, provides help in developing inflammation, particularly attraction of neutrophils and macrophages and induction of chemokine and antimicrobial protein production by epithelial cells.
5. B-cell activation results from recognition of soluble antigen by the BCR, processing of the antigen, and presentation by MHC class II antigens to Th2 cells. Interactions between the B cells and Th2 cells through adhesion molecules (e.g., CD40 and CD40L) are also required. Depending on the particular combination of cytokines produced by the Th2 cell, the B cells can undergo class-switch from making IgM antibody to making and secreting either IgA, IgE, or IgG.

6. The humoral immune response is divided into two phases, primary and secondary. These differ in the relative amounts of IgG produced—the secondary response having a much higher proportion of IgG relative to IgM. The two responses also differ in the speed with which each occurs after antigen challenge—the secondary response being much more rapid than the primary response because of the presence of memory cells in the secondary phase.
7. B cells become activated upon recognition of a particular antigen to proliferate and differentiate either into plasma cells that function as factories for the synthesis of large amounts of antibody that is specific for the recognized antigen or into memory B cells.
8. T-cell activation results from recognition by the TCR and CD8 of antigen presented by MHC class I. Appropriate intercellular adhesion molecules and cytokines, such as IL-2 from Th1 cells, are also necessary for efficient differentiation. T cells become cytotoxic T lymphocyte (CTLs) or memory T cells.
9. Superantigens are molecules produced by infectious agents that can bind to the TCR of the Th cell outside the normal antigen-binding site and to class II MHC on the APCs, resulting in activation of a large number of Th cells and excessive production of proinflammatory cytokines that may cause shock and death of the patient. Examples of these antigens, called *superantigens*, include the bacterial toxins that can cause toxic shock syndrome and food poisoning.

Effector Mechanisms

1. The antibodies that are produced by B cells affect antigens by several different mechanisms that can be categorized as either direct or indirect. Direct mechanisms are mediated by the antigen-binding portions of antibodies (the Fab portions containing the variable regions). This binding results in neutralization of the biologic activity of antigens and possibly

removal of the antigen by agglutination or precipitation. Indirect mechanisms depend on both the Fab and the non-antigen-binding portion of antibodies (the Fc portions containing the constant regions), which interact with components of innate immunity.

2. Antibodies of the systemic immune system function throughout the body, whereas antibodies of the secretory (mucosal) immune system—primarily immunoglobulins of the IgA class—are associated with bodily secretions and function to prevent pathogenic infection on epithelial surfaces.
3. T-cytotoxic cells (Tc cells) adhere directly to antigen presented by MHC class I on target cells (virus-infected cells or cancer cells) through the TCR, CD8, and a variety of adhesion proteins. This contact results in killing of the target by apoptosis through the release of perforin and granzymes and/or direct stimulation of apoptotic receptors on the target (e.g., Fas).
4. NK cells kill targets in a fashion similar to that of Tc cells. However, NK cells recognize target cells that do not express MHC class I.
5. Th1, Th2, and Th17 cells produce cytokines that amplify inflammation. Th1 cells secrete cytokines that activate M1 macrophages to increase phagocytosis and microbial killing. The most important Th1 cell cytokine for M1 macrophage activation is interferon- γ (IFN- γ). Th2 cells secrete cytokines (e.g., IL-4, IL-13) that activate M2 macrophages for healing and repair of damaged tissue (described in [Chapter 7](#)). Th17 cells secrete a set of cytokines (e.g., IL-17, IL-21, IL-22) that recruit phagocytic cells, particularly neutrophils and macrophages, to a site of inflammation.
6. T-regulatory (Treg) cells are a diverse group of T cells that control the immune response, usually suppressing the response and maintaining tolerance against self-antigens. This process occurs in the secondary lymphoid organs and other tissues; therefore it is referred to as peripheral tolerance.

7. B-regulatory (Breg) cells contain a population of B cells that functions in a similar fashion to Treg cells. Breg cells control peripheral tolerance through the production of immunosuppressive cytokines (IL-10, IL-35, TGF- β) that suppress proliferation of autoreactive Th cells.

Fetal and Neonatal Immune Function

1. The human neonate has a poorly developed immune response, particularly in the production of IgG. The fetus and neonate are protected in utero and during the first few postnatal months by maternal antibody that was actively transported across the placenta.
2. The maternal antibodies are slowly catabolized after birth until they disappear altogether by about 10 months of age. At birth, total IgG levels in the umbilical cord are near adult levels. The neonate begins producing IgG at birth, and the child's antibodies reach protective levels after about 6 months of age.

Aging and Immune Function

1. T-cell activity is deficient in older adults, and a shift in the balance of T-cell subsets is observed. These changes may result in increased susceptibility to infection.
2. Antibody production to specific antigens is inferior, although older adults tend to have increased levels of circulating autoantibodies.

Key Terms

Active immunity (active acquired immunity), 223

Adaptive (acquired) immunity, 220

Agglutination, 245

Initial Clinical Presentation, 273

Primary Immune Deficiencies, 275

Secondary Immune Deficiencies, 280

Evaluation and Care of Those with Immune Deficiency, 283

Replacement Therapies for Immune Deficiencies, 284

The immune system is a finely tuned network that protects the host against foreign antigens, particularly infectious agents. Sometimes this

network breaks down, causing the immune system to react inappropriately. Inappropriate immune responses may be (1) exaggerated against environmental antigens (allergy); (2) misdirected against the host's own cells (autoimmunity); (3) directed against beneficial foreign tissues, such as transfusions or transplants (alloimmunity); or (4) be insufficient to protect the host (immune deficiency). All of these can be serious or life threatening. Exaggerated immune responses (allergy) are the most common, but usually the least life threatening.

Hypersensitivity: Allergy, Autoimmunity, and Alloimmunity

Hypersensitivity is an altered immunologic response to an antigen that results in disease or damage to the host. *Hypersensitivity reactions* can be classified in two ways: by the source of the antigen that the immune system is attacking (allergy, autoimmunity, alloimmunity; [Table 9.1](#)) and by the mechanism that causes disease (types I, II, III, and IV; see [Table 9.3](#)). **Allergy** originally denoted both facets of the immune response: immunity, which is beneficial, and hypersensitivity, which is harmful. Allergy has now come to mean the deleterious effects of hypersensitivity to environmental antigens, and immunity means the protective responses to antigens expressed by disease-causing agents.

TABLE 9.1

RELATIVE INCIDENCES AND EXAMPLES OF HYPERSENSITIVITY REACTIONS*

TARGET ANTIGEN	MECHANISM			
	TYPE I (IMMUNOGLOBULIN E-[IgE] MEDIATED)	TYPE II (TISSUE SPECIFIC)	TYPE III (IMMUNE COMPLEX)	TYPE IV (CELL-MEDIATE)
Allergy	++++	+	+	++
Environmental antigens	Hay fever	Hemolysis in drug allergies	Gluten (wheat) allergy	Poison ivy allergy

Autoimmunity	±	++	+++	+
Self-antigens	May contribute to some type III reactions	Autoimmune thrombocytopenia	Systemic lupus erythematosus	Hashimoto thyroiditis
Alloimmunity	±	++	+	++
Another person's antigens	May contribute to some type III reactions	Hemolytic disease of the newborn	Anaphylaxis to IgA in IV gamma-globulin	Graft rejection

*The frequency of each reaction is indicated in a range from rare (±) to very common (++++). An example of each reaction is given.

Autoimmunity is a disturbance in the immunologic tolerance of self-antigens. The immune system normally does not strongly recognize the individual's own antigens. Healthy individuals of all ages, but particularly older adults, may produce low quantities of antibodies against their own antigens (*autoantibodies*), without development of overt autoimmune disease. Therefore, the presence of low quantities of autoantibodies does not necessarily indicate a disease state. Autoimmune diseases occur when the immune system reacts against self-antigens to such a degree that the person's own tissues are damaged by autoantibodies or autoreactive T cells. Many clinical disorders are associated with autoimmunity and are collectively referred to as **autoimmune diseases** (Table 9.2).

TABLE 9.2

DISORDERS ASSOCIATED WITH AUTOIMMUNITY

SYSTEM DISEASE	ORGAN OR TISSUE	PROBABLE SELF-ANTIGEN
Endocrine System		
Hyperthyroidism (Graves disease)	Thyroid gland	Receptors for thyroid-stimulating hormone on plasma membrane of thyroid cells
Autoimmune thyroiditis	Thyroid gland	Thyroglobulin; microsomes
Primary myxedema	Thyroid gland	Microsomes
Insulin-dependent diabetes	Pancreas	Islet cells, insulin, and insulin receptors on pancreatic cells
Addison disease	Adrenal gland	Surface antigens on steroid-producing cells; microsomes of adrenal cortex

Premature gonadal failure	Ovary	Interstitial cells; corpus luteum
Male infertility	Testis	Surface antigens on spermatozoa
Orchitis	Testis	Germinal epithelium
Female infertility	Ovary	Zona pellucida
Idiopathic hypoparathyroidism	Parathyroid gland	Surface antigens on chief cells (epithelial cells of gland)
Partial pituitary deficiency	Pituitary gland	Prolactin-producing cells; growth hormone-producing cells
Skin		
Pemphigus vulgaris	Skin	Intercellular substances in stratified squamous epithelium
Bullous pemphigoid	Skin	Basement membrane
Dermatitis herpetiformis	Skin	Basement membrane (immunoglobulin A [IgA])
Vitiligo	Skin	Surface antigens on melanocytes (melanin-producing cells)
Neuromuscular Tissue		
Polymyositis (dermatomyositis)	Muscle	Nuclear materials; myosin
Multiple sclerosis	Neural tissue	Unknown
Myasthenia gravis	Neuromuscular junction	Acetylcholine receptors; striations of skeletal and cardiac muscle
Polyneuritis	Nerve cell	Peripheral myelin
Rheumatic fever	Heart	Cardiac tissue (subsarcolemmal membrane); cross reaction with group A streptococcal antigen
Cardiomyopathy	Heart	Cardiac muscle
Postvaccinal or postinfectious encephalitis	Central nervous system	Central nervous system myelin or basic protein
Gastrointestinal System		
Celiac disease (gluten-sensitive enteropathy)	Intestine	Gluten
Ulcerative colitis	Colon	Mucosal cells
Crohn disease	Ileum	Unknown
Pernicious anemia	Stomach	Surface antigens of parietal cells; intrinsic factor
Atrophic gastritis	Stomach	Parietal cells

Primary biliary cirrhosis	Liver	Mitochondria; cells of bile duct
Chronic active hepatitis	Liver	Surface antigens, nuclei, microsomes, mitochondria or hepatocytes; smooth muscle
Eye		
Sjögren syndrome	Lacrimal gland	Antigens of lacrimal gland, salivary gland, thyroid, and nuclei of cells; immunoglobulin G (IgG)
Uveitis	Uveal structures	Antigens of the iris, ciliary body, and choroid
Connective Tissue		
Ankylosing spondylitis	Joints	Sacroiliac and spinal apophyseal joint
Rheumatoid arthritis	Joints	IgG; collagen
Systemic lupus erythematosus	Multiple sites	Numerous antigens in nuclei, organelles, and extracellular matrix
Mixed connective tissue disease	Multiple sites	Ribonucleoprotein and numerous other nucleoproteins
Polyarteritis nodosa (necrotizing vasculitis)	Arterioles (small arteries)	Unknown
Scleroderma (progressive systemic sclerosis)	Multiple organs	Nuclear antigens; IgG
Felty syndrome	Joints	IgG
Antiphospholipid antibody syndrome	Platelets, endothelial cells, trophoblast of placenta	Membrane phospholipids, especially phosphatidylserine
Renal System		
Immune complex glomerulonephritis	Kidney	Numerous immune complexes
Goodpasture syndrome	Kidney	Glomerular basement membrane
Hematologic System		
Idiopathic neutropenia	Neutrophil	Surface antigens on polymorphonuclear neutrophils
Idiopathic lymphopenia	Lymphocytes	Surface antigens on lymphocytes
Autoimmune hemolytic anemia	Erythrocytes	Surface antigens on erythrocytes
Autoimmune thrombocytopenic purpura	Platelets	Surface antigens on platelets
Respiratory System		
Goodpasture syndrome	Lung	Septal membrane of alveolus

Alloimmunity (also termed *isoimmunity*) occurs when the immune system of one individual produces a reaction against tissues of another individual. Alloimmunity can be observed during immunologic reactions against transfusions, transplanted tissue, or the fetus during pregnancy.

The mechanism that initiates the onset of hypersensitivity, whether it consists of allergy, autoimmunity, or alloimmunity, is not completely understood. It is generally accepted that genetic, infectious, and possibly environmental factors contribute to hypersensitivity. Most diseases caused by hypersensitivity develop because of the interactions of at least three variables: (1) an original “insult,” which alters **immunologic homeostasis** (a steady state of tolerance to self-antigens or lack of immune reaction against environmental antigens); (2) the individual's genetic makeup, which determines the degree of the resultant immune response from the effects of the insult; and (3) an immunologic process that causes the symptoms of the disease.

Mechanisms of Hypersensitivity

Diseases caused by hypersensitivity reactions can be characterized also by the particular immune mechanism that results in the disease (see [Table 9.1](#)). These mechanisms are apparent in most hypersensitivity reactions and have been divided into four distinct types: type I (immunoglobulin E [IgE]–mediated) hypersensitivity reactions, type II (tissue-specific) hypersensitivity reactions, type III (immune complex–mediated) hypersensitivity reactions, and type IV (cell-mediated) hypersensitivity reactions ([Table 9.3](#)).¹ This classification is artificial and seldom is a particular disease associated with only a single mechanism. The four mechanisms are interrelated, and in most hypersensitivity reactions, several mechanisms can be at work simultaneously or sequentially. Some of the mechanisms are secondary to the disease and not directly involved in the pathologic process, whereas others are the primary cause of tissue destruction.

TABLE 9.3

IMMUNOLOGIC MECHANISMS OF TISSUE DESTRUCTION

TYPE	NAME	RATE OF DEVELOPMENT	CLASS OF ANTIBODY INVOLVED	PRINCIPAL EFFECTOR CELLS INVOLVED	COMPLEMENT PARTICIPATION	EX D
I	IgE-mediated reaction	Immediate	IgE	Mast cells	No	Se
II	Tissue-specific reaction	Immediate	IgG, IgM	Macrophages in tissues	Frequently	Au
III	Immune complex-mediated reaction	Immediate	IgG, IgM	Neutrophils	Yes	Sys
IV	Cell-mediated reaction	Delayed	None	Lymphocytes, macrophages	No	Co

Ig, Immunoglobulin.

Hypersensitivity reactions require *sensitization* against a particular antigen that results in primary and secondary immune responses. An individual is sensitized when an adequate amount of antibodies or T cells is available to cause a noticeable reaction on reexposure to the antigen. Some individuals become sensitized quite rapidly (after an apparent single exposure to the antigen), whereas others require multiple exposures that may occur over years. After sensitization has been achieved, hypersensitivity reactions can be immediate or delayed, depending on the time between reexposure to the antigen and the onset of clinical symptoms. Reactions that occur within minutes to a few hours are termed **immediate hypersensitivity reactions**. **Delayed hypersensitivity reactions** may take several hours to appear and are at maximum severity days after reexposure to the antigen.

The most rapid and severe immediate hypersensitivity reaction is **anaphylaxis**. Anaphylaxis occurs within minutes of reexposure to the

antigen and can be either systemic (generalized) or cutaneous (localized).² Symptoms of systemic anaphylaxis include itching, erythema, headaches, vomiting, abdominal cramps, diarrhea, and breathing difficulties. The most severe reactions may include contraction of bronchial smooth muscle, laryngeal edema, and vascular collapse and decreased blood pressure that can lead to shock and death. Examples of systemic anaphylaxis are allergic reactions to bee stings, peanuts, eggs, and shellfish. Cutaneous anaphylaxis results in local symptoms, such as pain, swelling, and redness, which occur at the site of exposure to an antigen (e.g., a painful local reaction to an injected vaccine or drug).

Type I: IgE-Mediated Hypersensitivity Reactions

Type I (IgE-mediated) hypersensitivity reactions are mediated by antigen-specific IgE and the products of tissue mast cells³ (Fig. 9.1). Most common allergies (e.g., pollen allergies) are type I reactions. In addition, most type I reactions occur against environmental antigens and are therefore allergic. Because of this strong association, many healthcare professionals use the term *allergy* to indicate only IgE-mediated reactions. However, IgE can contribute to a few autoimmune and alloimmune diseases, and many common allergies (e.g., poison ivy) are not mediated by IgE.

A

FIGURE 9.1 Mechanism of Type I IgE-Mediated Reactions. A, Th2 cells are activated by antigen-presenting dendritic cells to produce cytokines, including IL-3, IL-4, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF). IL-3, IL-5, and GM-CSF attract and promote the survival of eosinophils. Other cytokines (e.g., IL-4) induce B cells to class-switch to IgE-producing plasma cells. The IgE coats the surface of the mast cell by binding with IgE-specific Fc receptors on the mast cell's plasma membrane (sensitization). Further exposure to the same allergen cross-links the surface-bound IgE and activates signals from the cytoplasmic portion of the IgE Fc receptors. These signals initiate two parallel and interdependent processes: mast cell degranulation and discharge of preformed mediators (e.g., histamine, eosinophil-chemotactic factor of anaphylaxis) and production of newly formed mediators such as arachidonic metabolites (leukotrienes, prostaglandins). Many local type I hypersensitivity reactions have two well-defined phases. The initial phase is characterized by vasodilation, vascular leakage, and, depending on the location, smooth muscle spasm or glandular secretions. These changes usually become evident within 5 to 30 minutes after exposure to the antigen. The late phase

occurs 2 to 8 hours later without additional exposure to the antigen. The late phase has more intense infiltration of tissues with eosinophils, neutrophils, basophils, monocytes, and Th cells and tissue destruction in the form of mucosal epithelial cell damage. **B**, Activation of mast cells leading to degranulation of preformed mediators (primary mediators) and synthesis of newly formed (de novo) mediators (secondary mediators). *ECF*, Eosinophilic chemotactic factor; *Fc*, fragment crystallizable; *Ig*, immunoglobulin; *IL*, interleukin; *NCF*, neutrophil chemotactic factor; *PAF*, platelet-activating factor; *Th*, T-helper.

In some individuals, exposure to an environmental antigen causes primarily IgE production. Repeated exposure to the antigen usually is required to elicit enough IgE so that the person becomes “sensitized.” IgE has a relatively short life span in the blood because it rapidly binds to very-high-affinity Fc receptors on the plasma membranes of mast cells (see [Fig. 9.1](#)). The subclass IgG4 also has specific receptors on the mast cell and may contribute to the type I mechanism. Antibody that binds to mast cells is termed **cytotropic antibody** (able to bind to cell surfaces) or **reagin** (skin-sensitizing antibody). Unlike Fc receptors on phagocytes, which bind IgG that has reacted with antigen, the Fc receptors on mast cells bind with IgE that has not previously interacted with antigen.

If further exposure of a sensitized individual to the antigen occurs, one molecule of antigen may bind simultaneously to two molecules of IgE-Fc receptor complexes on the mast cell's surface (cross-link) resulting in activation of intracellular signaling pathways and mast cell degranulation (see [Fig. 9.1, B](#), and [Chapter 7](#)). The antigen that triggers cross-linking must have at least two antigenic determinants on the same molecule. Sometimes an IgE-mediated response is beneficial to the host, as is the case of some immune reactions against parasites. (This mechanism is described in [Chapter 8](#) and illustrated in [Fig. 8.25](#).) The products of mast cell degranulation can modulate almost all aspects of an acute inflammatory response. (The effects of biochemical mediators released by mast cells are illustrated in [Fig. 7.11](#)).

The most potent mediator is histamine, which affects several key target cells. Acting through the H1 receptors, histamine contracts bronchial smooth muscles, causing bronchial constriction; increases vascular permeability, causing edema; and causes vasodilation,

increasing blood flow into the affected area (see [Figs. 7.3](#) and [7.12](#)). The interaction of histamine with H₂ receptors results in increased gastric acid secretion and a decrease of histamine released from mast cells and basophils. The action of histamine through H₂ receptors suggests an important negative-feedback mechanism that stops degranulation. That is, the released histamine inhibits release of additional histamine by interacting with H₂ receptors on the mast cells. Histamine also may affect control of the immune response through H₂ receptors on most cells of the immune system. Another important activity of histamine is enhancement of the chemotactic activity of other factors, such as eosinophil chemotactic factor of anaphylaxis (ECF-A), which attracts eosinophils into sites of allergic inflammatory reactions and prevents them from migrating out of the inflammatory site. (The role of the eosinophil in inflammation is discussed in [Chapter 7](#).) Blocking histamine receptors with antihistamines can control some type I responses.

Mast cells also initiate synthesis of bioactive lipid-derived mediators, such as leukotrienes, platelet-activating factor (PAF), and prostaglandins. Each is released much more slowly than histamine and can mediate similar, yet more prolonged, clinical symptoms, such as recruiting inflammatory cells (e.g., neutrophils, eosinophils), promoting vascular permeability and edema, inducing bronchoconstriction or rhinitis, and inducing further release of histamine from mast cells.⁴ Therapy includes the use of competitive inhibitors of receptors for lipid mediators. Montelukast (a leukotriene receptor inhibitor), rupatadine (a PAF receptor inhibitor), and others are in clinical use.

Type II: Tissue-Specific Hypersensitivity Reactions

Type II (tissue-specific) hypersensitivity reactions are generally characterized by a specific cell or tissue being the target of an immune response. In addition to major histocompatibility locus antigens (i.e., human leukocyte antigens [HLAs]; discussed in [Chapter 8](#)), most cells

have other antigens on their surfaces. Some of these other antigens are called **tissue-specific antigens** because they are expressed on the plasma membranes of only certain cells in specific tissues. Platelets, for example, have groups of antigens that are found on no other cells of the body. The symptoms of many type II diseases are determined by which tissue or organ expresses the particular antigen. Environmental antigens (e.g., drugs or their metabolites) may bind to the plasma membranes of specific cells (especially erythrocytes and platelets) and function as targets of type II reactions.

The five general mechanisms by which type II hypersensitivity reactions can affect cells are shown in [Fig. 9.2](#). All of these mechanisms begin with antibody binding to tissue-specific antigens or antigens that have attached to particular tissues. First, the cell can be destroyed by antibody (IgG or IgM) and activation of the complement cascade through the classical pathway. Formation of the membrane attack complex (C5-9) damages the membrane and may result in lysis of the cell (see [Fig. 9.2, A](#)). For example, erythrocytes are destroyed by complement-mediated lysis in individuals with autoimmune hemolytic anemia (see [Chapter 29](#)) or as a result of an alloimmune reaction to ABO-mismatched transfused blood cells.

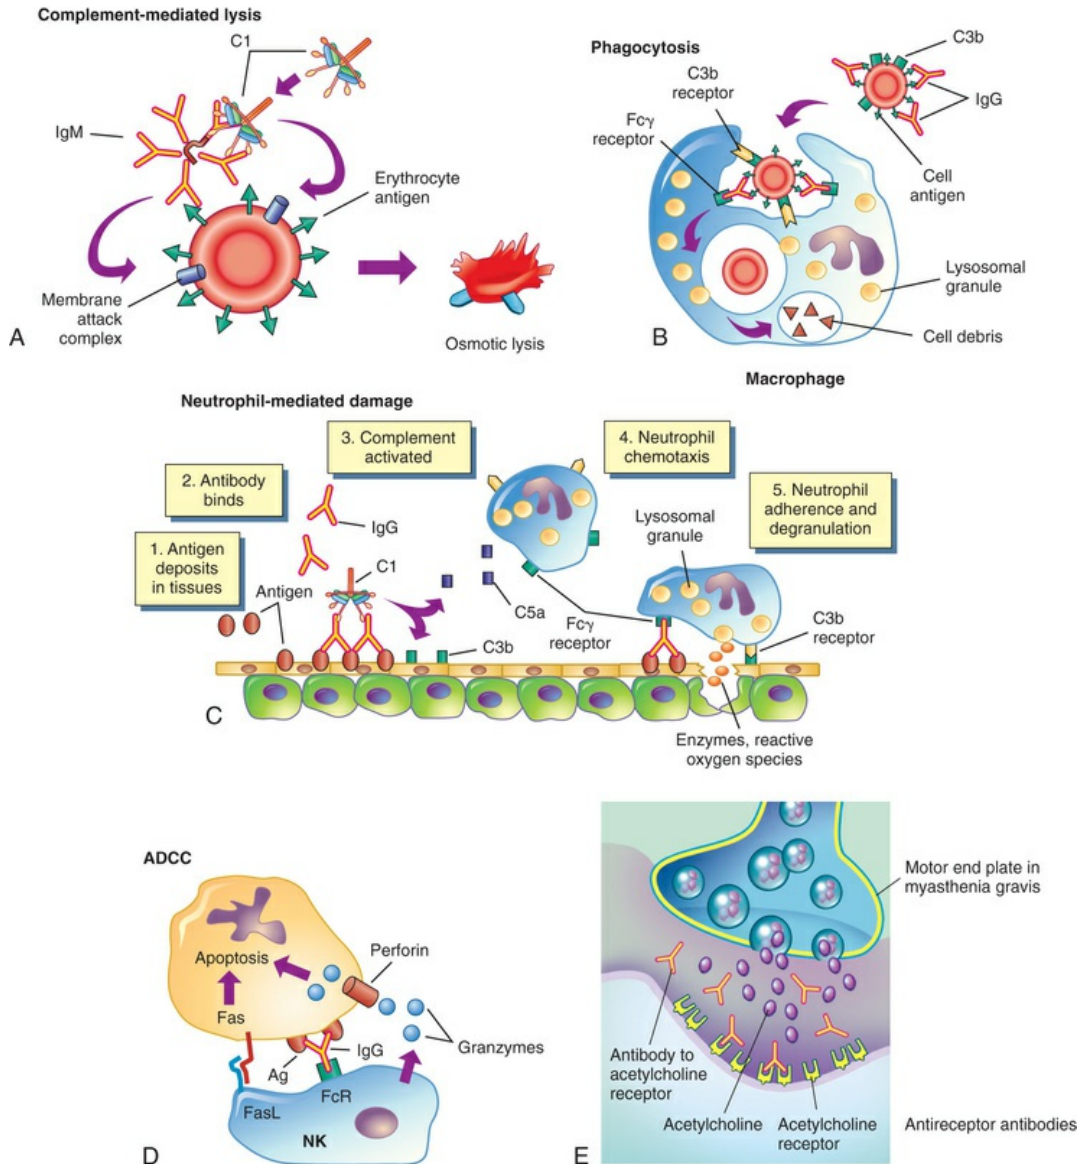

FIGURE 9.2 Mechanisms of Type II, Tissue-Specific, Reactions. Antigens on the target cell bind with antibody and are destroyed or prevented from functioning by **A**, complement-mediated lysis (an erythrocyte target is illustrated here); **B**, clearance (phagocytosis) by macrophages in the tissue; **C**, neutrophil-mediated immune destruction; **D**, antibody-dependent cell-mediated cytotoxicity (ADCC) (apoptosis of target cells is induced by granzymes and perforin produced by natural killer [NK] cells and interactions of Fas ligand [FasL] on the surface of NK cells with Fas on the surface of target cells); or **E**, modulation or blocking the normal function of receptors by antireceptor antibody. This example of mechanism **E** depicts myasthenia gravis in which acetylcholine receptor antibodies block acetylcholine from attaching to its receptors on the motor end plates of skeletal muscle, thereby impairing neuromuscular transmission and causing muscle weakness. *C1*, Complement component C1; *C3b*, complement fragment produced from C3, which acts as an opsonin; *C5a*, complement fragment produced from C5, which acts as a chemotactic factor for neutrophils; *Fcγ receptor*, cellular receptor for the Fc portion of IgG; *FcR*, Fc receptor.

Second, antibody may cause cell destruction through phagocytosis by macrophages. IgG and also C3b of the complement system are opsonins that bind to receptors on the macrophage (see [Fig. 9.2, B](#)). Phagocytosis of the target cell follows. (Phagocytosis is illustrated in [Figs. 7.15](#) and [7.16](#).) For example, antibodies against platelet-specific antigens or against red blood cell antigens of the Rh system coat those cells at low density, resulting in their preferential removal by phagocytosis in the spleen, rather than by complement-mediated lysis.

Third, antibody and complement may attract neutrophils. Either antigen expressed normally on the vessel walls or soluble antigen in the circulation (e.g., released from cells within the body or from infectious agents or by way of drugs or medications) that has been deposited on the surface of endothelial cells may bind antibody (see [Fig. 9.2, C](#)). The antibody initiates the complement cascade, resulting in the release of C3a and C5a, which are chemotactic for neutrophils, and deposition of complement component C3b. Neutrophils bind to the tissues through receptors for the Fc portion of antibody (Fc receptor) or for C3b and attempt to phagocytose the tissue. Because the tissue is large, phagocytosis cannot be completed; even so, neutrophils release their granules onto the healthy tissue. The components of neutrophil granules, as well as the several toxic oxygen products produced by these cells, will damage the tissue.

The fourth mechanism is **antibody-dependent cell-mediated cytotoxicity (ADCC)** (see [Fig. 9.2, D](#)). This mechanism involves a subpopulation of cytotoxic cells that are not antigen specific (natural killer [NK] cells). Antibody on the target cell is recognized by Fc receptors on the NK cells, which release toxic substances that destroy the target cell.

The fifth mechanism does not destroy the target cell, but rather causes it to malfunction. In this mechanism of type II injury, the antibody is usually directed against antigenic determinants associated with specific cell surface receptors, and the symptoms of the disease are a result of a direct effect of antibody binding alone (see [Fig. 9.2, E](#)). The antibody reacts with the receptors on the target cell surface and modulates the function of the receptor by preventing interactions with

their normal ligands, replacing the ligand and inappropriately stimulating the receptor, or destroying the receptor. For example, in the hyperthyroidism (excessive thyroid activity) of Graves disease, autoantibody binds to and activates receptors for thyroid-stimulating hormone (TSH) (a pituitary hormone that controls the production of the hormone *thyroxine* by the thyroid). In this way the antibody stimulates the thyroid cells to produce thyroxine. Under normal conditions, the increasing levels of thyroxine in the blood would signal the pituitary to decrease TSH production, which would result in less stimulation of the TSH receptor in the thyroid and a concomitant decrease in thyroxine production. Because the level of anti-TSH receptor antibody is not controlled by the pituitary, increasing amounts of thyroxine in the blood have no effect on antibody levels, and thyroxine production continues to increase despite decreasing amounts of TSH (see [Chapter 22](#)).

Type III: Immune Complex–Mediated Hypersensitivity Reactions

Mechanisms of Type III Hypersensitivity.

Most **type III (immune complex–mediated) hypersensitivity reactions** are caused by antigen-antibody (immune) complexes that are formed in the circulation and deposited later in vessel walls or extravascular tissues ([Fig. 9.3](#)). The primary difference between type II and type III mechanisms is that in type II hypersensitivity antibody binds to the antigen on the cell surface, whereas in type III the antibody binds to soluble antigen that was released into the blood or body fluids, and the complex is then deposited in the tissues. Type III reactions are not organ specific, and symptoms have little to do with the particular antigenic target of the antibody. The harmful effects of immune complex deposition are caused by complement activation, particularly through the generation of chemotactic factors for neutrophils. The neutrophils bind to antibody and C3b contained in the complexes and attempt to ingest the immune complexes.

FIGURE 9.3 Mechanism of Type III, Immune Complex–Mediated, Reactions. Immune complexes form in the blood from circulating antigen and antibody. Both small and large immune complexes are removed successfully from the circulation and do not cause tissue damage. Intermediate-sized complexes are deposited in certain target tissues in which the circulation is slow or filtration of the blood occurs. The complexes activate the complement cascade through C1 and generate fragments including C5a and C3b. C5a is chemotactic for neutrophils, which migrate into the inflamed area and attach to the IgG and C3b in the immune complexes. The neutrophils attempt unsuccessfully to phagocytose the tissue and in the process release a variety of degradative enzymes that destroy the healthy tissues. Fc γ receptor is the cellular receptor for the Fc portion of IgG.

They are often unsuccessful because the complexes are bound to large areas of tissue. During the attempted phagocytosis, large quantities of lysosomal enzymes are released into the inflammatory site instead of into phagolysosomes. The attraction of neutrophils and the subsequent release of lysosomal enzymes cause most of the resulting tissue damage.

Immune complexes can be of various sizes, depending on the relative amounts of antigen and antibody. Fairly large immune complexes are cleared rapidly from the circulation by tissue macrophages, whereas very small complexes eventually are filtered from blood through the kidneys, without any pathologic consequences. Intermediate-sized immune complexes (formed at a ratio of antigen to antibody that has a slight excess of antigen) are likely to be deposited in certain target tissues, where they have severe

pathologic consequences, such as inflammation in the kidneys (glomerulonephritis), the vessels (vasculitis), or the joints (arthritis or degenerative joint disease).

Immune Complex Disease.

The nature of the immune complexes may change during the progression of the disease, with resultant changes in the severity of the symptoms. Immune complex formation is dynamic because variations in the ratio of antigen to antibody, the class and subclass of antibody, and the quantity and quality of circulating antigen occur. Thus complexes formed early in a disease process may differ from those formed later, and several types of immune complexes may be present simultaneously. With the tremendous potential heterogeneity of immune complexes, it is not surprising that immune complex diseases are characterized by a variety of symptoms and periods of remission or exacerbation of symptoms.

Because many immune complexes activate complement very effectively, complement levels in the blood may decrease during active disease. At times the individual's blood may become **hypocomplementemic** (i.e., contains below normal amounts of complement activity). During type I, II, or IV hypersensitivity reactions, complement levels are unaffected, or some components of the complement cascade, such as C3, may even be increased.

Two prototypic models of type III hypersensitivity help explain the variety of diseases in this category. Serum sickness is a model of systemic type III hypersensitivities, and the Arthus reaction is a model of localized or cutaneous reactions.

Serum Sickness.

The systemic prototype of immune complex-mediated disease is called **serum sickness** because it was initially described as being caused by the therapeutic administration of foreign serum, such as horse serum that contained antibody against tetanus toxin.⁵ Foreign serum generally is not administered to individuals today, although serum sickness reactions can be caused by the repeated intravenous

administration of other antigens, such as drugs, and the characteristics of serum sickness are observed in systemic type III autoimmune diseases. Serum sickness–type reactions are caused by the formation of immune complexes in the blood and their subsequent generalized deposition in target tissues. Typically, affected tissues are the blood vessels, joints, and kidneys. Other symptoms include fever, enlarged lymph nodes, rash, and pain at sites of inflammation.

A form of serum sickness is **Raynaud phenomenon**, a condition caused by the temperature-dependent deposition of immune complexes in the capillary beds of the peripheral circulation. Certain immune complexes precipitate at temperatures below normal body temperature, particularly in the tips of the fingers, toes, and nose, and are called **cryoglobulins**. The precipitates block the circulation and cause localized pallor and numbness, followed by cyanosis (a bluish tinge resulting from oxygen deprivation) and eventually gangrene if the circulation is not restored.

Arthus Reaction.

An **Arthus reaction** is the prototypic example of a localized immune complex–mediated inflammatory response.⁶ It is caused by repeated local exposure to an antigen that reacts with preformed antibody and forms immune complexes in the walls of the local blood vessels. Symptoms of an Arthus reaction begin within 1 hour of exposure and peak 6 to 12 hours later. The lesions are characterized by a typical inflammatory reaction, with increased vascular permeability, an accumulation of neutrophils, edema, hemorrhage, clotting, and tissue damage.

Type IV: Cell-Mediated Hypersensitivity Reactions

Whereas types I, II, and III hypersensitivity reactions are mediated by antibody, **type IV (cell-mediated) hypersensitivity reactions** are mediated by T lymphocytes and do not involve antibody (Fig. 9.4). Type IV mechanisms occur through either cytotoxic T lymphocytes (Tc cells) or lymphokine-producing Th1 and Th17 cells. Tc cells attack and destroy cellular targets directly. Th1 and Th17 cells produce

cytokines that recruit and activate phagocytic cells, especially macrophages. Destruction of the tissue is usually caused by direct killing by toxins from Tc cells or by the release of soluble factors, such as lysosomal enzymes and toxic reactive oxygen species (ROS), from activated macrophages.

FIGURE 9.4 Mechanism of Type IV, Cell-Mediated, Reactions. Antigens from target cells stimulate T cells to differentiate into cytotoxic T cells (Tc cells), which have direct cytotoxic activity, and helper T cells (Th1 cells) involved in delayed hypersensitivity. The Th1 cells produce lymphokines (especially interferon-gamma [*IFN-γ*]) that activate the macrophage through specific receptors (e.g., *IFN-γ* receptor [*IFN γ R*]). The macrophages can attach to targets and release enzymes and reactive oxygen species that are responsible for most of the tissue destruction.

Clinical examples of type IV hypersensitivity reactions include graft rejection and allergic reactions resulting from contact with such substances as poison ivy and metals. A type IV component also may be present in many autoimmune diseases. For example, T cells against type II collagen (a protein present in joint tissues) contribute to the destruction of joints in rheumatoid arthritis; T cells against a thyroid cell surface antigen contribute to the destruction of the thyroid in autoimmune thyroiditis (Hashimoto disease); and T cells against an

antigen on the surface of pancreatic beta cells (the cell that normally produces insulin) are responsible for beta-cell destruction in insulin-dependent (type 1) diabetes mellitus.

A type IV hypersensitivity reaction in the skin was thoroughly described first by Ehrlich in 1891 and led to the development of a diagnostic skin test for tuberculosis.⁷ The reaction follows an intradermal injection of tuberculin antigen into a suitably sensitized individual and is called a *delayed hypersensitivity skin test* because of its slow onset—24 to 72 hours to reach maximum intensity. The reaction site is infiltrated with T lymphocytes and macrophages, resulting in a clear hard center (induration) and a reddish surrounding area (erythema).

Antigenic Targets of Hypersensitivity Reactions

Allergy

Allergy is a hypersensitivity response against an environmental antigen (**allergen**). Allergies are the most common hypersensitivity reactions. The most common allergies are type I hypersensitivities, although any of the other three mechanisms of hypersensitivity may cause allergic responses depending on the particular allergen.

Typical allergens that induce type I hypersensitivity include pollens (e.g., ragweed), molds and fungi (e.g., *Penicillium notatum*), foods (e.g., milk, eggs, shellfish), animals (e.g., cat dander, dog dander), cigarette smoke, components of house dust (e.g., fecal pellets of house mites), and almost anything else encountered in the environment. Allergens that primarily elicit type IV allergic hypersensitivities include plant resins (e.g., poison ivy, poison oak), metals (e.g., nickel, chromium), acetylates, and chemicals in rubber, cosmetics, detergents, and topical antibiotics (e.g., neomycin). Type II and type III allergic hypersensitivities are relatively rare but may include antibiotics (e.g., penicillin, sulfonamides) and soluble antigens produced by infectious agents (e.g., hepatitis B).

Usually a sensitization process involving multiple exposures to the allergen occurs before adequate amounts of antibody or T cells are

available to elicit a hypersensitivity response. In some instances, exposure to a particular allergen may not be apparent in the case of allergens that are drugs, additives, or preservatives in food. For example, an individual may become sensitized by drinking milk that contains trace amounts of penicillin used for treating cows for mastitis. Thus the first therapeutic exposure to penicillin may cause an unexpected hypersensitivity reaction. Additionally, penicillin shares a β -lactam structure with cephalosporin, so that one antibiotic may be sensitive against another.

Genetic Predisposition.

Certain individuals are genetically predisposed to develop allergies, particularly type I allergies, and are called **atopic**. In families in which one parent has an allergy, allergies develop in about 40% of the offspring. If both parents have allergies, the incidence in the offspring may be as high as 80%. (Principles of genetic inheritance are discussed in [Chapter 4](#).)

Atopic individuals tend to produce higher quantities of IgE and to have more Fc receptors for IgE on their mast cells. The airways and the skin of atopic individuals are also more responsive to a wide variety of both specific and nonspecific stimuli than are the airways and skin of individuals who are not atopic. Multiple genes have been associated with the atopic state, including polymorphisms in a large variety of cytokines that regulate IgE synthesis (e.g., interleukin [IL]-4, IL-5, IL-12, IL-13) and cellular receptors.

Clinical Symptoms of Type I Allergies

The clinical manifestations of type I reactions are attributable mostly to the biologic effects of histamine. Tissues most commonly affected contain large numbers of mast cells and are sensitive to the effects of histamine released from them. These tissues are found in the gastrointestinal tract, the skin, and the respiratory tract ([Fig. 9.5](#) and [Table 9.4](#)). The particular symptoms frequently reflect the main portal of entry for the allergen. For instance, pollens and other airborne allergens usually cause respiratory symptoms.

FIGURE 9.5 Type I Hypersensitivity Reactions. Manifestations of allergic reactions as a result of type I hypersensitivity include itching, angioedema (swelling caused by exudation), edema of the larynx, urticaria (hives), bronchospasm (constriction of airways in the lungs), hypotension (low blood pressure), and dysrhythmias (irregular heartbeat) because of anaphylactic shock, and gastrointestinal cramping caused by inflammation of the gastrointestinal mucosa. Photographic inserts show a diffuse allergic-like eye and skin reaction on an individual. The skin lesions have raised edges and develop within minutes or hours, with resolution occurring after about 12 hours. (Inserts from Male D et al: *Immunology*, ed 8, St Louis, 2013, Mosby.)

TABLE 9.4

CAUSES OF CLINICAL MANIFESTATIONS OF ALLERGY

TYPICAL ALLERGEN	MECHANISM OF HYPERSENSITIVITY	CLINICAL MANIFESTATION
Ingestants		
Foods	Type I	Gastrointestinal allergy
Drugs	Types I, II, III	Urticaria, immediate drug reaction, hemolytic anemia, serum sickness
Inhalants		
Pollens, dust, molds	Type I	Allergic rhinitis, bronchial asthma
<i>Aspergillus</i>	Types I, III	Allergic bronchopulmonary aspergillosis

<i>fumigatus</i>		
Thermophilic actinomycetes*	Types III, IV	Extrinsic allergic alveolitis
Injectants		
Drugs	Types I, II, III	Immediate drug reaction, hemolytic anemia, serum sickness
Bee venom	Type I	Anaphylaxis
Vaccines	Type III	Localized Arthus reaction
Serum	Types I, III	Anaphylaxis, serum sickness
Contactants		
Poison ivy, metals	Type IV	Contact dermatitis

*An order of fungi that is stimulated by warmth to grow and proliferate.

Modified from Bellanti JA: *Immunology III*, Philadelphia, 1985, Saunders.

Effects of allergens on the mucosa of the eyes, nose, and respiratory tract include conjunctivitis (inflammation of the membranes lining the eyelids), rhinitis (inflammation of the mucous membranes of the nose), and asthma (constriction of the bronchi). Symptoms are caused by vasodilation, hypersecretion of mucus, edema, and swelling of the respiratory mucosa. Because the mucous membranes lining the respiratory tract (accessory sinuses, nasopharynx, and upper and lower respiratory tracts) are continuous, they are all adversely affected. The degree to which each is affected determines the symptoms of the disease.

Urticaria, or **hives**, is a dermal (skin) manifestation of type I allergic reactions (see [Fig. 9.5](#)). The underlying mechanism is the localized release of histamine and increased vascular permeability, resulting in limited areas of edema. Urticaria is characterized by white fluid-filled blisters (wheals) surrounded by areas of redness (flares). The **wheal and flare reaction** is usually accompanied by itching. Not all urticarial symptoms are caused by allergic (immunologic) reactions. Some, termed *nonimmunologic urticaria*, result from exposure to cold temperatures, emotional stress, medications, systemic diseases, hyperthyroidism, or malignancies (e.g., lymphomas).

Gastrointestinal allergies are caused primarily by allergens that enter through the mouth—usually foods or medicines. When food is

the allergen, the active immunogen may be a product of food breakdown by digestive enzymes. Symptoms usually occur rapidly (frequently within minutes) and include vomiting, diarrhea, or abdominal pain and may be severe enough to result in malabsorption or protein-losing enteropathy, if the reactions are prolonged or recurrent. Systemic symptoms may range from urticaria to life-threatening anaphylactic reactions. The most common food allergies are milk, chocolate, eggs, soy, wheat, tree nuts, peanuts, shellfish, and fish.⁸ The incidence of food allergies in children is estimated at 2% to 10% and has been increasing. Most children (about 75%) outgrow food allergies, but most individuals with peanut allergy (about 80%) will remain sensitive through adulthood with the potential of severe reactions.

If possible, avoidance of the allergen is the best method to limit allergic responses. Approximately 30% of laboratory animal handlers have allergies to animal dander and must use face masks or other devices to avoid contact.

Although some type I allergic responses can be controlled by blocking histamine receptors with antihistamines, the primary mechanism of control is the autonomic nervous system. The autonomic nervous system includes biochemical mediators (e.g., epinephrine, acetylcholine) that, like the mediators of the inflammatory response, have profound effects on cells. These mediators bind to appropriate receptors on mast cells and the target cells of inflammation (e.g., smooth muscle), thereby controlling (1) the release of inflammatory mediators from mast cells and (2) the degree to which target cells respond to inflammatory mediators (see [Chapter 7](#)).

Allergic Disease: Bee Sting Allergy

An example of a life-threatening allergy is an anaphylactic reaction to a bee sting. Bee venoms contain a mixture of enzymes and other proteins that may serve as allergens. About 1% of children may have an anaphylactic reaction to bee venom. Within minutes they may develop excessive swelling (edema) at the bee sting site, followed by

generalized hives, itching, and swelling in areas distal from the sting (e.g., eyes, lips), and other systemic symptoms including flushing, sweating, dizziness, and headache. The most severe symptoms may include gastrointestinal (e.g., stomach cramps, vomiting), respiratory (e.g., tightness in the throat, wheezing, difficulties breathing), and vascular (e.g., low blood pressure, shock) reactions. Severe respiratory and vascular reactions may lead to death.

If a child has had a previous anaphylactic reaction to bee stings, the chance of having another is about 60%. During the reaction the administration of antihistamines has little effect because histamine has already bound H1 receptors and initiated severe bronchial smooth muscle contraction. Most individuals carry self-injectable epinephrine. Autonomic nervous system mediators, such as epinephrine, bind to specific receptors on smooth muscle and reverse the effects of histamine and result in muscle relaxation. Similar anaphylactic reactions have been described against peanuts and other nuts, shellfish, fish, milk, eggs, and some medications.

Tests of IgE-Mediated Allergy

Allergic reactions can be life threatening; therefore, it is essential that severely allergic individuals be made aware of the specific allergen against which they are sensitized and instructed to avoid contact with that material. Several tests are available, including food challenges, skin tests with allergens, and laboratory tests for measurements of total IgE and allergen-specific IgE in the blood.⁹

Reactivity to a particular food allergen may be tested by controlled administration of small doses of the suspected allergen in order to evoke a mild allergic response. This approach can be dangerous if the individual has a history of anaphylactic responses. A safer approach is injection of an allergen into (intradermal) or onto (epicutaneous or prick test) the skin. If the individual is allergic to a particular allergen, a local wheal and flare reaction may occur within a few minutes at the site of injection. The diameter of the flare reaction is usually indicative of the individual's degree of sensitivity to that allergen. In the most severely allergic individuals, even the extremely small amounts of

allergen used for the skin test may evoke a systemic anaphylaxis. Skin test is also contraindicated if the individual is using medications that may affect the test or has diffuse dermatitis, which would make the reaction difficult to interpret.

A variety of laboratory tests can detect IgE antibodies in serum. These assays have various commercial acronyms, depending on whether they are radioimmunoassays (RIAs; reactivity detected by measuring a radioactive reagent) or enzyme immunoassays (EIAs or ELISA [enzyme-linked immunosorbent assay]; reactivity detected by measuring a color change caused by an enzyme-labeled reagent). One set of assays measures circulating levels of total IgE, with atopic individuals usually having elevated levels. Other assays are capable of measuring circulating levels of specific IgE antibodies against selected allergens. The amount of IgE against a specific allergen correlates well with the degree of skin test reactivity and the severity of clinical symptoms related to the same allergen, although the laboratory test is less sensitive.

Desensitization.

Clinical **desensitization** to allergens can be achieved in some individuals. Minute quantities of the allergen are injected in increasing doses over a prolonged period. The procedure may reduce the severity of the allergic reaction in the treated individual and works best for routine respiratory tract allergens and biting insect allergies (80% to 90% rate of desensitization over 5 years of treatment). However, this form of therapy is associated with a risk of systemic anaphylaxis, which can be severe and life threatening. Food allergies have been very difficult to suppress, but some promising trials are underway to evaluate desensitization by oral or sublingual administration of increasing amounts of allergen.¹⁰

The mechanisms by which desensitization occurs may be several, one of which is the production of large amounts of so-called blocking antibodies, usually circulating IgG. A **blocking antibody** presumably competes in the tissues or in the circulation for binding with antigenic determinants on the allergen so that the allergen is “neutralized” and

is unable to bind with IgE on mast cells. Sublingual desensitization (another approach that works best with some food allergies) produces sIgA and circulating IgG that may prevent the allergen from accessing mast cells. Desensitization injections also may stimulate the generation of clones of T-regulatory lymphocytes, which inhibit hypersensitivity by suppressing the production of IgE or modifying the Th1/Th2 interactions in favor of production of antiinflammatory cytokines.

Other approaches to suppressing type I allergic responses have been tested, with some preliminary success. An example is injection of anti-IgE antibody directed against the Fc portion of the IgE in order to decrease binding of IgE to mast cells.

Type IV Allergic Hypersensitivities.

The allergens that induce a type IV allergic reaction are mostly haptens that react with normal self-proteins in the skin. When presented in this fashion, these antigens are recognized by pattern recognition receptors (PRRs) on antigen-presenting cells in the skin and induce a cell-mediated response. (Pattern recognition receptors are discussed in [Chapter 7](#).) The primary result is an allergic **contact dermatitis** that is confined to the area of contact with the allergen. The best-known example is poison ivy ([Fig. 9.6](#)). The antigen in that instance is a plant catechol, *urushiol*, that reacts with normal skin proteins and evokes a cell-mediated immune response.

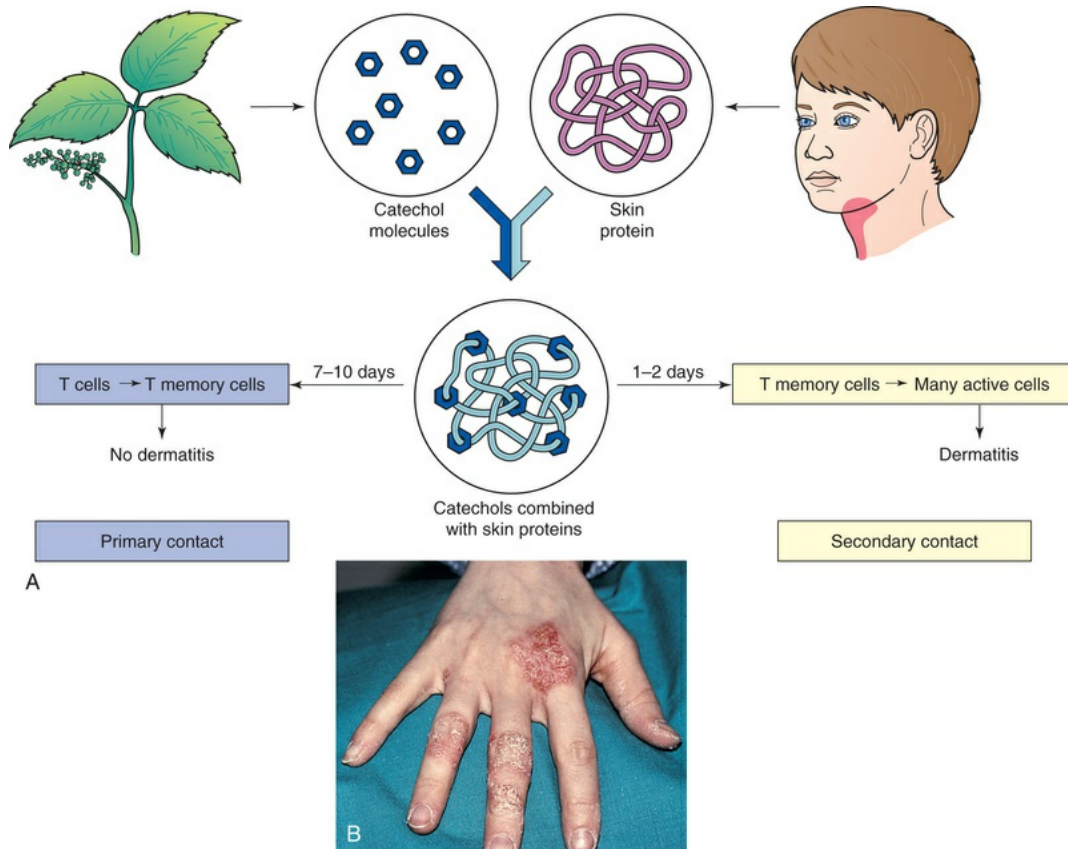

FIGURE 9.6 Development of Allergic Contact Dermatitis, a Delayed Hypersensitivity Reaction. **A**, Shown here is the development of allergy to catechols from poison ivy. No dermatitis results from the primary contact because the antigens (catechols) are sensitizing the immune response and producing memory T cells. Secondary contact, however, quickly activates a type IV, cell-mediated reaction that causes dermatitis. **B**, This contact dermatitis was caused by a delayed hypersensitivity reaction that led to vesicles and scaling at the sites of contact. (From Damjanov I, Linder J: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

As noted, type I hypersensitivity reactions may result in a skin reaction (e.g., hives formed during an allergic reaction to a particular food). The distribution of the lesions may suggest whether the reaction is caused by immediate (type I) or delayed (type IV) hypersensitivity mechanisms. Immediate hypersensitivity reactions, termed **atopic dermatitis**, are usually characterized by widely distributed lesions, whereas contact dermatitis (delayed hypersensitivity) consists of lesions only at the site of contact with the allergen, such as a metal allergy to jewelry (see [Fig. 9.6](#)).¹¹

Types II and III Allergic Hypersensitivities.

Type II allergic hypersensitivities are usually against allergenic haptens that bind to the surface of cells and elicit an IgG or IgM response. For instance, allergic reactions against many drugs (e.g., penicillin, sulfonamides) occur after the drug binds to proteins on the plasma membranes of a person's cells and becomes immunogenic. The immune system attacks the allergen on the cell membrane and destroys the cell as well. In allergic reactions to penicillin, the immunogenic antigen is a metabolite of penicillin catabolism that binds to the plasma membranes of erythrocytes or platelets and induces an antibody response that destroys the cells (type II hypersensitivity), causing anemia or thrombocytopenia. Type II allergic reactions also can occur against antigens of infectious diseases. For instance, encephalitis secondary to a rubella infection may result from damage to cells of the nervous system by an immune response against rubella virus antigen on the cell's plasma membrane.

Type III allergic reactions occur after the formation of immune complexes containing soluble allergens. For instance, Arthus reactions may be observed after injection, ingestion, or inhalation of allergens. Skin reactions can follow subcutaneous or intradermal inoculation with drugs, fungal extracts, or antigens used in skin tests. Gastrointestinal reactions, such as gluten-sensitive enteropathy (celiac disease), follow ingestion of antigen, usually gluten from wheat products (see [Chapter 42](#)). Allergic alveolitis is a type III acute hemorrhagic inflammation of the air sacs (alveoli) of the lungs resulting from inhalation of fungal antigens, usually particles from moldy hay (farmer's lung) or pigeon feces (pigeon breeder's disease) (see [Chapter 36](#)). Circulating drugs (e.g., penicillin) or antigens produced from infectious diseases (e.g., hepatitis B, streptococcal infection) may form circulating immune complexes that are deposited in the circulation (vasculitis) or the kidneys (glomerulonephritis).

Autoimmunity

Autoimmune diseases originate from the coincidence of an initiating event in a genetically predisposed individual leading to an autoimmune mechanism that affects specific target tissues or cells.

Some autoimmune diseases can be familial and attributed to the presence of a very small number of susceptibility genes. Affected family members may not all develop the same disease, but have different disorders characterized by a variety of hypersensitivity reactions, including autoimmune and allergic. For instance, the HLA antigen B27 (HLA is discussed further under Transplantation and Transfusion) is a risk factor for developing **ankylosing spondylitis (AS)**, an autoimmune inflammatory disease of the spine. Ninety-five percent of individuals diagnosed with AS express HLA-B27, whereas only 4% to 8% of the general population expresses this antigen ([Table 9.5](#)). Although most autoimmune diseases appear as isolated events without a positive family history, susceptibility for developing such diseases appears to be linked to a combination of multiple genes.

TABLE 9.5

EXAMPLES OF ASSOCIATIONS BETWEEN SPECIFIC HLA ALLELES AND DISEASE

DISEASE	HLA ALLELE	RR
Acute anterior uveitis	B27	14
Addison disease	DR3	6
Ankylosing spondylitis	B27	90
Behçet syndrome	B51	4
Celiac disease	DR3	11
Chronic active hepatitis	DR3	13
Dermatitis herpetiformis	DR3	16
Diabetes (type 1)	DR3	5
	DR4	6
	DR3/DR4	20
Goodpasture syndrome	DR2	16
Graves disease	DR3	4
Hashimoto disease	DR11	3
Multiple sclerosis	DR2	4
Myasthenia gravis	DR3	3
Pemphigus vulgaris	DR4	13
Postgonococcal arthritis	B27	14

Reiter syndrome	B27	37
Rheumatoid arthritis	DR4	4
Sjögren syndrome	DR3	9
Systemic lupus erythematosus	DR3	6

HLA, Human leukocyte antigen; *RR*, the approximate relative risk, which is the frequency of a disease in individuals with the particular HLA allele compared with individuals without that allele.

Genetic Factors.

Genetic factors that contribute to autoimmunity are easier to identify than the original insult that initiates the disease. It is fairly well established that autoimmune diseases can be familial. Affected family members may not all develop the same disease, but several members may have different disorders characterized by a variety of hypersensitivity reactions, including autoimmune and allergic reactions.

Associations with particular autoimmune diseases have been identified for a variety of major histocompatibility complex (MHC) alleles (see [Chapter 8](#)) or non-MHC genes. The specific HLA alleles of susceptible and resistant individuals have been analyzed for almost every known disease and, almost universally, individuals with certain diseases are more likely than the general population to have a specific HLA allele or set of alleles.¹² Some associations are strong; others are more tenuous (see [Table 9.5](#)). The reason some HLA alleles are associated with inappropriate immune function is unclear, but it may directly involve the ability of particular HLA molecules to present antigen or the use of particular HLAs as receptors for disease-causing microorganisms. These genes may determine an individual's susceptibility to specific infectious agents or the capacity of that individual to mount an immune response against specific antigens. Therefore, an individual of a specific HLA type may have an inappropriate or exaggerated immune responses against a microorganism resulting in a hypersensitivity reaction.

A large variety of non-MHC genes also have been identified as risk factors for the development of specific autoimmune diseases. Most of

these genes encode for inflammatory cytokines or costimulatory molecules found on the cell surface.

Breakdown of Tolerance.

Individuals are usually tolerant to their own antigens. Tolerance is a state of immunologic control so that the individuals do not make a detrimental immune response against their own cells and tissues. *Central tolerance* develops in humans during the embryonic period as autoreactive lymphocytes are either eliminated or suppressed in the primary lymphoid organs during differentiation and proliferation of immature T or B lymphocytes (see [Figs. 8.9](#) and [8.12](#)). Clones of cells with antigen receptors for self-antigens are deleted. *Peripheral tolerance* is maintained in the secondary lymphoid organs through the action of T-regulatory lymphocytes or antigen-presenting dendritic cells. The key term in the definition of tolerance is *detrimental immune response* because autoimmune antibodies frequently are present at low, but measurable, levels in the blood of most individuals. They may perform a useful function, such as removing low levels of cellular debris from the blood, and are quantitatively and qualitatively regulated to avoid autoimmune disease. Autoimmune disease results more commonly from a breakdown of this peripheral tolerance rather than a defect in central tolerance.

An initiating event results in a breakdown of tolerance to an individual's own antigens. A great deal of research has progressively identified genetic risk or predisposing factors in autoimmune diseases, but, in the vast majority of autoimmune diseases, the nature of the initiating event and the mechanism by which it breaks tolerance are unclear. Several potential mechanisms have been suggested.

Sequestered Antigen.

The induction of central tolerance requires that the self-antigen be present in the fetus and exposed to the developing fetal immune system. Some self-antigens may not normally encounter the immune system in either fetal or adult life, but are sequestered or hidden from the immune system in **immunologically privileged sites**, so named

because foreign tissues can be transplanted into these sites with less chance of immunologic rejection. For example, several sites (e.g., anterior chamber of the eye, the brain) are separated from the circulation by barriers (blood-ocular and blood-brain barriers) that offer protection against many immune cells and lead to relatively poor lymphatic drainage. Lymphocytes that enter these sites encounter tissue that expresses Fas ligand (FasL) and tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL). These molecules induce the lymphocytes to undergo apoptosis, thus protecting the tissue. Self-antigens in these sites are protected by sequestration and an active protective mechanism. However, if the barriers are damaged, antigenic sensitization can occur, and the resultant antibodies and lymphocytes can enter the site and cause additional damage to the tissue. For instance, physical trauma to one eye may result in release of sequestered antigen into the blood or lymphatics, resulting in immunologic injury to the other eye (sympathetic uveitis).¹³

Infectious Disease.

A long-standing hypothesis is that foreign antigens from infectious microorganisms can initiate autoimmune disease through a process of **molecular mimicry**. Some antigens of infectious agents so closely resemble (mimic) a particular self-antigen that antibodies or T cells produced to protect against the infection also recognize the self-antigen as foreign (**cross-reactive antibody** or **T cell**). The relationship between many autoimmune diseases and predisposing infections, such as the link between enterovirus infection and type 1 diabetes, and the link between a variety of infectious microorganisms and autoimmune thyroid disease are being investigated.^{14,15}

The only clearly defined example so far is acute rheumatic fever that may occur after a group A streptococcal sore throat.¹⁶ In some individuals with group A streptococcal sore throat or infection of the skin or mucosa, the M protein and group A carbohydrate in the bacterial capsule mimic (*antigenic mimicry*) normal antigens in the heart valves and induce antibodies that also react with proteins (e.g.,

cardiac myosin and others) in the heart valve, damaging the valve, and allowing the influx of CD4+ cells with specificities towards normal valvular antigens. Only a small number of individuals whose heart proteins have similar antigens to the bacterial capsular antigens are normally affected. Thus acute rheumatic fever is initiated by a type II autoimmune hypersensitivity that may be augmented by a type IV hypersensitivity.

Additionally, some streptococcal infections also release soluble bacterial antigens into the blood that form circulating immune complexes with antibacterial antigens. The complexes may deposit in the kidneys and initiate an immune complex-mediated glomerulonephritis (inflammation of the kidney). Thus soluble streptococcal antigens may, by a type III hypersensitivity mechanism, elicit a poststreptococcal glomerulonephritis. Because the circulating antigens are bacterial and thus environmental, this complication may be defined as a type III allergic reaction.

Neoantigen.

In certain situations, a neoantigen that induces an allergic reaction may also lead to autoimmunity. Many **neoantigens** (new antigens) are haptens that become immunogenic after binding to self-proteins. The immune reaction against the neoantigen may lead to an immunologic reaction against normal antigenic determinants on the protein. Other new antigenic determinants may result from posttranslational modifications of a normal protein so that one or more amino acids are chemically altered (e.g., addition or removal of amino acid side groups, phosphorylation) without affecting the protein's function. Many experimental autoimmune diseases (e.g., experimental autoimmune thyroiditis) can be initiated by immunization with molecules containing neoantigenic determinants.

Neoantigens may result from genetic or epigenetic modifications or posttranslational modification, particularly in response to lifestyle (e.g., smoking, diet, consumption of alcohol or coffee, exposure to organic solvents). These conditions are under investigation, but to date only associations rather than clear causative relationships have

been found.¹⁷

Forbidden Clone.

During differentiation and proliferation of lymphoid stem cells into immature T and B lymphocytes (see [Figs. 8.9](#) and [8.12](#)), some lymphocytes produce receptors that react with self-antigens. Many autoreactive lymphocytes interact with self-antigens and other costimulatory molecules on the surface of thymic epithelial cells and are induced to undergo clonal deletion by a process of apoptosis. Thus lymphocytes reactive against self-antigen are prevented, or “forbidden,” from maturing. Autoimmunity may result from the survival of a forbidden clone and its proliferation later in life.

Defective Peripheral Tolerance.

Tolerance to some self-antigens is controlled in the secondary lymphoid organs. This process is controlled by a variety of cells, including antigen-presenting dendritic cells and members of a family of T-regulatory lymphocytes (Treg cells) that normally suppress immune responses against self. Defects in particular regulatory cells may result in expansion of clones of autoreactive cells and the development of autoimmune disease. Systemic lupus erythematosus, which is characterized by the production of a large array of autoantibodies, may be caused by a general breakdown in the regulatory network.

Silent Imitators of Autoimmune Disease.

The mechanism for imitation of autoimmune diseases may already be within all humans. Two very interesting potential mechanisms are being explored (see [What's New? Silent Initiators of Autoimmune Disease: Microchimerism and Endogenous Retroviruses](#)).

What's New?

Silent Initiators of Autoimmune Disease: Microchimerism and Endogenous Retroviruses

Two normally silent conditions have been studied in relationship to the onset of autoimmune diseases. Both **microchimerism** and endogenous retroviruses are conditions that have unknown roles in normal physiology, but may be triggers for autoimmune diseases.

A rapidly growing body of evidence suggests that humans are in a state of **microchimerism (Mc)**: possessing a small number of cells originating from another individual.¹ The placenta routinely allows bidirectional passage of both maternal and fetal cells beginning as early as 6 months' gestation. Most gravid women (having been pregnant) have detectable fetal cells (fetal Mc) in their blood and many organs (e.g., white blood cells, hepatocytes, kidney tubular epithelium, neurons and glia, cardiomyocytes, endothelial cells, intestinal epithelium, and islet beta cells), which apparently originated as fetal stem cells that differentiated in the maternal tissues. Microchimerism persists for decades after pregnancy.

The fetal cells appear to be regulated by T-cell cytokines: TGF- β and IL-10.² If regulation is diminished, the fetal cells may initiate a chronic inflammatory reaction leading to tissue damage and potential autoimmune reactions. Many autoimmune diseases are associated with increased numbers of male cells in the diseased organs (e.g., scleroderma, dermatomyositis, Sjögren syndrome, thyroiditis, primary biliary cirrhosis, hyper- and hypothyroidism, and systemic lupus erythematosus), suggesting that Mc may contribute to the etiology of these diseases.¹ The role of microchimerism in autoimmune thyroid disease is enveloped in contradictory data. Levels of fetal cells are elevated in the blood in women with autoimmune thyroid diseases: Graves and Hashimoto disease,³ whereas others have reported fewer fetal cells associated with these diseases.⁴ Thus it cannot yet be determined whether the foreign cells are initiators of autoimmune damage. Thus these observations remain intriguing but of unknown significance.

Another silent potential trigger of autoimmune disease is activation of human endogenous retroviruses (HERVs). Infectious retroviruses, such as HIV, are well-known. What most do not know is that 8% of the human genome is of retroviral origin. It appears

that 30 to 40 million years ago, humans were infected by simple retroviruses that inserted themselves into the genome of gametes, thus becoming inheritable.⁵ The endogenous retroviral inserts contained regions of control of expression, the *gag* gene that encoded matrix and capsid proteins (Gag proteins), the *pol* region that encoded retroviral enzymes, and the *env* gene for envelope (Env) proteins. Most HERV genes are inactivated. The genome contains approximately 10,000 retroviral sequences, but only about 50 functional open reading frames so that several Gag, Pol, and Env proteins can be expressed. These genes are usually silent until activated for unknown reasons.

Several HERV genes are activated and expressed in tissues undergoing autoimmune processes. They have been described in tissue related to rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), multiple sclerosis, systemic sclerosis, and Sjögren syndrome. An unresolved hypothesis is that some HERV proteins mimic normal proteins, inducing autoantibodies that attack normal proteins, and triggering autoimmune inflammation.⁶ Gag proteins are expressed by HERV K-10 and the Fc region of IgG1, which also is the target for rheumatoid factor, a pathologic autoantibody associated with RA. Several HERVs, especially HRES-1 Gag protein, are activated during SLE. HRES-1 Gag has homology with at least nine autoantigens that are common targets in SLE. Two HERV loci (HERV-Fc1 on the X chromosome and HERV-K13 on chromosome 19) appear to synergize and increase the risk for Mc.⁷

Alloimmunity

Alloimmunity occurs when an individual's immune system reacts against antigens on the tissues of other members of the same species. Genetic diversity is the norm in humans. Diversity also is observed among self-antigens, so that two individuals may have different antigens on their tissues and, therefore, make an immune response against each other's tissues. Some self-antigens, such as the ABO blood group, have limited diversity with very few different antigens being expressed in the population, whereas others, such as the HLA system, have tremendous diversity.

Two clinically relevant examples of this reactivity are (1) several transient neonatal diseases (in which the maternal immune system becomes sensitized against antigens expressed by the fetus) and (2) transplant rejection and transfusion reactions (in which the immune system of a recipient of an organ transplant or blood transfusion reacts against antigens on the donor cells).

Transient Neonatal Alloimmunity.

Because the fetus is a hybrid between the mother and father, it expresses paternal antigens that are not found in the mother. Occasionally these fetal antigens cross the placenta and elicit an immune response in the mother (e.g., production of alloantibodies against the fetal antigens). The maternal alloantibody may be transported across the placenta into the fetal circulation, bind to the fetal cells, and produce alloimmune disease in the fetus and neonate. The mother's immune system produces the antibody, but because the cells do not express the target antigen, the mother has no symptoms of the disease.

Neonatal alloimmune disease may be secondary to maternal autoimmune diseases in which the mother produces an IgG autoantibody specific for maternal self-antigens that are found on fetal

cells as well. Therefore, symptoms of the same autoimmune disease may affect mother and child, even though the autoantibody is being produced only by the mother's immune system. This form of disease usually occurs only in association with type II (tissue-specific) hypersensitivity reactions. It does not occur in association with IgE-mediated (type I) reactions, immune complex-mediated (type III) reactions, or cell-mediated (type IV) reactions because the immunologic factors (IgE, immune complexes, T cells) that cause these reactions do not readily cross the placenta and enter the fetal circulation in sufficient quantity.

Symptoms of the alloimmune disease may be present in utero or immediately after birth and may be fatal to the fetus or neonate. At birth, maternal circulating antibody can no longer enter the child, and if symptoms are successfully treated, the disease will disappear as the maternal antibody is catabolized.¹⁸ Examples of maternal immunologic hypersensitivity diseases in which the child can be affected include the following antibody-mediated diseases:

1. Graves disease—an autoimmune disease in which maternal antibody against the receptor for TSH causes neonatal hyperthyroidism
2. Myasthenia gravis—an autoimmune disease in which maternal antibody binds with receptors for neural transmitters on muscle cells (acetylcholine receptors), causing neonatal muscular weakness (see [Chapter 18](#))
3. Immune thrombocytopenic purpura—a disease in which both autoimmune and alloimmune variants in maternal antiplatelet antibody destroy platelets in the fetus and neonate (see [Chapter 30](#))
4. Alloimmune neutropenia—a disease in which maternal antibody against neutrophils destroys neutrophils in the neonate
5. Systemic lupus erythematosus—an autoimmune disease in which diverse maternal autoantibodies induce anomalies (e.g., congenital heart defects) in the fetus or cause pregnancy loss

6. Rh and ABO alloimmunization (e.g., erythroblastosis fetalis)—a disease in which maternal antibody against erythrocyte antigens induces anemia in the child (see [Chapter 31](#))

Autoimmune and Alloimmune Diseases

Many examples of autoimmune or **alloimmune diseases** have been described. Several basic principles are exemplified by two examples: systemic lupus erythematosus (an autoimmune disease) and tissue rejection (i.e., transplant rejection or transfusion reaction) (an alloimmune phenomenon). Most of the classic autoimmune diseases, including disorders of the endocrine system (autoimmune thyroiditis and Graves disease), hematologic system (the hemolytic and pernicious anemias), nervous system (myasthenia gravis), and connective tissue in joints (rheumatoid arthritis), are discussed in Unit II of this book.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic, multisystem, inflammatory disease and is one of the most common, complex, and serious of the autoimmune disorders. SLE is characterized by multiple immune disorders that result in the production of a large variety of autoantibodies against nucleic acids, erythrocytes, coagulation proteins, phospholipids, lymphocytes, platelets, and many other self-components.¹⁹ The most characteristic autoantibodies produced in SLE are against nucleic acids (e.g., single-stranded deoxyribonucleic acid [DNA], double-stranded DNA), histones, ribonucleoproteins, and other nuclear materials.

Deposition of circulating immune complexes containing antibody against DNA produces tissue damage in individuals with SLE. DNA and DNA-containing immune complexes have a high affinity for glomerular basement membranes and therefore may be selectively deposited in the glomerulus ([Fig. 9.7](#)). (Kidney structures are described in [Chapter 38](#).) The presence of DNA in the circulation increases from cellular damage in response to trauma, drugs, or

infections and is usually removed in the liver. Removal of circulating DNA is slowed in the presence of immune complexes, thereby increasing the potential for deposition in the kidney. (The liver's role in removing waste products from the blood is discussed in [Chapter 41](#).) Deposition of immune complexes composed of DNA and antibody also causes inflammatory lesions in the renal tubular basement membranes, brain (choroid plexus), heart, spleen, lung, gastrointestinal tract, skin (see [Fig. 9.7](#)), and peritoneum.

A, Section from a kidney showing a glomerulus with deposits of IgG (*arrow*, indicating bright areas of staining). B, Section of the skin showing deposition of IgG along the dermal-epidermal junction (*arrow*, indicating bright green staining). (A courtesy Dr. Helmut Rennke, Department of Pathology, Brigham and Women's Hospital, Boston; B courtesy Dr. Richard Sontheimer, Department of Dermatology, University of Texas Southwestern Medical School,

Dallas.)

SLE, as with most autoimmune diseases, occurs more often in women (approximately a 10:1 predominance of females), especially in the 20- to 40-year-old age group. Blacks are affected more often than whites (about an eightfold increased risk). A genetic predisposition for the disease has been implicated on the basis of increased incidence in twins and the existence of autoimmune disease in the families of individuals with SLE.

A transient lupus-like syndrome that is indistinguishable both clinically and in the laboratory from spontaneously occurring SLE can develop from the prolonged use of medications, particularly hydralazine (an antihypertensive agent) and procainamide (an antidysrhythmic drug). In genetically susceptible individuals, certain environmental agents, such as ultraviolet light, and several infectious agents may trigger lupus-like immune reactions.

Clinical manifestations of SLE include arthralgias or arthritis (90% of individuals), vasculitis and rash (70% to 80% of individuals), renal disease (40% to 50% of individuals), hematologic abnormalities (50% of individuals, with anemia being the most common complication), and cardiovascular diseases (30% to 50% of individuals). A recent study of male and female individuals with SLE reported gender-based differences in the incidence of SLE-related symptoms.²⁰ Females more commonly developed alopecia, photosensitivity, oral ulcers, malar rash, lupus anticoagulant, arthritis, and serositis with pleurisy, whereas males more commonly developed thrombocytopenia, anti-dsDNA, and renal involvement.

As with most autoimmune diseases, the disease process develops slowly (up to 10 years from occurrence of the first autoantibody until diagnosis)²¹ and is characterized by frequent remissions and exacerbations. Because the signs and symptoms affect almost every body system and tend to be intermittent, SLE is extremely difficult to diagnose. This has led to the development of a list of 11 common clinical findings,²² which has been modified slightly to increase sensitivity of the diagnosis.²³ The serial or simultaneous presence of at least four of them indicates that the individual has SLE.²⁴

1. Facial rash confined to the cheeks (malar rash)
2. Discoid rash (raised patches, scaling)
3. Photosensitivity (development of skin rash developed as a result of exposure to sunlight)
4. Oral or nasopharyngeal ulcers
5. Nonerosive arthritis of at least two peripheral joints
6. Serositis (pleurisy, pericarditis)
7. Renal disorder (persistent proteinuria of >0.5 g/day or >3 g/day on dipstick or cellular casts)
8. Neurologic disorders (seizures or psychosis in the absence of known causes)
9. Hematologic disorders (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia)
10. Immunologic disorders (antibodies against double-stranded DNA [dsDNA] or Smith [Sm] antigen, false-positive serologic test for syphilis, or antiphospholipid antibodies [anticardiolipin antibody or lupus anticoagulant])
11. Presence of antinuclear antibody (ANA)

Laboratory diagnosis is usually based on a positive ANA screening test; about 98% of persons with SLE are positive, but a substantial number of false-positives occur in healthy individuals and those with other diseases. Because SLE is a progressive and slowly developing disease, some laboratory tests, including the ANA, may be positive years before the onset of clinical symptoms.²⁵ Detection of a positive ANA is usually followed by one or more specific tests (e.g., antibodies against Sm, dsDNA) that are complicated by low sensitivity (only a portion of individuals with SLE will be positive, although the number of false-positives is low).

There is no cure for SLE or most other autoimmune diseases. In the 1950s, the expected survival rate at 5 years after diagnosis was only 50%. Because of improved diagnosis and treatment of SLE the 2004 expected survival rate 20 years after diagnosis was 78%.²⁶ Fatalities resulting from SLE are usually related to cardiovascular disease with infection and other organ failure almost as common. The goals of

treatment are to control symptoms and prevent further damage by suppressing the autoimmune response. Mild forms of SLE are treated with nonsteroidal antiinflammatory drugs, such as aspirin, ibuprofen, or naproxen, to reduce inflammation and relieve pain. Low-dose corticosteroids, such as prednisone, are often prescribed with higher doses used for more serious active disease. Antimalarial medications (e.g., hydroxychloroquine) are preferred treatments for individuals with stable disease. Immunosuppressive drugs (e.g., methotrexate, azathioprine, or cyclophosphamide) are used to treat individuals with severe symptoms involving internal organs who have not responded to high-dose corticosteroids. Ultraviolet light can worsen symptoms (known as flares), and protection from sun exposure is helpful. Prolonged use of certain drugs can cause transient SLE-like symptoms, and the medication history is important for diagnostic evaluation.

Other therapeutic approaches have been attempted for SLE and other autoimmune diseases. Several decades ago preparations of intravenous immune globulin (IVIg), which was routinely used to replenish antibodies in persons with antibody deficiencies, were administered to children with autoimmune thrombocytopenia (an autoimmune disease in which platelets were destroyed by an autoantibody). IVIg therapy resulted in a rebound of platelet levels and temporary resolution of the thrombocytopenia. IVIg is currently being used for a variety of autoimmune diseases, including SLE. A monoclonal antibody, belimumab, inhibits a factor that activates B cells and has been used in some individuals with SLE. Other reagents have specifically targeted and suppressed B and T cells that are participating in autoimmune responses.²⁷ This approach has been somewhat successful in SLE, rheumatoid arthritis, and other autoimmune diseases. Improved outcomes may be available in the future with the continued advances in medical research and the use of stem cell treatments.

Transfusion Reactions

Red blood cells (erythrocytes) express several important surface

antigens, known collectively as the **blood group antigens**, that can be targets of alloimmune reactions. More than 80 different red cell antigens are grouped into several dozen blood group systems. The most important of these, because they provoke the strongest humoral alloimmune response, are the ABO and Rh systems.

ABO System.

Human blood transfusions were carried out as early as 1818, but they were often unsuccessful. Sometimes after a transfusion, the recipient's red blood cells would clump together, thereby blocking the capillaries and causing death in some instances. In 1901 Karl Landsteiner reported that this reaction was related to the ABO antigens located on the surface of erythrocytes.

The **ABO blood group** consists of two major carbohydrate antigens, labeled A and B ([Fig. 9.8](#)), that are expressed on virtually all cells. These are codominant so that both A and B can be simultaneously expressed, resulting in an individual having any one of four different blood types. The erythrocytes of persons with blood type A express the type A carbohydrate antigen (i.e., carry the A antigen), those with blood type B express the B antigen, those with blood type AB express both A and B antigens on the same cell, and those of blood type O express neither the A nor the B antigen. A person with type A blood also has circulating antibodies to the B carbohydrate antigen. If this person receives blood containing B antigens (i.e., blood from a type AB or B individual), a severe transfusion reaction occurs and the transfused erythrocytes are destroyed by agglutination ([Fig. 9.9](#)) or complement-mediated lysis. Similarly, a type B individual (whose blood contains anti-A antibodies) cannot receive blood from a type A or type AB donor. Type O individuals, who have neither A nor B antigen but have both anti-A and anti-B antibodies, cannot accept blood from any of the other three types. These naturally occurring antibodies, called **isohemagglutinins**, are IgM and are induced early in life by similar antigens expressed on naturally occurring bacteria in the intestinal tract.²⁸

FIGURE 9.8 ABO Blood Types. This figure shows the antigens and antibodies associated with the ABO blood groups. The surfaces of erythrocytes of individuals with blood group O have the core H antigenic carbohydrate. Their sera contain IgM antibodies against both A and B carbohydrates. In individuals of the blood group A, some of the H antigens have been modified into A antigens by the addition of *N*-acetylgalactosamine (*NAGA*). The sera of these individuals have IgM antibodies against the B antigen. In individuals with blood group B, some of the H antigens have been modified into B antigens by the addition of galactose (*Gal*). These individuals have IgM antibodies against the A antigen in their sera. In individuals of the blood group AB, some of the H antigens have been modified into both the A and the B antigens. These individuals do not have antibody to either A or B antigens. *Fuc*, Fucose.

FIGURE 9.9 Mismatched Transfused Blood Cells. Agglutination of erythrocytes caused by anti-A blood-typing serum. (Copyright Ed Reschke.)

Because individuals with type O blood lack both types of antigens, they are considered **universal donors**, meaning that anyone can accept their red blood cells. Similarly, type AB individuals are considered **universal recipients** because they lack both anti-A and anti-B antibodies and can be transfused with any ABO blood type. When large volumes of *whole blood* (i.e., cells plus plasma) are transfused, however, antibodies in the *donor's* blood can bind to antigenic determinants on the *recipient's* erythrocytes, causing agglutination of the recipient's own cells. Preparations of pooled immunoglobulins are routinely administered intravenously (IVIg) to treat those who have immune deficiencies lacking antibodies (discussed later in this chapter). Transfusion reactions can occur if the IVIg contains excess levels of isohemagglutinins against the recipient's A or B antigens.²⁹ Harmful transfusion reactions can be prevented only by complete and careful ABO matching between donor and recipient.³⁰ Because ABO antigens are also expressed on all other cells, except platelets, ABO typing and matching also must be performed before organ transplantation.

Rh System.

The **Rh blood group** is a group of antigens expressed only on red blood cells. This group is the most polymorphic system of red cell antigens, consisting of at least 50 separate antigens. At least five major antigens and a large number of rare variants have been identified and

are expressed primarily on erythrocytes. The major antigens are contained on two proteins encoded from two closely linked genes, *RHD* and *RHCE*. The RhD protein expresses the dominant antigen, which determines whether an individual is Rh-positive or Rh-negative. Individuals who express the D antigen on the RhD protein are Rh-positive, whereas individuals who do not express the D antigen are Rh-negative. The letter *d* is used to indicate lack of D. Rh-positive individuals can have either a *DD* or a *Dd* genotype, whereas Rh-negative individuals have the *dd* genotype. About 15% of North American whites are Rh-negative, whereas the Rh-negative genotype is much less common among members of other ethnic groups. Rh-negative individuals can make anti-D if exposed to Rh-positive erythrocytes, but because the letter *d* is used to indicate the lack of the D antigen and does not represent a different antigen, Rh-positive individuals do not produce an antibody against *d*. The second protein, RhCE, expresses two different antigens, C and E, each of which has two different alleles (*C* or *c*, *E* or *e*). Therefore, four potential haplotypes of C and E antigens are commonly observed: *CE*, *Ce*, *cE*, and *ce*.

A disease called **hemolytic disease of the newborn** was most commonly caused by IgG anti-D alloantibody produced by Rh-negative mothers against erythrocytes of their Rh-positive fetuses (see [Chapter 31](#)).³¹ The mother's antibody crossed the placenta and destroyed the red blood cells of the fetus. The occurrence of this particular form of the disease has decreased dramatically because of the use of prophylactic IgG anti-D immunoglobulin (e.g., Rh₀[D] immunoglobulin).³² By mechanisms that are still not completely understood, administration of anti-D antibody within a few days of exposure to RhD-positive erythrocytes completely prevents sensitization against the D antigen. Because hemolytic disease of the newborn related to the D antigen has been controlled, alloantibodies against the other Rh antigens (usually C, c, or E) have become more important. In general, these alloantibodies are associated with a less severe hemolytic disease.

A form of autoimmune hemolytic anemia is often caused by

autoantibodies against Rh antigens, especially the e antigen.³³ This variant is caused by IgG antibodies that react with erythrocytes at normal body temperature (thus called *warm autoimmune hemolytic anemia*) and increase phagocytic destruction of the red blood cell. This characteristic differentiates the warm variant from another form of autoimmune hemolytic anemia, which is caused by IgM autoantibodies that react optimally with erythrocytes in the cooler portions of the body (e.g., fingers, toes) and is referred to as *cold autoimmune hemolytic anemia*.

Graft Rejection

Molecules of the **major histocompatibility complex (MHC)** were discussed in [Chapter 8](#) as antigen-presenting molecules. MHC molecules also are a major target of transplant rejection. As a result of studies of transplantation, the human MHC molecules are also referred to as **human leukocyte antigens (HLAs)**, and the different MHC genetic loci are commonly called HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ, and HLA-DP. Additional genes for complement components (e.g., C4, factor B) also are contained in the MHC region and are referred to as *class III loci*. The class I (HLA-A, -B, and -C) and class II MHC loci (HLA-DR, -DQ, and -DP) are the most genetically diverse (polymorphic) of any human genetic loci. Within the human population, the number of possible different alleles (i.e., forms of the gene) expressed by each locus is astounding. For example, more than 300 different HLA-A molecules are expressed in the population. These numbers are based on the polymorphism of observed DNA sequences and may not reflect differences in function.

Clearly, not every allele is expressed in the same individual. Humans have two copies of each MHC locus (one inherited from each parent) that are codominant so that molecules encoded by each parent's genes are expressed on the surface of every cell, except erythrocytes. Within an individual, each locus will express only one allele. For instance, each person will have at most two different HLA-A proteins (one from each parent). The specific combination of alleles at the six major HLA loci on one chromosome (A, B, C, DR, DQ, and

DP) is termed a *haplotype*. Each individual has two HLA haplotypes, one from the paternal chromosome 6 and another from the maternal chromosome. Odds dictate that children will share one haplotype with half their siblings and either no haplotypes or both haplotypes with a quarter of their siblings. Thus the chance of finding a match among siblings is 25%. Because of the tremendous number of possible alleles expressed throughout the population, the probability of matching any two unrelated individuals is extremely small.

Not all HLA loci are equally important; matching at the HLA-DR locus appears to be the most critical for graft acceptance, and matching at HLA-A and HLA-B of slightly lesser importance. (These loci also are discussed in [Chapter 8](#).)

Transplant rejection may be classified as hyperacute, acute, or chronic, depending on the amount of time that elapses between transplantation and rejection. **Hyperacute rejection** is immediate and rare. When the circulation is reestablished to the grafted area, the graft may immediately turn white (the so-called *white graft*) instead of a normal pink. Hyperacute rejection usually occurs in recipients with preexisting antibody (type II reaction) to HLA antigens on vascular endothelium in the graft. The antibodies may have resulted from rejection of a previous graft or from prior blood transfusions that contained platelets and white blood cells with foreign HLA. Additionally, about half of women who have had multiple pregnancies have circulating antibodies against their husband's HLA antigens. As the circulation to the graft is established, antibodies bind to the vascular endothelial cells in the grafted tissue and activate the inflammatory response, including the coagulation cascade, which results in stasis of blood flow into the tissue (see Fig. E 9.1 on Evolve). (Coagulation is described in [Chapters 7](#) and [28](#).) Biopsies of the graft often show deposits of antibody (IgG and IgM), complement, and neutrophils. This condition is rare because of effective pretransplantation cross-matching during which a recipient is tested for antibodies against the HLA antigens of the potential donor.

Acute rejection is primarily a cell-mediated immune response that occurs within days to months after transplantation. This type of

rejection occurs when the recipient develops an immune response against unmatched HLAs after transplantation. Sensitization is usually initiated by the recipient's lymphocytes interacting with the donor's dendritic cells within the transplanted tissue, resulting in induction of recipient Th1 and Tc cells against the donor's antigens. The Th1 cells release cytokines that activate infiltrating macrophages, and the Tc cells directly attack the endothelial cells in the transplanted tissue. A biopsy of the rejected organ usually shows an infiltration of lymphocytes and macrophages characteristic of a type IV reaction. Immunosuppressive drugs may delay or lessen the intensity of acute rejection.

Another form of acute rejection, *acute antibody-mediated rejection*, has recently been recognized and accounts for about 10% of acute rejections. This form of rejection is mediated by antibody and complement. The predominant antibodies are against HLA antigens or, on occasion, autoantigens in the graft (e.g., vimentin, angiotensin receptor), but, unlike those antibodies that cause hyperacute rejection, are not present at the time of transplantation. Sensitization takes 2 weeks or longer and results in the accumulation of antibody, complement, neutrophils, and thrombi in the vasculature of the graft (a type II hypersensitivity reaction).

Chronic rejection may occur after a period of months or years of normal function. It is characterized by slow, progressive organ failure. Chronic rejection usually results from a weak cell-mediated immunologic (type IV) reaction against minor histocompatibility antigens on the grafted tissue. However, antibodies against HLA and other antigens also may cause chronic rejection through activation of complement or antibody-dependent cellular cytotoxicity (ADCC) with NK cells.

Deficiencies in Immunity

Disorders resulting from immune deficiency are the clinical sequelae (results) of impaired function of one or more components of the immune or inflammatory response (e.g., B cells, T cells, phagocytes,

complement) (Table 9.6). An **immune deficiency** is the failure of these mechanisms of self-defense to function at their normal capacity, resulting in increased susceptibility to infections. A **primary (congenital) immune deficiency** is caused generally by a genetic anomaly, whereas a **secondary (acquired) immune deficiency** is caused by another illness, such as cancer or viral infection, or by normal physiologic changes, such as aging. Acquired forms of immune deficiency are far more common than the congenital forms.

TABLE 9.6

CLASSES OF PRIMARY IMMUNE DEFICIENCIES

CLASSIFICATION	EXAMPLE	MUTATION	IMMUNE DEFICIENCY
Combined Deficiencies Without Nonimmunological Abnormalities			
SCID: No WBC stem cells	Reticular dysgenesis	Unknown	Complete lack of white blood cells
SCID: Enzyme defects	Adenosine deaminase (ADA) deficiency	<i>ADA</i>	Complete, few, or no T, B, or NK cells
	Purine nucleoside phosphorylase (PNP) deficiency	<i>PNP</i>	Few T or NK cells
SCID: Cytokine receptor defects	X-linked	<i>IL-2Rγ</i>	Partial or no maturation of Th and NK cells (T ⁻ , B ⁺ , NK ⁻)
	Autosomal Janus kinase 3 deficiency IL-7 receptor deficiency	<i>JAK3</i> <i>IL-7Rα</i>	Absence of T and NK cells (T ⁻ , B ⁺ , NK ⁻) Absence of T cells (T ⁻ , B ⁺ , NK ⁺)
SCID: Antigen presentation defects	Bare lymphocyte syndrome MHC class I deficiency	<i>TAP1</i> or <i>TAP2</i>	Abnormal cytotoxic T-cell activity
	Bare lymphocyte syndrome MHC class II deficiency	Multiple	Abnormal helper T-cell activity
SCID: TCR/BCR defects	RAG-1 or RAG-2 deficiency	<i>RAG-1/RAG-2</i>	Lack of maturation of T or B cells; normal NK cells
SCID: TCR defects	CD45 deficiency CD3 deficiency	CD45 CD3 γ , δ , or ϵ	Partial to incomplete T-cell maturation, normal B

	ZAP-70 deficiency	chains <i>ZAP-70</i>	and NK cells
Combined Deficiencies With Nonimmunological Abnormalities			
Cytoskeletal defect	Wiskott-Aldrich syndrome (WAS)	<i>WASP</i>	Altered T and B cells; decreased IgM; thrombocytopenia, eczema
DNA repair defect	Ataxia-telangiectasia (AT)	<i>ATM</i>	Altered T and B cells; absent IgA; ataxia, telangiectasia
Defective primary lymphoid organ for T-cell development	DiGeorge syndrome	Development of 3rd and 4th pharyngeal pouches	Little or no T-cell maturation; small or absent thymus, hypoparathyroidism (diminished Ca levels, tetany), facial defects
Predominantly Antibody Deficiencies			
B-cell receptor signaling	Bruton/X-linked agammaglobulinemia Autosomal agammaglobulinemia	<i>Btk</i> IgM μ chain	Little or no B-cell maturation or antibody
Class-switch: hyper-IgM	X-linked hyper-IgM syndrome Autosomal hyper-IgM syndrome AICD deficiency	CD40 ligand CD40 <i>AICD</i>	Little or no class-switch to IgG or IgA, with overproduction of IgM
Class-switch: selective	IgG subclass deficiency	Unknown	Defective switch to an IgG subclass
	Selective IgA deficiency	Unknown	Defective switch to IgA
	Common variable immune deficiency	Multiple	Defective switch to ≥ 1 antibody class
Immune Dysregulation			
Decreased cellular killing	Perforin deficiency	Perforin (<i>PRF1</i>)	Decreased or absent Tc and NK cells
Bacterial killing defect	Chédiak-Higashi syndrome	<i>CHS1</i>	Defective lysosomal granules
Phagocyte Defects			
Neutropenia	Severe congenital neutropenia	Elastase, neutrophil-expressed (<i>ELAINE</i>)	Severe deficiency in neutrophils
	Cyclic neutropenia	Elastase (<i>ELA2</i>)	Mild periodic neutropenia

Bacterial killing	Chronic granulomatous disease	NADPH oxidase	Defective production of H ₂ O ₂
	Myeloperoxidase deficiency	Myeloperoxidase (MPO)	Mild killing defect
Diapedesis defect	Leukocyte adhesion deficiency-1 (LAD-1)	CD18	Defective invasion
	Leukocyte adhesion deficiency-2 (LAD-2)	Glycosylation pathway	Defective invasion
Innate Immunity Defects			
Macrophage response defect	Chronic mucocutaneous candidiasis	Mutations in Th17 or macrophage IL-17 receptor	Little or no response to <i>Candida</i>
Autoinflammatory Disorders			
Control of inflammasome	Familial Mediterranean fever	<i>MEFV</i>	Excess IL-1 β production
Complement Defects			
Classical pathway	C1q, r, s; C4; or C2 deficiency	C1q, r, or s; C4; or C2	Defective classical pathway, intact alternative pathway
Lectin pathway	Mannose-binding lectin (MBL) deficiency	<i>MBL</i>	Defective lectin pathway
Alternative pathway	Properdin, factor D or B deficiency Factor H, factor I deficiency	Properdin, factor D or B Factor H, factor I	Defective alternative pathway Secondary C3 deficiency
C3	C3 deficiency	C3	Entire complement cascade blocked
Terminal pathway	C5, C6, C7, C8, or C9 deficiency	C5, C6, C7, C8, or C9	Membrane attack complex blocked, normal opsonization and chemotaxis

AICD, Activation-induced cytidine deaminase; *ATM*, ataxia-telangiectasia mutated serine/threonine kinase; *Btk*, Bruton tyrosine kinase; *CHS1*, Chédiak-Higashi syndrome 1 (also known as *LYST*, lysosomal trafficking regulator); *IL-2R γ* , interleukin-2 receptor gamma chain; *IL-7R α* , interleukin-7 receptor alpha chain; *MEFV*, Mediterranean fever gene; *MHC*, major histocompatibility complex; *NADPH*, nicotinamide adenine dinucleotide phosphate; *NK*, natural killer cell; *RAG*, recombination activating gene; *SCID*, severe combined immune deficiency; *TAP*, transporter associated with antigen processing; *TCR/BCR*, T-cell receptor/B-cell receptor; *WASP*, Wiskott-Aldrich syndrome protein; *WBC*, white blood cell;

ZAP, zeta-chain associated protein.

Initial Clinical Presentation

The clinical hallmark of immune deficiency is a tendency to develop unusual or recurrent, severe infections. The most severe primary immune deficiencies develop in young children 2 years old and younger. Frequent infections are normal in preschool and school-age children, who normally have 6 to 12 infections per year, of which 3 or 4 are ear infections, and adults may have 2 to 4 infections per year. Most of these are not severe and are limited to viral infections of the upper respiratory tract, recurrent streptococcal pharyngitis, or mild otitis media.

Potential immune deficiencies are considered if the individual has had severe, documented bouts of pneumonia, severe otitis media, sinusitis, bronchitis, septicemia, or meningitis or infections with rare opportunistic microorganisms that normally are not pathogenic or usually confined to one site (e.g., *Pneumocystis jirovecii*, disseminated *Candida* infection, cytomegalovirus [CMV]). Infections are generally recurrent with only short intervals of relative health, and multiple simultaneous infections are common. Individuals with primary immune deficiencies often have eight or more purulent ear infections, two or more serious sinus infections, and two or more pneumonias, recurrent abscesses or infections in unusual sites, or persistent fungal infections (particularly thrush in a child at least 1 year old) within a year. Invasive fungal infections are rare in healthy individuals and strongly indicate a defective immune system. Recurrent internal infections, such as meningitis, osteomyelitis, or sepsis, are common. Prolonged antibiotic use is commonly ineffective by oral or injected routes and may necessitate intravenous administration. Children frequently present with failure to thrive because of chronic diarrhea and other chronic symptoms. A familial history of immune deficiency may be found in some types of primary deficiency.

Routine care of individuals with immune deficiencies must be tempered with the knowledge that the immune system may be totally ineffective. It is unsafe to administer conventional immunizing agents

or blood products to many of these individuals because of the risk of causing an uncontrolled infection. Infection is a particular problem when attenuated vaccines that contain live but weakened microorganisms are used (e.g., live polio vaccine; vaccines against measles, mumps, and rubella).

The type of recurrent infections that manifest may indicate the type of immune defect. Deficiencies in T-cell immune responses associated with recurrent infections are caused by certain viruses (e.g., varicella, vaccinia, herpes, cytomegalovirus), fungi and yeasts (e.g., *Candida*, *Histoplasma*), or certain atypical microorganisms (e.g., *P. jirovecii*). B-cell deficiencies and phagocyte deficiencies, however, are suggested if the individual has documented, recurrent infections with microorganisms that require opsonization (e.g., encapsulated bacteria) or viruses against which humoral immunity is normally effective (e.g., rubella). Some complement deficiencies resemble defects in antibody or phagocyte function, but others are characterized by disseminated infections with bacteria of the genus *Neisseria* (*Neisseria meningitidis* and *Neisseria gonorrhoeae*).

Much of the current understanding of the development of the immune system and the interactions of the cells in the immune response was developed by studying congenital and acquired immune deficiencies or, as they have been called, “experiments of nature.” Many immune deficiencies result from selective alteration or removal of one component of the immune system. The importance of that component can be understood by observing the effect of its removal on the remainder of the immune response.

Primary Immune Deficiencies

Most primary immune deficiencies are the result of single gene defects (Fig. 9.10). Generally, the mutations are sporadic and not inherited: a family history exists in only about 25% of individuals. The sporadic mutations occur before birth, but the onset of symptoms may be early in neonatal life or later, depending on the particular syndrome. In approximately 60% of the cases, symptoms of immune deficiency appear within the first 2 years of life, whereas other immune

deficiencies are progressive, with the onset of symptoms appearing in the second or third decade of life. The most common symptoms include sinusitis (68% of individuals), pneumonia (51%), ear infections (51%), diarrhea (30%), and bronchitis (55%), with the incidence varying depending on the specific syndrome.

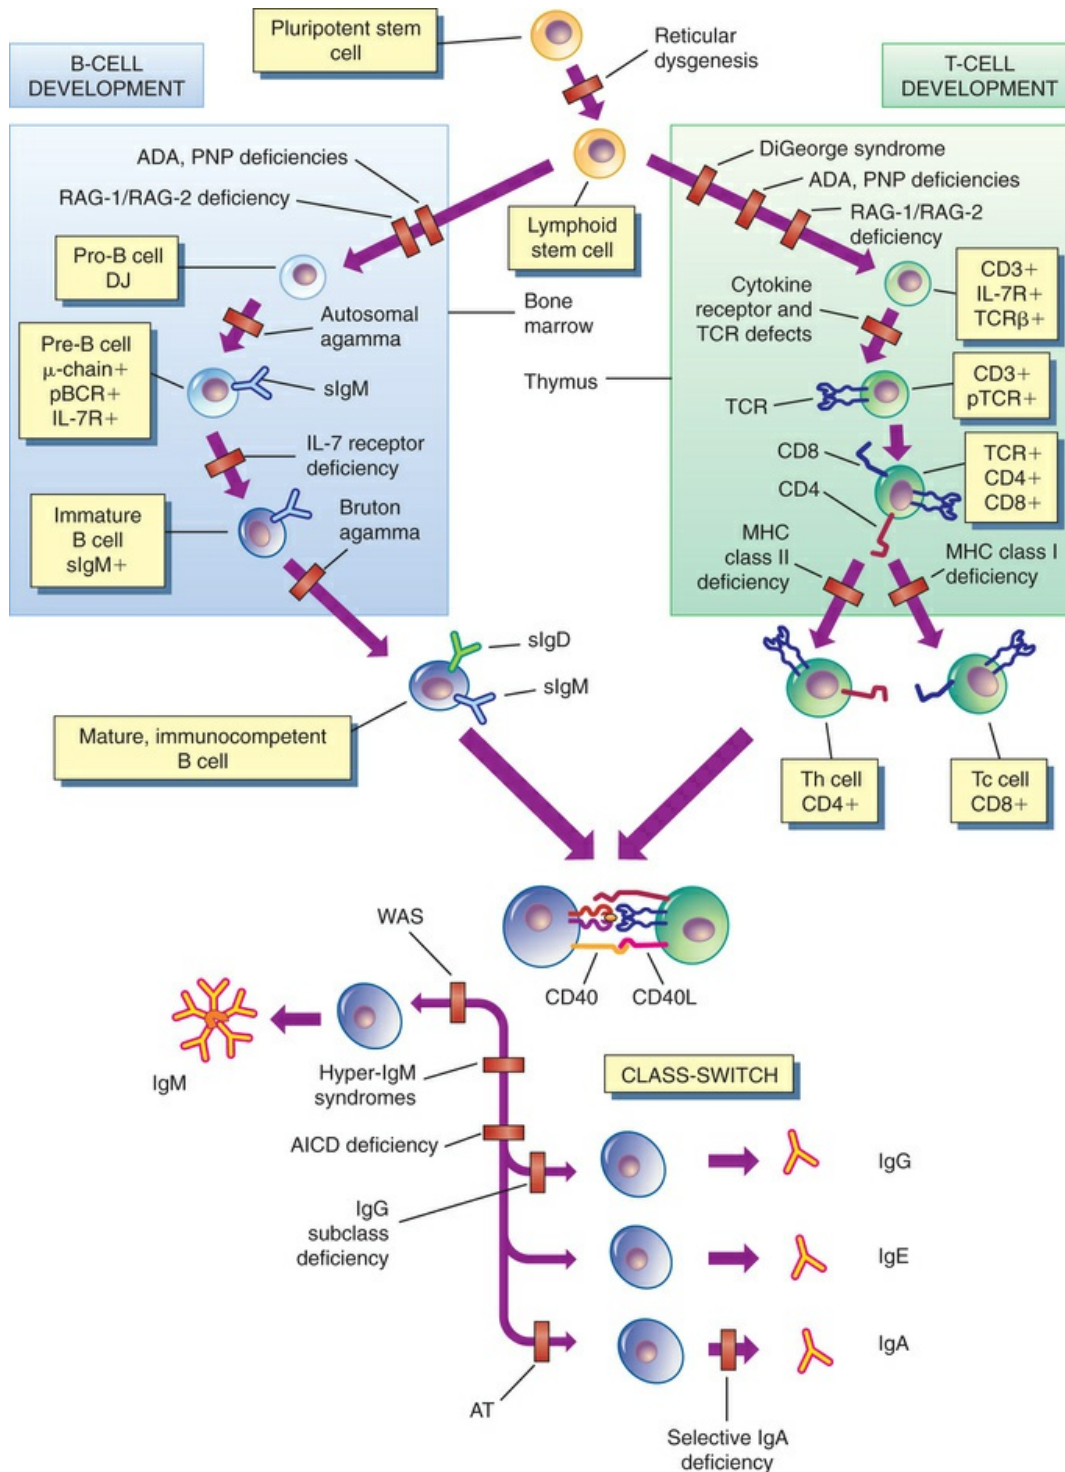

FIGURE 9.10 Lymphocyte Development Defects. This diagram shows defects in lymphocyte development that may account for congenital (primary) immune deficiencies. See the text and refer to [Figs. 8.9](#) and [8.12](#) for more detailed information. Pluripotent stem cell indicates the common stem cells for lymphocytic, granulocytic, and monocytic lineages. Cytokine receptor defects include X-linked severe combined immunodeficiency (SCID) (IL-2 receptor defect), JAK3 defects, and IL-7 receptor defects. T-cell receptor (TCR) defects include defects in CD3, CD45, and ZAP-70. Neither

common variable immune deficiency nor chronic mucocutaneous candidiasis is included in this figure because the cause of these defects remains unknown. See [Table 9.6](#) for further information on each defect. *ADA*, Adenosine deaminase deficiency; *agamma*, agammaglobulinemia; *AICD deficiency*, activation-induced cytidine deaminase deficiency; *AT*, ataxia-telangiectasia; *MHC*, major histocompatibility complex; *PNP*, purine nucleoside phosphorylase deficiency; *RAG*, recombination-activating enzyme; *slgM* and *slgD*, surface IgM and IgD, respectively; *WAS*, Wiskott-Aldrich syndrome.

Individually, primary immune deficiencies are very rare. For instance, only 30 to 50 new cases of severe combined immune deficiency are diagnosed in the United States yearly. However, more than 200 different genetic defects resulting in immune deficiencies have been identified, and the number is growing rapidly. Together, primary immune deficiencies are more common than cystic fibrosis, hemophilia, childhood leukemia, or many other well-known diseases. Many are subtle with minor deficiencies, but several lead to recurrent life-threatening infections. An estimated 50,000 cases of clinically significant primary immune deficiency have been reported in the United States. The gender distribution depends on the specific disease, but in general those diagnosed within the first 2 years of life have a male preponderance (5 : 1) because many are X-linked, whereas those diagnosed later are evenly distributed. The three most commonly diagnosed deficiencies are common variable immune deficiency (34% of individuals with primary immune deficiencies), selective IgA deficiency (24%), and IgG subclass deficiency (17%).

Primary immune deficiencies have recently been reclassified into nine groups, based on which principal component of the immune or inflammatory systems is defective.³⁴ On occasion a particular immune deficiency may be listed under two categories because the predominant mechanism may not be fully understood. To provide a better understanding of the diversity and severity of primary immune deficiencies, only a very few selected examples will be discussed.

Combined Deficiencies without Nonimmunologic Abnormalities

A great deal of knowledge about the evolution of bone marrow stem

cells into functional lymphocytes came from studying children with deficiencies of more than one type of lymphocyte (combined immune deficiencies). The most severe group of immune deficiencies is **severe combined immune deficiency (SCID)**. The most severe form of SCID is **reticular dysgenesis** (failure of blood cells to develop), in which a common stem cell for all white blood cells is absent; therefore, T cells, B cells, and phagocytic cells never develop (see [Fig. 9.10](#)). Most children with reticular dysgenesis die in utero or very soon after birth. Most typically, a defect occurs after stem cells become committed to developing into lymphocytes (lymphoid stem cells); therefore, most individuals with SCID have normal numbers of granulocytes.

Most individuals with SCID have few detectable lymphocytes in the circulation and secondary lymphoid organs (spleen, lymph nodes). The thymus is usually underdeveloped because of the absence of T cells. Immunoglobulin levels, especially IgM and IgA, are absent or greatly reduced.

At least 20 different forms of SCID have been identified. Depending on the specific genetic mutation, the defect may involve T cells, B cells, and NK cells or may suppress the function of one cell type more severely with relatively minor effects on the others. SCID often results in few or absent T and B lymphocytes in the circulation and secondary lymphoid organs (spleen, lymph nodes). The thymus is usually hypoplastic (underdeveloped) because of the absence of T cells. Immunoglobulin levels, especially of IgM and IgA, are absent or greatly reduced, although IgG levels may be almost normal in the first months of life because of the presence of maternal antibodies. In the most severe defects, death occurs at about 1 year of life.

All three cells are adversely affected (T⁻, B⁻, NK⁻) in SCID; it develops from an autosomal recessive enzymatic defect in **adenosine deaminase (ADA) deficiency**, resulting in the accumulation of toxic purine metabolites to which rapidly dividing cells, such as lymphocytes, are especially sensitive (see [Fig. 9.10](#)). ADA deficiency accounts for about 16% of all persons with SCID. The development of T cells, B cells, and NK cells is arrested very early, and very few lymphocytic cells are found in the blood. Mutation of another purine

metabolism enzyme, purine nucleoside phosphorylase (**purine nucleoside phosphorylase [PNP] deficiency**), is less severe than ADA deficiency (see [Fig. 9.10](#)). T cells and NK cells appear to be more susceptible to mutations in PNP so that B-cell function can be relatively normal (T⁻, B⁺, NK⁻).

X-linked SCID results from a common defect in most of the important cytokine receptors needed for lymphocyte maturation (e.g., IL-2, IL-4, IL-7, and others). T cells and NK cells are preferentially affected (T⁻, B⁺, NK⁻), but the defect often results in the production of immature B cells that cannot respond well to antigen because of the lack of Th cells. The most common (44% of those with SCID) is an X-linked SCID resulting from a defect in the IL-2 receptor gamma (γ)-chain (IL-2R γ). This protein is a component of several receptors for cytokines, including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. A similar, but autosomal, deficiency occurs with a mutation in JAK3 (**JAK3 deficiency**), which is an enzyme (a tyrosine kinase) that associates with IL-2R γ in normal cells and communicates information from the receptor to the nucleus. Thus cells with defects in JAK3 cannot respond to cytokines that bind to these receptors on the cell surface. Another autosomal form of SCID results from mutations in the α chain of the IL-7 receptor (**IL-7 receptor deficiency**). IL-7 is necessary for the maturation of T cells within the thymus, so that this deficiency has relatively normal levels of B cells and NK cells (T⁻, B⁺, NK⁺).

Even if nearly adequate numbers of B and T cells are produced, their cooperation may be defective. The **bare lymphocyte syndrome** is a group of immune deficiencies characterized by an inability of lymphocytes and macrophages to produce major histocompatibility complex (MHC) class I or class II molecules. Without MHC molecules, antigen presentation and intercellular cooperation cannot occur effectively (see [Fig. 9.10](#)). **MHC class I deficiency** results from mutations in the genes for the transporters associated with antigen processing (TAP1 or TAP2), which control the transport of antigenic protein fragments across the endoplasmic reticulum and the formation of MHC class I/antigen complexes for transportation to the cell surface (see [Fig. 8.15](#)). Because MHC class I molecules

preferentially present antigen to CD8⁺ T_c cells, the resultant deficiency is of CD8⁺ cytotoxic cells, with normal levels of CD4⁺ helper cells and normal antibody production. **MHC class II deficiency** is more severe. A variety of mutations prevent normal production of MHC class II molecules, which present antigen to CD4⁺ helper cells. Because of defective recruitment of T-helper cells, normal antibody responses are greatly suppressed. Children with this deficiency develop life-threatening infections and usually die before age 5 years.

T and B lymphocytes possess receptors for antigen, whereas NK cells do not. Those receptors result from a process of genetic rearrangement of *V* and *J* genes to form the variable regions of the L chain (B-cell receptor [BCR]) and the α chain (T-cell receptor [TCR]) and the *V*, *D*, and *J* genes to form the variable regions of the H chain (BCR) and the β chain (TCR). Successful genetic rearrangement is controlled by two recombination activating enzymes (RAG-1 and RAG-2). **RAG-1** or **RAG-2 deficiencies** are autosomal recessive and result in arrested lymphocyte development from blocked recombination of variable regions of B-cell and T-cell receptors (see [Fig. 9.10](#)), whereas NK cells are not affected (T⁻, B⁻, NK⁺).

Forms of partial SCID, with the defect being primarily of T cells, arise from mutations in several components of the TCR complex (see [Fig. 9.10](#)). The TCR is a complex organization of proteins that react with antigen (α and β chains) and then provide an intracellular signal to the nucleus (γ , δ , and ϵ chains [collectively called CD3] and the associated molecules CD45 and ZAP-70). Examples of these deficiencies include mutations in CD3, CD45, or ZAP-70. The T-cell defect in each can range from mild to severe in nature, with normal B lymphocytes and NK cells (T⁻, B⁺, NK⁺). Although B cells are normal, antibody production may be depressed because of the lack of Th cells.

Combined Deficiencies with Nonimmunologic Abnormalities

Some combined immune deficiencies are associated with other

characteristic defects, some of which appear to be unrelated to the immune system yet may be life threatening by themselves. These associated symptoms can be useful diagnostically and can clarify the pathophysiology of the disease. **Wiskott-Aldrich syndrome (WAS**, an X-linked recessive disorder) results from sporadic mutations in the WAS protein (WASP), which is involved in intracellular signaling and regulation of the cell's actin cytoskeleton (see [Fig. 9.10](#)). Defects in the cytoskeleton lead to the classic symptoms of thrombocytopenia (with resultant bleeding disorders), scaly eczema, and recurrent infections. IgA and IgG levels are usually normal, but antibody responses against antigens that elicit primarily an IgM response, such as polysaccharides from bacterial capsules (e.g., *Pseudomonas aeruginosa*, *Streptococcus pneumoniae* [*S. pneumoniae*], *Haemophilus influenzae* [*H. influenzae*]) are deficient. Persons with WAS also have a very high risk of lymphoid malignancies (leukemias and lymphomas).

Ataxia-telangiectasia (AT) is an autosomal recessive disorder resulting from a large variety of sporadic mutations in the *ATM* gene, which encodes a protein involved in repair of double-stranded breaks in DNA. Affected infants often develop ataxia (unsteady gait), which usually becomes apparent when the child is learning to walk. The neurologic defect may eventually lead to confinement in a wheelchair. Telangiectasia (dilation of capillaries) can occur in the eyes and skin, especially on the ears, neck, and extremities. Both B cells and T cells are variably affected and unrepaired double-stranded DNA breaks are commonly observed in the regions encoding the T-cell and B-cell receptors. About 70% of those with AT are IgA deficient, occasionally accompanied by deficiencies in IgG (see [Fig. 9.10](#)). Individuals with AT are at high risk for developing leukemias and lymphomas.

DiGeorge syndrome (congenital thymic aplasia or hypoplasia and diminished parathyroid gland development) is caused by the lack or partial lack of the thymus, resulting in greatly decreased T-cell numbers and function and life-threatening viral, fungal, and intracellular bacterial infections.³⁵ The defect is usually attributed to deletions on chromosome 22 (some deletions also have been identified on chromosome 10),³⁶ about 25% of which are inherited. The deleted

region encodes information for formation of organs that originate from the third and fourth pharyngeal pouches during the twelfth week of gestation. Defective development of the third and fourth pharyngeal pouches during embryogenesis results in the thymic defects, lack of the parathyroid gland (causing an inability to regulate calcium concentration), major structural defects in the heart and the aorta (resulting in inadequate blood flow and inadequate oxygenation of the tissues), and abnormal facial characteristics (e.g., underdeveloped chin, low-set ears, shortened structure of the upper lip) (see Fig. E 9.2 on Evolve). Low blood calcium levels cause the development of tetany or involuntary rigid muscular contraction.

Predominantly Antibody Deficiencies

Predominantly antibody deficiencies result from defects in B-cell maturation or function and are the most common immune deficiencies. T-cell immune responses are not affected in pure B-lymphocyte deficiencies. These deficiencies are widely characterized by lower levels of circulating immunoglobulins (**hypogammaglobulinemia**) or occasionally totally or nearly absent immunoglobulins (**agammaglobulinemia**). Recurrent infections range from life threatening to mild, depending on the severity of the deficiency. Characteristic infections include encapsulated bacteria (e.g., *S. pneumoniae*, *H. influenzae*) that may cause pneumonia or sepsis and other microorganisms that cause infections of the sinuses, ears, and gastrointestinal tract.

One of the most severe **B-lymphocyte deficiencies** is **Bruton agammaglobulinemia**. This condition results from mutations in the gene for Bruton tyrosine kinase (*Btk*)—an enzyme involved in intracellular signaling from several B-cell receptors, including the IgM B-cell antigen receptor, the IL-5 receptor, and the IL-6 receptor. Ineffective signaling results in the arrest of the development in the bone marrow of early cells in the B-cell lineage into mature B cells³⁷ (see Fig. 9.10). Somewhat less than a third of the mutations are sporadic. Few or no circulating mature B cells are present, although T-cell number and function are normal. At 6 months of life, the

approximate normal serum concentrations of immunoglobulins are the following: IgG, 400 mg/dL; IgM, 40 mg/dL; and IgA, 30 mg/dL. In 6-month-old children with Bruton agammaglobulinemia, serum IgG levels are much less than 100 mg/dL, and IgM and IgA are almost absent.

An autosomal recessive form of agammaglobulinemia (**autosomal agammaglobulinemia**) results from other mutations in the B-cell receptor. The most common is a mutation of the mu (μ) chain of the IgM portion of the receptor. This mutation prevents intracellular signaling after antigen binds to the receptor, leading to blocked maturation, the absence of antibody production, and very severe infections.

Common variable immune deficiency is the most commonly diagnosed immune deficiency. As the name implies, the presentation is very heterogeneous. It is characterized by hypogammaglobulinemia, but the particular class of antibody that is decreased varies. Most individuals have low amounts of IgG, which may or may not be accompanied by decreased levels of IgA or IgM, or both, with normal numbers of B cells. Some may have accompanying T-cell defects. Multiple genetic defects in terminal differentiation account for this condition, although the specific defects have not been identified in most people. The age of onset of symptoms, such as recurrent bacterial respiratory tract infections, is generally later than most primary immune deficiencies (late 20s). Secondary complications include arthritis (infectious and noninfectious), gastrointestinal symptoms (malabsorption, chronic diarrhea), autoimmune disease (anemia, thrombocytopenia, endocrine diseases), and cancer (of the lymphoid system, skin, and gastrointestinal tract).

Some defects may involve a particular class of antibody, such as **selective IgA deficiency**, in which only IgA is suppressed. Because many affected individuals are asymptomatic, the true incidence is uncertain, although clinically relevant symptoms may occur in 1 in 700 to 1 in 400 individuals. Individuals with selective IgA deficiency are able to produce other classes of immunoglobulins but fail to produce IgA (see [Fig. 9.10](#)). Many will have B cells that have

undergone class-switch to IgA but, for unknown reasons, cannot undergo the terminal steps of differentiation to IgA-secreting plasma cells.

Affected individuals may have a history of recurring sinus, pulmonary, and gastrointestinal infections, particularly chronic intestinal candidiasis (infection with *C. albicans*). Complications of IgA deficiency include severe allergic disease and autoimmune diseases. Selective IgA deficiency is two or three times more common in atopic individuals than in others. Secretory IgA normally may prevent the uptake of allergens from the environment, so that IgA deficiency may lead to a more intense challenge to the immune system by prolonged exposure to environmental antigens.

One of the most severe complications of IgA deficiency is an anaphylactic reaction that can follow administration of blood products that contain IgA. Serious anaphylactic reactions can occur in individuals totally lacking IgA because the immune system recognizes donor IgA as a foreign antigen. Initial sensitization can occur in fetal life through exposure to maternal IgA that leaks across the placenta or later through the ingestion of maternal IgA in breast milk or bovine IgA in cow's milk. Sensitization also can occur with initial administration of blood products containing IgA. The individual's primed immune system then acts against donor IgA on subsequent exposure.

Several defects in antibody class-switch have been identified (see [Fig. 9.10](#)). A defect in a DNA editing enzyme (**activation-induced cytidine deaminase deficiency; AICD deficiency**) also inhibits class-switch. During class-switch and movement of the H chain genetic information for the variable region to a different constant region gene, the double-stranded DNA must be cut and mended. This enzyme is responsible for cutting and mending the DNA; thus IgM may be overproduced and levels of IgG and IgA diminished.

Deficiencies in certain subclasses of antibody (**IgG subclass deficiency**), particularly IgG₂, may result from a defect in switch to a particular subclass constant region (see [Fig. 9.10](#)). The level of IgG₂ subclass is often increased in response to polysaccharide antigens

such as those on the surface of encapsulated bacteria. Low levels of IgG2 may be responsible for recurrent risk for pneumonias caused by these bacteria. Whether IgG subclass deficiencies are unique immune deficiency conditions is unclear because many are apparently early indications of the development of common variable immune deficiency or are secondary to selective IgA deficiency.

X-linked or autosomal recessive hyper-IgM syndrome results from a mutation in the CD40 ligand (**CD40L deficiency**) or, less commonly, the CD40 receptor (**CD40 deficiency**), respectively.³⁸ The CD40/CD40L interaction provides an important signal between T-helper (Th) cells and B cells during the initiation of class-switch (see [Fig. 8.18](#)). A critical ligand-receptor interaction occurs between the receptor CD40 on the B cell and its ligand (CD154 or CD40L) on the Th cell. A mutation in CD40L or CD40 results in **defective class-switch**, decreased or absent production of IgG and IgA, poor development of memory B cells, and overproduction of IgM, resulting in increased infections with opportunistic bacteria. T-cell immunity is not affected. This particular immune deficiency is co-listed as a combined immune deficiency because of the potential of mutations that affect either the Th cell or the B cell.

Immune Dysregulation

The classification of immune dysregulation presents causes of immune deficiencies and includes conditions in which the regulation of components of the immune system is predominant.

Perforin deficiency results from a mutation in perforin, which is an important component of cellular killing by cytotoxic T cells and NK cells (see [Fig. 8.26](#)), resulting in decreased or absent Tc and NK cells. Several other deficiencies result from mutations in secretory vesicle function, including fusion with the cell membrane and other aspects of the process. Mutations in interleukin IL-10 or its receptor IL-10R suppress the production or response to IL-10 (an immunosuppressive cytokine), resulting in excessive inflammation and an increased risk for early-onset inflammatory bowel disease, or recurrent respiratory disease.³⁹

Chédiak-Higashi syndrome results from a defect in the movement of cytoplasmic granules and is caused by an autosomal recessive mutation in the lysosomal trafficking regulator gene (*CHS1*). The CHS1 protein helps control movement of granules to cellular membranes in preparation for degranulation. As a result of these mutations, the granules remain in the cytoplasm and form large aggregates that are readily apparent microscopically. Leukocytes from individuals with Chédiak-Higashi syndrome have decreased chemotaxis, granular fusion, and bacterial killing. Platelet granules also may be affected, resulting in prolonged bleeding, and partial albinism can occur because of defects in melanocyte granules. Affected children develop recurrent infections of the skin, respiratory tract, and mucous membranes, especially with gram-positive bacteria.

Phagocyte Defects: Numbers, Function, or Both

Phagocyte defects range from inadequate numbers of phagocytes (e.g., **severe congenital neutropenia**) to defects in phagocyte function that can result in recurrent infections ([Fig. 9.11](#)). Because phagocytosis is generally aided by bacterial opsonization with IgG or C3b, infection occurs with the same group of microorganisms (encapsulated bacteria) that are associated with antibody and complement deficiencies.

FIGURE 9.11 Phagocytic Defects. Several genetic defects in the process leading up to and including phagocytosis result in increased susceptibility to bacterial infections. See the text and refer to Fig. 7.15 for more detailed information. The phagocyte leaves the bloodstream and enters the tissue through interactions between leukocyte and endothelial adhesion molecules and the process of diapedesis. The cell is attracted to the inflammatory site by chemotaxis, where it encounters opsonized bacteria, and attaches to and engulfs the microorganism. Inside the phagocyte the bacteria are killed and broken down by the combination of lysosomal granule constituents and reactive oxygen products of the hexose-monophosphate shunt and nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. *C3R*, C3 receptor, which includes the C3b receptor (*C3bR*); *FcγR*, receptor for the Fc portion of IgG; H_2O_2 , hydrogen peroxide; O_2^- , reactive oxygen.

Inadequate numbers of phagocytes, particularly neutrophils (severe congenital neutropenias), result in a variety of recurrent and severe bacterial infections beginning early in life. Approximately 50% of these individuals have mutations in the gene for elastase, neutrophil-expressed (*ELANE*). Other mutations have been identified (e.g., *WAS* gene) in the other 50%. A milder form, **cyclic neutropenia**, is autosomal dominant with almost 100% of affected individuals having

a mutation in the *ELA2* gene. Changes in neutrophil levels are cyclic and may remain at or near normal for 2 to 3 weeks, followed by periods of neutropenia lasting a few days to weeks. During the neutropenia, the individual has increased susceptibility to recurrent bacterial infections.

Chronic granulomatous disease (CGD) is a group of disorders resulting from severe X-linked (about 70% of the individuals) or autosomal defects in the respiratory burst necessary for the myeloperoxidase–hydrogen peroxide system, a major means of bacterial destruction using the enzyme myeloperoxidase, halides (e.g., chloride ion), and hydrogen peroxide (H_2O_2).⁴⁰ Neutrophils and other phagocytes switch much of their glucose metabolism to the hexose-monophosphate shunt during phagocytosis. A byproduct of this pathway is the conversion of molecular oxygen by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase into highly reactive oxygen derivatives, including hydrogen peroxide. Mutations in NADPH oxidase or other components of the NADPH oxidase complex result in deficient production of hydrogen peroxide and other oxygen products. Thus affected individuals have adequate myeloperoxidase in the primary granules and halide but lack the necessary hydrogen peroxide, resulting in recurrent severe pneumonias; tumor-like granulomata in lungs, skin, and bones; and other infections with some opportunistic microorganisms, such as *Staphylococcus aureus*, *Serratia marcescens*, and *Aspergillus* spp. The symptoms usually appear in the first 2 years of life.

Recurrent infections occur with rather innocuous catalase-positive microorganisms, whereas infections with more virulent catalase-negative microorganisms (e.g., *S. pneumoniae*) are rare. Most microorganisms produce their own hydrogen peroxide as a byproduct, which accumulates in the phagocytic vacuole and can be used by the phagocyte's myeloperoxidase to kill the microorganism. Some microorganisms also produce the enzyme catalase, which breaks down hydrogen peroxide. Thus catalase-negative microorganisms donate hydrogen peroxide to the phagocyte's myeloperoxidase, leading to their own death. Catalase-positive

microorganisms, however, destroy the bacterial hydrogen peroxide and survive to cause infection.

A deficiency in another component of the myeloperoxidase–hydrogen peroxide system, **myeloperoxidase deficiency**, is a relatively mild disorder characterized by a complete or partial deficiency in myeloperoxidase. Individuals do not have severe recurrent infections because most infectious bacteria are sensitive to direct killing by many of the toxic oxygen molecules produced by NADPH oxidase. The exception is the person with concurrent diabetes, who may have recurrent disseminated candidiasis.

Other phagocytic deficiencies include defects in various leukocyte adhesion molecules (leukocyte adhesion deficiency) that prevent adherence to the vascular endothelium and diapedesis. **Leukocyte adhesion deficiency, type 1 (LAD-1)** results from an autosomal recessive mutation in CD18, which is a β_2 -integrin chain that is shared by several different receptors. **Leukocyte adhesion deficiency, type 2 (LAD-2)** results from a defect in adding the monosaccharide fucose to carbohydrates on the phagocyte surface. Surface carbohydrates with fucose are ligands for selectins on the endothelium and leukocytes. These and other defects in leukocyte adhesion molecules usually result in increased levels of neutrophils in the blood (leukocytosis, because they cannot leave the circulation) and in increased recurrent bacterial and fungal infections.

Additional deficiencies diminish the leukocyte's capacity to respond to cytokines. Defects in the interferon- γ receptor result in increased susceptibility to infection with pathogenic intracellular bacteria, such as *Mycobacteria* and *Salmonella*.

Defects in Innate Immunity

Some immune deficiencies are characterized by a defect in the capacity to produce a protective innate response against microorganisms. The inherited form of **chronic mucocutaneous candidiasis** presents with mild to extremely severe recurrent infections of the skin, nails, and mucous membranes with *Candida albicans*. In this condition, the response of macrophages to Th17

lymphocytes is defective because of mutations in IL-17 produced by Th17 lymphocytes or the IL-17 receptor on macrophages.⁴¹ Thus the macrophage cannot be adequately activated to defend against *Candida albicans*.

Autoinflammatory Disorders

Autoinflammatory disorders are characterized by abnormally high levels of inflammation secondary to mutations in control of inflammasome activation or in defects in cellular receptors of cytokines designed to decrease inflammation. These disorders are frequently related to diminished control of infections of epithelial surfaces. **Familial Mediterranean fever** is an autosomal recessive disorder in eastern Mediterranean populations that results in uncontrolled release of IL-1 β by inflammasomes in granulocytes and monocytes.⁴² Affected individuals present with skin rashes, usually of the lower extremities, and fever.

Complement Deficiencies

Complement activation is a necessary component of protection against many infectious agents, particularly bacteria. IgG and complement components, such as C3b, are opsonins and facilitate phagocytosis by neutrophils and macrophages. Thus **complement deficiencies** often resemble antibody deficiencies. Recurrent life-threatening infections at an early age with encapsulated bacteria (e.g., *Haemophilus influenzae* and *Streptococcus pneumoniae*) that are very sensitive to opsonin-assisted phagocytosis may occur.

Activation of C3 is central to the complement cascade. All three pathways of complement activation (i.e., classical, alternative, and lectin pathways) result in activation of C3 into C3b and C3a; C3b is a major opsonin and also is the activator of the terminal components of the cascade (C6 through C9). **C3 deficiency** is the most severe complement deficiency (Fig. 9.12). Factor I and factor H are major regulators of the complement cascade and control the level of spontaneous activation of C3. **Factor I deficiency** and **factor H**

deficiency can be severe because they lead to increased spontaneous destruction of C3 and a secondary C3 deficiency.

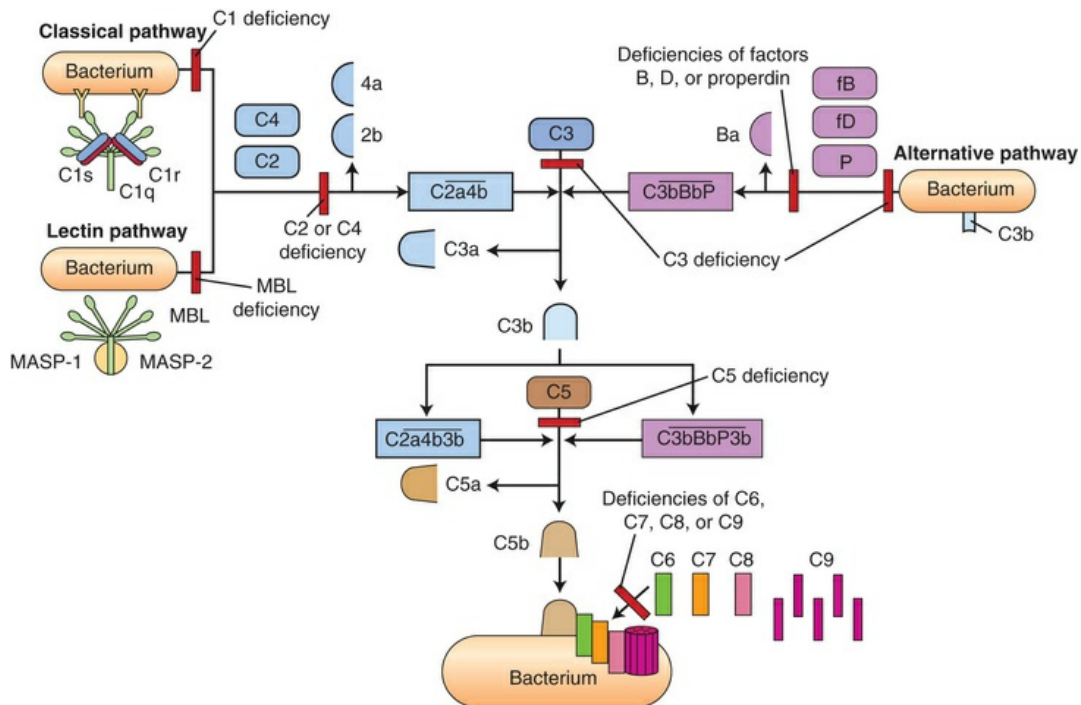

FIGURE 9.12 Complement Defects. The complement cascade is initiated through three pathways: the classical pathway, the lectin pathway, and the alternative pathway. Each of the three pathways produces a C3 convertase, which activates C3 leading to the formation of a C5 convertase. The activation of C5 initiates formation of the membrane attack complex. For more details, see the text and Fig. 7.6. The most severe defect is a C3 deficiency because it blocks all three pathways. *MASP*, MBL-associated serine protease; *MBL*, mannose-binding lectin.

Deficiencies of lesser severity have been described in each of the pathways of complement activation. Defects in the classical pathway (i.e., C1, C2, C4) result in increased risk for recurrent infections, sometimes severe, with encapsulated bacteria at an early age.⁴³ Defects in the early components of the classical pathway also result in a SLE-like syndrome that may be complicated by kidney disease (glomerulonephritis), suggesting a role of these components in removal of naturally occurring immune complexes from the circulation.⁴⁴ **C2 deficiency**, more so than **C1** or **C4 deficiencies**, also has an increased risk for recurrent respiratory tract infections with

encapsulated bacteria. **Mannose-binding lectin (MBL) deficiency** is the primary defect of the lectin pathway of complement activation.⁴⁵ The defect results in increased risk of infection with microorganisms that have polysaccharide capsules rich in mannose, particularly the yeast *Saccharomyces cerevisiae*, and encapsulated bacteria such as *Neisseria meningitides* and *S. pneumonia*. **Properdin deficiency** is the most common defect in the alternative pathway, is associated with recurrent infections with *Neisseria meningitides*, and is X-linked, whereas all other complement deficiencies are autosomal recessive. Symptoms generally appear in the second decade of life.

Deficiencies of any of the terminal components of the complement cascade (C5, C6, C7, or C8 deficiencies) are associated with increased infections with only one group of bacteria—those of the genus *Neisseria*, particularly *Neisseria meningitides*. *Neisseria* usually causes localized infections (meningitis or gonorrhea), but terminal pathway defects result in an 8000-fold increased risk for systemic infections with atypical strains of these microorganisms. **C9 deficiency** is the most common terminal pathway defect, appears primarily in Japanese populations, and is generally asymptomatic. The other deficiencies of the terminal pathway are extremely rare, but are characterized by more aggressive infections. The risk for systemic infections with *Neisseria* is also increased in those with deficiencies of C2, factor D, factor B, and properdin.

Secondary Immune Deficiencies

Secondary, or acquired, immune and inflammatory deficiencies are far more common than primary deficiencies. These deficiencies are complications of other physiologic or pathophysiologic conditions (Table 9.7). Although secondary deficiencies are common, many are not clinically relevant. In many cases, the degree of the immune deficiency is relatively minor and without any apparent increased susceptibility to infection. Alternatively, the immune system may be substantially suppressed, but only for a short duration, thus minimizing the incidence of clinically relevant infections. Some secondary immune deficiencies (e.g., AIDS or immunosuppression by

cancer), however, are extremely severe and may result in recurrent life-threatening infections.

TABLE 9.7

EXAMPLES OF SECONDARY IMMUNE DEFICIENCIES

CAUSE OF DEFICIENCY	EXAMPLES
Normal physiologic conditions	Pregnancy Premature infants Infancy Aging
Psychologic stresses	Emotional trauma Eating disorders
Dietary insufficiencies	Protein-calorie malnutrition Protein loss syndromes (e.g., nephrotic syndrome, protein-losing enteropathy) Vitamin deficiencies
Malignancies	Hematologic malignancies (e.g., Hodgkin disease, acute or chronic leukemia, myeloma) Solid tumors (e.g., sarcomas, carcinomas)
Chronic diseases	Diabetes Cystic fibrosis Alcoholic cirrhosis Sickle cell disease Aplastic anemia Autoimmune diseases (e.g., systemic lupus erythematosus)
Chromosome abnormalities	Trisomy 21 (Down syndrome)
Environmental agents	Ultraviolet light Ionizing radiation Chronic hypoxia
Physical trauma	Burns
Medical treatments	Stress from surgery Anesthesia Immunosuppressive treatments (e.g., corticosteroids, antilymphocyte antibodies) Splenectomy Anticonvulsive medications Cancer treatment (e.g., cytotoxic drugs, ionizing radiation) Hematopoietic stem cell transplants

Infections	Congenital infections (e.g., rubella, cytomegalovirus, hepatitis B) Acquired infections (e.g., AIDS)
Lifestyle	Alcohol abuse

Normal Physiologic Conditions

The competence of an individual's immune system varies throughout life. Pregnancy itself is considered by many to be an immunocompromised condition. Pregnant women may have decreased reactivity or altered results in several tests of the immune system, including skin tests against various antigens, circulating numbers of T lymphocytes, and other very general tests. Pregnancy itself, however, is not associated with a marked change in infections, suggesting that the mother's immune system is not severely altered.

The newborn child is immunologically immature. Although T-cell immune responses may be normal or near normal, other components of the immune system (especially antibody production) are just beginning to mature. Beginning at about 32 weeks of pregnancy, the placenta transports maternal antibodies into the fetal blood to protect the child during the first months of life (see [Fig. 8.29](#)). After the delivery, the level of the mother's antibodies slowly decreases in the newborn so that maternal antibodies no longer protect the child by about 6 months of life. By 6 to 8 months, the newborn should be efficiently protected by antibodies produced by its own B cells. In some infants, the development of antibody production is delayed, and a transient low level of antibody may persist for several months (**transient hypogammaglobulinemia of infancy**), during which the child has increased susceptibility to infections. Premature infants are particularly immunologically immature and are at increased risk for neonatal infections. The blood of infants born before 32 weeks' gestation is generally devoid of maternal antibody. However, if the infant is born prematurely, the degree of immunologic immaturity is greater and places the child at a significant risk of developing infections.

Aging is also associated with a progressive depression in immune responses. Older adults generally have more severe bacterial and

fungal infections, greater difficulty resolving those infections, and lower responses to vaccination. Several meaningful changes occur during aging, although variations in the degree of change and a corresponding increased susceptibility to infection can be considerable among individuals. The thymus involutes over time, resulting in decreased production of fresh T cells. A concurrent depletion of T-memory cells results in depressed responses to both new and “recall” antigens. A shift toward Th2 cells also may occur with a resultant decrease in Th1 cytokines. Total numbers of B cells may decrease. Numbers of NK cells may remain normal, although their activity is decreased. Similarly, neutrophil numbers may remain normal, with decreased phagocytosis and killing.

Psychologic Stress

The relationship between emotional stress and depressed immune function has become an area of intense clinical and research interest. For many decades anecdotal reports have suggested that increased incidences of infection and malignancy are associated with periods of both intense stress (e.g., the loss of a loved one, divorce) and relatively minor stress (e.g., final examination periods at colleges and universities). In addition, early studies showed that immune function, as demonstrated by delayed hypersensitivity skin test results, could be depressed through posthypnotic suggestion.

The mechanisms of the relationship between emotional stress and the immune system are now beginning to be understood. Many lymphoid organs are innervated and can be affected by nerve stimulation. In addition, lymphocytes have receptors for many hormones (e.g., sex hormones, neurotransmitters, and neuropeptides) and can respond to changing levels of these chemicals with increased or decreased function. For instance, stress-induced catecholamines affect the expression of adhesion molecules and the movement of lymphocytes among lymphoid organs. (Further discussion of the effects of stress on susceptibility to disease is the subject of [Chapter 11.](#))

Physical Trauma

Trauma that compromises the epithelial barrier also predisposes an individual to infection. Burn victims are susceptible to severe bacterial infections. Thermal burns appear to be associated with suppressed neutrophil function (especially chemotaxis), complement levels, cell-mediated immunity, and primary humoral responses, although secondary humoral responses are normal. The mechanism of this immunosuppression may be twofold. Blood from burned individuals contains nonspecific immunosuppressive factors (all immune responses are suppressed, regardless of the antigen involved). In addition, burn victims also have increased regulatory T-cell function, which may increase antigen-specific suppression.

Environmental Agents

Individuals are constantly exposed to environmental agents that affect the immune system. UV light from sun exposure or tanning salons induces apoptosis of lymphoid stem cells, increases production of Treg cells that suppress defenses against cancer, and increases production of antiinflammatory cytokines.

Dietary Insufficiencies

Nutritional status can have a profound effect on immune function, and malnutrition is the predominant cause of secondary immune deficiencies worldwide. Severe deficits in protein or calorie (protein-calorie malnutrition) intake lead to immune deficiencies. Marasmus (deficiency in calories) and kwashiorkor (deficiency in protein, but adequate calories) have similar outcomes. T-cell-rich areas of primary (thymus) and secondary lymphoid tissue are greatly affected, resulting in impaired T-cell function. Antibody levels are normal but neutrophil function (chemotaxis, phagocytosis, bacterial killing), complement levels, and NK activity are impaired, resulting in infections with microorganisms that are normally destroyed by opsonization and phagocytosis.

Deficient zinc intake can profoundly depress both T- and B-cell

function. Zinc is required as a cofactor for at least 70 different enzymes, some of which are found in lymphocytes and are necessary for their function. Secondary zinc deficiencies may be associated with malabsorption syndrome (failure to absorb zinc), chronic renal disease (loss of zinc in the urine), chronic diarrhea (loss of zinc through the gut), or burns or severe psoriasis (loss of zinc through the skin). Deficiencies of other enzyme cofactors, such as vitamins (e.g., pyridoxine, pantothenic acid, folic acid, and vitamins A, C, E, and B₁₂), also may result in severe depressions of B- and T-cell function, phagocytosis, and complement activity.

Chronic Diseases

Chronic diseases of the cardiovascular, gastrointestinal, and renal systems are commonly complicated by a secondary immune suppression. Nephrotic syndrome from inflammation of the kidneys results in loss of protein through the kidneys, proteinuria (increased protein in the urine), and resultant hypoproteinemia (diminished protein in the blood). The loss of IgG may increase susceptibility of infection. Protein-losing enteropathy results from conditions that damage the surface of the gastrointestinal tract (e.g., inflammatory bowel diseases, such as Crohn disease, ulcerative colitis, celiac disease, gastrointestinal [GI] infections, cancer of the GI tract). Although circulating levels of immunoglobulin are diminished because of loss through the GI tract and catabolism, increased susceptibility to infections is rare.

Metabolic Diseases or Genetic Syndromes

Diabetes results in altered glucose metabolism and suppresses many aspects of the immune and inflammatory responses, including phagocytosis and chemotaxis, and lymphocyte proliferation. The effects of trisomy 21 are less severe, but primarily include diminished neutrophil function. People with cystic fibrosis have decreased airway clearance of bacteria, thus increasing the probability of major respiratory tract infections.

Malignancies

Many malignancies are complicated by a wasting syndrome (cachexia) in the later stages, which can suppress the immune system secondary to the resultant malnutrition. The effect is commonly nonspecific, resulting in a generalized deficiency of the immune response and a greatly increased susceptibility to developing life-threatening infections. In fact, many people with malignancies die from infection rather than from direct effects of the tumor.

Other malignancies (e.g., lymphomas, leukemias, plasmacytomas) present with an early and more specific immune depression. Non-Hodgkin lymphoma may result in an antibody deficiency in the most advanced stages of the disease. Hodgkin lymphoma, however, may suppress the immune system even before the onset of symptoms, with worsening of the suppression as the disease progresses. Individuals usually present with depletion of T cells with normal production of T-cell-independent antibodies. In general, leukemia is characterized by normal T- and B-cell responses until progression to terminal stages. Chronic lymphocytic leukemia commonly suppresses B-cell differentiation but does not affect T-cell function. Depressed production of antibodies results in increased susceptibility to fatal infection. Plasmacytomas (malignancies of plasma cells) result in greatly diminished antibodies because the malignant cells are displacing normal plasma cells and increased catabolism of immunoglobulins results in increased susceptibility to infections against which antibody is protective. T-cell immunity remains intact.

Medical Treatments

Medical treatments themselves may produce suppression of immune responses. Surgery and administration of anesthesia can suppress T- and B-cell function. Transient, severe lymphopenia (loss of circulating lymphocytes) is a common postoperative condition that can last as long as a month. Surgery to remove the spleen (splenectomy) can result in a depressed IgM response against encapsulated bacteria (especially *S. pneumoniae*, *H. influenzae*, *Staphylococcus aureus*, Group A

streptococci, and *Neisseria meningitidis*) and decreased levels of opsonins.

Corticosteroids are intentionally used to suppress the immune system and control hypersensitivity diseases (especially autoimmune disease) or prevent rejection of transplants. They predominantly inhibit T-cell function, prevent lymphocyte proliferation, inhibit production of critical cytokines, and suppress monocyte/macrophage functions; but they do not affect neutrophils. Because of their nonspecific activity, however, immune responses against infectious agents also can be suppressed, increasing an individual's susceptibility to infection.

Many drugs and other treatments that are used to fight cancer (e.g., cytotoxic cancer chemotherapeutic agents, irradiation) are not specific for cancer cells, but are designed to attack cells in susceptible stages in their cell cycles or rapidly proliferating cells, which includes cells of the immune system as well as malignant cells. Cytotoxic agents may affect all lymphocyte subsets or may only affect a specific stage of the immune response. For instance, azathioprine and methotrexate affect response after antigenic challenge, whereas cyclophosphamide affects response before and after exposure to antigen. Cyclosporine A preferably affects CD4⁺ cells. The immunosuppressive effects of chemotherapeutic drugs are exacerbated by concurrent treatment with ionizing radiation (x-rays), which also affects rapidly dividing cells. T cells, particularly CD4⁺ cells, are most sensitive. Phagocytes, which have a much slower proliferation rate, are relatively resistant to the effects of irradiation. Depending on the dose of irradiation administered, the entire immune system may be depleted.

The list of medications that affect the immune response is ever increasing and includes analgesics, antithyroid medications, anticonvulsants, antihistamines, antimicrobial agents, antilymphocyte antibodies, and tranquilizers.

Infections

Many infectious microorganisms successfully invade the human body using mechanisms for fighting off specific immune/inflammatory

responses against themselves (discussed in [Chapter 10](#)). However, some infectious agents more broadly suppress the immune response. HIV is one of the few microorganisms that directly attacks the central processes involved in the development of an immune response (discussed in detail in [Chapter 10](#)). It infects and destroys the T-helper cell, which is necessary to provide help for the maturation of both plasma cells and T-cytotoxic cells. Therefore, HIV suppresses the immune response against itself and secondarily creates a generalized immune deficiency by suppressing the development of immune responses against other pathogens and opportunistic microorganisms.

Several other viruses (e.g., measles; hepatitis B; and herpes viruses, such as Epstein-Barr virus [EBV], cytomegalovirus [CMV], and herpes simplex viruses) may suppress various components of the immune response. CMV, herpes virus, and hepatitis B virus in particular can establish congenital infections through transmission from an infected mother to the child in utero or at birth when the child's immune system is immature. These children may have suppressed immune responses, although the degree of the deficiency is not usually severe. However, as the child's immune system develops, the viral antigens may be partially seen as “self” so that a chronic infection is established.

Measles virus can infect both B and T cells and macrophages. Infection may result in lymphopenia and a suppressed T-cell response that are generally transient. Acute infections with herpes viruses may transiently suppress the immune system. EBV infects B cells and may cause infectious mononucleosis, although most EBV infections are asymptomatic. The virus enters a stage of latency in memory B cells. In some cases, EBV may suppress both CD4+ and CD8+ T cells and NK cells. Immunosuppression is generally transient and not severe. CMV infects mucosal epithelium and can infect macrophages where antigen processing and presentation may be impaired.

Other infections may lead to a relatively broad suppression of immune responses. *Mycobacterium leprae* causes two forms of leprosy: tuberculoid leprosy, in which an active T-cell immunity contains and kills the infecting bacteria; and lepromatous leprosy, in which the

infected individual's T-cell immunity is severely depressed but high levels of antibody are produced. The T-cell deficit is characterized by suppressed T-cell IL-2 production and antigen-specific T-cell responses. Some fungal infections may suppress the immune response. In disseminated *Candida albicans* infections, T-cell responses and neutrophil chemotaxis are suppressed to various degrees. Similar immunosuppression may be observed in individuals with disseminated histoplasmosis (infections with *Histoplasma capsulatum*). The most severe form of acute malaria (caused by the parasite *Plasmodium falciparum*) suppresses specific antibody responses against protein and polysaccharide antigens by dysregulation of CD4+ T-cell function and decreased IL-2 production.

Evaluation and Care of Those with Immune Deficiency

Routine care of individuals with immune deficiencies must be tempered with the knowledge that the immune system may be totally ineffective. Administration of conventional immunizing agents or blood products to these individuals may be unsafe because of the risk that the immunizing agent will cause an uncontrolled infection. Attenuated vaccines contain live but weakened microorganisms (e.g., live polio vaccine; vaccines against measles, mumps, and rubella) that can cause disseminated infection. Although the vaccine virus is attenuated enough to be destroyed by a normal immune system, it can survive, multiply, and cause severe disease in an immune-deficient recipient. Additionally, even healthy recipients of vaccines containing live microorganisms can shed those microorganisms for a short time, increasing the risk of infection to family members or other close associates who are immune deficient. Even simple procedures, such as penetrating the skin for routine blood tests, may lead to fatal septicemia (bacterial infection of the blood) in the immune-deficient person.

Individuals with immune deficiencies are also at risk for **graft-versus-host disease (GVHD)**. Mature T cells in a transplanted graft

(e.g., transfused blood) are capable of a destructive cell-mediated reaction against unmatched histocompatibility antigens on the tissues in the graft recipient. Symptoms of an acute graft-versus-host reaction usually appear within 10 to 30 days after the transplant. The primary targets for GVHD are the skin (e.g., rash, loss or increase of pigment, thickening of skin), liver (e.g., damage to bile duct, hepatomegaly), mouth (e.g., dry mouth, ulcers, infections), eyes (e.g., burning, irritation, dryness), and gastrointestinal tract (e.g., severe diarrhea) and may lead to death from infections.

GVHD is not a problem when the recipient is immunocompetent, that is, has an immune system that can control the donor's lymphocytes. If, however, the recipient's immune system is deficient, the grafted T cells remain unchecked and attack the recipient's tissues. Most GVHD is prevented by treating whole blood with irradiation to kill white blood cells before transfusion.

The most common presenting symptom of immune deficiencies is recurrent severe infections. Significant information concerning the nature of the specific immune deficiency can be obtained by noting the types of infection, as well as certain characteristics of the affected individual, including gender, age of disease onset, the presence of any associated anomalies, family history, and risk factors associated with secondary immune deficiencies.⁴⁶ Humoral deficiencies are generally characterized by recurrent sinopulmonary infections with encapsulated bacteria, gastrointestinal malabsorption, and poor growth. T-cell defects generally present with failure to thrive, chronic diarrhea, persistent thrush, and opportunistic infections (e.g., *Mycobacterium*, *Pneumocystis*, *Candida*, and certain viruses). Phagocytic defects are usually associated with recurrent abscesses, oral ulcers, and infections with specific bacteria (e.g., catalase-positive bacteria). Complement defects may be linked to SLE-like disease and recurrent and disseminated infections with *Neisseria* spp.

A variety of laboratory tests are available to evaluate specific immune deficiencies (Table 9.8). The choice of which particular tests to perform is determined on the characteristics described previously. A basic screening test is a **complete blood count (CBC)** with a

differential. The CBC provides information on the numbers of red cells, white cells, and platelets, and the differential indicates the quantities of lymphocytes, granulocytes, and monocytes in the blood. Quantitative determination of immunoglobulins (IgG, IgM, IgA) is a screening test for antibody production, and an assay for total complement (total hemolytic complement, CH₅₀) is useful if a complement defect is suspected.

TABLE 9.8

LABORATORY EVALUATION OF IMMUNODEFICIENCIES

FUNCTION TESTED	LABORATORY TEST	INTERPRETATION OF TEST
Tests of Humoral Immune Function		
Antibody production	Total immunoglobulin levels	Presence of antibody-producing B cells
	Levels of isohemagglutinins	Capacity to produce specific IgM antibodies
	Levels of antibodies against vaccines—especially diphtheria and tetanus toxoids	Capacity to produce specific IgG antibodies
B-cell numbers	Numbers of lymphocytes with surface immunoglobulin	Presence of circulating B cells
Tests of Cellular Immune Function		
Delayed hypersensitivity	Skin test reaction against previously encountered antigens—especially <i>Candida albicans</i> or tetanus toxoid	Presence of antigen-responsive T cells and skin test cellular interactions (e.g., lymphokine activity and macrophage function)
T-cell numbers	Numbers of T cells forming rosettes with sheep erythrocytes or expressing membrane CD3 or CD11 antigen	Presence of circulating T cells
T-cell proliferation in vitro	Proliferative response to nonspecific mitogens (e.g., phytohemagglutinin)	Capacity of all T cells to divide in response to nonspecific stimulation (mitogens)
	Proliferative response to antigens (e.g., tetanus toxoid)	Capacity of antigen-reactive T cells to respond to antigen

Many PIDs result from single gene mutations.⁴¹ Diagnosis can frequently be confirmed by appropriate genetic analysis. If the nature

of the immune deficiency remains uncertain after the screening tests, additional relatively common tests can be performed. For instance, subpopulations of lymphocytes (T or B) can be quantified using characteristic surface markers, such as surface immunoglobulin for B cells and CD3 for T cells. T-cell populations can be further subdivided using additional surface markers, such as CD4 (T-helper cells) or CD8 (T-cytotoxic cells). For antibodies, routine assays are available to quantify subclasses of IgG, such as IgG2.

An additional level of testing would include determination of immune responses against specific antigens. Determination of isohemagglutinins is informative about antigen-specific IgM production. Antibody responses to vaccines (e.g., tetanus, pertussis, measles, diphtheria, hepatitis B) are usually indicative of IgG responses. T-cell immunity against specific antigens can be measured by skin tests against antigens to which the individual had been exposed: "recall antigens." These include antigens from vaccines (e.g., mumps, tetanus) or from microorganisms with which the person had a previous active infection (e.g., *Candida*). An adequate T-cell immunity results in a positive delayed hypersensitivity skin test reaction.

If the tests do not identify the immune deficiency, more esoteric tests are offered by reference laboratories or research laboratories. These include quantification of individual complement components, in vitro proliferation (mitogenic response) of T or B cells to antigens or nonspecific mitogens, and a variety of tests of phagocyte function (e.g., nitroblue tetrazolium test [NBT] for hexose-monophosphate shunt activity, specific tests for phagocytosis, chemotaxis, or bacterial killing).

Replacement Therapies for Immune Deficiencies

Diagnosis of primary immune deficiencies (PIDs) and administration of appropriate therapy remain a problem. Most individuals with such deficiencies are initially seen by primary care physicians, particularly family practice physicians or pediatricians. Most primary immune deficiencies are rare, affecting about 1 in 1200 individuals in the

United States. The most common primary immune deficiency disease is common variable immune deficiency (about 1 in 2400 individuals). The variable presentations of this disorder lead to difficult diagnosis. The average time span from onset of the immune deficiency to diagnosis has been estimated to be longer than 12 years. The most common PIDs handled by primary care physicians are selective IgA deficiency and chronic granulomatous disease.⁴⁷

Gamma-Globulin Therapy

Many immune deficiencies can be successfully treated by replacing the missing component of the immune system. Individuals with B-cell deficiencies that cause hypogammaglobulinemia or agammaglobulinemia are usually treated by administration of immune gamma-globulin by intramuscular or intravenous (IVIg) routes. Administration by subcutaneous injection has been recently approved and is replacing intramuscular injections. Ig contains antibody-rich fractions prepared from plasma pooled from large numbers of donors. Administration of gamma-globulin replaces the individual's antibodies temporarily; these antibodies have a half-life of 3 to 4 weeks. Thus individuals must be treated repeatedly to maintain a protective level of antibodies in the blood. Gamma-globulin therapy has become routine for common variable immune deficiency, hyper-IgM syndromes, SCID, and X-linked agammaglobulinemia (Bruton).

The schedule and dosage of gamma-globulin vary among individuals and are primarily determined by body weight, the degree of gammaglobulinemia, and the incidence of infections in the individual. Commercial gamma-globulin preparations usually contain small amounts of IgM and IgA. Individuals with selective IgA deficiency occasionally develop allergic reactions to IgA in gamma-globulin preparations.

Individuals who need larger amounts of IgM or IgA can be given fresh frozen plasma in monthly IV infusions. Complications associated with plasma therapy include the potential transmission of blood-borne viruses for which no assay is yet available. The plasma is irradiated to destroy immunocompetent T cells to avoid GVHD in

individuals with accompanying T-cell deficiencies. Administration of fresh frozen plasma is successful in individuals with WAS (IgM deficient), AT (IgA deficient), or complement component deficiencies.

Transplantation and Transfusion

Several primary immune deficiencies originate from defects in lymphoid stem cells that interfere with their development in the primary lymphoid organs. Some of these (e.g., SCID, WAS, leukocyte adhesion defect) have benefited from replacement of stem cells through transplantation of bone marrow, umbilical cord cells, or other cell populations that are rich in stem cells.

The source of donor cells, particularly bone marrow, may contain a mixed population of stem cells and more mature T lymphocytes. In order to avoid GVHD, the preferred donor would be matched with the recipient for HLA antigens. Several other diseases involving depletion of the bone marrow (i.e., aplastic anemia, leukemia requiring eradication of tumor cells in the marrow) also are treated by bone marrow transplantation. At least 75% of bone marrow transplants between individuals who are matched for HLA are accepted. In immunocompetent recipients, most rejections of HLA-matched transplants occur because of recognition of minor histocompatibility antigens by individuals who have received multiple blood transfusions and are, as a result, sensitized against those antigens, which are not evaluated in tissue typing. For stem cell transplants, differences in minor histocompatibility antigens may lead to GVHD. Because HLA antigens are inherited in a codominant fashion, the preferred donor would be a relative, especially a sibling. Although the donor is not tested for minor histocompatibility antigens, the use of a close relative also would minimize differences at those loci.

Chronic GVHD appears in 30% to 50% of transplants between HLA-matched siblings and in 60% to 70% of transplants between unrelated donors. Symptoms may appear about 4 to 7 months after the transplant, but may begin much earlier or later. Depletion of T cells from bone marrow before transplantation significantly lowers the

incidence of both acute and chronic GVHD. One method of doing this is to infuse the graft with monoclonal antibody against plasma membrane antigens found only on mature T cells. Another method is to use fetal tissue as the graft. For example, fetal liver, which contains stem cells but not immunocompetent lymphocytes, is sometimes grafted in place of bone marrow if an HLA-matched donor cannot be found.

Steroids are commonly used to suppress GVHD in recipients of bone marrow transplants performed to treat certain malignancies or primary immune deficiencies. In cases where steroids are ineffective, promising new data support the use of **mesenchymal stem cells (MSCs)**. Stem cells are relatively undifferentiated cells and can be obtained from a variety of sources (e.g., embryos, bone marrow, adult tissues). MSCs are present in all adult tissues. These particular stem cells undergo differentiation into other cell types and, more importantly, have potent immunosuppressive properties. Several recent clinical trials have demonstrated complete suppression of GVHD in a large number of recipients of MSCs.

Reconstitution of thymic function can benefit individuals lacking a thymus or thymic function (e.g., DiGeorge syndrome, ataxia-telangiectasia, or chronic mucocutaneous candidiasis). The procedure involves transplantation of fetal thymic tissue, which lacks immunocompetent T cells, or thymic epithelial cells (the cells that produce the thymic hormones) from which mature T cells have been removed. In some individuals transplantation increases the number of circulating mature T cells, but in most cases improvement is only temporary.

Enzymatic defects that cause SCID (e.g., adenosine deaminase deficiency) have been treated successfully with transfusions of glycerol frozen-packed erythrocytes. The donor erythrocytes contain the needed enzyme and can, at least temporarily, provide sufficient enzyme for normal lymphocyte function. An alternative method is administration of purified adenosine deaminase that has been stabilized with polyethylene glycol (PEG).

Treatment with Soluble Immune Modulators

The administration of soluble materials that affect lymphocyte function can restore T-cell function, especially in individuals with WAS or chronic mucocutaneous candidiasis. Successful for some individuals is the use of transfer factor, a low-molecular-weight nucleoprotein prepared from lymphocyte lysates, which can confer specific reactivity against certain antigens. Thymosin, a thymic hormone, also has been used, although with limited success. Cytokine therapy also has been effective in some cases of chronic granulomatous disease.

Gene Therapy

The first successful therapeutic replacement of defective genes was performed in two girls with SCID caused by an ADA deficiency.⁴⁸ The normal gene for ADA was cloned and inserted into a retroviral vector.⁴⁹ The gene for ADA replaced some retroviral genes, resulting in a virus that carried the normal human gene but was thought not to cause disease. The virus was used to infect bone marrow stem cells from these children. The retrovirus inserted the normal ADA gene into the individuals' genetic material. The genetically altered stem cells were infused into the children, resulting in partial reconstitution of their immune systems, although multiple treatments were needed and the need for infusion of packed erythrocytes was still required. However, retroviral-mediated gene therapy for other diseases, such as X-linked SCID, chronic granulomatous disease (CGD), and Wiskott-Aldrich Syndrome (WAS), but not to treat ADA deficiency, resulted in the induction of leukemia.⁵⁰ Current gene therapy using alternative modified viral vectors has alleviated those complications.⁵¹ New gene therapy trials using newly developed vectors have been performed for ADA deficiency, X-linked SCID, CGD, and WAS. The outcomes have significantly improved for ADA deficiency (100% survival) with most individuals gaining protective immunity and no complications related to viral vector.⁵² Gene therapy has become standard care for individuals without well-matched sibling donors for stem cell

transplant.

Summary Review

Hypersensitivity: Allergy, Autoimmunity, and Alloimmunity

1. Inappropriate immune responses are misdirected responses against the host's own tissues (autoimmunity); directed responses against beneficial foreign tissues, such as transfusions or transplants (alloimmunity); exaggerated responses against environmental antigens (allergy); or insufficient responses to protect the host (immune deficiency).
2. Allergy, autoimmunity, and alloimmunity are collectively known as hypersensitivity reactions.
3. Mechanisms of hypersensitivity are classified as type I (IgE-mediated) reactions, type II (tissue-specific) reactions, type III (immune complex-mediated) reactions, and type IV (cell-mediated) reactions.
4. Hypersensitivity reactions can be immediate (developing within minutes to a few hours) or delayed (developing within several hours or days).
5. Anaphylaxis, the most rapid immediate hypersensitivity reaction, is an explosive reaction that occurs within minutes of reexposure to the antigen and can lead to cardiovascular shock.
6. Allergens are antigens that cause allergic responses.
7. Type I (IgE-mediated) hypersensitivity reactions are mediated through the binding of IgE to Fc receptors on mast cells and cross-linking of IgE by antigens that bind to the Fab portions of IgE. Cross-linking causes mast cell degranulation and the release of histamine (the most potent mediator) and other inflammatory substances.
8. Histamine, acting through the H1 receptor, contracts bronchial

smooth muscles, causing bronchial constriction; increases vascular permeability, causing edema; and causes vasodilation, increasing blood flow into the affected area. Histamine with H₂ receptors results in increased gastric acid secretion and a decrease of histamine released from mast cells and basophils.

9. Histamine enhances the chemotaxis of eosinophils into sites of type I allergic reactions.
10. Atopic individuals tend to produce higher quantities of IgE and to have more Fc receptors for IgE on their mast cells.
11. Type II (tissue-specific) hypersensitivity reactions are caused by five possible mechanisms: complement-mediated lysis, opsonization and phagocytosis, neutrophil-mediated tissue damage, antibody-dependent cell-mediated cytotoxicity, and modulation of cellular function.
12. Type III (immune complex–mediated) hypersensitivity reactions are caused by the formation of immune complexes that are deposited in target tissues, where they activate the complement cascade, generating chemotactic fragments that attract neutrophils into the inflammatory site. Neutrophils release lysosomal enzymes that result in tissue damage.
13. Intermediate-sized immune complexes are the most likely to have severe pathologic consequences.
14. Immune complex disease can be a systemic reaction, such as serum sickness, or a localized response, such as the Arthus reaction.
15. Type IV (cell-mediated) hypersensitivity reactions are caused by either cytotoxic T lymphocytes (T_c cells) or lymphokine-producing Th₁ cells.
16. Typical allergens include pollen, molds and fungi, certain foods (milk, eggs, fish, peanuts), animals, certain drugs, cigarette smoke, and house dust.
17. Clinical manifestations of allergic reactions usually are confined to the areas of initial intake or contact with the allergen. Ingested allergens induce gastrointestinal symptoms,

airborne allergens induce respiratory tract or skin manifestations, and contact allergens induce allergic responses at the site of contact.

18. Autoimmune diseases originate from the coincidence of an initiating event in a genetically predisposed individual leading to an autoimmune mechanism that affects specific target tissues or cells. Central tolerance develops during the embryonic period. Peripheral tolerance is maintained in secondary lymphoid organs by regulatory T lymphocytes or antigen-presenting dendritic cells.
19. Autoimmune disease can be caused by the exposure of a previously sequestered antigen, the development of a neoantigen, the complications of infectious disease, the emergence of a forbidden clone of lymphocytes, or the consequence of ineffective peripheral tolerance. The mechanism for imitation of autoimmune diseases may already be within humans.
20. Alloimmunity is the immune system's reaction against antigens on the tissues of other members of the same species.
21. Alloimmune disorders include transient neonatal disease, in which the maternal immune system becomes sensitized against antigens expressed by the fetus; transplant rejection; and transfusion reactions, in which the immune system of the recipient of an organ transplant or blood transfusion reacts against foreign antigens on the donor's cells.
22. SLE is a chronic, multisystem, inflammatory disease and is one of the most serious of the autoimmune disorders. SLE is characterized by the production of a large variety of autoantibodies.
23. Hyperacute graft rejection (preexisting antibody) is immediate and rare, acute rejection is cell mediated and occurs days to months after transplantation, and chronic rejection is caused by inflammatory damage to endothelial cells as a result of a weak cell-mediated reaction.
24. Red blood cell antigens may be the targets of autoimmune or

alloimmune reactions. The most important of these, because they provoke the strongest humoral immune response, are the ABO and Rh systems.

Deficiencies in Immunity

1. Disorders resulting from immune deficiency are the clinical sequelae of impaired function of components of the immune or inflammatory response, phagocytes, or complement.
2. Immune deficiency is the failure of mechanisms of self-defense to function in their normal capacity.
3. Immune deficiencies are either congenital (primary) or acquired (secondary). Primary immune deficiencies are caused by genetic defects that disrupt lymphocyte development, whereas secondary immune deficiencies are secondary to disease or other physiologic alterations.
4. The clinical hallmark of immune deficiency is a propensity to unusual or recurrent severe infections. The type of infection usually reflects the immune system defect.
5. The most common infections in individuals with defects of the cell-mediated immune response are fungal and viral, whereas infections in individuals with defects of the humoral immune response or complement function are primarily bacterial.
6. Defects in B-cell function are diverse, ranging from a complete lack of the human bursal equivalent function, the lymphoid organs required for B-cell maturation (as in Bruton agammaglobulinemia), to deficiencies in a single class of immunoglobulins (e.g., selective IgA deficiency).
7. DiGeorge syndrome (congenital thymic aplasia or hypoplasia) is characterized by complete or partial lack of the thymus (resulting in depressed T-cell immunity) and the parathyroid glands (resulting in hypocalcemia) and the presence of cardiac anomalies.
8. SCID is a total lack of T-cell function and a severe (either partial or total) lack of B-cell function. SCID can result from

mutations in critical enzymes (ADA deficiency, PNP deficiency), in cytokine receptors (X-linked SCID, JAK3 deficiency, IL-7 receptor deficiency), or in antigen receptors (RAG-1/RAG-2 deficiencies, CD45 deficiency, CD3 deficiency, ZAP-70 deficiency). Other combined defects may result from deficiencies in antigen-presenting molecules (bare lymphocyte syndrome), cytoskeletal proteins (WAS), or DNA repair (ataxia-telangiectasia).

9. Almost any portion of the complement cascade may be defective. The most severe defect is C3 deficiency, which results in recurrent life-threatening bacterial infections. Defects in proteins of the membrane attack complex usually result in unusual disseminated infections with bacteria of the *Neisseria* spp.
10. Defects in phagocyte function, which include insufficient numbers of phagocytes or defects of chemotaxis, phagocytosis, or killing, can result in recurrent life-threatening infections such as septicemia and disseminated pyogenic lesions.
11. Autoinflammatory disorders are characterized by abnormally high levels of inflammation secondary to mutations in control of inflammasome activation or in defects in cellular receptors of cytokines designed to decrease inflammation. These disorders are frequently related to diminished control of infections of epithelial surfaces. Autoinflammatory disorders are characterized by abnormally high levels of inflammation secondary to mutations in control of inflammasome activation or in defects in cellular receptors of cytokines designed to decrease inflammation. These disorders are frequently related to diminished control of infections of epithelial surfaces.
12. Acquired immunodeficiencies are caused by superimposed conditions, such as aging, malnutrition, infections, malignancies, physical or psychologic trauma, environmental factors, some medical treatments, or other diseases.
13. Deficiencies in immunity usually are treated by replacement therapy. Deficient antibody production is treated by

replacement of missing immunoglobulins with commercial gamma-globulin preparations. Lymphocyte deficiencies are treated with the replacement of host lymphocytes with transplants of bone marrow, fetal liver, or fetal thymus from a donor.

Key Terms

ABO blood group, 271
Activation-induced cytidine deaminase deficiency (AICD deficiency), 278
Acute rejection, 273
Adenosine deaminase (ADA) deficiency, 275
Agammaglobulinemia, 277
Allergen, 263
Allergy, 255
Alloimmune disease, 269
Alloimmunity, 255
Anaphylaxis, 256
Ankylosing spondylitis (AS), 267
Antibody-dependent cell-mediated cytotoxicity (ADCC), 260
Arthus reaction, 263
Ataxia-telangiectasia (AT), 277
Atopic, 263
Atopic dermatitis, 266
Autoimmune disease, 255
Autoimmunity, 255
Autosomal agammaglobulinemia, 278
Autosomal recessive hyper-IgM syndrome, 278
Bare lymphocyte syndrome, 277
Blocking antibody, 265
Blood group antigen, 271
B-lymphocyte deficiency, 278
Bruton agammaglobulinemia, 278

CD40 deficiency, 278
CD40L deficiency, 278
C1 deficiency, 280
C2 deficiency, 280
C3 deficiency, 280
C4 deficiency, 280
C9 deficiency, 280
Chédiak-Higashi syndrome, 278
Chronic granulomatous disease (CGD), 279
Chronic mucocutaneous candidiasis, 280
Chronic rejection, 273
Common variable immune deficiency, 278
Complement deficiency, 280
Complete blood count (CBC), 284
Contact dermatitis, 266
Cross-reactive antibody (T cell), 268
Cryoglobulin, 263
Cyclic neutropenia, 279
Cytotropic antibody, 256
Defective class-switch, 278
Delayed hypersensitivity reaction, 256
Desensitization, 265

For most of human history infection was the primary disease-related cause of death including bubonic/pneumonic plague, Spanish influenza and smallpox. Modern public health initiatives, vaccination programs, and the use of antibiotics have greatly progressed prevention and treatment of infectious diseases. As a result of these initiatives, naturally occurring smallpox has been eradicated from the globe (the last reported case was in 1975 in Somalia), measles is almost eradicated in the Western Hemisphere, and many diseases, such as tuberculosis and polio, are on the decline. In the United States in 2014, influenza/pneumonia was the eighth and septicemia was the eleventh ranked cause of death in adults, and bacterial **sepsis** was the seventh leading cause of neonatal deaths.¹ However, infectious disease remains a significant threat to life in many parts of the world, particularly in low income countries where prevention is less effective. In these countries 5 of the top 10 causes of death are attributable to infection: lower respiratory tract infections (#1), HIV/AIDS (#2), diarrheal diseases (#3), malaria (#6), and tuberculosis (#8).

Infectious disease remains a significant cause of morbidity and mortality because of the emergence of previously unknown infections, the reemergence and spread of old infections that were thought to be under control, and the development of infectious agents that are resistant to multiple antibiotics. The causes for these occurrences are numerous and include the following:

- Vast and rapid urbanization in many areas of the world, resulting in a breakdown in public health programs and a more rapid spread of infection
- Poverty and social inequality
- War and famine

- Global travel, allowing more rapid spread of disease from isolated areas to virtually any point around the world in a few hours
- Human encroachment into wilderness areas, resulting in contact with previously sequestered infectious agents
- Practice of prescribing antibiotics excessively or not taking antibiotics for a complete course of therapy; or, even when appropriately used, over administration of antibiotics facilitates the emergence of antibiotic-resistant microorganisms
- Denial of a problem by governments, allowing infections to spread in an uncontrolled way
- Diminished use of effective insecticides
- Increased global warming, allowing insect vectors to spread into and breed in areas that were previously too cool for them

Emerging Infections

The emergence of previously unknown infections is not a new event in human history. However, the current rate may be unprecedented. Within 1 generation, more than 40 previously unknown infections have arisen. Some of these infections were harbored in animals and spread to humans with significant clinical impacts (e.g., severe acute respiratory syndrome [SARS-coronavirus] from bats, Middle East respiratory syndrome [MERS] from dromedary camels).³ These are referred to as **zoonotic infections**. Zika virus also is an example of a recently emerging infection that has spread globally (see [What's New? Zika Virus](#)). Several have extremely high mortality rates of more than

50%, including SARS (in those older than 65 years), Ebola virus, Marburg virus, “mad cow” disease, Nipah virus (up to 75%), and acquired immunodeficiency syndrome (AIDS) (almost 100% in untreated persons). However, most either spread very slowly (e.g., AIDS) or initially appear in relatively isolated areas and are effectively controlled by quarantine (e.g., Ebola virus). Although none of these infections has developed into worldwide scourges, the potential of reversion to more rapidly spreading variants is a concern of public health agencies. In 2015 the World Health Organization (WHO) developed a list of emerging viral diseases that need urgent attention based on the probability of causing severe epidemics and the lack of medical countermeasures.⁴ These included MERS, SARS-coronavirus, Nipah virus, and hemorrhagic fevers associated with Ebola, Marburg virus, Lassa fever, Rift Valley fever, and Crimean Congo hemorrhagic fever.

What's New?

Zika Virus

The spread of Zika virus (ZIKV) is the most recent example of an infection emerging from a limited geographical region and rapidly becoming a global health risk of yet unknown impact. Extensive discussions of ZIKV can be found at numerous websites, particularly at those of the World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC). ZIKV was discovered in rhesus monkeys in 1947 in the Zika forest of Uganda and in 1948 in local mosquitoes. ZIKV is a member of the Flavivirus family, which includes West Nile virus, dengue virus, yellow fever virus, and tick-borne encephalitis virus. The principal vectors are *Aedes aegypti* and occasionally *A. albopictus*. One or both of these mosquitoes are distributed throughout most of the United States.¹

The first human cases were found in Uganda and neighboring Tanzania in 1952 and in Nigeria in 1953. ZIKV was progressively detected in western Africa and southern Asia, but human infection

was rare. In 2007 the first major outbreak occurred. On the island of Yap in Micronesia about 5000 individuals (73% of the population) were infected.² Symptoms were relatively mild, and most individuals were asymptomatic. In 2008 the first case in the United States was reported. The number of sexually transmitted cases has progressively increased. ZIKV has been found in semen, sperm, and vaginal fluid and can be transmitted during virtually any kind of sexual activity.³ Semen contains infectious virus for up to 6 months after the onset of symptoms and is transmissible at any stage (i.e., before, during, and well after symptoms) or from an individual with a subclinical infection.

ZIKV can be transmitted from mother to child during pregnancy or delivery. Transmission through breast-feeding has not been reported. ZIKV appears to be neurotropic (specifically infects neural tissue). Major fetal complications include miscarriage, fetal death, microcephaly, and ocular disorders. In asymptomatic pregnant women, the risk of microcephaly is relatively low (approximately 1%). In symptomatic women, the incidence is higher (some estimate as high as 29%). Congenital microcephaly presents as a significantly smaller head because of diminished cerebral cortex development and frequently results in early neonatal death.⁴

Adult complications are relatively few but also neurologic, primarily a postinfection Guillain-Barré syndrome (GBS) that occurs in about 2 of 10,000 individuals.⁵ GBS is a suspected autoimmune disorder of peripheral nerves leading to peripheral symptoms (e.g., weakness, tingling in the arms or legs, difficulty breathing, complete paralysis, and potentially death because of respiratory failure).

The CDC has been closely monitoring ZIKV infections within the United States and U.S. territories. As of September 6 2017, the CDC has reported 231 symptomatic cases in the United States and 554 cases in U.S. territories.⁶

Very few alternatives are available to limit the spread of ZIKV and attempts to eradicate the vector by destruction of breeding sites are the most effective approach. Prevention includes limiting travel

to sites where ZIKV is endemic preventing access of mosquitoes to homes, using insect repellents on exposed skin, and wearing clothing that covers most of the body surfaces in ZIKV-infected areas.

At least 20 previously known infections have reemerged including a new strains of cholera, malaria, yellow fever, dengue fever, diphtheria, plague, and Marburg virus. The incidence of tuberculosis has risen by almost 33% between the mid-1980s and early 1990s. Although the United States is relatively free of most of these diseases, the effects of global warming and relaxed control of vectors may result in resurgence. West Nile virus, spread by mosquitoes, has spread throughout the continental United States, Canada, and Mexico.⁵

Many common infections previously controlled by antibiotics or vaccination have reemerged because of antibiotic resistance or secondary to decreased compliance with recommended vaccinations. Examples of these infections include *Streptococcus pneumoniae*,

Staphylococcus aureus, tuberculosis, diarrheal diseases, malaria, meningitis, respiratory tract infections, sexually transmitted infections (STIs), and **human immunodeficiency virus (HIV)**. Additionally, noncompliance with recommended vaccinations has led to outbreaks of diseases that were once under control (e.g., measles and pertussis).

Added to this collage of microbiologic dangers is the rising risk of bioterrorism. Agents such as smallpox, anthrax, and plague are continuing threats to public health and safety.

Microorganisms and Humans: a Dynamic Relationship

For many microorganisms the human body is a hospitable site in which to grow and flourish because of sufficient nutrients and appropriate conditions of temperature and humidity. Frequently, a symbiotic relationship exists, in which both humans and microorganisms benefit ([Box 10.1](#)). These microorganisms make up the *normal microbiome*—the resident microorganisms found in different parts of the body, including the skin, mouth, gastrointestinal tract, respiratory tract, and genital tract (see [Chapter 7](#)). For instance, the normal bacterial microbiome of the human gut is provided with nutrients from ingested food, produces enzymes that facilitate the digestion and use of many of the more complex molecules found in the human diet, produces antibacterial factors (e.g., bacteriocins, colicins) that prevent colonization by pathogenic microorganisms, and produces usable metabolites (e.g., vitamin K, B vitamins). This beneficial homeostasis is normally maintained through the physical integrity of the gut and other mechanisms that sequester these microorganisms on the mucosal surface.

Box 10.1

The Many Relationships Between Humans

and Microorganisms

Symbiosis: Benefits only the human; no harm to the microorganism

Mutualism: Benefits the human and the microorganism

Commensalism: Benefits only the microorganism; no harm to the human

Pathogenicity: Benefits the microorganism; harms the human

Opportunism: A situation in which benign microorganisms become pathogenic because of decreased human host resistance

Microorganisms and Infections

Clinical Infectious Disease

Microorganisms are generally classified based on different morphologic characteristics and life cycles. However, groups of disease-causing microorganisms share many properties related to clinical disease, processes of infection, and evasion of human protective systems. The clinical process of infection occurs in the following four distinct stages:

- *Incubation period*—the period from initial exposure to the infectious agent and the onset of the first symptoms, during which the microorganisms have entered the individual, undergone initial colonization, and begun multiplying, but are at insufficient numbers to cause symptoms; this period may last from several hours to years

- *Prodromal stage*—the occurrence of initial symptoms, which are often very mild and include a feeling of discomfort and tiredness
- *Invasion period*—the pathogen is multiplying rapidly, invading farther and affecting the tissues at the site of initial colonization as well as other areas; the immune and inflammatory responses have been triggered; symptoms may be specifically related to the pathogen or to the inflammatory response
- *Convalescence*—in most instances, the individual's immune and inflammatory systems successfully remove the infectious agent and symptoms decline; alternatively, the disease may be fatal or may enter a latency phase with resolution of symptoms until reactivation at a later time

Clinical manifestations of infectious disease vary depending on the pathogen, the organ system affected, and the intensity of the inflammatory response. The disease may be clinical (measurable infection-related symptoms) or subclinical (no apparent symptoms although the individual is infected). Effects of infection may be acute or chronic, secondary to the immune and inflammatory responses, or a direct consequence of toxins or injury to infected cells. The initial symptoms are typically fatigue, malaise, weakness, and loss of concentration. Generalized aching and loss of appetite are common complaints. However, the hallmark of most infectious diseases is fever.

Fever is not failure of the body to regulate temperature; rather,

body temperature is being regulated to a higher level than normal. The hypothalamus functions as a central thermostat and regulates temperature (see [Chapter 16](#)). Pyrogens are agents that can produce fever. Those derived from outside the host are termed **exogenous pyrogens** and those produced by the individual's inflammatory response are termed **endogenous pyrogens**. Exogenous pyrogens indirectly affect the hypothalamus through the release of endogenous pyrogens by cells of the host. A number of cytokines have been identified as endogenous pyrogens: interleukin-1 and interleukin-6 (IL-1 and IL-6), interferon (IFN), tumor necrosis factor (TNF), and others (see [Fig. 16.8](#)). These cytokines raise the thermoregulatory set point through stimulation of prostaglandin synthesis in both thermoregulatory (brain) and nonthermoregulatory (peripheral) tissue. Fever is considered a beneficial adaptive host-defense response in infection (e.g., killing of temperature-sensitive microorganisms).

Several factors influence the capacity of a microorganism to cause disease:

- *Communicability*: the ability to spread from one individual to others and cause disease (measles and pertussis spread very easily; HIV is of lower communicability)
- *Immunogenicity*: the ability to induce an immune response
- *Infectivity*: the ability to invade and multiply in the host
- *Mechanism of action*: how the microorganism damages tissue
- *Pathogenicity*: the ability to produce disease—success depends on communicability, infectivity, extent of tissue damage, and virulence

- *Portal of entry*: the route by which a microorganism infects the host (e.g., direct contact, inhalation, ingestion, or bites of an animal or insect)
- *Toxigenicity*: the ability to produce soluble toxins or endotoxins, factors that greatly influence the degree of virulence
- *Virulence*: the capacity to cause severe disease, for example, measles virus is of low virulence; rabies virus is highly virulent

Infectious diseases also are classified by their prevalence and spread within the community:

- *Endemic*: diseases with relatively high but constant rates of infection in a particular population
- *Epidemic*: the number of new infections in a particular population greatly exceeds the number usually observed
- *Pandemic*: an epidemic that spreads over a large area, such as a continent or worldwide (see Table E 10.1 on Evolve)

As a consequence of the relative severity of clinical infection and the ability to successfully treat the infection, some infections are considered relatively minor inconveniences, such as the common cold, and others have a major impact because of severe morbidity and mortality. In the United States, the Centers for Disease Control and Prevention (CDC) have developed a National Notifiable Diseases

Surveillance System.⁶ An evolving list of notifiable infectious diseases is maintained to monitor, control, and prevent the spread of disease. STIs are among the most common reportable diseases in 2015: *Chlamydia* (>1.5 million cases), gonorrhea (about 400,000 cases), HIV (>33,000 cases), and syphilis (>23,000 cases).

Process of Infection

The process of infection includes colonization, invasion, multiplication, and dissemination of pathogenic microorganisms. Many potentially pathogenic microorganisms reside within the normal microbiome without causing severe disease. The symbiotic relationship with the normal flora is maintained by physical barriers (e.g., skin and lining of respiratory and intestinal tracts), the complexity of the microbiome, and inflammatory and immune systems. Microorganisms that may cause infection if the protective barriers or defensive systems are weakened are referred to as *opportunistic microorganisms*. Physical damage to the intestinal tract during trauma or surgery releases intestinal bacteria into the bloodstream, potentially leading to sepsis, shock, and death. Cuts in the skin may allow normally contained bacteria (e.g., *S. aureus*) to cause local infections (e.g., abscesses, boils) and invade further and infect various organs. Alterations in the microbiome by antibiotics may allow local overgrowth of opportunistic microorganisms (e.g., *Clostridium difficile*, *Candida albicans*). Immune deficiencies may allow invasive systemic infections (e.g., systemic fungal infections) (see [Chapter 9](#)).

Unlike opportunistic infectious agents, *true pathogens* have devised means to circumvent the individual's defenses (discussed in [Chapters 7](#) and [8](#)) and cause infection. Infection with these agents is usually dependent on adequate numbers of microorganisms rather than compromise of the host's defenses. The estimated minimum number of microorganisms needed to cause infection (minimum infective dose) varies greatly with the particular pathogen: *Vibrio cholerae* (10^3 to 10^8 microorganisms), norovirus and rotavirus (10–100), *Giardia lamblia* parasitic diarrhea (10), and *Mycobacterium tuberculosis* (<10).

Pathogenic microorganisms usually exist in reservoirs (a natural habitat where the microorganism can multiply), such as the environment (e.g., contaminated water, soil), vertebrate animals, or another human who is infected. An individual may obtain an infectious microorganism from a reservoir either directly or indirectly.

Direct transmission may occur through direct contact with infections of another individual, such as the skin lesions of impetigo (*S. aureus*, *Streptococcus pyogenes*), fungal skin infections (athlete's foot), scabies (mites), lice (head or body lice), oral herpes, and STIs (see [Chapter 27](#)).

Vertical transmission is the spread of microorganisms from mother to child across the placenta (e.g., *T. pallidum*, *Listeria monocytogenes*, cytomegalovirus [CMV], *Toxoplasma gondii*), ascending the birth canal from vaginal colonization or during delivery (e.g., group B *Streptococcus*, *Escherichia coli*, *C. trachomatis*, *N. gonorrhoeae*, hepatitis B virus, HIV, *C. albicans*), or through the breast milk (e.g., *S. aureus*, HIV). Spread of microorganisms from one person to another is *horizontal transmission*.

Indirect transmission occurs from contact with contaminated materials, which can range from towels to food or through a vector. Transmission by indirect physical contact may occur with materials that the infected individual came in contact (e.g., towels, sheets, clothing, toys, bandages) and is a common route of transmission for *S. aureus*. Iatrogenic transmission occurs inadvertently as a result of medical procedures, such as contaminated transfusions, transplants, implants, and catheters. Many infectious microorganisms are transmitted on the surface of objects that penetrate the skin or from dirt that contaminates wounds, such as spores of *Clostridium perfringens* (gas gangrene) and *C. tetani* (tetanus).

Respiratory transmission may occur by means of several mechanisms. Coughing or sneezing generally creates a mist that can be inhaled from the air for considerable time. This mechanism readily transmits many viral diseases, including the common cold, influenza, mumps, and measles. Infected individuals also may produce airborne droplets that settle on environmental surfaces. Several viral and bacterial diseases may be spread in this manner, including pertussis,

influenza, pneumonia, legionnaires disease, and rubella. Other microorganisms may be airborne by circulating air that carries microorganisms picked up from the soil, dried droppings, or other sites. Most pathogenic fungi (e.g., *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*) grow as saprophytes in the environment and are transmitted by inhalation of spores and initially present as pulmonary infections but may spread to other sites in the body.

Many ingested substances (food, water) may be contaminated by minuscule amounts of human feces (*fecal-oral transmission*) that transmits *Salmonella* (salmonella food poisoning), cholera, hepatitis A virus, poliovirus, rotavirus, norovirus, *Giardia lamblia*, and many others that cause minor or major gastrointestinal diseases.

Zoonotic infections may be directly transmitted from animals, such as transmission of the rabies virus through bites. Most zoonotic infections are transmitted indirectly by means of *vector-borne transmission* (primarily insects). Mechanical vectors (e.g., housefly) passively transfer parasitic, bacterial, fungal, or viral microorganisms on the outside of their body from contaminated material to an individual. Biologic vectors (e.g., insects [*arthropods*]) feed off the blood of infected individuals. The infectious agent usually undergoes part of its life cycle within the arthropod, including multiplication, and is transmitted through bites or stings. Biologic vectors are responsible for some of the most severe blood-borne diseases. Important arthropods include mosquitoes (spreads malaria [*Plasmodium* spp.], arboviruses [arthropod-borne viruses], dengue hemorrhagic fever), tsetse fly (spreads trypanosomes such as *Trypanosoma cruzi*, which causes Chagas disease in South America, and *T. brucei*, which causes sleeping sickness in Africa), fleas (plague [*Yersinia pestis*], typhus [*Rickettsia prowazekii*], leishmaniasis [protozoan parasite *Leishmania* spp.]), and deer tick (Lyme disease [*Borrelia burgdorferi*]).

During transmission successful pathogens usually undergo initial adherence to tissue at the site of entrance to the body. Several produce localized infections without tissue invasion (e.g., *V. cholera* in the

intestinal tract), whereas others require spread from the initial site of colonization. Colonization begins when the microorganism stabilizes adherence to tissue through specific surface receptors. Adherence helps protect the microorganism from removal by mechanical, nonspecific forces, such as coughing of respiratory mucus. Adherence occurs between ligands/receptors on the microorganism and on the surface of cells, the specificity of which results in localization of an infectious agent to particular sites (**tissue tropism**), such as the confinement of common cold viruses to the respiratory tract.

Although discussions of infectious diseases generally focus on single microorganisms that can be isolated and identified, they frequently exist in the body as part of complex multicellular masses called **biofilms**.⁷ Biofilms consist of mixed species of microorganisms, including bacteria and fungi, immersed in a highly organized extracellular matrix produced by the microorganisms. Growth in biofilms offers survival advantages of protection by trapping components of the host's defenses and antibiotics.⁸ The closely organized structure allows for exchange of genetic information for antibiotic resistance and other defense mechanisms. Biofilms form on implanted medical devices (e.g., catheters, pacemakers, implanted heart valves, prosthetic joints, dentures) and are associated with chronic infections (e.g., persistent nasopharyngeal colonization with staphylococci; otitis media; diabetes-associated foot ulcers; infected burns; vaginitis; osteomyelitis; pneumonia secondary to cystic fibrosis; diseases of the oral cavity related to dental plaque, such as dental caries and periodontitis).

Invasion follows colonization. Successful infectious agents have developed mechanisms to penetrate the tissues and evade the host's nonspecific and specific defenses (inflammation and immunity). The process of invasion is closely linked to tissue damage. Extracellular pathogens generally invade by means of direct extension into the surrounding tissue and access to the lymphatics and bloodstream, from which they spread to internal organs. This form of invasion requires a variety of virulence factors, including adhesion molecules and toxins, which may directly lead to tissue damage. Obligate

intracellular pathogens, such as intracellular bacteria, parasites, and viruses, spread directly from cell to cell or by release of infectious microorganisms into extracellular fluid or blood from which they infect another cell. Some intracellular microorganisms may enter a latency phase within infected cells without spread or cellular damage until reactivation of the microbe occurs (e.g., herpes simplex virus, CMV, tuberculosis).

The presence of infectious microorganisms in the blood is generally referred to as **bacteremia** (bacteria in blood), **viremia** (viruses in blood), or **fungemia** (fungi in blood) and is usually related to transport and spread to other organs. **Septicemia** is multiplication of microorganisms (particularly bacteria) in the blood.

Classes of Infectious Microorganisms

Infectious disease can be caused by microorganisms that range in size from 20 nm (poliovirus) to 10 m (tapeworm). Classes of pathogenic microorganisms and their characteristics are summarized in [Table 10.1](#) and discussed in detail in the following sections.

TABLE 10.1

CLASSES OF MICROORGANISMS INFECTIOUS TO HUMANS

CLASS	SIZE	SITE OF REPRODUCTION	EXAMPLE
Bacteria	0.8–15 mcg	Skin	Staphylococcal wound infection
		Mucous membranes	Cholera
		Extracellular	Streptococcal pneumonia
		Intracellular	Mycobacterium tuberculosis
Chlamydiae	200–1000 nm	Intracellular	Urethritis
Rickettsiae	300–1200 nm	Intracellular	Rocky Mountain spotted fever
Mycoplasma	125–350 nm	Extracellular	Atypical pneumonia
Fungi	2–200 mcg	Skin	Tinea pedis (athlete's foot)
		Mucous membranes	Candida (e.g., thrush)
		Extracellular	Sporotrichosis
		Intracellular	Histoplasmosis

Protozoa	1–50 mm	Mucosal	Giardiasis
		Extracellular	Sleeping sickness
Helminths	3 mm–10 m	Intracellular	Trichinosis
		Extracellular	Filariasis
Virus	20–300 nm	Intracellular	Poliomyelitis

Infectious Bacteria

Bacteria are prokaryotic unicellular microorganisms with no nuclei, mitochondria, or membrane-bound organelles. They are generally divided into several groups:

- *True bacteria* divide by binary fission and may have a variety of morphologies, including cocci (spherical), bacilli (rod shaped), vibrios (comma-shaped rods), or spirilla (twisted, rod shaped). Most disease-causing bacteria fall into this classification.
- *Filamentous bacteria* may have branching, mycelium-like structures that resemble fungi. Examples include *Mycobacterium tuberculosis* and *Mycobacterium leprae* that respectively cause tuberculosis and leprosy.
- *Spirochetes* are flexible spiral filaments that are motile and most are anaerobic. Pertinent examples include *Borrelia recurrentis* (relapsing fever), *Treponema pallidum* (syphilis), and *Borrelia burgdorferi* (Lyme disease).
- *Mycoplasma* lack a rigid cell wall and are small and pleomorphic. They are the smallest and

simplest members of the bacteria. *Mycoplasma pneumoniae* causes atypical pneumonia, and *Mycoplasma genitalium* is a suspected cause of urethritis and pelvic inflammatory disease.

- *Rickettsia* are strict intracellular parasites that can be rod-shaped, spherical, or pleomorphic. They are typically spread by insect vectors and cause Rocky Mountain spotted fever (*Rickettsia rickettsii*) and typhus (*R. prowazekii*).

- *Chlamydia* are also strict intracellular parasites, but with more complex intracellular life cycles. The primary chlamydial pathogen is *Chlamydia trachomatis*, which causes the most common bacterial STI (pelvic inflammatory disease) and eye infections (conjunctivitis).

Bacteria also can be categorized as gram negative or gram positive. Gram-negative bacteria do not retain crystal violet dye in the Gram-staining process whereas gram-positive bacteria do retain crystal violet dye. Gram-negative bacteria also have a lipopolysaccharide (LPS) coat in the outer membrane, which consists of lipid A, a core polysaccharide, and O antigen. The LPS coat also is known as endotoxin (Fig. 10.1). Common bacterial pathogens are listed in Table 10.2.

FIGURE 10.1 Gram-Positive and Gram-Negative Bacteria. A, The structure of the bacterial cell wall determines its staining characteristics with Gram stain. Gram-positive bacteria have a thick layer of peptidoglycan (*left*). Gram-negative bacteria have a thin peptidoglycan layer and an outer membrane of lipopolysaccharide (LPS) (*right*). B, Example of a gram-positive (darkly stained microorganisms, *arrow*) group A *Streptococcus*. This microorganism consists of cocci that frequently form chains. C, Example of a gram-negative (pink microorganisms, *arrow*) *Neisseria meningitidis* in cerebrospinal fluid. *Neisseria* form complexes of two cocci (diplococci). (A from Murray PR et al: *Medical microbiology*, ed 7, Philadelphia, 2013, Saunders; B, C from Murray PR et al: *Medical microbiology*, ed 4, St Louis, 2002, Mosby.)

<i>Staphylococcus aureus</i>	Gram +	Facultative anaerobic	Extracellular
<i>Staphylococcus epidermidis</i>	Gram +	Facultative anaerobic	Extracellular

Mechanisms of Bacterial Invasion and Tissue

Bacterial Invasion.

Many bacteria have specialized surface structures that contribute to the structural integrity of biofilms and provide adherence to cells and tissue during invasion. **Pili** (also called **fimbriae**) are thin, rodlike projections from the bacterial surface⁹ (Fig. 10.2). Pathogenic strains of *E. coli* involved in urinary tract infections have a variety of different specific pili-associated adhesion molecules (i.e., adhesins), including mannose-binding protein that binds with glycoproteins specifically expressed on the bladder epithelium.

FIGURE 10.2 Attachment of *Escherichia coli* through Pili. A, Transmission electron micrograph showing pili (arrows) of pathogenic *E. coli*. B, Scanning electron micrograph of *E. coli* (orange) attached by pili (arrows) to bladder epithelium (blue). (A courtesy Eric Buckles and Paula J. Fernandes; B modified from Wein A et al: *Campbell-Walsh urology*, ed 9, Philadelphia, 2007, Saunders.)

Flagella (used for bacterial motion) also express adhesins. *Vibrio cholerae* expresses adhesins for fibronectin, a common component of mucosal cell surfaces. Adhesion to connective tissue components, such as fibronectin (*S. pyogenes* [group A streptococci], *S. aureus*, *T. pallidum*), collagen, laminin, and vitronectin are common sites of bacterial adherence.

Several microorganisms use complement-related receptors for initial attachment. *Neisseria* spp. adhere to urinary tract epithelial cell membrane-associated cofactor protein (CD46), which is a complement-regulatory protein that protects cells by inactivating C3b and C4b. Others use different components of the CR3-C3b/C3bi receptor-ligand system on the surface of monocytes/macrophages for adherence including *Bordetella pertussis*, *Legionella pneumophila* (legionnaires disease), and *M. tuberculosis*.

Toxins and Bacterial Products.

Bacterial pathogens produce a variety of toxic molecules that may kill the individual's cells, disrupt the tissue, and protect against inflammation. **Exotoxins** are proteins released during microbial growth and they may have specific or broad effects on connective tissue and cells. Exotoxins are classified by their mode of action. Type I toxins bind to the cell surface and alter cell function, type II toxins cause membrane damage, and type III toxins enter the cell.

Type I toxins include superantigens and heat-stable enterotoxins (i.e., toxins that target the intestinal tract). Superantigens (SAGs) (discussed in [Chapter 8](#)) are molecules that react with major histocompatibility complex (MHC) class II proteins on the surface of antigen-presenting cells and the T-cell receptor (TCR), independent of the specificity of the TCR. SAGs activate many more cells than a specific antigen would and lead to overproduction of proinflammatory cytokines, such as IL-1, IL-6, and TNF- α . SAGs are responsible for several diseases, including food poisoning (heat-stable enterotoxins of *S. aureus* and *C. perfringens*), toxic shock syndrome (toxic shock syndrome toxin [TSST] of *S. aureus*), and scarlet fever (erythrogenic toxin of *S. pyogenes*). *E. coli* secretes small-molecular-weight heat-stable enterotoxins that bind

to membrane-bound guanylate cyclase, resulting in increased levels of cyclic guanosine monophosphate (cGMP) and loss of cellular electrolytes and water.

Type II toxins are membrane-damaging molecules of several subtypes. Cholesterol-dependent toxins are cytolytic. They bind to the cell surface and assemble to construct an extremely large pore, similar to C9 of the complement system and perforin produced by T-cytotoxic cells¹⁰ (see [Chapters 7](#) and [8](#)). Cholesterol is required for formation of the pore. The pore leads to rapid exchange of calcium and water and cell death. *S. pneumoniae* secretes the cholesterol-dependent toxin pneumolysin, which can facilitate colonization of the lungs as well as protect the bacteria from macrophages. Type II toxins also include a subtype called *RTX cytotoxins*, which contain repeats in protein sequence. An example is α -hemolysin from *E. coli*. The α -hemolysin is a virulence factor that predominantly causes urinary tract infection and lysis of erythrocytes as a source of nutrients, but also protects *E. coli* by lysis of macrophages and lymphocytes. A third subtype of type II toxins includes enzymatically active toxins. *C. perfringens*, found in soil and as a wound contaminant, is the cause of gas gangrene. The major virulence factor is an α -toxin with phospholipase activity that results in hemolysis, as well as hydrolysis of membrane phospholipids of other cells.

Type III toxins are generally A-B toxins and the most common bacterial toxin. *A-B toxins* are referred to as *binary toxins* because two different components are required for activity: separately secreted A (active) and B (binding) components. The B components are activated by proteases either in the extracellular fluid or on the surface membrane of the target cell. Multiple activated B components organize on the cell membrane to form a complex with which A components bind for transportation into the cell. Overgrowth of *C. difficile* in the colon is a common complication of prolonged antibiotic therapy that kills much of the commensal microbiome. *C. difficile* secretes membrane-disrupting toxins A (an enterotoxin) and B (a cytotoxin) that damage the mucosa and result in watery diarrhea and potentially life-threatening pseudomembranous colitis.¹¹ *Clostridium*

botulinum produces the most potent toxin known, botulinum toxin, which is a paralytic neurotoxin that blocks the release of acetylcholine at nerve-muscle synapses and results in flaccid paralysis and death. Examples of A-B toxins include botulinum, tetanospasmin, *Corynebacterium diphtheriae* (diphtheria cytotoxin), *P. aeruginosa* (exotoxin A), and *Bacillus anthracis* (anthrax toxin).

A subset of A-B toxins is AB₅ toxins, examples of which are *B. pertussis* (pertussis toxin), *S. dysenteriae* (Shiga toxin), and *V. cholerae* (cholera heat-labile enterotoxin). AB₅ toxins form a complex of an A component noncovalently bound in a ring of five B components. During endocytosis, the A component is activated and alters cellular function usually by inactivating signaling pathways, increasing intracellular cyclic adenosine monophosphate (cAMP), or other means. The A component of anthrax A-B toxin is a zinc-metalloproteinase that prevents intracellular signaling. Diphtheria is a respiratory tract infection with systemic complications caused by an A-B toxin that inhibits messenger RNA (mRNA) translation and causes low blood pressure, necrosis in the heart and liver, degeneration of myelin sheaths, and death. The AB₅ cholera toxin leads to increased adenylate cyclase activity, which affects chloride channels, causing an efflux of chloride, water, and other salts into the intestinal lumen. Shiga toxin, another AB₅ toxin, binds to carbohydrates on the cell surface of the endothelium of the intestine, kidney, and brain. Shiga toxin is secreted by several pathogens, including *E. coli* O157:H7, a contaminant of food or water. Ingestion of Shiga toxin may initially cause bloody diarrhea followed by hemolytic uremic syndrome (hemolytic anemia, acute kidney failure, thrombocytopenia), which is especially severe and fatal in children.¹²

Another type of toxin is endotoxin. Unlike secreted exotoxins, **endotoxin** (also called **lipopolysaccharide [LPS]**) is contained in the cell walls of gram-negative bacteria and is released during lysis (or destruction) of the bacteria (see Fig. 10.1). The innermost part of LPS, *lipid A*, is made of polysaccharides and fatty acids and is responsible for the substance's toxic effects. Endotoxin also may be released during bacterial growth or during treatment with antibiotics.

Therefore antibiotics cannot prevent the effects of the endotoxin.

The release of a sufficient amount of endotoxin can lead to fatal **endotoxic shock (septic shock)**, which is one of the leading causes of death in intensive care units. Bacteria that produce endotoxins are called *pyrogenic bacteria* because they stimulate the release of inflammatory mediators that produce fever and cause the local and systemic effects of inflammation (Fig. 10.3). Once in the blood, endotoxins cause the release of vasoactive peptides and cytokines that affect blood vessels, producing vasodilation, which reduces blood pressure; causes decreased oxygen delivery; and produces subsequent cardiovascular shock (see Chapter 49). Endotoxin can activate the coagulation cascade, leading to the syndrome of disseminated (or diffuse) intravascular coagulation (see Chapter 29). Additionally, endotoxin induces the release of TNF- α by macrophages. TNF is a potent proinflammatory cytokine, also called *cachectin* because of its role in promoting cachexia (wasting syndrome) in individuals with cancer. (Cachexia is discussed in Chapter 12; cytokines are discussed in Chapters 7 and 8.)

FIGURE 10.3 The Many Activities of Lipopolysaccharide (LPS). Bacterial endotoxin (LPS) activates almost every aspect of inflammation. The release of LPS from gram-negative bacteria triggers successive waves of cytokine production, including tumor necrosis factor (TNF), interleukin-1 (IL-1), interleukin-6 (IL-6), and interleukin-8 (IL-8), and secondary mediators of inflammation, such as nitric oxide (NO) and platelet-activating factor (PAF). At low levels of LPS the effect is local. Moderate levels of LPS cause more systemic inflammatory responses. High levels of LPS may lead to septic shock and death. ARDS, Acute respiratory distress syndrome; DIC, disseminated intravascular coagulation. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders; Modified from Abbas AK et al: *Cellular and molecular immunology*, ed 4, Philadelphia, 2000, WB Saunders.)

In addition to toxins, bacteria can also release enzymes that promote infection. The enzymes are not specific for any particular cell or cell receptor, but facilitate spread of the microorganism and are sometimes called *invasins*. A secondary effect may be considerable damage to the tissues and organs.

The site of infection contains a broad spectrum of proteases, lipases, deoxyribonucleases (DNases), and other enzymes secreted by microorganisms. The secretion of most toxic enzymes is common to

broad groups of pathogens, whereas others discussed here are more limited to particular strains. Some proteases contribute to the defense against the immune and inflammatory systems by digesting components of the plasma systems (complement, clotting, fibrinolysis), immunoglobulins, cytokines, and antimicrobial peptides. Most also will weaken the surrounding connective tissue to allow invasion. Connective tissue is vulnerable to digestion by proteases that break down hyaluronic acid, collagen, fibrin, elastin, laminin, and glycosaminoglycans. Hyaluronidase is frequently produced by streptococci, staphylococci, and clostridia to break down hyaluronic acid polymers in the matrix. Collagenase is a product of several clostridia, breaking down the intercellular matrix in muscle during gangrene. Neuraminidase is especially useful for intestinal pathogens, such as *V. cholerae* and *S. dysenteriae*, degrading the sialic acid that strengthens the intestinal epithelial junctions. Kinases, such as streptokinase and staphylokinase, activate plasminogen to digest large clots that interfere with bacterial spread.

Many enzymes also will digest membranes of tissue cells leading to lysis and release of nutrients that are useful to the microorganisms. Some hemolysins (those that lyse erythrocytes) or leukocidins (those that lyse phagocytes) are pore-forming toxins, but others are enzymes (e.g., lecithinases or phospholipases) that digest lipids in the membrane, resulting in hemolysis or cell death. *C. perfringens* produces phospholipases and lecithinases that remove the polar head groups from cell membrane phospholipids or destroy phosphatidylcholine (lecithin) in the membranes of most cells.

Several enzymes perform a secondary role in invasion as adhesins to matrix components.¹³ *Yersinia pestis* (plague) expresses a plasminogen activator protease that can activate plasminogen to plasmin, which can dissolve clots and activate collagenase. When expressed on the bacterial surface, it binds strongly to laminin in the matrix and facilitates invasion. *S. agalactiae* (group B *Streptococcus*) produces a serine protease, a C5a peptidase, that degrades the chemotactic factor C5a, but also has a high binding affinity for fibronectin.

Destructive Immune and Inflammatory Responses to Bacterial Infection.

Much of the tissue damage caused by infections is secondary to the inflammatory and immune responses. Infectious microorganisms routinely initiate an immune and inflammatory response, including infiltrates of phagocytic cells and a wide variety of T cells, production of antibody, and activation of plasma systems (complement, clotting) (see [Chapters 7, 8, and 9](#)). Some are specific to antigens (T cells, antibodies) expressed by the microorganism, whereas others are not antigen-specific (phagocytes). Cytokines and chemokines secreted by inflammatory and immune cells are designed to inhibit the proliferation and spread of infectious agents; however, most also are damaging to the surrounding tissue.

Antibodies will react with antigens expressed by the microorganism. Overproduction of antigen released as soluble molecules will lead to reaction with antibody and formation of immune complexes in the circulation or in tissue and activation of inflammatory systems. Because the antigen is from an exogenous source, the mechanism of tissue destruction would be classified as allergic and would be type II if expressed on the cell surface or type III if immune complexes are in the circulation (see [Chapter 9](#)). For example, individuals infected with *S. pyogenes* or *T. palladium* are at risk for developing symptoms of type III hypersensitivity reactions including kidney disease and vascular inflammation.

The typical immune and inflammatory reaction against intracellular microorganisms or persistent infections involves a cell-mediated response with infiltration of T cells and macrophages, as well as neutrophils. The inflammatory site is rich in proinflammatory cytokines and as the individual's response increases so do the destructive effects on surrounding healthy tissue. Many of these infections are very difficult to eradicate, leading to progressively increasing production of cytokines. Persistent infections (e.g., *M. tuberculosis*) may lead to formation of *granulomas*, which cause further destruction of the infected organ (e.g., the lung).

Bacterial Evasion of Immune and Inflammatory Systems.

Evasion of the individual's immune and inflammatory systems is multifaceted, and the most successful pathogens incorporate several mechanisms (Table 10.3).

TABLE 10.3

MECHANISMS USED BY MICROORGANISMS TO DEFEND AGAINST INFLAMMATION AND IMMUNITY

STRATEGY	BACTERIA	FUNGI	PARASITES	VIRUSES
Rapid division	Initial proliferation in protective environment	NA	NA	Rapid proliferation viruses with small genomes
Protection against phagocytosis and intracellular destruction	Intracellular bacteria block granule fusion, survive in phagolysosomes, enter and multiply in cytoplasm. Capsules with antiphagocytic and anticomplement activities, toxins to kill phagocytes (e.g., α -toxin and leukocidin).	Multiplication in phagosomes, inhibition of lysosomal enzymes. Polysaccharide capsule, toxins that inhibit phagocytosis.	Resistance to lysosomal enzymes, block granule fusion, enter and multiply in cytoplasm. Glycocalyx, toxins that inhibit phagocytosis.	Obligative intracellular life cycle, latency (e.g., herpes simplex virus in dorsal root ganglia)
Blocking antigen recognition	Adsorption of fibronectin or IgG (e.g., protein A), sialic acid capsule. Large diversity of surface molecules, phase changes in pili or membrane proteins, strain-to-strain serotype differences.	Changes in surface antigens	Adsorption of IgG by Fc receptor. Changing morphologic forms during life cycle, antigen switching.	Enveloped viruses with plasma membrane. Viral enzymes that produce translational errors, antigen shift and drift, diversity of serotypes.
Blocking the immune	Proteases for IgA and IgG,	Stimulation of antiinflammatory	IgG and IgA proteases.	Secretion of viral proteins to

response	degrade complement, defensins, and cathelicidins Shedding of surface antigens. Proteases degrade complement (e.g., C3b, C5a), capsules that prevent complement deposition, inhibitors of complement components and convertases. Induction of anergy, direct suppression of Th cell development.	cytokines, inhibition of proinflammatory cytokines.	Shedding of surface antigens. Degrade or inactivate C3b, C3a, and C5a; break down C3 convertase. Release of soluble antigens that induce "tolerance," polyclonal B-cell activation, induction of antiinflammatory cytokines, cytotoxic molecules.	neutralize antibody, molecules to neutralize cytokines. Cellular complement inhibitors in envelope. Infect and kill immune cells, inhibit Tc and natural killer (NK) recognition of major histocompatibility complex (MHC), inhibit antigen presentation.
----------	--	---	---	--

IgA, Immunoglobulin A; *IgG*, immunoglobulin G; *NA*, not applicable; *Th*, T helper cell.

Rapid Progression.

Rapid progression is an evasive mechanism limited to bacteria and viruses. Because the primary immune response may take 3 to 5 days to reach protective levels, some pathogens proliferate at rates that surpass the development of the immune system. An example is *V. cholerae*, that causes severe vomiting and watery diarrhea, which has a 60% mortality rate and develops within 2 to 3 days of ingestion of the bacteria.

Bacterial Protection Against Phagocytosis and Intracellular Destruction.

Antiphagocytic capsules are expressed by most bacterial pathogens involved in pneumonia and meningitis (Fig. 10.4). **Capsules** are mostly polysaccharide, although proteins also may be capsular components. Examples include the thick polysaccharide covering of the pneumococcus (*S. pneumoniae*), the waxy capsule surrounding the tubercle bacillus (*M. tuberculosis*), the polysaccharide “slime” capsule of *P. aeruginosa*, and the M protein of *S. pyogenes*.

FIGURE 10.4 Bacterial Capsule. Gram stain of a sputum sample from an individual with pneumococcal pneumonia ($\times 1000$ magnification). The sputum is rich in polymorphonuclear (PMN) cells and slightly elongated, gram-negative cocci (*Streptococcus pneumoniae*). Clear areas (arrows) around the bacteria indicate capsules. (Modified from Mandell G, Bennett J, Dolin R: *Principles and practice of infectious diseases*, ed 7, Philadelphia, 2010, Churchill Livingstone.)

Some bacterial toxins and extracellular enzymes kill phagocytic cells (e.g., *P. aeruginosa* exotoxin A). Staphylococcal hemolysins and toxins from *B. anthracis* and *B. pertussis* decrease phagocytic and chemotactic activities and may be toxic to the cell. Streptococcal products, such as streptolysin O, bind to cholesterol in the membrane of the phagolysosome and initiate destruction through the cytoplasmic release of lysosomal enzymes.

Normally a macrophage would efficiently kill bacteria, but mechanisms for intracellular survival have evolved to the benefit of

the infectious agent. *Intracellular bacteria* can survive and even multiply in macrophages (*Brucella*, *Listeria*, *M. leprae*, *M. tuberculosis*) or in other cells. Bacterial killing results from fusion of lysosomal granules with the phagosome to produce a phagolysosome and activation of oxygen-dependent and oxygen-independent mechanisms. *M. tuberculosis* produces toxins that prevent phagosome-lysosome fusion so that the environment in the phagosome remains relatively nontoxic.

A second means of avoiding killing is neutralization of the toxic environment of the phagolysosome. Production of catalase and superoxide dismutase (*N. gonorrhoeae*, *Brucella abortus*) destroys toxic oxygen products produced by the hexose-monophosphate shunt.

A third means of avoiding killing is escape from the phagosome. Lysins (e.g., hemolysin of *Shigella*, listeriolysin O and phospholipase C of *L. monocytogenes*, phospholipase A of *Rickettsia* spp.) are secreted enzymes that break down the phagosome membrane, releasing the bacteria into the cytoplasm where they multiply.¹⁴

Blocking Recognition of Bacterial Antigens.

Pathogens that coat themselves with human proteins may “fool” the immune system by masking antigens. Some bacterial surface proteins (e.g., protein G of *S. pyogenes*) bind the Fc portion of antibody, thus forming a protective coat of “self” protein. Binding through the Fc holds the antibody in an orientation that does not allow complement activation or phagocytosis. *T. pallidum* coats itself with fibronectin. Capsules may contain sialic acid (e.g., *E. coli* K-12), which closely resembles the sialic acid on the surface of most human cells, or hyaluronic acid (e.g., group A streptococci), which is the basic substance in normal connective tissue.

Antigenic variation allows the pathogen to alter surface antigens that are the targets of protective immune responses. Thus as the individual develops protective levels of antibodies, the pathogen responds by changing antigens and becoming resistant. The three primary mechanisms of antigenic variation are *mutation* (a change or error in gene structure that results in variant expression of antigen);

recombination (the exchange of DNA fragments between cells resulting in a new DNA sequence and variance of antigen expression); and *gene switching* (the switching of genes on and off resulting in variation of antigen expression).

Neisseria use pili to adhere to epithelium, and antibody against these antigens can abrogate adherence. *Neisseria* undergoes *phase shifts* during which pili antigens are changed by progressive silencing of 1 set of 10 or 11 available pili genes and activation of others that express different antigens. Many bacteria have a large number of different antigenic types (serotypes) across the species. At least 80 different strains of group A streptococci express different serotypes of the capsular M protein. *S. pneumoniae* has at least 100 different serotypes based on capsular polysaccharides. Some gram-negative bacteria can revert to “rough” forms in which serotype-specific carbohydrates are deleted, thus becoming resistant to antibody and activation of complement.

Blocking the Immune Response to Bacteria.

Bacteria may spontaneously release surface molecules that bind to and neutralize antibody. These include endotoxin from gram-negative bacteria and capsular antigens from *S. pneumoniae* and *N. meningitidis*. The secretion of large amounts of soluble antigen may lead to formation of immune complexes.

Bacteria may break down molecules of the immune or inflammatory system. An **IgA protease** produced by meningitis-causing microorganisms and other related bacteria (*N. gonorrhoeae*, *N. meningitidis*, *H. influenzae*, *S. pneumoniae*) cleaves IgA at the hinge region into ineffective Fc and Fab'₂ regions. *Salmonella* membrane protease degrades nonspecific antimicrobial molecules like defensins and cathelicidins.

Complement is a major component of the defense against bacterial infection through production of opsonin (C3b) and chemotactic factors (C3a, C5a) for neutrophils. Teichoic acid in the gram-positive cell wall provides resistance against complement-mediated lysis. Bacterial regulatory proteins (e.g., *Borrelia* complement-regulator-acquiring

protein, *Neisseria* porins, and members of the *Streptococcus* M protein family) affect complement activation, including destabilization of the C3 convertase complex or degradation of the opsonin C3b.¹⁵ *Pseudomonas* produces elastase (breaks down C3 of the complement system) and a 56-kDa protease (breaks down the chemotactic factor C5a).

Some bacterial pathogens can broadly suppress immune responses against their own antigens, as well as other antigens unrelated to the infectious agent. Chronic bacterial infections, like leprosy (*M. leprae*) and tuberculosis (*M. tuberculosis*), induce anergy (suppressed response to multiple antigens) in infected hosts. *Helicobacter pylori* releases LPS that binds to dendritic cells and blocks development of T-helper 1 (Th1) cells, produces toxins that block the T-cell IL-2 receptor signaling pathway, thus inhibiting maturation of Th cells, and induces a Th17 response that impairs inflammatory responses.¹⁶

One of the most common bacterial infections is *Staphylococcus aureus* and it is described in [Box 10.2](#).

Box 10.2

Example of Bacterial Pathogenesis: *Staphylococcus aureus*

Infection with *S. aureus* is an example of how mechanisms of bacterial pathogenesis come together. *S. aureus* is a commensal microorganism that resides on the skin and nasal passages (30% of individuals are nasal carriers), but also is an opportunistic pathogen. Minor skin infections may result if the integrity of the skin is compromised by cuts or abrasions or if hair follicles are infected. Most infections are relatively mild and localized as red and swollen eruptions on the skin containing pus or other drainage (see [Figure](#)). If not treated appropriately, more severe abscesses (pus-filled nodules in skin tissue), boils (pus-filled nodular infection of hair follicle), carbuncles (cluster of boils), or cellulitis (red and diffuse infection of inner layers of skin, dermis, and subcutaneous

fat) may develop.

Invasive disease results from more extensive skin damage (e.g., eczema, trauma, surgical wounds, or injection sites for intravenous drug abuse). Extensive biofilms can develop on inert materials (e.g., intravenous catheters, indwelling medical devices, or prosthetic joints). *S. aureus* can spread to the circulation (bacteremia, septicemia) and infect the heart valves (endocarditis), bones (osteomyelitis), and joints (infectious arthritis), and form abscesses in internal organs.

Chronic medical conditions requiring hospitalization (e.g., diabetes, cancer, vascular disease, pulmonary disease, or surgery) weaken the immune system and increase the risk for invasive *S. aureus* infection. For instance, *S. aureus* is a major cause of diabetic foot ulcers resulting in limb amputation or death.¹ *S. aureus* also has become a major cause of hospital-acquired (nosocomial) infections. Healthcare providers and visitors to hospitals can easily become carriers by direct skin-to-skin contact or contact with items or surfaces (e.g., clothing, towels, or bandages) contaminated by another individual's infection. Untreated *S. aureus* bacteremia has an 80% fatality rate. Because of the prevalence of multiple antibiotic resistance (see [Emerging Infections](#)), even appropriate treatment has a 15% to 50% fatality rate depending on the individual's age and health.

An unusually large number of virulence factors contribute to invasive infection by *S. aureus*. Invasion is initiated by adherence to extracellular matrix (e.g., laminin, fibrin, fibronectin) and endothelium. Two fibronectin-binding proteins bridge between fibronectin and cellular $\alpha 5\beta 1$ integrin, triggering bacterial uptake by endocytosis in endothelium, epithelial cells, and other cells. *S. aureus* can proliferate within cells and destroy infected cells. Adherence to fibronectin also facilitates the formation of biofilms.² Spread to bone and joints, enhanced by attachment to collagen, occurs in osteomyelitis and septic arthritis-causing strains. Staphylococci also produce a polysaccharide capsule that mediates attachment to prosthetic devices, as well as protects against

phagocytosis.

S. aureus is very susceptible to antibody and complement-mediated neutrophil phagocytosis, but has developed a variety of effective defenses. IgG antibody is neutralized by cell surface staphylococcal protein A (SPA) and secreted staphylococcal binder of immunoglobulin. Both bind IgG at the Fc region. This IgG orientation prevents binding to surface antigens, prevents activation of complement, and masks the bacterium with human proteins. Additional masking with self-protein is provided by bacterial coagulase that activates coagulation to produce a coat of fibrin, which also inhibits phagocytosis. *S. aureus* inhibits the complement cascade at several key points. The thick peptidoglycan layer and a thin capsule prevent complement from binding with the bacterial membrane. Secreted complement inhibitor proteins and enzymes (e.g., staphylokinase) inhibit or break down most protective components of the complement cascade.

Neutrophil phagocytic and bactericidal functions are directly inhibited by *S. aureus*. The primary mechanism of bacterial killing by neutrophils involves recognition of bacterial products by Toll-like receptor-2 (TLR2) and activation of oxygen-dependent killing. *S. aureus* produces chemokine receptor blockers (e.g., staphopain A), chemotaxis inhibitors that prevent neutrophil binding to endothelium and extravascularization (e.g., chemotaxis inhibitory protein, superantigen-like protein), metalloprotease inhibitors to prevent migration through tissue, phagocytosis inhibitors, and lysins that kill neutrophils. Bacterial protection includes blocking of TLR2 recognition of staphylococcal lipoproteins and peptidoglycan, several enzymatic inhibitors of oxygen-dependent killing in phagosomes (e.g., catalase, superoxide dismutase, hydrogen peroxide reductase, and glutathione peroxidase), and inhibitors of lysosomal granule proteases (e.g., elastase). Bacterial production of adenosine, an antiinflammatory molecule, inhibits the neutrophil respiratory burst, degranulation, and platelet-activated coagulation. *S. aureus* also produces a cell-bound pigment (carotenoid) that “quenches” singlet oxygen within the phagocyte.

S. aureus modifies B- and T-cell responses. A variety of superantigens interfere with normal T-cell function, including diminished proliferation of antigen-specific T-helper cells. Adenosine secretion modulates T-cell activation, decreases expression of antigen-presenting major histocompatibility molecules in macrophages and dendritic cells, and suppresses the production of IL-12 that normally drives differentiation of Th1 cells.

Secretion of exotoxins contributes to the pathophysiology of *S. aureus* infection. Many toxins are the result of uptake of new extrachromosomal genetic information from the environment, conjugation with other bacteria, or infection of bacteria with phages (viruses that infect bacteria).³ Thus different strains of *S. aureus* express different toxin profiles. More than 20 type I toxins (superantigens, heat-stable enterotoxins) have been associated with *S. aureus* infections. Staphylococcal enterotoxins are the most common cause of food poisoning with vomiting and diarrhea. The staphylococcal toxic-shock syndrome toxin-1 (TSST-1) causes the most common form of that potentially fatal disease. Exfoliative toxins are responsible for scalded skin syndrome in newborns.⁴ These toxins are enzymes that digest the intercellular desmosomes that maintain the integrity of skin, causing separation of the epidermis. The skin peels off as would burned skin.

A battery of membrane-damaging toxins (hemolysins) mediates destruction of cells from outside (to protect against phagocytosis or open cellular barriers for invasion) or from inside (escape from phagocytic cells). *S. aureus* α -hemolysin (i.e., alpha-toxin) is a type II toxin that produces large pores in cell membranes, resulting in lysis of erythrocytes, breakdown of epithelial barriers, escape from a phagosome, and lysis of the macrophage plasma membrane, causing escape into the surrounding environment. Leukocidins are lytic toxins that bind to receptors on the cell surface and lyse most phagocytes. Although not yet fully understood, these leukocidins are expressed mostly by strains that cause necrotizing skin infections.

S. aureus additionally secretes a variety of enzymes that

nonspecifically aid invasion and defend against the immune and inflammatory response. These include lipases, proteases (e.g., a neutral protease, collagenase), nucleases (e.g., DNase), catalases, coagulases (e.g., staphylocoagulase and von Willebrand factor that activate prothrombin and deposit small amounts of fibrin on the bacteria, preventing phagocytosis and contributing to formation of abscesses and biofilms), and staphylokinase (activates plasminogen to allow escape from fibrin clots).

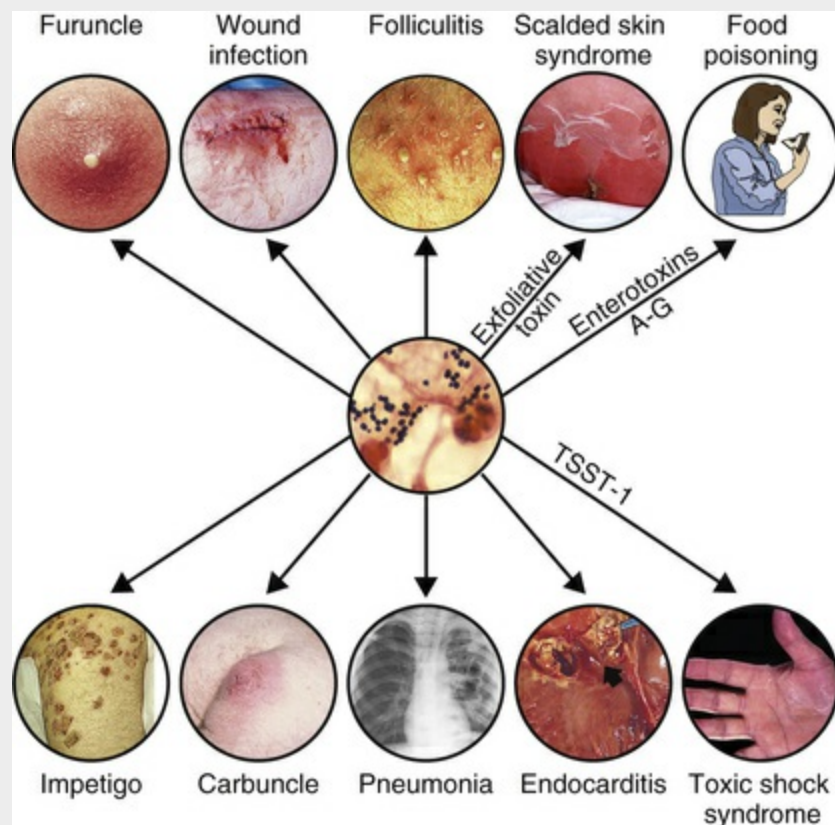

FIGURE *Staphylococcus aureus* Infections. Different strains of *S. aureus* (gram-positive cocci in sputum from an individual with pneumonia [center photograph]) cause a variety of infections. The particular infection may depend on the toxin produced: exfoliative toxin (scalded skin syndrome), enterotoxins A–G (food poisoning), or toxic shock syndrome toxin-1 (TSST-1). (Toxic shock syndrome, carbuncle, impetigo, and wound infection photos from Cohen J, Powderly WG: *Infectious diseases*, ed 3, St Louis, 2010, Mosby; Folliculitis photo from Goldman L, Ausiello D: *Cecil medicine*, ed 24, Philadelphia, 2012, Saunders; Center photo and photos of food poisoning and endocarditis from Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders; Furuncle photo from Long S et al: *Principles and practice of pediatric infectious diseases*, ed 4,

Infectious Fungi

Fungi are eukaryotic microorganisms with thick, rigid cell walls and the capacity to form a variety of complex structures (Fig. 10.5). Fungi may grow as a **mold** with branched filaments or as a meshwork mycelium structure (e.g., *Aspergillus* spp., causing aspergillosis), **yeast** with ovoid or spherical shapes (*Candida albicans*, which causes candidiasis), or **dimorphic** with a yeastlike appearance in tissue and mycelium in culture (e.g., *Histoplasma capsulatum*, which causes histoplasmosis, a respiratory disease). Molds are aerobic and yeasts are facultative anaerobes. The cell wall is composed of polysaccharides that differ from the peptidoglycans of bacteria and are resistant to bacterial cell wall inhibitors, such as penicillin and cephalosporin. In contrast to bacteria, the cytosol of fungi contains organelles: mitochondria, Golgi apparatus, microtubules,

microvesicles, endoplasmic reticulum, and nuclei. Many of the antifungal drugs (e.g., amphotericin B, ketoconazole, fluconazole) used to treat deep or systemic infections are toxic to the host because the fungal cell composition is similar to that of the human cell. Common pathologic fungi are summarized in [Table 10.4](#).

TABLE 10.4

COMMON PATHOGENIC FUNGI

PRIMARY SITE OF INFECTION	FUNGUS	DISEASE (PRIMARY)	SYMPTOMS
Cutaneous (no tissue invasion, inflammatory response)	Dermatophytes <i>Trichophyton mentagrophytes</i> <i>Trichophyton rubrum</i>	Tinea pedis (athlete's foot) Tinea cruris (jock itch) Tinea corporis (ringworm)	Scaling, fissures, itching Rash, itching Lesion, raised border, scaling
	<i>Candida albicans</i>	Cutaneous candidiasis	Lesions in most areas of skin, mucous membranes, thrush, vaginal infection
Subcutaneous (tissue invasion)	<i>Sporothrix schenckii</i>	Sporotrichosis	Ulcers or abscesses on skin and other organ systems
Systemic (dimorphic; causes disease in healthy individuals)	<i>Stachybotrys chartarum</i> or "black mold"	Black mold disease	Rash, headaches, nausea, pains
	<i>Coccidioides immitis</i>	Coccidioidomycosis	Valley fever, flulike symptoms
	<i>Histoplasma capsulatum</i>	Histoplasmosis	Lung, flulike symptoms, disseminates to multiple organs, eye
	<i>Blastomyces dermatitidis</i>	Blastomycosis	Flulike symptoms, chest pains
Systemic (opportunistic)	<i>Aspergillus fumigatus</i> , <i>Aspergillus flavus</i>	Aspergillosis	Invasive to lungs and other organs
	<i>Pneumocystis jiroveci</i>	Pneumocystis pneumonia (PCP)	Pneumonia
	<i>Cryptococcus neoformans</i>	Cryptococcosis	Pneumonia-like illness, skin lesions, disseminates to brain, meningitis
	<i>Candida albicans</i>	Systemic candidiasis	Sepsis, endocarditis, meningitis

Infection with a fungus is called **mycosis**. Many pathogenic fungi (e.g., *H. capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*) grow as saprophytes in the environment and are transmitted by inhalation or contamination of wounds. Other medically relevant fungi either exist as human commensals or cause relatively mild infections (superficial mycoses) of the skin, nails, hair, and mucous membranes of the mouth and vagina. These include dermatophytes (e.g., tineas) and yeasts (e.g., *Candida*, *Aspergillus*, *Cryptococcus*).

Human-to-human transmission is the primary means of transmission of dermatophytes, for instance, *Tinea pedis* (athlete's foot), *T. capitis* (ringworm of scalp), and *T. unguium* (fungal infection of nails). Systemic mycosis generally results from inhalation of spores present in a contaminated environment and initially presents as a pulmonary infection. Infection that disseminates to other organs can be life threatening. Systemic mycosis caused by opportunistic fungi is usually secondary to immunosuppression caused by genetic defects, infections such as HIV, cancer, and drugs used to prevent transplant rejection.

Fungi are diagnosed by microscopic observation of specimens treated with potassium hydroxide and stained to enhance visualization of spheres and filaments. Specimens also can be cultured. Skin tests are available for species of *Aspergillus*.

Mechanisms of Fungal Invasion and Tissue Destruction.

Specific adherence to the epithelium is provided by several polysaccharides on the fungal surface. Glucan, mannan, glycoprotein, and chitin molecules adhere with host receptors, including Toll-like receptors (TLRs), mannose receptors, and cadherins. A cell wall adhesion molecule, agglutinin-like sequence 3 (ALS3), on several fungi (e.g., *C. albicans*) promotes adherence to epithelial cells as well as silicone, thus facilitating infection of implants and other medical devices.

Pneumocystis jiroveci infection is a major concern in individuals with AIDS. As with many fungi, *Pneumocystis* has two life-cycle forms: a cyst form and a trophic form. The cyst form is dormant, more globular

with a thick wall, and when ruptured releases multiple spores. The trophic form (trophozoite) is the infectious and proliferative form. Two surface proteins, glycoprotein A (gpA) and major surface glycoprotein (MSG), mediate attachment of the trophozoite to alveolar epithelial cells leading to the development of pneumonia.

Fungal Toxins and Products.

Pathogenic fungi do not commonly produce toxins as virulence factors. The only identified peptide toxin related to virulence is a cytolytic toxin (candidalysin) that is crucial for *C. albicans* infection of mucosa.¹⁷ A sulfur-containing mycotoxin that induces apoptosis of many cells of the inflammatory and immune system is produced by *A. fumigatus*. Several toxins secreted by molds in the environment cause disease without fungal infection. Mycotoxins are produced by molds that grown on nuts, beans, and grains. Ingestion of these toxins affects muscle coordination, causes tremors, and may be fatal. Other fungal toxins may cause cancer; aflatoxins produced by some *Aspergillus* are especially carcinogenic.

By mechanisms similar to those described for bacteria, fungal infections damage tissue directly by secretion of enzymes and indirectly by initiation of an inflammatory response. Secreted enzymes, such as proteases, phospholipases, and elastases, damage cells and intercellular matrix, leading to breakdown of tissue and cellular necrosis.

Destructive Immune and Inflammatory Responses to Fungal Infection.

The typical immune and inflammatory reaction against fungal infections involves a cell-mediated response with infiltration of T cells, macrophages, and neutrophils. Fungal infections can be very difficult for these systems to eradicate, leading to progressively increasing production of proinflammatory cytokines. Hyperinflammatory responses enhance virulence of *A. fumigatus* by increasing adhesion and invasiveness. Thus as the host's response increases so do the destructive effects on surrounding healthy tissue. In cases of

persistent infection, granulomas form and compromise the normal function of the infected tissue.

Pulmonary exposure to spores or soluble antigens also may elicit an IgE response and allergic pneumonitis (inflammation of the lungs). Examples include allergic bronchopulmonary aspergillosis and allergic fungal sinusitis, both of which are type I allergic reactions (see [Chapter 9](#)). Excessive degranulation of mast cells may even cause anaphylactic shock.

Fungal Evasion of Immune and Inflammatory Systems.

The host defense against fungal infection includes the fungistatic properties of neutrophils and macrophages. T lymphocytes are crucial in limiting the extent of infection and producing cytokines to further activate macrophages.

Resistance to the individual's protective mechanisms is a complex process that requires the expression of multiple genes at different stages and different sites of infection. Pathogenic fungi are generally dimorphic (e.g., *H. capsulatum*, *B. dermatitidis*, *C. immitis*) and readily adapt to the host environment, responding to temperature variations, low oxygen levels, more alkaline pH, and other conditions in the host tissue by undergoing changes in morphology and switching from avirulent mold forms to virulent yeast forms. Similar conditions also trigger yeasts (e.g., *C. albicans*) to switch from the yeast form to its more virulent hyphal form. As with parasites, rapid progression is not a major factor in immune evasion by fungi.

Fungal Protection Against Phagocytosis and Intracellular Destruction.

Encapsulated yeast cells (e.g., *Cryptococcus neoformans*) are more resistant to phagocytosis than unencapsulated yeast. A capsule is antiphagocytic by masking surface PAMPs (pathogen associated molecular patterns) and inhibiting recognition by PRRs (pattern recognition receptors) on phagocytes and epithelial cells (see [Chapter 7](#)).

Aspergillus fumigatus and many other fungi produce toxic

metabolites (e.g., gliotoxin) that inhibit macrophage and neutrophil phagocytosis. Molecules like gliotoxin may suppress inflammation, including suppression of mast cell activation, degranulation, and secretion of leukotrienes and cytokines.

Even if successfully ingested by phagocytic cells, fungi have developed complex processes for intracellular survival. Pathogenic fungi are generally dimorphic (e.g., *H. capsulatum*, *B. dermatitidis*, *C. immitis*) and readily adapt to the host environment, responding to temperature variations, low oxygen levels, more alkaline pH, and other conditions in the host tissue by undergoing changes in morphology and switching from avirulent mold forms to virulent yeast forms. The yeast form of *Histoplasma* replicates in phagosomes and phagolysosomes. Some yeasts also produce proteins that inhibit the activity of lysosomal proteases. The macrophage may be destroyed as a result of membrane modification by the fungus or, in the case of *Histoplasma*, may harbor the fungus in granulomas. Breakdown of the granulomas over time results in release of viable fungi and recurrence of the infection.

Blocking Recognition of Fungal Antigens.

Altered antigen expression affords protection against the developing immune responses, although this defense strategy is used only by selected fungal pathogens. *Pneumocystis* contains approximately 80 different gpA and MSG genes, only 1 of which is expressed at a time. Modulation of these antigens provides resistance against immune destruction.

Blocking the Immune Response.

Several yeasts stimulate the production of immunosuppressive cytokines, resulting in down-regulation of the individual's immune response. The yeast *C. neoformans* suppresses inflammation by inhibiting production of the proinflammatory cytokines TNF- α and IL-12 and inducing production of the antiinflammatory cytokine IL-10. The overall result is suppression of macrophage function and protection against killing.

Candida albicans is a common cause of infection reviewed in [Box 10.3](#).

Box 10.3

Example of Fungal Pathogenesis: *Candida albicans*

C. albicans is the most common cause of fungal infections in humans. It is an opportunistic microorganism that is a commensal in the normal microbiome of many healthy individuals, residing in the skin, gastrointestinal tract, mouth (in 30% to 55% of healthy individuals), and vagina (in 20% of healthy women), and is normally under the control of local defense mechanisms, including members of the bacterial microbiome that produce antifungal agents. In healthy individuals, infection remains localized to the dermis (e.g., diaper rash, thrush, mild vaginal yeast infection). In those whose normal microbiome has been disturbed by antibiotic therapy (e.g., resulting in diminished levels of *Lactobacillus* in the vaginal microbiome) *Candida* overgrowth may occur, resulting in more severe vaginitis or oropharyngeal infection.

In immunocompromised individuals, particularly those with diminished levels of neutrophils (neutropenia), disseminated infection may occur. *Candida* is the most common fungal infection in people with cancer (particularly acute leukemia and other hematologic cancers), transplantation (bone marrow and solid organ), and HIV/AIDS.

Invasive candidiasis may result from biofilms on materials that provide direct entrance into the blood (e.g., indwelling catheters, intravenous lines, peritoneal dialysis) and medical implants or other devices (e.g., pacemakers, prosthetic joints, dentures). More than 5 million central venous catheters are placed yearly. Most recipients are immunosuppressed secondary to their illness or therapy, and more than 50% develop biofilms resulting in about 100,000 deaths.¹ The strength of the biofilm results partially from

strong intercellular adherence mediated by hyphal cells.

Like most pathogenic yeasts, *Candida* is dimorphic and undergoes morphologic changes from unicellular yeast to filamentous hyphal forms under conditions found in the environment (e.g., alkaline pH, elevated temperature, and changes in serum factors) or inside phagolysosomes (e.g., low pH, hydrolytic enzymes, antimicrobial peptides, and the presence of reactive oxygen species).

Candida expresses diverse surface adhesion molecules that permit adherence to materials in implants, epithelium, extracellular matrix, and formation of the biofilm and tissue invasion. *Candida* can colonize a variety of sites in the individual, apparently the result of adhesins that have broad specificity.²

The biofilm also contains a very complex extracellular matrix with fungal enzymes and other components that provide extensive resistance to the immune response, antibiotics, and environmental changes that could damage the fungus. Individuals must be treated with very high doses of antifungal antibiotics with potential toxicity to the kidneys and liver. Antibiotic resistance increases, however, as *Candida* up-regulates expression of efflux pumps that are the primary means of antibiotic resistance (see the section on [Antimicrobials](#)).

Adaptation to the environment also results in altered profiles of surface antigens and surface carbohydrates that are identified as pathogen-associated molecular patterns (PAMPs) and a resultant increased resistance to destruction by innate and acquired immunity. Immune suppression may occur secondary to induction of the cytokine granulocyte-monocyte colony-stimulating factor (GM-CSF) that suppresses monocyte/macrophage function, including antigen presentation and production of components of the complement cascade. Decreased production of C3 results in less opsonization (C3b) and production of chemotactic activity (C3a) for phagocytes.

Disseminated candidiasis may involve several internal organs, including abscesses in the kidney, brain, liver, and heart, and is characterized by persistent or recurrent fever, gram-negative

shocklike symptoms (hypotension, tachycardia), disseminated intravascular coagulation (DIC), and death. The mortality rates of sepsis or disseminated candidiasis are in the range of 30% to 40%. *Candida* secretes several enzymes that function as virulence factors and contribute to spread and tissue destruction.

Infectious Parasites and Protozoans

Parasitic organisms establish symbiosis with another species in which the parasite benefits at the expense of the other species. Parasites range from unicellular protozoa to large worms. Parasitic worms (helminths) include intestinal and tissue nematodes (roundworms such as hookworms, pinworms, and ascariasis) and flatworms such as flukes (e.g., liver fluke, lung fluke, blood fluke) and tapeworms. A protozoan is a eukaryotic, unicellular microorganism with a nucleus and cytoplasm. Pathogenic protozoa primarily include sporozoa (e.g., *Plasmodium*, which causes malaria, and *Cryptosporidium*, which causes diarrhea), amoebae (e.g., *Entamoeba histolytica*, which causes amoebic dysentery), and flagellates (e.g., *Giardia lamblia*, which causes diarrhea, *Trypanosoma*, which causes sleeping sickness, and *Leishmania*, which causes skin ulcers and a visceral form that infects the spleen and liver). The most common parasitic infections in the United States include *Toxoplasma gondii* (a lifelong infection that may cause blindness and miscarriage) and *Trichomonas vaginalis* (a common STI). Parasites are common causes of infections worldwide, with a significant effect on mortality and morbidity in developing countries. Important parasites of humans are listed in [Table 10.5](#).

TABLE 10.5**PARASITES THAT ARE IMPORTANT IN HUMANS**

CATEGORY	SUBGROUP	SPECIES	DISEASE	ORGANS AFFECTED/SYMPTOMS
Protozoa	Amoeboid	<i>Entamoeba histolytica</i>	Amebiasis	Dysentery, liver abscess
	Flagellate	<i>Giardia lamblia</i>	Giardiasis*	Diarrhea
		<i>Leishmania donovani</i> , <i>L. tropica</i>	Leishmaniasis	Sores on skin, progression to liver, spleen
		<i>Trichomonas vaginalis</i>	Trichomoniasis	Inflammation of reproductive organs
		<i>Trypanosoma cruzi</i> , <i>T. brucei</i>	Chagas disease: African sleeping sickness	Generalized, blood, lymph nodes, progressing to cardiac and central nervous system (CNS)
	Ciliate	<i>Balantidium coli</i>	Balantidiasis	Small intestines, invasion of colon, diarrhea
	Sporozoa (nonmotile)	<i>Cryptosporidium parvum</i> , <i>C. hominis</i>	Cryptosporidiosis*	Intestine, diarrhea
		<i>Plasmodium</i> spp.	Malaria	Blood, liver
		<i>Toxoplasma gondii</i>	Toxoplasmosis*	Intestine, eyes, blood, heart, liver
Helminths	Flukes (trematodes)	<i>Fasciola hepatica</i>	Fasciolosis	Liver destruction
		<i>Paragonimus westermani</i>	Lung fluke disease	Granuloma in lung, spinal cord
		<i>Schistosoma mansoni</i>	Schistosomiasis	Blood, diarrhea, bladder, generalized symptoms
	Tapeworms (cestodes)	<i>Taenia solium</i>	Pork tapeworm	Encysts in muscle, brain, liver
	Roundworms (nematodes)	<i>Ascaris lumbricoides</i>	Ascariasis	Intestinal obstruction, bile duct obstruction
		<i>Necator americanus</i> (hookworm)	Hookworm disease	Intestinal parasite
		<i>Trichuris trichiura</i> (whipworm)	Trichuriasis	Diarrhea

		<i>Trichinella spiralis</i>	Trichinosis*	Intestine, diarrhea, muscle, CNS, death
		<i>Wuchereria bancrofti</i>	Filariasis, elephantiasis	Lymphatics
		<i>Enterobius vermicularis</i> (pinworm)	Pinworm infection	Intestines
		<i>Strongyloides stercoralis</i> (threadworm)	Strongyloidiasis	Intestinal parasite, skin infection
		<i>Onchocerca volvulus</i>	Onchocerciasis	Blindness, dermatitis

* Most common in the United States.

Mechanisms of Parasite Invasion and Tissue Destruction

Parasite Invasion.

Parasite invasion of tissue can be broadly characterized as by extracellular or intracellular mechanisms. There is considerable variation within both mechanisms because of complex life cycles, means of transmission, and unique adaptations among parasites. A common component of invasion is adherence to and breakdown of connective tissue and basement membranes.

Helminths may infect the gastrointestinal tract or enter through the skin. An example is *Schistosoma mansoni*, a blood fluke infection where the aquatic larval form attaches to and penetrates the skin using a family of proteases that degrade elastin and other skin components. After entering the circulatory system, the parasite may burrow into other organs.

Extracellular parasites enter through the gastrointestinal tract (e.g., *Entamoeba histolytica*, *Giardia lamblia*), the vagina as STIs (*Trichomonas vaginalis*), or through the skin in bites (*Trypanosoma brucei*). After attachment to the lining of the gastrointestinal tract or vagina, extracellular parasites undergo evolution to more invasive forms.

Most intracellular protozoan parasites can only reproduce within host cells and are therefore **obligatory intracellular parasites**. These include *Leishmania* spp. (leishmaniasis causing ulcers of skin and

internal organs), *Toxoplasma gondii* (toxoplasmosis with possible latent infection of the brain and eye), *Cryptosporidium parvum* (cryptosporidiosis causing watery diarrhea), and *Plasmodium* spp. (malaria). Infections are obtained by ingestion of contaminated food or water or through bites from insect vectors. Invasion is mediated by adhesion to lectins on cells near the site of infection and invasion of the tissue using a host of proteases and other enzymes. Very soon these protozoa invade cells (i.e., fibroblasts, mesenchymal cells) or undergo phagocytosis (i.e., macrophages) where reproduction occurs resulting in progressive cell lysis and spread to neighboring cells.

Toxins and Parasite Products.

Toxins are not as prevalent in the pathogenesis of parasitic diseases as in bacterial diseases. *C. parvum* produces hemolysin H4, which is very similar to *E. coli* O157:H7 and disrupts cell membranes. *E. histolytica* produces a small-molecular weight pore-forming toxin (amoebapore) that inserts pores into the membrane of intestinal cells resulting in increased calcium influx, efflux of water, and diarrhea. Endotoxin is normally associated with gram-negative bacteria, but similar molecules are produced by African trypanosomes and *Plasmodium falciparum* (most severe form of malaria).

Most of the tissue damage caused by parasites is secondary to the release of enzymes such as proteases and phospholipases. These enzymes help invasion by destroying surrounding extracellular matrix and tissue.

Destructive Immune and Inflammatory Responses to Parasite Infection.

Because of their size, tissue damage caused by large multicellular parasites is generally a direct result of parasitic accumulation in the tissue or secondary to the individual's immune and inflammatory responses. Large infestations may lead to physical loss of function in a tissue or organ. For instance, a large number of intestinal parasites (e.g., the roundworm *Ascaris lumbricoides*, tapeworms, and *Giardia* spp.) compete for and prevent uptake of nutrients, leading to various

forms of malabsorption, blocked uptake of fats, or anemia from malabsorption of B₁₂, or from large amounts of blood loss. Some roundworms (e.g., *Wuchereria bancrofti* and *Brugia malayi*) block the lymphatics and cause accumulation of large amounts of lymph in tissues (i.e., elephantiasis). The larvae of tapeworms (e.g., *Taenia solium*) encyst in and prevent normal function of organs (e.g., muscle, liver, eye), which is particularly dangerous in the human brain.

Parasitic infections may also damage tissue through exacerbated inflammation or initiation of immune hypersensitivity reactions. *C. parvum* induces considerable release of proinflammatory cytokines from epithelial cells, inducing influx of inflammatory cells and increased tissue destruction. Ascaris larvae migrate to bronchi causing pulmonary inflammation. IgE-mediated anaphylactic responses have been observed associated with infections with helminths and African trypanosomes. Helminth parasites (e.g., schistosomiasis) may deposit eggs in organs (e.g., the liver) leading to a chronic cell-mediated response and persistent production of proinflammatory cytokines with formation of granulomas. Rapid progression is not used as a protective mechanism for parasites.

Parasite Protection Against Phagocytosis and Intracellular Destruction.

Several parasites (*Leishmania* spp.) are obligative intracellular organisms of monocytes and macrophages. *Leishmania* uses components of the complement system for entrance into macrophages. Once in the macrophage, several mechanisms are used to facilitate survival of parasites. *T. gondii* produces toxins that prevent phagosome-lysosome fusion so that the environment in the phagosome remains relatively nontoxic. *E. histolytica* (amoebiasis) releases phospholipase and pore-forming proteins that disrupt the phagocyte's plasma membrane. *T. cruzi* (Chagas disease, sleeping sickness) escapes from the phagosome and grows in the macrophage cytoplasm. *Leishmania* reproduces within phagocytic cells and inhibits respiratory burst and chemotaxis.

Blocking Recognition of Parasitic Antigens.

Pathogens that coat themselves with human proteins may be disguised and “fool” the immune system. For instance, schistosomes and trypanosomes mask their antigens by absorbing IgG by the Fc portion of the molecule.

Much more commonly, those pathogens that undergo part of their life cycle in humans, or may assume multiple morphologic forms during infection, also will undergo antigenic changes related to the stage in the life cycle or morphology. Some protozoa have developed very complex alterations in surface antigens using **gene switching**. For example, African trypanosomes, carried by tsetse flies, can vary the structure of their antigenic coat (variant surface glycoproteins) using gene switching thus allowing them to be protected from immune defenses. Newly produced antibodies will not recognize the variant antigen coat allowing the trypanosome to survive.

Parasite Blocking of the Immune Response.

Parasites use an array of mechanisms to block protective immune responses including: (1) secretion of enzymes that degrade immunoglobulins (schistosomes); (2) inactivation of complement (e.g. *Echinococcus* spp., *Leishmania* spp. and trypanosomes); (3) prevention of antigen processing by macrophages (*Leishmania*); (4) inhibition of complement mediated phagocyte chemotaxis (*E. hisolytica*); and (5) inhibition of T-cell function (schistosomes). These responses may be pathogen specific or non-specific.

Malaria, a plasmodium parasite, has been very successful at mounting immune defenses and is a significant cause of morbidity and mortality throughout the world. Details related to malaria are presented in [Box 10.4](#).

Box 10.4

Parasitic Pathogenesis: *Plasmodium* and Malaria

Malaria is one of the most common debilitating infections worldwide. The WHO estimated that in 2015 there were 214 million new cases of malaria worldwide and more than 400,000 malaria-related deaths, more than 90% occurring in Africa, and most of whom were children.¹ Malaria is caused by five species of *Plasmodium* parasites that infect humans (*P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, *P. knowlesi* [a simian parasite that causes human malaria primarily in Malaysia]), although two species account for the most cases and deaths.² *Plasmodium falciparum* is the most prevalent in Africa and accounts for most fatalities. Infection results in severe chills, high fever, sweating, headache, muscle pains, vomiting, severe anemia, and pulmonary edema. Neurologic complications may result from infected red blood cells (RBCs) adhering to endothelium in capillaries of the brain causing hypoxia and degradation of neural tissue.³ The most severely affected individuals may develop cardiovascular collapse, shock, coma, and death. *P. vivax* is the primary cause of malaria outside of Africa. Symptoms are severe flulike in nature and with less morbidity and mortality than observed with *P. falciparum*. All forms of malaria are characterized by paroxysm (cyclic chills followed by fever). Cycles range from every 2 days for *P. vivax* to 36 hours for *P. falciparum*.

The life cycle of *Plasmodium* requires two hosts: mosquito and human. The parasite undergoes a sexual reproductive cycle in the salivary gland of the female *Anopheles* mosquito and is transmitted to humans during a blood meal. The infectious form (sporozoite) enters the tissue and migrates to the bloodstream. The sporozoite has the capacity to traverse through cells in the tissue, mediated by a variety of parasitic proteins that bind to specific substance on the cell surface and facilitate entry.⁴

The parasite enters hepatocytes using sporozoite proteins that bind to sulfated molecules on endothelial cells and Kupffer cells. Protection against malaria may occur by means of stage-specific immune responses against different phases of the life cycle: invasive stage, hepatic stage, pre-erythrocyte stage, erythrocyte stage, and sexual stages. Phagocytic cells, like Kupffer cells, are the primary

means of protection against the prehepatic invasive stage and hepatic stage. Traversal of phagocytic cells results in modulation of the cell's cytokine profile, causing downregulation of proinflammatory cytokines (e.g., IL-6, TNF- α) and upregulation of antiinflammatory cytokines (e.g., IL-10), blocked production of reactive oxygen species, and reduced expression of class I MHC to suppress antigen presentation.⁵ The parasite in the blood avoids destruction by phagocytes in the spleen by expressing adhesion proteins that cause adherence and sequestration along the walls of the small vessels.

Sequestration in the liver begins an asymptomatic stage during which several rounds of multiplication occur. *P. vivax* and *P. ovale* can remain dormant in the liver for years, protected from the immune system by intracellular residence. In the hepatocytes, the parasites transform to the merozoite form, thousands of which are released into the blood during hepatocyte rupture and infect erythrocytes.

The blood-borne phase and infection of erythrocytes begin the symptomatic stage of the disease (see [Figure](#)). *P. falciparum* uses a variety of parasite surface proteins (e.g., merozoite surface protein-1 [MSP-1]) for adhesion to erythrocyte membrane glycoproteins and entrance into the cell.⁶ *P. vivax* seems to use the erythrocyte Duffy antigen for adhesion. Thus individuals who are negative for the Duffy blood group antigen are naturally resistant to *P. vivax* malaria.

Symptoms of malaria occur after an approximate 2-week period from the initial mosquito bite and are the result of asexual multiplication in the erythrocytes and cell lysis upon the release of daughter parasites that reinfect other erythrocytes. During this erythrocytic cycle, the merozoites mature into male and female gametocytes within the erythrocyte, which after another blood meal can establish another cycle of further sexual multiplication in the mosquito vector. The erythrocytic cycle will resolve, but many relapses will occur upon new cycles of merozoite release from infected hepatocytes.

During the erythrocytic cycle, the infected individual produces protective antibodies against antigens expressed on the surface of infected erythrocytes. *Plasmodium* expresses several families of antigens on the erythrocyte's surface and uses antigen variation through gene switching diversity to mitigate the effects of antibody.

Other antigen-directed responses contribute to protection of the parasite. Antibodies against *P. falciparum* asparagine-rich protein enhance merozoite invasion of erythrocytes, which is further facilitated by the addition of complement. The PfEMP1 antigen also can protect the infected erythrocyte by epitope masking. The antigen contains Fc binding sites where IgM antibody, regardless of specificity, is bound by its Fc region, thus masking the PfEMP1 epitopes. Parasites also can bind complement regulator factor, factor H, which protects the parasite from damage by activated complement factors.

Malarial infection also may induce immune suppression by inhibiting macrophage and dendritic cell phagocytosis, as well as inducing apoptosis of antigen-presenting cells. Phagocytic cell function is diminished by a malarial pigment (hemozoin), which is taken up and reduces the ability to phagocytize merozoites or infected erythrocytes. Numbers of CD4 and CD8 T-cells are diminished by apoptosis combined with induction of immunosuppressive Treg cells.

Malarial parasites have developed broad drug resistance including against chloroquine, the previous mainstay of the preventive and therapeutic arsenal of antimalarial drugs. Drug resistance appears to result from increased activity of drug transporters that eliminate the drugs from the parasitic microorganism.

Infectious Viruses

Viruses are extremely simple microorganisms and do not possess any of the metabolic organelles found in prokaryotes (e.g., bacteria) or eukaryotes (e.g., human cells). The basic viral structure (virion) consists of nucleic acid protected by a protein shell, the capsid. The

capsid may take many characteristic shapes: helical, icosahedral, or large pleomorphic (Fig. 10.6). Some viruses also have the capsid surrounded by a protective envelope, which consists of the plasma membrane from the previously infected cell.

FIGURE 10.6 Electron Micrographs of Representative Viral Structures. A, Rotavirus: particles with a double shell and a characteristic “wheel-and-spoke” appearance. B, Epstein-Barr virus: icosahedral enveloped DNA virus. C, Adenovirus: particles with characteristic icosahedral structures. D, Paramyxovirus: spherical enveloped RNA virus. RNA is seen spilling out of the disrupted virus. (A from Long S, Pickering L, Prober C: *Principles and practice of pediatric infectious diseases*, ed 3, Philadelphia, 2005, Saunders; B and D photos courtesy Science Source; © Photo Researchers, Inc., New York, NY; C from Mandell GL, Bennett JE, Dolin R: *Mandell, Douglas, and Bennett’s principles and practice of infectious diseases*, ed 7, Philadelphia, 2010, Churchill Livingstone.)

Viruses are classified by the format of nucleic acid in the virion, which may be RNA or DNA and either single-stranded (ss) or double-stranded (ds), and by whether the virus uses the enzyme reverse

transcriptase (RT) for replication. Thus seven classifications are used: dsDNA (e.g., herpesvirus, smallpox virus), ssDNA (parvovirus), dsRNA (rotavirus), ssRNA +sense (+sense functions as mRNA) (e.g., hepatitis A and C viruses, SARS virus, poliovirus, rhinovirus), ssRNA –sense (e.g., Ebola virus, Marburg virus, influenza virus, hantavirus, Lassa virus, and viruses that cause measles, mumps, and rabies), ssRNA +sense with RT (e.g., HIV), and dsDNA with RT (e.g., hepatitis B virus).

Viral diseases are the most common afflictions of humans. Examples of human diseases caused by specific viruses are listed in [Table 10.6](#).

TABLE 10.6

HUMAN DISEASES CAUSED BY SPECIFIC VIRUSES

BALTIMORE CLASSIFICATION	FAMILY	VIRUS	ENVELOPE	MAIN ROUTE OF TRANSMISSION
dsDNA	Adenoviruses	Adenovirus	No	Droplet contact
	Herpesviruses	HSV-1	Yes	Direct contact with saliva or lesions
		HSV-2	Yes	Sexually, contact with lesions during birth
		HSV-8	Yes	Saliva and genital body fluids
		Epstein-Barr virus (EBV), HSV-4	Yes	Saliva
		Cytomegalovirus (CMV), HSV-5	Yes	Body fluids, mother's milk, transplacental
		Varicella-zoster virus (VZV)	Yes	Droplet contact
ssDNA	Papovaviruses	Papillomavirus	No	Direct contact

dsRNA	Reoviruses	Rotavirus	No	Fecal-oral
ssRNA+	Picornaviruses	Coxsackievirus	No	Fecal-oral, droplet contact
		Hepatitis A virus	No	Fecal-oral
		Poliovirus	No	Fecal-oral
		Rhinovirus	No	Droplet contact
	Flaviviruses	Hepatitis C virus	Yes	Blood, sexually
		Yellow fever virus	Yes	Mosquito vector
		Dengue virus	Yes	Mosquito vector
		West Nile virus	Yes	Mosquito vector
	Togaviruses	Rubella virus	Yes	Droplet contact, transplacental
	Coronaviruses	SARS	Yes	Droplets in aerosol or direct contact
	Caliciviruses	Norovirus	No	Fecal-oral
ssRNA-	Orthomyxoviruses	Influenza virus	Yes	Droplet contact
	Paramyxoviruses	Measles virus	Yes	Droplet contact
		Mumps virus	Yes	Droplet contact
		Parainfluenza virus	Yes	Droplet contact
		Respiratory syncytial virus (RSV)	Yes	Droplet contact, hand-to-mouth
	Rhabdoviruses	Rabies virus	Yes	Animal bite, droplet contact
	Bunyaviruses	Hantavirus	Yes	Aerosolized animal fecal material
	Filoviruses	Ebola virus	Yes	Direct contact with body fluids
		Marburg virus	Yes	Direct contact with body fluids

	Arenavirus	Lassa virus	Yes	Aerosolized animal fecal material
ssRNA+ with RT	Retroviruses	HIV	Yes	Sexually, blood products
dsDNA with RT	Hepadnaviruses	Hepatitis B virus	Yes	All body fluids

AIDS, Acquired immunodeficiency syndrome; *DNA*, deoxyribonucleic acid; *ds*, double-stranded; *HIV*, human immunodeficiency virus; *HSV*, herpes simplex virus; *RNA*, ribonucleic acid; *RT*, reverse transcriptase; *SARS*, severe acute respiratory syndrome; *ss*, single-stranded.

Mechanisms of Invasion and Tissue Destruction

Viral Invasion.

Viral pathogens directly destroy or damage cells as part of their replication in infected cells. Viruses are obligatory intracellular microorganisms; thus transmission is frequently from one infected cell to an uninfected cell. The viral life cycle involves several steps: *attachment* to the target cell (determines host range and tropism), *penetration* (by endocytosis or membrane fusion), *uncoating* (release of viral nucleic acid from the viral capsid by viral or host enzymes), replication (synthesis of viral proteins and mRNA), *assembly* (formation of new virions), and *release* (by lysis or budding).

Attachment involves specific interactions between surface proteins on the virus and receptors on the cell to be infected. The specificity of the virus for these receptors and the distribution of receptors throughout the individual's tissues dictate the range of host cells that a particular virus can infect. An example is Epstein-Barr virus (EBV, which causes mononucleosis) binds to complement receptor 2 (CR2) on B lymphocytes. Once bound, the virion penetrates the plasma membrane by envelope fusion with cellular membranes or receptor-mediated endocytosis (Fig. 10.7).

A

B

C

FIGURE 10.7 Stages of Viral Entrance during Infection of a Cell. The viral life cycle includes 1, attachment; 2, uncoating; 3, replication; and 4, release. Viral entrance into a cell is by one of three mechanisms. **A**, Some enveloped viruses (e.g., HIV) express fusion proteins that (1) bind to receptors on the target cell and (2) mediate membrane fusion and release of the viral nucleocapsid directly into the cytoplasm. (3) Within the cytoplasm the virus uncoats the protective nucleocapsid and releases viral nucleic acid and (4) release by exocytosis. **B**, Other enveloped viruses (e.g., influenza virus) (1) bind to receptors that trigger (2) receptor-mediated endocytosis of the virion particle. (3) The endosome fuses with lysosomes. The relative acidic conditions in the endosome trigger membrane fusion, formation of fusion pores, breakdown of the capsid, and (4) release of viral nucleic acid into the cytoplasm. **C**, Viral particles without an envelope (e.g., poliovirus) (1) express viral spikes that bind to the cell membrane and (2) initiate receptor-mediated endocytosis of the viral particle. (3) The acidic conditions in the endosome cause capsid breakdown and formation of pores in the endosomal membrane through which viral nucleic acid enters the cytoplasm and (4) release of virus.

Most RNA viruses directly produce mRNA, which is translated into viral proteins, and genomic RNA, which is eventually packaged into new viruses. DNA viruses are transcribed in the nucleus into mRNA before protein translation in the cytoplasm. Some viruses can enter a period of latency during which production of a new virus ceases with concurrent resolution of disease symptoms. One particular family of viruses, retroviruses (e.g., HIV), carries the enzyme *reverse transcriptase* that creates a double-stranded DNA provirus that integrates into the host cell's chromosomal DNA, and may be transmitted to the daughter cells during mitosis. By this process, viral genes can become part of the genetic information of the cell and its progeny. Insertion into the DNA is random. If viral DNA is inserted at a nonessential site the cell may be unaffected, if into an essential gene the cell may undergo death, and if insertion modifies genes related to normal growth the cell may be transformed (become cancerous). Episomal latency is associated with viral genes outside the cell DNA (*episome*), in a linear or circular conformation, either in the cytoplasm or in the nucleus. Episomal latency is characteristic of herpesviruses (e.g., HSV-1 and 2, EBV). Latency must be actively maintained by *latency-associated transcript (LAT)* genes that inhibit apoptosis. The infected cell will remain functional, and the virus will remain dormant until activated. HSV1 (herpes simplex) is latent as a circular double-

stranded DNA in the nuclei of peripheral neurons and may be reactivated to a lytic cycle in response to stress, sunlight, diet, or other events.²⁰ Reactivation results in shedding of virions from nerves into the mucosa of the mouth or genitals.

At the end of the replicate phase, new virus particles are released from the cell for transmission of the viral infection to neighboring uninfected cells. The method of release depends on the particular virus. Enveloped viruses are released through *budding*, in which shed viral particles are enveloped in the plasma membrane from the surface of the infected cell. Viral envelope proteins are inserted into the membrane and cluster at sites of budding. Translation of viral-specific mRNA produces capsid and matrix proteins that assemble and incorporate viral nucleic acid. Budding is not immediately destructive to the cell, whereas nonenveloped viruses are commonly released in large numbers concurrent with the destruction of the cell. Some viruses induce a progressive apoptosis during which virions are packaged in apoptotic vesicles. The vesicles are portions of the plasma membrane released from the dying cell. Vesicles will break down and release virions into the surrounding environment. Apoptotic vesicles also may undergo phagocytosis by macrophages and establish infections (e.g., HIV) in the macrophage. Other viruses are released by exocytosis, during which the cell may not be destroyed. New viral particles in the cytoplasm are packaged in vesicles, transported to the cell surface, and released. This process is generally used by nonenvelope viruses.

Toxins and Viral Products.

Generally, viruses rarely produce toxins or other destructive products that cause tissue damage. The products of viral genes are directed toward adherence to target cells, providing components of the reproductive cycle, and evasion of immune and inflammatory responses. Some products that are important to the viral life cycle may therefore indirectly lead to cellular destruction. An exception to the rarity of viral toxins is the rotavirus nonstructural protein (NSP4). NSP4 is an enterotoxin that affects intracellular calcium levels in

intestinal cells resulting in water efflux and diarrhea, particularly in infants and children.

Destructive Immune and Inflammatory Responses to Viral Infection.

Most of the symptoms of viral infection (e.g., fever, aches, nausea) are generally mild, caused by the individual's own inflammatory response to infection, and usually resolve in a relatively short time. More severe local cellular effects may result from destruction of infected cells by lymphocytes. The dermal and ocular lesions of HSV infection result from T-cell mediated cytotoxicity of infected epithelial cells. A Th2 cell response is primarily responsible for severe respiratory syncytial virus related lesions in the lower respiratory tract (see [Chapter 8](#)). Many viruses induce excessive production of proinflammatory cytokines (e.g., IL-1, IL-2, IL-6, and many more), mediators (e.g., prostaglandins, histamines), and reactive oxygen species, all of which contribute to tissue damage.

Hepatitis viruses provoke immune and inflammatory responses that may damage infected and noninfected hepatic cells. Hepatitis A (HAV) and hepatitis B (HBV) viruses may cause acute liver damage, whereas hepatitis C (HCV) virus infection is usually subclinical with no apparent liver damage. The degree of T cell infiltration of the liver is related to the degree of liver pathology. CD8-positive T-cytotoxic cells attack and destroy virus-infected liver cells (see [Chapter 8](#)). HBV and HCV activate Th17 cells that contribute to inflammation of the liver. Individuals with high amounts of circulating viral antigen (e.g., hepatitis B) are at risk for developing symptoms of type III hypersensitivity reactions including kidney disease and vascular inflammation (see [Chapter 9](#)).

Viral Evasion of Immune and Inflammatory Systems

Rapid Progression of Viruses.

Some viruses, particularly those with small genomes, rapidly proliferate after the initial infection and produce a large number of

virions more quickly than the immune system can develop. By the development of an effective adaptive immune response in 4 or 5 days, the virus has spread and caused severe clinical disease.

Viral Protection Against Phagocytosis and Intracellular Destruction.

Viruses are the prime examples of intercellular survival. As obligatory intracellular pathogens, viruses hide and proliferate within cells and away from normal inflammatory or immune responses. Viral particles that spread through the blood to infect other cells encounter antibodies, which in most cases cure the infection. Thus most viral infections are self-limiting.

Interferons are particularly effective against many viral infections, and viral survival mechanisms have evolved to mitigate these effects.

A great many viruses have developed methods of blocking every step of type I interferon cascade, thus preventing production of IFN1 by infected cells and induction of antiviral substances in neighboring cells.

Viruses encounter intracellular PRRs designed to bind viral substances and initiate protective innate responses (discussed in [Chapter 7](#)). Successful viral pathogens have developed mechanisms to either block TLR recognition of viral substances or prevent TLR signaling.

Blocking Recognition of Viral Antigens.

Enveloped viruses are excellent examples of how this mechanism may succeed. The viral capsid is completely surrounded by a cellular plasma membrane that is highly similar to that of an uninfected cell. Only a few critical differences exist. In order to infect another cell, the virion expresses membrane-associated viral envelope proteins that are critical for the intercellular fusion process. These proteins are virus-specific and targets for protective immune responses. Other viruses, such as the HCV, coat themselves with normal proteins from the infected host, such as lipoproteins, that mask the viral epitopes from circulating antibody.

Some viruses (e.g., HIV) increase antigenic diversity by incorporating frequent functional translational errors. Viral enzymes can create small errors in reading mRNA leading to minor changes in the viral proteins. These changes are not at functionally critical sites but may provide resistance to specific and nonspecific defense mechanisms. In a manner similar to bacteria, other viruses have multiple stable antigenic serotypes. A person who recovers from an infection with one serotype may not have protective immunity against other serotypes of the same virus. At least 100 different serotypes of rhinovirus can cause the “common cold,” which explains why individuals can catch many colds throughout their lives.

Blocking the Immune Response to Viral Infection.

HIV and other viruses have developed the capacity to infect and kill immune cells, thus protecting themselves but also leading to a broad immunosuppression against other antigens. This process is discussed more thoroughly in the section on AIDS.

Some viruses have developed mechanisms for interfering with antigen processing and presentation by major histocompatibility complex (MHC) class I molecules. Endogenous antigens, such as viral antigens, are normally degraded by proteasomes, transported into the endoplasmic reticulum, and complexed with MHC class I molecules for expression on the cell surface and presentation to appropriate cells of the immune response (see [Chapter 8](#)). Many of the herpesviruses and retroviruses prevent steps in this process. For instance, EBV inhibits degradation by the proteasomes. HSV can prevent binding of the antigenic peptide to MHC class I. Inhibition of antigen presentation by MHC class I prevents the generation of effective T-cell immune responses.

CMV has developed a unique modification of affecting MHC processing. Natural killer (NK) cells are the principal defenders against tumor cells or virally infected cells that are not recognized by T-cytotoxic cells because of downregulated MHC expression. NK cell function is suppressed, however, if the infected cell expresses class I MHC molecules. CMV is capable of preventing antigen presentation

by MHC class I and stimulates the expression of a MHC-like molecule that cannot present antigen but suppresses NK cells. Thus CMV-infected cells are protected from both T-cytotoxic cells and NK cell killing.

Some viruses also have the capacity to produce molecules that mimic cytokines or their ligands and neutralize the effects of cytokines, such as IL-1 and TNF- α . Cells infected with vaccinia virus (the less virulent vaccine relative of smallpox virus) produce a protein that can bind to IL-1. These molecules are frequently called *cytokine decoys*.

Viruses are sensitive to complement activation. Protection can be provided by incorporation of complement inhibitors into the envelope (e.g., HIV and vaccinia). CMV induces complement inhibitors on the surface of infected cells. HSV expresses a cell surface protein (glycoprotein C-1) that binds and inhibits C3b, as well as blocks formation of the membrane attack complex.

Influenza viruses causes significant seasonal epidemics throughout the world. [Box 10.5](#) reviews the pathogenesis of influenza.

Box 10.5

The Pathogenesis of Influenza

Influenza is an ssRNA (-strand) virus with a segmented genome. It is transmitted through aerosols or body fluids and is highly infectious. The virions attach to and enter respiratory epithelial cells. Symptoms begin 1 to 4 days after infection and may include chills, fever, sore throat, muscle aches, severe headaches, coughing, weakness, and generalized discomfort. Nausea and vomiting may occur in children. Infection may lead to viral pneumonia or secondary bacterial pneumonia, both of which can be fatal, particularly in young children and older adults. The normal rate of infectivity is about 5% to 15%, with a mortality rate of about 0.1%, and in most cases recovery occurs in 1 to 2 weeks.

The influenza virion is enveloped and expresses two surface proteins that are essential to virulence: hemagglutinin (HA) and

neuraminidase (NA). The HA is a glycoprotein that binds to the carbohydrate sialic acid which is richly expressed on the surface of respiratory epithelium. The HA molecule is cut by a human protease, thus signaling a process of endocytosis that internalizes the virus into an endosomal vacuole.¹ The endosomal vacuole is acidic (about pH 5), which initiates HA-dependent fusion between the viral envelope and endosomal membrane.² The viral core disassembles and releases viral RNA (vRNA) and core proteins into the cytoplasm. The virion carries an RNA-dependent RNA polymerase that transcribes the vRNA into +strand ssRNA copies that are used to produce more vRNA. Viral proteins are translated and new HA and NA molecules are inserted into the plasma membrane and cluster. Copies of vRNA and capsid proteins are assembled underneath the HA and NA clusters and begin the budding process. HAs on the budding virus remain attached to surface glycans; new virions must be released by the action of the neuraminidase (NA) that cuts the sialic acid. Thus HA is essential for entrance and NA is essential for release of new virions. The infected cell usually dies during this process.

Antibodies against the HA and NA antigens are responsible for protection against influenza infection. Infections are seasonal and protection gained from the previous year's infection is partial and does not totally protect against influenza in the following year because the HA and NA antigens undergo yearly change. Usually antigenic variation is relatively minor (**antigenic drift**) and results from mutations. Yearly revaccination is necessary to produce immunity against changes resulting from antigenic drift. Two major groups of influenza virus, influenza A and influenza B, infect humans and both undergo drift. Influenza A and influenza B contain 8 RNA segments that encode at least 10 proteins. Influenza A infects birds and some mammals. Influenza B infects mostly humans and seals and undergoes antigenic drift much more slowly than influenza A.

Several major variants of HA (18 forms, numbered 1–18) and NA (11 forms, numbered 1–11) have been identified for influenza A.

One particular viral strain will express a single HA and a single NA. The particular HA and NA variant being expressed becomes part of the nomenclature of the particular yearly viral strains (e.g. strain H3N2), important for the development of yearly vaccines.

Influenza A periodically undergoes major antigenic changes (**antigenic shifts**) (see [Figure](#)). Shifts occur in animals coinfecting by a human and an avian strain of influenza. Because the genome is segmented, the segments can undergo recombination during which the human virus obtains a new HA or NA antigen. When such changes occur, previous protective antibodies may not be effective, resulting in a major pandemic and more severe disease.

As with most vaccines, not everyone is protected. Research is in progress to induce protective antibody responses against common surface antigens shared by genetically diverse influenza viruses thus providing a long lasting protection.

Pharmacologic therapy may lessen the severity of symptoms. Competitive neuraminidase inhibitors, such as oseltamivir (Tamiflu), bind to NA and inhibit enzymatic activity, thus preventing spread of the virions between cells. If the NA mutates, the drugs may lose inhibitory capacity, which may explain observations of the rapid development of drug resistance.

Several variables affect the pathophysiology of influenza infections. Less aggressive strains primarily infect epithelium lining the upper respiratory tract. The proliferation of virus within infected cells results in tissue damage far in excess to what is seen with cold viruses. More aggressive strains can infect cells that are deeper in the lungs and produce even more tissue damage. The differences are related somewhat to the particular HA antigen expressed on the virus. The HA normally binds to α 2-6 sialylated glycans in the upper respiratory tract. The highly pathogenic H5N1 influenza virus binds to upper respiratory tract cells and also to α 2-3 sialylated glycans on pneumocytes (cells lining the alveoli of the lungs) leading to severe pneumonia.

Influenza has several virulence factors that contribute to the pathophysiology. All influenza strains can inhibit the innate

antiviral interferon response. The influenza ssRNA is recognized by intracellular pattern recognition receptors (PRRs), such as Toll-like receptor-7 (TLR7) which induce the production of antiviral type I interferons (IFNs).

The primary difference between strains of low or high pathogenicity is the intensity of cytokine and chemokine production. Tissue damage typically attracts macrophages that induce apoptosis of epithelial cells, thus increasing the amount of damage. The more pathogenic viruses induce more tissue damage and a level of cytokine and chemokine production that is referred to as a *cytokine storm*. Pulmonary damage is greatly exacerbated, resulting in diffuse alveolar damage, hyaline membrane formation, and fibrin deposition, all of which may lead to respiratory failure. Systemic cytokine levels are greatly elevated, resulting in multiorgan dysfunction. The unexpectedly large number of deaths in the 20 to 39 age group during the 1918 influenza pandemic appeared to be related to an excessive number of neutrophils attracted to the lungs and to an intense cytokine storm reflecting their healthy and highly responsive immune systems.

FIGURE Antigenic Shifts in Influenza Virus. One theory proposes that antigenic shifts occur when a human influenza virus (*blue*) and an avian influenza virus (*red*) co-infect a species that is permissive for both. The eight ssRNA strands are coexpressed in the same infected cell, resulting in mixing of the strands so that a hybrid virus can be produced. The hybrid virus indicated here contains all the genetic information of the original virus that infected humans, but contains a new hemagglutinin (HA)-containing strand from the avian virus. This virus expresses a new

HA antigen and will be less susceptible to residual immunity that normally provides partial protection against yearly influenza infections. *M*, Matrix (M1) and membrane protein (M2); *NA*, neuramidase; *NP*, nucleoprotein; *NS*, nucleotide sequences; *PA*, polymerase acidic protein; *PB1*, polymerase basic protein 1; *PB2*, polymerase basic protein 2.

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Acquired Immunodeficiency Syndrome

The most notable form of secondary or acquired immune deficiency is caused by the human immunodeficiency virus (HIV). HIV causes **acquired immunodeficiency syndrome (AIDS)**. HIV is a retrovirus that infects and depletes a portion of the immune system (CD4+ Th cells), making individuals extremely susceptible to life-threatening infections and malignancies ([Fig. 10.8](#)).

FIGURE 10.8 Clinical Symptoms of AIDS. A, Severe weight loss and anorexia. B, Biopsy-proven Kaposi sarcoma lesions. C, Perianal vesicular and ulcerative lesions of herpes simplex infection. D, Deterioration of vision from cytomegalovirus retinitis leading to areas of infection; unless treated, the progressive impairment will lead to blindness. (A and D from Taylor PK: *Diagnostic picture tests in sexually transmitted diseases*, London, 1995, Mosby; B and C from Morse SA, Holmes KK, Ballard RC, editors: *Atlas of sexually transmitted diseases and AIDS*, ed 4, London, 2011, Saunders.)

When AIDS was recognized as a major health epidemic in sub-Saharan Africa and in the United States in the early 1980s, an AIDS diagnosis was considered a death sentence, with a near 100% mortality rate within 2 years of the diagnosis of AIDS. With the advent of aggressive treatment with antiretroviral drugs in the mid-1990s and widespread public health campaigns, HIV/AIDS has become a chronic and manageable illness with many infected individuals having a near normal life span. Currently, about half of the 18 million individuals living with HIV/AIDS in Africa are being

administered antiretroviral drugs.²¹ As yet, however, antiviral medications are not fully available at an affordable price in many parts of the world where HIV/AIDS remains the major cause of morbidity and mortality.

The transmission of HIV in Africa is predominantly heterosexual, whereas the distribution of individuals with HIV/AIDS in the United States reflects the primary means of transmission within the original cohort. Although isolated cases of what was later identified as AIDS occurred in the United States as early as 1959, the appearance of the AIDS epidemic has been linked to several gay males who had contracted HIV infection during visits to the Caribbean, probably Haiti.²² Initial reports of outbreaks in the United States were of gay men who developed *Pneumocystis carinii* pneumonia²³ and aggressive Kaposi sarcoma,²⁴ both of which were uncommon and mostly observed in immune-deficient individuals. The epidemic then spread to intravenous drug abusers and heterosexuals. In 2014 (the latest available statistics) 44,073 men and women were newly diagnosed with HIV infection with gay or bisexual men representing 67% of all individuals and 83% newly diagnosed men.²⁵ Women represented 19% of newly diagnosed individuals with 87% of women contracting HIV through heterosexual encounters. As a result of aggressive antiretroviral therapy and public education, the transmission to women had declined by about 40% over the previous decade. About 6% of all individuals newly diagnosed with HIV were associated with intravenous drug abuse. In 2015, 18,303 people were diagnosed with AIDS, and since the early 1980s, 1,216,917 people have been diagnosed with AIDS. In 2014, 6721 deaths were attributed directly to HIV infection. An estimated 650,000 individuals with a diagnosis of AIDS have died since the early 1980s.

Transmission of HIV

HIV is a blood-borne pathogen present in body fluids with the typical routes of transmission: blood or blood products, intravenous drug abuse, heterosexual and homosexual activity, and maternal-child transmission before or during birth. The CDC estimates that 91% of

new HIV infections in the United States result from sexual activity with those who are undiagnosed or diagnosed but not treated for HIV infection.

As with all blood-borne infections, healthcare providers are at increased risk of contracting the infection from an individual's blood. Since the strict implementation of universal precautions and the use of post-exposure prophylaxis with antiretroviral drugs, infection of healthcare providers is extremely rare.

Pathogenesis of HIV

HIV-1 was initially isolated by researchers at the Pasteur Institute as the lymphadenopathy/AIDS virus (LAV), a discovery for which they received the 2008 Nobel Prize in Medicine.²⁶ A second major and less virulent variant, HIV-2, was identified later and is found mostly in western Africa. HIV is a member of the retrovirus family, which carries genetic information in the form of two identical copies of single-stranded RNA (Fig. 10.9 see the genetic map of HIV-1, Fig. E 10.1 on Evolve). The RNA copies are packaged in the viral particle within a capsid constructed of viral capsid protein p24. The capsid also contains two viral enzymes: reverse transcriptase and integrase. Retroviral particles are contained in a plasma membrane envelope originating during release from the infected cell. The membrane contains two viral proteins (gp41 and gp120), referred to as envelope proteins. Between the envelope and capsid are viral matrix proteins underlying the envelope and another viral enzyme, a protease.

FIGURE 10.9 HIV-1: Structure. The HIV-1 virion consists of a core of two identical strands of viral RNA molecules, three viral enzymes (integrase [IN], protease [PR], and reverse transcriptase [RT]) and a capsid. The capsid is further encased in a matrix consisting primarily of a viral protein. The outer surface is an envelope consisting of the plasma membrane of the cell from which the virus budded (lipid bilayer) and two viral glycoproteins: a transmembrane gp41 and a noncovalently attached surface protein, gp120. (Modified from Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

As with all other viruses, the life cycle must begin with attachment and entrance into its cellular target. HIV is primarily tropic for CD4+ T-helper cells, although macrophages and dendritic cells also express CD4 and can be infected. Attachment occurs between the viral envelope proteins and CD4 (Fig. 10.10). The envelope protein gp41 is anchored in the plasma membrane and is referred to as the TM (transmembrane) protein. The N-terminal portion of TM consists of very hydrophobic amino acids. The TM associates with a gp120 envelope protein, called the SU (surface protein), which contains binding sites for CD4. When the SU protein attaches to CD4, it undergoes a conformational change that allows further recognition of cell surface chemokine receptors, primarily CCR5, and exposure of the TM hydrophobic tail, which interacts with the lipid region of the T cell and initiates a process of fusion between the viral envelope and the

cellular membrane. The fusion event releases the viral capsid into the cellular cytoplasm, where it undergoes uncoating (shedding of capsid proteins) and release of viral RNA and enzymes.

FIGURE 10.10 Life Cycle and Possible Sites of Therapeutic Intervention of HIV-1. The HIV-1 life cycle is susceptible to blockage at several sites. Some agents could block the attachment and entrance of the virus (entrance inhibitors). Reverse transcriptase inhibitors (e.g., azidothymidine [AZT]) prevent the reverse transcription of viral RNA into DNA. Drugs also may be able to inhibit the viral integrase (integrase inhibitors) and prevent insertion of the provirus into the host's chromosomes. Protease inhibitors specifically inhibit the viral protease and prevent the processing of the gp160 into viral capsid and matrix proteins. (Modified from Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

The third step in the life cycle, integration, is controlled by **reverse transcriptase**, which converts single-stranded viral RNA into double-stranded DNA. The viral **integrase** inserts viral DNA into the infected cell's DNA, where it may remain dormant. If replication is activated, the *gag* gene encodes a large precursor protein that undergoes posttranslational modification by the viral protease to generate smaller matrix (e.g., p17) and capsid proteins (e.g., p24). The *env* gene encodes a large gp160 glycoprotein that is processed by a cellular

protease (furin) into the TM and SU proteins. The capsid and nuclear components of the virus undergo assembly in the cytoplasm, and the Env proteins are inserted into the plasma membrane. The assembled particle buds from the cell surface as an infectious virion.

The major immunologic finding in AIDS is the striking decrease in the number of CD4⁺ Th cells. Several mechanisms of Th cell killing are used.²⁷ The replication and release of new virions triggers apoptotic cell death of the infected cell. The release of death ligands (e.g., Fas ligand [FasL], TNF) initiates apoptosis in neighboring uninfected Th cells. The infected Th cell also becomes a target for killing by CD8⁺ T-cytotoxic cells.

Clinical Manifestations of HIV

With the advent of antiretroviral drugs, the early identification of HIV infection is essential. The CDC has issued a new system for staging HIV infection at diagnosis and during monitoring of therapeutic effectiveness and managing the disease.²⁸ The stages are adapted for every age group and based primarily on diagnostic laboratory tests. Stage 0 disease covers the first 180 days after infection, and stages 1 to 3 are based primarily on the CD4 cell counts to monitor disease progression.

The lymphoid areas of the mucosal surfaces are the primary sites of initial infection, particularly if the mucosa has been damaged. Dendritic cells and mucosal T cells probably spread the infection to other peripheral lymphoid organs (especially follicular dendritic cells in the lymph nodes). Production of new virus particles proceeds rapidly with increasing viremia. HIV RNA may be detected in the plasma by 10 days after an acute infection and HIV p24 antigen detected about 4 to 10 days after viral RNA (Fig. 10.11). Indication of an individual's immune response quickly follows. HIV-specific IgM antibody is detected about 3 to 5 days after p24 antigen and levels of IgG begin rising soon afterwards and remain elevated throughout the disease process. As with most immune responses against viral diseases, the IgM levels are usually transient. The appearance of viral RNA in the plasma is indicative of viremia and the appearance of

infectious virus in the body fluids, an indication that infected individuals can transmit HIV to other individuals.

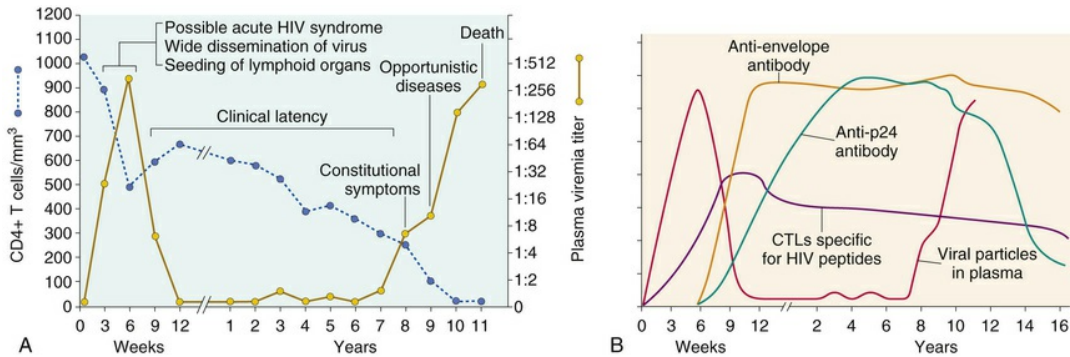

FIGURE 10.11 Typical Course of Progression from HIV Infection to AIDS in Untreated Persons. **A**, Within weeks after infection, the person may experience symptoms of acute HIV syndrome. During this early period the virus progressively infects mucosal T cells and dendritic cells, propagates, and spreads to the lymphoid organs, with a sharp decrease in the number of circulating CD4+ Th cells. The resulting immune response usually induces a period of clinical latency, during which viral replication and T-cell destruction continue in the lymph nodes, although the individual is generally asymptomatic. As the disease progresses, the person may develop HIV-related disease (constitutional symptoms)—a variety of symptoms of acute viral infection that do not involve opportunistic infections or malignancies. When the number of CD4+ cells is critically suppressed, the person becomes susceptible to a variety of opportunistic infections and cancers. The length of time for progression from HIV infection to AIDS may vary considerably from person to person. **B**, Antibody and Tc cell (cytotoxic T lymphocytes [CTLs]) levels change during the progression to AIDS. During the initial phase, antibodies against HIV-1 are not yet detectable (window period), but viral products, including p24 antigen, viral RNA, and infectious virus, may be detectable in the blood a few weeks after infection. Most antibodies produced against envelope proteins in the early phase are absorbed onto viral particles in the blood and are not detectable by most routine assays. During the latent phase of infection, antibody levels against p24 and other viral proteins, as well as HIV-specific CTLs, generally increase and then remain constant until the development of AIDS. As the immune system becomes severely depressed and excess viral antigen is released into the blood, measurable antibody levels decrease. Disease progression usually ends in the death of the untreated individual. (A redrawn from Fauci AS, Lane HC: Human immunodeficiency virus disease: AIDS and related conditions. In Fauci AS et al, editors: *Harrison's principles of internal medicine*, ed 14, New York, 1997, McGraw-Hill; B from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.)

From 40% to 90% of individuals in stage 0 will experience symptoms of acute viral syndrome. Symptoms may include fever, fatigue, headache, lymphadenopathy, pharyngitis, myalgia (muscle

pain), arthralgia (joint pain), and a skin rash that can be extensive. Without knowledge of exposure to HIV, the infected individual may suspect a self-limiting influenza or infectious mononucleosis condition. By 180 days, the initial burst of viremia and acute viral syndrome will have resolved. The infected individual will be asymptomatic, yet infectious HIV is present in body fluids and the process of HIV-mediated destruction of CD4 cells has just begun.

Stages 1 through 3 are determined by diminishing CD4 T-cell counts, adjusted for normal age-related levels. In the first year of life, the normal CD4 T-cell count is the highest and decreases with age. For instance, stage 1 disease is classified after 180 days of infection and the CD4 T-cell counts are still normal: ≥ 1500 cells/ μL at <1 year, ≥ 1000 cells/ μL at 1 through 5 years, and ≥ 500 cells/ μL at 6 years to adult. Stage 2 is characterized by diminished numbers of CD4 T cells: 750 to 1499 cells/ μL at <1 year, 500 to 999 cells/ μL at 1 through 5 years, and 200 to 499 cells/ μL at 6 years to adult. Stage 3 is defined as AIDS, determined by CD4 T-cell counts of <750 , <500 , or <200 cells/ μL for the respective age groups, or the development of AIDS-related opportunistic infections, regardless of the CD4 T-cell count ([Box 10.6](#)).

Box 10.6

Stage 3 AIDS-Defining Opportunistic Infections and Neoplasms Found in Individuals With HIV Infection

Protozoal and Helminthic Infections

Cryptosporidiosis, chronic intestinal (>1 month's duration)

Isosporiasis, chronic intestinal (>1 month's duration)

Toxoplasmosis of brain, onset at age >1 month

Fungal Infections

Candidiasis (esophageal, bronchi, tracheal, or pulmonary)
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Histoplasmosis, disseminated or extrapulmonary
Pneumocystis jiroveci (previously known as "*Pneumocystis carinii*") pneumonia

Bacterial Infections

Bacterial infections, multiple or recurrent*
Mycobacterium avium complex or *Mycobacterium kansasii*,
disseminated or extrapulmonary
Mycobacterium tuberculosis of any site, pulmonary,*
disseminated, or extrapulmonary
Mycobacterium, other species or unidentified species,
disseminated or extrapulmonary
Pneumonia, recurrent*
Salmonella septicemia, recurrent

Viral Infections

Cytomegalovirus disease (other than liver, spleen, or nodes),
onset at age >1 month
Cytomegalovirus retinitis (with loss of vision)
Herpes simplex: chronic ulcers (>1 month's duration) or
bronchitis, pneumonitis, or esophagitis (onset at age >1
month)
Progressive multifocal leukoencephalopathy
Varicella-zoster virus (localized or disseminated)

Neoplasms

Cervical cancer, invasive[†]
Kaposi sarcoma

Lymphoma, Burkitt (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain

HIV-Associated Disorders[‡]

Encephalopathy attributed to HIV
Wasting syndrome attributed to HIV

—————

*Only among children aged <6 years.

†Only among adults, adolescents, and children aged ≥6 years.

‡Suggested diagnostic criteria for these illnesses, which might be particularly important for HIV encephalopathy and HIV wasting syndrome, are described in the following references: Data from 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults, *MMWR Recomm Rep* 41(RR-17):1–19, 1992; 1994 revised classification system for human immunodeficiency virus infection in children less than 13 years of age, *MMWR Recomm Rep* 43(RR-12), 1994.

Treatment and Prevention of HIV

The current regimen of **highly active antiretroviral therapy (HAART)** for treatment of HIV infection is a combination of drugs that attack different portions of the viral replication pathway.²⁹ Since the FDA approval of zidovudine (AZT), more than 25 antiretroviral agents representing 6 different classes have been approved to treat HIV/AIDS and several others are in various stages of testing.

Classes of antiretroviral agents include inhibitors of the enzyme reverse transcriptase (nucleoside/nucleotide reverse transcriptase inhibitors [NRTIs] and non-nucleoside reverse transcriptase inhibitors [NNRTIs]), inhibitors of the viral protease (protease inhibitors [PIs]), entry and intercellular fusion inhibitors that prevent attachment of the

virus to the target cell or prevent fusion between HIV and the cell membrane, and inhibitors of the viral integrase enzyme (integrase strand transfer inhibitors [INSTIs]).²⁹ A sixth group of drugs are pharmacokinetic enhancers, such as cobicistat (COBI), that are administered with some PIs and INSTIs. Enhancers affect intestinal transport proteins and liver enzyme that would normally break down some antiretroviral drugs, thus allowing smaller doses to be used. Many other drugs are in clinical testing, including Gag maturation inhibitors (prevent enzymatic activation of Gag precursor protein), gp120 inhibitors (prevent conformational changes necessary for attachment and entry process), and broadly neutralizing antibodies (bind to proteins on viral envelope and prevent attachment).

The recommended first-line treatment is a combination of two NRTIs and a third drug from another class (see [Fig. 10.10](#)). Many drug combinations are available in a single pill, facilitating compliance. The specific regimen and drugs may vary based on a variety of an individual's characteristics. Other drugs (e.g., entry inhibitors) are reserved for those who develop resistance to first-line drugs.

The goals of therapy are reduction of viral load in fluids, reduced HIV-associated morbidity, prolonged survival, and prevention of HIV transmission. The plasma viral load is frequently suppressed below detectable levels within weeks. With treatment beginning at the time of diagnosis, transmission has decreased by about 90%. Retroviral preventive treatment of uninfected partners of those who are HIV infected has diminished transmission by 96%. Without treatment, the progression from acute infection to AIDS takes 9 to 10 years, with death occurring within 2 to 3 years. Death from AIDS-related diseases has been reduced significantly since the introduction of HAART; those who respond well to HAART may survive for several decades. Continued suppression of HIV/AIDS progression absolutely requires daily and continuous use of medications.

However, many people do not respond to HAART therapy; those who do respond are not “cured,” and resistant variants to these drugs have been identified. Individuals who initiate antiretroviral therapy will still have a shortened life expectancy secondary to HIV-associated

persistent immune activation. Continued systemic inflammation secondary to persistent HIV infection and toxicity of available drugs increase the risk for developing chronic and potentially fatal morbidities. Complications include dyslipidemia (imbalance of blood lipids), insulin resistance, lipodystrophy (changes in body composition, either loss or accumulation of fat), decreased bone density and increase in incidence of fractures, diabetes, renal disease, and liver disease. The risk of cardiovascular disease is increased twofold.³⁰

Antiretroviral drug therapy does not cure HIV/AIDS because the HIV genome incorporates into the DNA of the infected cells that may act as reservoirs and release viral particles if therapy is stopped. The primary reservoir is probably long-lived CD4+ memory T cells, although contribution to the reservoir may include other infected cells, such as macrophages, dendritic cells, astrocytes, microglia, and hematopoietic progenitors.³¹ HIV also may persist in regions where the antiviral drugs are not as effective, such as the central nervous system (CNS). HIV penetrates the CNS early in the infection and persists despite successful treatment with antiretroviral drugs. Neural infection leads to viral encephalitis and apoptosis of neurons. The incidence of HIV-associated dementia was about 20% in untreated individuals, but antiretroviral therapy has reduced that number to about 5% and decreased the severity. Dementia is now rarely seen.

Ultimately, the best hope for preventing the spread of HIV infection is development of an effective vaccine. Most common antiviral vaccines (e.g., rubella, mumps, influenza) induce protective antibodies that block the initial infection. Only one vaccine (rabies) is used after the infection has occurred. That approach is successful because the rabies virus proliferates and spreads very slowly. Whether an HIV vaccine would be effective in either preventing or treating HIV infection is problematic, and the results of recent vaccine trials have for the moment dampened enthusiasm. Characteristics of HIV have been difficult to overcome. HIV-1 commonly undergoes random mutations that result in an extreme and changing antigenic diversity.³² During transmission, bodily fluids may contain a variety of viral

antigenic types so that effective vaccines may need to induce protection against a broad spectrum of HIV surface antigens.

Pediatric HIV

Neonates become HIV infected from their mothers by the passage of the virus across the placenta during pregnancy, by contact with infected maternal blood at childbirth, or through the milk during breast-feeding. The transmission rate in the United States was about 13%, but has been reduced to 1% with the use of prenatal antiviral therapy beginning early in pregnancy, the implementation of neonatal prophylaxis, and the avoidance of breast-feeding.

Without prenatal treatment, symptoms of HIV infection usually develop within 6 months of neonatal life, 20% get opportunistic infections within the first year, and life expectancy is generally less than 3 years. Because of aggressive clinical intervention, there are currently fewer than 50 cases of pediatric HIV infection diagnosed yearly in the United States.

The presence of passive maternal antibody limits the use of HIV antibody testing in infants in the high-risk category up to 18 months of age. The current recommended diagnostic procedure is testing initially for HIV nucleic acid: viral RNA in plasma, or DNA within cells. Determination of whether the child is infected is based on repeated negative test results.²⁷ Two negative nucleic acid test results at 2 and 4 weeks after birth is considered a “presumptive” uninfected state. A “definitive” uninfected is defined as two nucleic acid test results at 1 and 4 months. Combined HAART is initiated immediately in infants and leads to reduced viral latency, a 76% reduction in AIDS-related mortality, and many children reaching the adolescent period with functional immune systems.

Complications in children undergoing HAART are related to metabolic disorders, including insulin resistance and dyslipidemia.²⁷ Because of the metabolic complications of HAART and the ongoing HIV-associated inflammation, half of HIV-infected children are at increased risk of coronary disease. Most HIV-infected children who reach adulthood will have indications of coronary artery

abnormalities. A third or less of children will present with low bone density, but with no increase in fractures.

A particularly vulnerable site of HIV infection in infants and children is the CNS. HIV encephalopathy is more common in the advanced stages. Because survival of children with HIV has been prolonged with effective treatment, the incidence of progressive encephalopathy has increased. For diagnosis of HIV-related neurologic effects, at least one of the following progressive findings needs to be present for at least 2 months, in the absence of a concurrent illness other than HIV that could explain the following findings:

- Failure to attain or loss of developmental milestones, or loss of intellectual ability, verified by standard developmental scale or neuropsychologic tests
- Impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy demonstrated by computed tomography (CT) or magnetic resonance imaging (MRI) with serial imaging required in children less than 2 years of age
- Acquired symmetrical motor deficits manifested by affecting a child 1 month of age or older

The onset of progressive encephalopathy may be a prognostic indicator of a poor outcome.

Other insults may accompany HIV in a young child and affect growth and development, such as drug exposure, prematurity, chronic illness, and a chaotic social atmosphere. The pathogenesis of

HIV encephalopathy in children is poorly understood, but the presence of inflammatory mediators may be a contributing factor.

Countermeasures Against Pathogens

An extremely effective means of countering infectious microorganisms is rigorous use of environmental infection control measures, including control of insect vector populations, establishment of modern sanitation facilities, provision of clean water and uncontaminated food supplies, and other measures. Additionally, prophylactic or therapeutic procedures have been developed to prevent pathogens from initiating disease (vaccines) or to subdue the pathogen once the disease process has started (antimicrobials). Vaccine development has focused successfully on preventing the most severe and common infections (Table 10.7). With the initial success of antibiotic therapy there was no perceived need for vaccination against many common and non-life-threatening infections. The increasing problem of antibiotic-resistant pathogens, however, forced a reappraisal of that strategy, and a greater emphasis is being placed on the development of new vaccines.

TABLE 10.7

REDUCTION IN VACCINE-PREVENTABLE DISEASES IN THE UNITED STATES

DISEASE	BASELINE 20th CENTURY ANNUAL CASES*	2015 CASES [†]	% REDUCTION
Diphtheria	175,885	0	100.0
Measles	503,282	188	99.9
Mumps	152,209	1329	95.1
Pertussis	147,271	20,762	85.9
Smallpox	48,164	0	100.0
Polio	16,316	0	100.0
Rubella	47,745	5	99.9
Tetanus	1314	29	97.8
<i>Haemophilus influenzae</i> type b,	20,000	4138	79.9

* Average number of reported cases over multiple years before initiation of vaccine (Centers for Disease Control and Prevention: *MMWR Morb Mortal Wkly Rep* 48[12]:243–248, 1999; *Morb Mortal Wkly Rep* 57[11]:289–291, 2008).

Infection Control Measures

Although effective means of safeguarding populations from exposure to infectious disease are well known, lack of implementation or breakdowns in application of these initiatives have led to the reemergence of some infectious diseases. These diseases include cholera, dengue fever and West Nile virus.

Sewage removal and other public health initiatives are now the expected norm in developed countries. The quality of water and food, as well as disposal of human and animal waste, remains poor in many developing countries. Rapid urbanization as well as other problems (e.g., poverty, overcrowding, mass relocation of people because of war, rapid destruction of forests) has put pressure on already inadequate systems. A 1991 outbreak of cholera in Peru resulted in an estimated 1100 deaths in Peru and more than 4000 deaths in Latin America, and was attributed to problems with infrastructure, including inadequate sanitation.

Additionally, previously successful programs designed to control the breeding of insect vectors have been reversed. Despite an international emphasis on draining standing water that provides breeding grounds for mosquitoes, large unmanaged areas still abound. A very successful international mosquito eradication program resulted in decreasing incidence of mosquito-borne diseases. Some regions were declared “free” of mosquito-borne diseases. However, lack of access to pesticides, and failure or delay in initiating fumigation and larvicide programs for mosquitoes has resulted in

rebound of mosquito-related diseases in previously disease-free regions in some parts of the world. The consequence is increasingly severe outbreaks of viral disease. An example is outbreaks of dengue virus and West Nile virus in areas of India in the last several years. This problem is exacerbated by the development of insecticide-resistant mosquitoes.

Antimicrobials

Antibiotics are natural products of fungi, bacteria, and related microorganisms and kill or inhibit the growth of other microorganisms. They are basically microbial defense mechanisms by which one microorganism can defend itself against another. The goal of antibiotic therapy is elimination of the pathogenic microorganism. Some antibacterial antibiotics are **bactericidal** (kill the organism), whereas others are **bacteriostatic** (inhibit growth until the organism is destroyed by the individual's own protective mechanisms). The mechanisms of action of most antibiotics are (1) inhibition of the function or production of the cell wall, (2) prevention of protein synthesis, (3) blockage of DNA replication, or (4) interference with folic acid metabolism. Because viruses use the biochemical pathways of the host's cells, there has been far less success in developing specific antiviral antibiotics.

Antibiotic resistance observed clinically is of major importance and has become a problem worldwide. As the use of penicillin became widespread, Alexander Fleming, the discoverer of penicillin, frequently warned about the development of penicillin resistance, and the first bacterial penicillinase (enzyme that destroyed penicillin; β -lactamase) was described in 1940 by Fleming's collaborators. At least 1000 variations of β -lactamase have since been discovered. Being natural products of microorganisms that exist in nature, resistance mechanisms also developed in nature. Genes related to antibiotic resistance have been characterized from samples of permafrost that were dated at 30,000 years ago from the oral microbiome of 2000-year-old skeletons, from the gut microbiome of a Peruvian mummy dated near 1000 AD, and from several other samples that greatly predate the

era of therapeutic antibiotics.³³ As might be expected, environment antibiotic resistance has increased greatly since the use of antibiotics in agriculture.

The CDC publishes a list of antibiotic resistance threats ranked as urgent, serious, and concerning available at: https://www.cdc.gov/drugresistance/biggest_threats.html and <https://www.cdc.gov/drugresistance/threat-report-2013/index.html>.³⁴ They estimated that more than 2 million antibiotic-resistant illnesses occur in the United States yearly, resulting in more than 23,000 deaths. The trend is progressing toward more infectious agents being resistant to multiple antibiotics, such as the classification of extensively drug-resistant TB that is resistant to all of the first- and second-line drugs and the cases of some vancomycin-resistant infections that are resistant to almost all antibiotics (see [What's New? Totally Antibiotic-Resistant Infections Are Here!](#)).

What's New?

Totally Antibiotic-Resistant Infections Are Here!

The apparently unstoppable evolution by which bacteria add and horizontally transfer plasmids containing new antibiotic resistance genes has increased the fear of encountering microorganisms with total resistance to all available antibiotics (pan-antibiotic resistance).

Two antibiotics have been used as drugs-of-last-resort to treat infections with gram-negative microorganisms. Carbapenem is a β -lactam antibiotic similar to penicillin but with greater resistance to standard β -lactamases. Colistins (polymyxin E) are polypeptide antibiotics used to treat many gram-negative infections. Resistance genes have been recently described. In 2008, the enzyme New Delhi metallo- β -lactamase (NDM)-1 gene (*bla*_{NDM-1}) conferred resistance to multiple carbapenems and in 2015 the colistin resistance 1 gene (*mcr-1*) was reported in China. Both resistance genes have spread globally. The presence of either NDM-1 or *mcr-1* resistance gene on a plasmid with other resistance genes may confer a state of pan-

antibiotic resistance. Several reports of this scenario have been published recently. In Germany, 2 individuals infected with *Serratia marcescens* with the *NDM-1* gene in addition to other resistance genes were resistant to 32 different antibiotics representing 8 different groups of antimicrobials.¹ In India, an individual with an aggressive eye infection (keratitis) with *Pseudomonas aeruginosa* was resistant to multiple antibiotics representing eight groups of antimicrobials.² The danger of increased incidences of pan-antibiotic resistance has increased even further when a German group discovered bacteria with *mcr-1* and *NDM-1* genes on the same plasmid.³

Pan-antibiotic resistant infections have now been identified in the United States. The first report of an infection with a microorganism expressing *mcr-1* came from Pennsylvania. The individual presented with a urinary tract infection with *E. coli* that expressed *mcr-1*.⁴ A similar case from New Jersey involved an elderly man with a urinary tract infection with *E. coli* that contained both *mcr-1* and an *NDM* gene. The infection was resistant to both colistin and carbapenems.⁵ In both reports, the infection remained treatable only because the bacterial plasmid did not carry the entire repertoire of available resistance genes.

The most recent report, however, confirms the presence of pan-antibiotic resistant microorganisms in the United States. An elderly female presented in Nevada with a wound infected with *Klebsiella pneumoniae* resistant to all 26 available antibiotics and died of septic shock 2 months after being admitted to the hospital.⁶ She had a history of multiple hospital admissions in India (where bacteria expressing the *NDM-1* resistance gene are prevalent) related to a broken femur and osteomyelitis.

Although a major effort is being taken to prevent pan-antibiotic resistant infections from entering the United States and spreading from individual to individual, encountering these microorganisms more often should be expected. These highly dangerous infections will not be limited to bacteria. A case of pan-antibiotic resistant, opportunistic yeast, *Trichosporon dermatis*, was recently reported in

the Netherlands.⁷ The persistent infection was resistant to all conventional therapy and the individual died from multiorgan failure.

Antibiotic resistance may result from a variety of inherited processes that can coexist in different combinations in the same

microorganism. Resistance genes can be spread within the bacterial community by *horizontal gene transfer*. Genetic information can be transferred by means of transformation (uptake of short DNA fragments from the environment), by transduction (transfer of DNA by means of viruses that infect bacteria, bacteriophages), or by conjugation (transfer of DNA, usually in the form of circular *plasmids*, through pili connecting the bacteria). A single plasmid may contain a large amount of genetic information for multiple types of antibiotic resistance.

Enzymatic inactivation of antibiotics is one of the most common forms of resistance. The β -lactam antibiotics contain a β -lactam ring central to their structures and are bactericidal by inhibiting formation of the bacterial cell wall. The initial class of β -lactam antibiotics (e.g., penicillin, cephalosporins) blocked synthesis of the gram-positive cell wall, whereas newer broad-spectrum β -lactam antibiotics (e.g., carboxypenicillins) also affect gram-negative cell wall synthesis. Resistance is conferred by enzymatic (**β -lactamase**) destruction of the antibiotic. Another class of antibiotics, aminoglycosides (e.g., streptomycin, neomycin, gentamicin), is bactericidal primarily to gram-negative aerobic bacteria and against tuberculosis by binding to sites on ribosomal RNA (rRNA) and inhibiting protein synthesis. Resistance is conferred by **aminoglycoside-modifying enzymes (AMEs)**, which acetylate and inactivate aminoglycoside.

Another major form of antibiotic resistance is caused by **multi-drug-resistance transporters (MDRs)**. MDRs are members of a diverse and widely expressed family of transmembrane proteins that are designed to protect the cell by diminishing the rate of intracellular accumulation of antimicrobials by preventing entrance or, more commonly, increasing active efflux of the antibiotic. At least six different bacterial MDR families have been identified, with their genes also primarily carried on plasmids that can be transferred to other bacteria.³⁵ Expression of MDRs is not limited to bacteria; *C. albicans* uses multiple MDRs as efflux pumps for antibiotics. Individual MDRs are capable of transporting and simultaneously protecting microorganisms from several antibiotics (e.g., kanamycin,

erythromycin, doxycycline).

Other methods of antibiotic resistance are less common, but still important in understanding the combination of protective mechanisms leading to multidrug resistance.³⁶ Antibiotics gain entrance to bacteria by passing through the cell wall. Resistance may result from sequestration or decreased uptake of the antibiotic. Thickened cell walls or biofilms trap antibiotics in the extracellular matrix to prevent access to bacteria. Decreased uptake also may result from modification of the cell wall; *P. aeruginosa* undergoes minor changes in cell wall chemistry and becomes resistant to the uptake of β -lactam antibiotics. Additional mechanisms protect the molecular target of particular antibiotics. The target may be altered by mutation or other means.

Genetic amplification and overproduction of the target molecule result in excessive numbers of targets and reduced antibiotic sensitivity (e.g., increased resistance to sulfonamides in some streptococci). *Target bypass* is a resistance mechanism resulting from switch from an antibiotic-sensitive metabolic to one that is more antibiotic resistant. Some bacteria have gained resistance to sulfonamide by converting from use of environmental *para*-aminobenzoic acid for conversion to folic acid, which is an antibiotic-sensitive step in nucleic acid synthesis, to the direct use of environmental folic acid. The target molecule also can be protected by novel bacterial proteins that block the antibiotic binding site. Multi-antibiotic resistance results from the simultaneous application of a combination of mechanisms. **Methicillin-resistant *Staphylococcus aureus* (MRSA)** caused an international healthcare crisis. Outside of the United States, MRSA accounts for 80% of *S. aureus* infections. MRSA produces a β -lactamase. Normally β -lactamase-resistant broad-spectrum antibiotics (e.g., methicillin) can be substituted. However, MRSA also carries an extra-chromosomal gene *mecA* for resistance to methicillin. The *mecA* gene encodes a penicillin-binding protein (PBP2a) with a lower affinity for β -lactams and, therefore, less sensitivity to inhibition by antibiotics. Resistance to aminoglycoside antibiotics is accomplished by expression of AMEs, production of

excess *para*-aminobenzoic acid, and spontaneous mutation of rRNA with a lower affinity for antibiotics. Resistance to the glycopeptide antibiotic vancomycin is controlled by the gene *vanA*, which results in alterations in peptidoglycans and loss of the vancomycin-binding site. Antibiotic sequestration also occurs in the thick peptidoglycan layer and within biofilms. MRSA expresses four different classes of multi-drug-resistance transporters.³⁷ Fusidic acid, one of few drugs for MRSA, binds to the ribosome and prevents protein synthesis. Resistance results from small proteins that bind to the target and prevent interactions with the antibiotic.³⁸

Multiple antibiotic resistance has appeared and can be related to overuse of antibiotics and not completing an antibiotic regimen. Overuse of antibiotics leads to the destruction of the normal microbiome, allowing the selective overgrowth of antibiotic-resistant strains or pathogens that had previously been kept under control. For example, treatment with clindamycin can compromise the normal intestinal microbiome allowing the overgrowth of *C. difficile* and the development of pseudomembranous colitis. Lack of compliance in completing a therapeutic antibiotic regimen allows the selective resurgence of microorganisms that are more relatively resistant to the antibiotic.

With the development of multiple antibiotic-resistant strains, creativity in addressing this challenge must be rekindled. New antibiotics may solve a portion of the problem or may exacerbate it further as pathogens develop resistance to new antibiotics as well. Available antibiotics that prove to be no longer effective must be replaced with alternative forms of therapy, including the increased development and use of vaccines.

In that context, an old treatment has been revisited: the administration of lytic bacteriophages. **Bacteriophages** are viruses that specifically infect bacteria and, in the case of lytic phages, result in bacterial death and lysis. The advantages of bacteriophage therapy are numerous: cocktails of complementary phages can be used, phages can progressively infiltrate a biofilm that traps antibiotics, and phages can be genetically engineered to express enzymes that weaken

the biofilm. Bacterial resistance to phages may occur related to alteration of phage receptors on the bacteria. However, this therapeutic agent clearly needs to be explored further and studies are in progress to test the effect of bacteriophage therapy on *P. aeruginosa* chronic lung infections.³⁹

Active Immunization: Vaccines

Contracting and surviving an infectious disease is the most effective means of developing lifelong immunity against a particular pathogen. However, some infections cause a great deal of morbidity and mortality. The purpose of vaccination is to induce active immunologic protection before exposure to the risks of debilitating or fatal infection. For each vaccine an initial immunization protocol is developed to produce large numbers of memory cells and a sustained protective secondary immune response in the greatest number of individuals. Even under optimized protocols, vaccines are not completely protective. For every vaccine a small percentage of recipients do not produce a protective immune response, referred to as primary vaccine failure. Failure to induce an immune response occurs in about 10% of recipients of measles (rubeola), mumps, rubella, and hepatitis B vaccines, and inactivated influenza vaccine may only protect 30% to 40% of adults 65 or older.⁴⁰ A recently approved, high-dose injectable vaccine with four times the amount of influenza antigen is now recommended for increased protection of adults 65 or older.

In general, vaccine-induced protection does not persist as long as infection-induced immunity; thus booster injections may be necessary to maintain protection throughout life. *Secondary vaccine failure* results if appropriate booster immunizations are not administered. Many adults vaccinated against diseases that are more severe in childhood will not get routine boosters. Although not developing debilitating illness, they may become asymptomatic carriers and infect unvaccinated children. The CDC maintains the most current immunization schedules for people of all ages.

Mass vaccination programs have led to major changes in the health of the world's population.⁴¹ For example global eradication of

smallpox by 1979. In 1994 polio was declared officially eradicated in all the Americas. The goal of the WHO is to eradicate polio worldwide by 2022.

Rubella and congenital rubella syndrome were declared eliminated in the Americas in 2015, and in 2016 measles was eradicated. Although eliminated in the Americas, measles and rubella have not been eliminated elsewhere and infected visitors from other countries may transmit the infection to individuals who have not been vaccinated. A certain percentage of the population (usually about 85%, with a range of 75% to 99% depending on the particular microorganism) should be immunized in order to achieve protection of the total population, referred to as *herd immunity*. The principles of calculating herd immunity are based on several parameters: the number of susceptible individuals who may become infected in an unvaccinated population from an initial case, the time interval over which the infection may spread, and the effectiveness of the vaccine.

An individual infected with measles can infect 12 to 18 other individuals over about 2 weeks. If the desired level of herd immunity is not achieved, outbreaks of infection can occur. The WHO declared that measles was eradicated in the United States in 2000, and many parents became either complacent or resistant to immunization. This resulted in at least 23 outbreaks of measles in 2014 triggered by exposure to infected visitors to the United States or travel by U.S. citizens to areas where measles was still endemic. Most of the infected individuals had no history of immunization and the required level of herd immunity had not been maintained.⁴² The incidence of pertussis (whooping cough) in the United States has also reflected resistance to vaccination. In 2004, 32 pertussis outbreaks were published; analysis of 8 of these found that 59% to 93% of infected individuals were intentionally not vaccinated. Immunization programs in several European countries have been disrupted by anti-vaccine groups. As a result, the incidence of pertussis increased by 10 to 100 times compared with neighboring countries that maintained a high incidence of immunization.

Resistance to routine vaccination has arisen for many reasons,

particularly potential vaccine dangers. As with any medicine, complications can arise, including pain and redness at the injection site, fever, allergic reactions to vaccine ingredients, infection associated with attenuated viruses in immunodeficient individuals, and others. Additionally, some individuals in the United States and Europe became concerned that vaccines, particularly those containing the preservative thimerosal, induced autism in children. Thimerosal is a mercury-containing compound that has been used as a preservative since the 1930s. Multiple studies concluded that neither vaccines nor thimerosal was associated with the onset of autism.^{43,44} The debate related to thimerosal and many other environmental chemicals to autism is still under investigation.^{45,46} Although no cases of mercury toxicity have been reported secondary to vaccination, thimerosal was removed from all vaccines by 2001 with the exception of inactivated influenza vaccines.

Development of a successful vaccine depends on many factors. These include characterizing the desired protective immune response (e.g., antibody, T cell), identifying the appropriate antigen to induce that response (i.e., immune responses against some antigens on an infectious agent are ineffective or even increase the risk for infection), determining the most effective route of administration (e.g., injected, oral, inhaled), optimizing the number and timing of vaccine doses to induce protective immunity in a large proportion of the at-risk population, and deciding the most effective, yet safe, form in which to administer the vaccine. For instance, most vaccines against viral infections (e.g., measles, mumps, rubella, *Varicella zoster* [chickenpox], yellow fever) contain live viruses that are weakened (**attenuated**) to continue expressing the appropriate antigens but are unable to establish more than a limited and easily controlled infection. The limited proliferative capacity of attenuated live viruses appears to afford better long-term protection than using purified viral antigen. Exceptions are the vaccines against hepatitis B, which uses a recombinant viral protein, and hepatitis A, which is an inactivated (killed) virus.

Even attenuated viruses can, however, establish life-threatening

infections in vaccine recipients whose immune system is congenitally deficient or suppressed (see [Chapter 9](#)). Two different vaccines were developed against polio. The Sabin vaccine is an attenuated virus that is administered orally (oral polio vaccine [OPV]). It provides systemic protection and induces a secretory immune response to prevent growth of the poliovirus in the intestinal tract. The live attenuated vaccine causes polio in some children who have unsuspected immune deficiencies (about 1 case in 2.4 million doses). The Salk vaccine is a completely inactivated virus administered by injection (inactivated polio vaccine [IPV]). It induces protective systemic immunity but does not provide adequate secretory immunity. Therefore even if the individual is protected from systemic infection the “wild-type” poliovirus can transiently infect the intestinal mucosa, be shed, and spread to others. For example, when polio was epidemic, the live oral vaccine was preferred; however, about eight cases of paralytic polio per year in the United States result from the vaccine strain proliferating in individuals with inadequate immune systems. As a result, the CDC currently recommends vaccination with the killed virus.

Some common bacterial vaccines are killed microorganisms or extracts of bacterial antigens. *S. pneumoniae* (pneumococcus) is a major cause of pneumonia, particularly in the young and adults with compromised lung function secondary to smoking, asthma, and other lung diseases. Of the more than 90 known strains of this microorganism, only a few cause the most severe illnesses. The current vaccines against pneumococcal pneumonia consist of a mixture of capsular polysaccharides. The conjugated vaccine is recommended for young children in whom the pure polysaccharide vaccine is not very immunogenic. A similar vaccine is available for *H. influenzae* type B (Hib), which is a cause of pneumonia and meningitis in children.

Some bacterial diseases are caused by potent bacterial toxins that act locally or systemically. These include diphtheria, cholera, and tetanus. Vaccination against the toxins is achieved using **toxoids**—purified toxins that have been chemically detoxified without loss of

immunogenicity. Pertussis (whooping cough) vaccine was changed from a killed whole cell vaccine to an acellular vaccine that contained the pertussis toxin and additional bacterial antigens.

With so many available vaccines there has been an effort to mix vaccines in order to minimize the number of required injections. An example is DPT, now usually contains diphtheria (D) and tetanus (T) toxoids and acellular pertussis vaccine (aP). More recent mixtures include DTaP mixed with inactivated poliovirus, hepatitis B vaccine, or *H. influenzae* antigen or a mixture of these.

Passive Immunotherapy

Passive immunotherapy is a form of countermeasure against pathogens in which preformed antibodies are given to the individual. This form of therapy has been used for decades. Horse serum that contained antibodies was used to treat diphtheria, pneumococcal pneumonia, tetanus, and other diseases in the early twentieth century. However, because of foreign proteins in the serum, many individuals developed an immune reaction against the horse proteins and an immune complex-mediated serum sickness. Passive immunotherapy with human immunoglobulin has been approved for several infections, including hepatitis B and hepatitis A. Treatment of potential rabies infection after a bite combines passive and active immunization. The rabies virus proliferates very slowly. Individuals who have been bitten receive a one-time injection with human rabies immune globulin to further slow viral proliferation, followed by multiple injections with a killed viral vaccine to induce greater protective immunity.

A recent example of passive immunotherapy is the 2014 to 2016 outbreak of Ebola virus in West Africa, the largest outbreak of Ebola infection ever observed: 28,616 cases with 11,310 fatalities (a 40% mortality rate). No vaccine was available. An experimental mixture of monoclonal antibodies against the virus rapidly increased circulating antibody titers and diminished viral load by more than eightfold.⁴⁷

In the past, vaccines and therapeutic antibodies were developed for only the deadliest pathogens. With the increase in antibiotic-resistant

microorganisms, the development and widespread use of new vaccines and passively administered antibodies against these microorganisms must be considered.

Summary Review

Emerging Infections

1. Emergence of previously unknown infections, reemergence of old infections thought to be controlled, and the development of infections resistant to multiple antibiotics or vaccination are significant causes of death and morbidity.

Microorganisms and Humans: A Dynamic Relationship

1. The human body is a hospitable site for microorganisms to grow and flourish. These microorganisms make up the *normal microbiome* of the body.
2. The beneficial homeostasis between humans and microorganisms is maintained through the physical integrity of the gut and other mechanisms that sequester these microorganisms on the mucosal surface.
3. The symbiotic relationship with the normal microbiome can be altered by injury, compromising protective barriers including the skin and mucous membranes.

Microorganisms and Infections

1. Clinical infectious disease occurs in four distinct stages: (1) incubation period, (2) prodromal state, (3) invasion period, and (4) convalescence.
2. The hallmark of most infectious diseases is fever. Body

- temperature is regulated at a higher than normal level.
3. Several factors influence the capacity of a pathogen to cause disease, including communicability, immunogenicity, infectivity, mechanisms of action, pathogenicity, entry portal, toxigenicity, and virulence.
 4. Infectious diseases also are classified by their prevalence and spread as endemic, epidemic, and pandemic.
 5. The process of infection includes colonization, invasion, multiplication, and dissemination.
 6. When an individual's immune system is deficient, the person can become infected with opportunistic infections.
 7. True pathogens in adequate numbers can circumvent an individual's defenses and directly cause infection.
 8. Infectious microorganisms usually exist in reservoirs (e.g., contaminated soil, contaminated water or food, breast milk), animals, or another human.
 9. Direct transmission of pathogens can occur by direct physical contact, ingestion or inhalation, or placental transfer.
 10. *Indirect transmission* occurs from contact with contaminated materials, which can range from towels to food or through a vector.
 11. As part of colonization, the microorganism stabilizes the adherence to tissue through surface receptors and can then invade surrounding tissue.
 12. Because tissue is warm and nutrient rich, most microorganisms undergo *rapid* multiplication. Viral pathogens replicate within infected cells, and some bacteria are intracellular pathogens and replicate in macrophages and other cells.
 13. Successful spreading requires a variety of virulence factors, including adhesion molecules, toxins, and the ability to evade immunity.
 14. Mixed species of microorganisms can come together and form slimy biofilms and anchor themselves to various surfaces and resist immune defenses.

15. Stable colonization of bacteria requires adhesion. Many bacteria attach through pili (fimbriae), surface glycoproteins, or complement-related receptors.
16. Invasion results in direct confrontation with an individual's defense mechanisms, including complement, antibodies, and phagocytes (neutrophils, macrophages). Evasion of these defenses can result in bacteremia or viremia or fungemia and sepsis.
17. Bacteria can protect against phagocytosis by producing toxins that destroy phagocytic cells and extracellular enzymes that digest complement, clotting factors, immunoglobulins, cytokines, and antimicrobial peptides and promote extracellular spreading.
18. Classes of infectious microorganisms include bacterial, fungal, parasitic, protozoal, and viral.
19. Bacteria are divided into several groups—“true bacteria,” filamentous, spirochetes, mycoplasma, rickettsia, and chlamydia—and can be categorized as gram negative or gram positive.
20. Many bacteria have specialized surface structures such as pili and flagella that promote adhesion and tissue invasion.
21. Bacteria can produce a variety of toxic molecules that may kill the individual's cells, disrupt tissue, and protect the individual against inflammation.
22. Exotoxins are released by bacteria during bacterial growth and can damage cell membranes, activate second messengers, and inhibit protein synthesis.
23. Endotoxins are contained in the cell walls of gram-negative bacteria and released during lysis of the bacteria. Bacteria that produce endotoxins are called *pyrogenic bacteria* because they activate inflammation and produce fever. They also can activate the coagulation cascade and release cachectin (TNF).
24. Inflammatory and immune responses to infection can cause tissue damage through excessive production of inflammatory cytokines, excessive activation of antibodies, and infiltration of

T cells, macrophages, and neutrophils.

25. Other self-protective mechanisms for bacteria and other pathogens include degradation of immune molecules, neutralization of immune molecules, complement evasion, immune suppression, and escape from the phagosome.
26. Some bacteria (and viruses) proliferate more rapidly than the development of immune defenses causing severe clinical disease.
27. Some bacteria (like viruses) evade immune defenses by surviving inside immune cells.
28. Some bacteria can coat the Fc portion of an individual's antibody, preventing complement activation or phagocytosis.
29. Antigenic variation allows pathogens to alter surface molecules that express antigens that are the targets of protective immune responses. The pathogen thus becomes resistant.
30. Some bacteria can release molecules that bind to and neutralize antibody or form immune complexes that deposit in tissue, causing damage.
31. Some bacteria can degrade immunoglobulins or components of the complement system.
32. Some bacteria can suppress immune responses that block T cells or impair the signals in the inflammatory response or interfere with antigen processing and presentation.
33. *S. aureus* has numerous virulence factors that promote invasive infection. It has become a major cause of hospital-acquired (nosocomial) infections and antibiotic resistance.
34. Fungal infection is called *mycosis*. Most pathologic fungi are from the environment and transmitted by human-to-human contact, inhalation, or contamination of wounds.
35. Fungi have polysaccharide surface molecules that promote adhesion to epithelial tissue.
36. Fungi can produce toxins that promote infection, evade immune responses, or cause cancer (aflatoxins).
37. Some fungi secrete enzymes that damage tissue and initiate

pathogenic inflammatory responses including hypersensitivity reactions.

38. Some fungi can survive in phagocytes and resist lysosomal destruction.
39. *C. albicans* is the most common cause of fungal infections in humans. It resides in the skin, gastrointestinal tract, mouth, and vagina. Local defense mechanisms, including members of the bacterial microbiome, produce antifungal agents. The infection remains localized in individuals with an intact immune system.
40. Parasitic organisms establish a symbiosis with another species, whereby the parasite benefits. They range from unicellular protozoa to large worms.
41. Parasites adhere to and break down connective tissue and basement membranes allowing penetration and entry to the circulatory system.
42. Some parasites only reproduce within host cells (obligatory intracellular parasites).
43. Some parasites evade immune defenses by secreting cytotoxic molecules or by antigenic variation.
44. Malaria is one of the most common infections worldwide. It is transmitted through the bite of an infected *Anopheles* mosquito. The parasite (*Plasmodium*) enters the bloodstream, survives in the liver, and invades parenchymal cells. After several rounds of division, the liver cell ruptures and thousands of parasites enter the blood, infecting red blood cells.
45. Viruses are intracellular microorganisms. The viral life cycle is completely intracellular and involves several stages: attachment, penetration, uncoating, replication, assembly, and release of new virions.
46. Viruses are classified by the format of nucleic acid in the virion, (RNA or DNA and either single-stranded [ss] or double-stranded [ds]), and by whether the virus uses the enzyme reverse transcriptase (RT) for replication.

47. Successful viruses use a variety of mechanisms for bypassing immune rejection, including rapid division, intracellular survival, coating with self-proteins, antigenic variation, neutralization, complement evasion, and immune suppression.
48. Viruses inside the infected cell have several harmful effects, including inhibition of DNA, RNA, or protein synthesis; disruption of lysosomal membranes, resulting in lytic enzyme release; promotion of cell apoptosis; fusion of adjacent cells (i.e., giant cells); transformation into a neoplastic cell; and alteration of antigenic properties (i.e., decreasing immune effectiveness).
49. An example of viral infection is influenza, an ssRNA virus transmitted through aerosol and body fluids, and there are several variant forms. Influenza viruses undergo antigen shifts allowing them to evade protection from vaccines.

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

1. AIDS is a viral disease caused by HIV.
2. HIV infects and depletes a portion of the immune system (T cells), making individuals susceptible to life-threatening infections and malignancies.
3. HIV/AIDS remains a major cause of death worldwide.
4. Aggressive antiretroviral therapy and public health campaigns have stabilized the number of new cases and deaths in the United States from HIV/AIDS and other parts of the world where there is access to therapy.
5. HIV is a blood-borne pathogen present in body fluids with typical routes of transmission: blood or blood products, intravenous drug abuse, heterosexual and homosexual activity, and maternal-child transmission before or during birth.
6. The primary surface receptor on HIV is the envelope

glycoprotein gp120, which binds to the CD4 molecule found mostly on the surface of T-helper cells. Several other important co-receptors have been identified.

7. HIV is a member of the *retrovirus* family, which carries genetic information in the form of RNA. An enzyme, reverse transcriptase (RT), converts RNA into a double-stranded DNA. Another enzyme, an *integrase*, inserts the new DNA into the infected cell's genetic material. On activation, translation of the viral information may be initiated, forming new virions, resulting in lysis and death of the infected cell, and shedding infectious HIV particles.
8. The major immunologic finding in AIDS is the striking decrease in the number of CD4⁺ Th cells.
9. The presence of circulating antibody against HIV indicates infection by the virus, although many individuals are asymptomatic.
10. The current treatment for HIV infection is a combination of drugs called highly active antiretroviral therapy (HAART) that attacks different portions of the viral replication pathway.
11. Mother-to-child transmission has been reduced to 1% with prenatal treatment of HIV infection.
12. Neonates become HIV infected by placental transmission or through breast-feeding.
13. Children with HIV are at increased risk of coronary artery disease.

Countermeasures Against Pathogens

1. Effective means of countering infectious microorganisms are rigorous use of environmental infection control measures, including control of insect vector populations, establishment of modern sanitation facilities, and provision of clean water and uncontaminated food supplies. Prophylactic or interventive procedures include vaccines and antimicrobials.
2. Passive immunotherapy has been effective using previously

- formed human immunoglobulin for diseases such as hepatitis A and B, rabies, and ebola.
3. With antibiotic-resistant pathogens, a greater emphasis is placed on the development of new vaccines.

*AGING and Stress: Stress-Age
Syndrome, 340*

To observe the obvious, modern society is full of stress. As a culture, Westerners are champions of the work ethic, a Protestant philosophy originating in the sixteenth century that views idleness as taboo. Stressful experiences include daily hassles, major life events (e.g., loss of loved one, life-threatening illness, loss of job), social isolation, early-life social deprivation, abuse, trauma, work-related stress, work-life balance, low-socioeconomic status (SES), and many other events. For

example, the pressure to remain in contact despite illness, travel, vacation, and other events that used to provide socially acceptable temporary absences is now customary in the American, and indeed global, culture. When added to other well-identified stressors, such as financial problems, the individual may suffer and develop symptoms that reflect the so-called *stress-related disorders*.

When thinking about stress, one must consider the factors producing a perception of stress, which begin when the brain perceives a stimulus as stressful and then, in turn, promote adaptational and survival-related physiologic responses. However, when the psychologic perception of environmental demand exceeds the adaptive capacity of the individual to cope, stress may lead to negative affective and health-related disease states.^{1,2} Another way to think about stress involves the short- or long-term consequences of stress. Today, most researchers consider acute stress to be immunoenhancing (protective) whereas chronic, unremitting stress is thought to be immunosuppressive (destructive).^{1,2} A variety of adverse life circumstances affects the pool of circulating leukocytes, involves transcription with increased expression of genes that promote **inflammation**, and decreased expression of genes that promote antiviral responses.³ Chronic inflammation contributes to many diseases and drives contemporary morbidity and mortality.

Historical Background and General Concepts

Walter B. Cannon used the term *stress* to encompass both physiologic and psychologic ideas as early as 1914.⁴ He applied the engineering concept of stress and strain in a physiologic context and believed that emotional stimuli also were capable of causing stress. In 1946 Hans Selye popularized these same findings, viewing stress as a biologic phenomenon.⁵ Originally, Selye inadvertently discovered the biologic syndrome of stress while he was attempting to discover a new sex hormone by injecting crude ovarian extracts into rats.⁵ He repeatedly

found that three structural changes occurred: (1) enlargement of the cortex of the adrenal gland, (2) atrophy of the thymus gland and other lymphoid structures, and (3) development of bleeding ulcers in the stomach and duodenal lining. Selye soon discovered that these manifestations were not specific to injected ovarian extracts but also occurred after he exposed the rats to other noxious stimuli, such as cold, surgical injury, and restraint. He called these stimuli *stressors*. Selye concluded that this triad or syndrome of manifestations represented a nonspecific response to noxious stimuli, naming it the **general adaptation syndrome (GAS)**. He identified the three following successive stages of the GAS: (1) the alarm stage or reaction, in which the central nervous system (CNS) is aroused and the body's defenses are mobilized (e.g., “fight or flight”) (Fig. 11.1); (2) the stage of resistance or adaptation, during which mobilization contributes to “fight or flight”; and (3) the stage of exhaustion, where continuous stress causes the progressive breakdown of compensatory mechanisms (acquired adaptations) and homeostasis. Exhaustion marks the onset of certain diseases (diseases of adaptation).

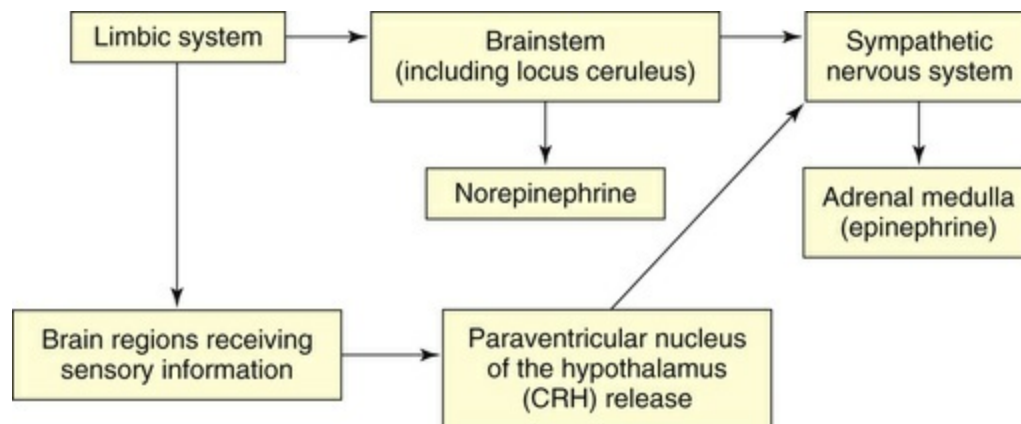

FIGURE 11.1 Neural Recognition and Response to Real or Predicted Stressors. *CRH*, Corticotrophin-releasing hormone.

Initially one becomes alarmed by a stressor that activates the hypothalamus and sympathetic nervous system (see Figs. 11.1 and 11.2). The resistance or adaptation phase begins with the actions of the hormones cortisol, norepinephrine, and epinephrine. Exhaustion (also

known as allostatic overload; discussed later) occurs if stress continues and adaptation is not successful, ultimately causing impairment of the immune response, heart failure, and kidney failure, leading to death.

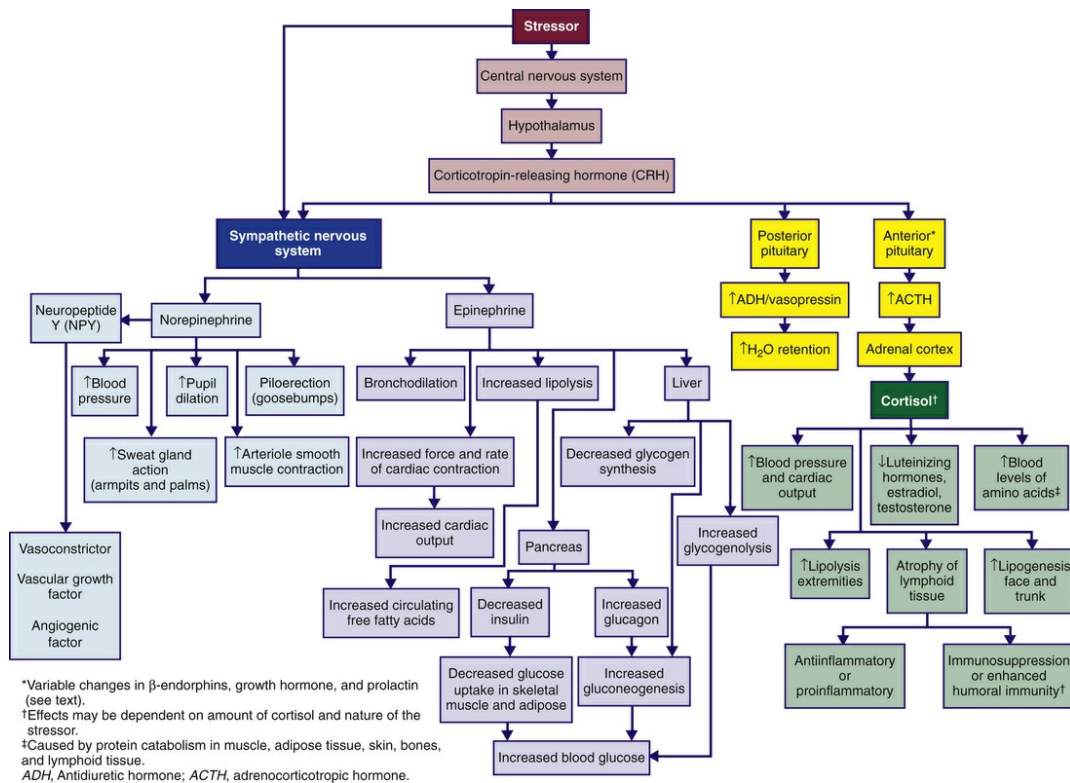

FIGURE 11.2 The Stress Response.

From a physiologic perspective, what is emerging across the disciplines involved—molecular biology, immunology, neurology, endocrinology, and behavioral science—is a more holistic and complex model that involves biochemical relationships of the CNS, autonomic nervous system (ANS), the **hypothalamic-pituitary-adrenal (HPA) axis** (Fig. 11.3), and the immune system that causes the stress responses identified by Selye.

FIGURE 11.3 Hypothalamic-Pituitary-Adrenal (HPA) Axis. The response to stress begins in the brain. The hypothalamus is the control center in the brain for many hormones including corticotropin-releasing hormone (CRH). *ACTH*, Adrenocorticotropic hormone.

Concepts of Stress, Homeostasis, and Allostasis

Selye believed that stressors cause a general or nonspecific response. However, research in the past 50 years has shown the remarkable

sensitivity of the central nervous system and endocrine system to psychologic influences (emotion is included as a psychologic factor that modulates social stress). Thus, although Selye's identification of the GAS is regarded as tremendously important and the cornerstone of stress research, the idea that stress is a purely physiologic response is vastly oversimplified. In the mid-1950s, studies showed that activation of the adrenal cortex occurred in humans in response to psychologic stressors,⁶ in monkeys with conditioned emotional responses,⁷ and in humans subjected to a stressful interview technique.⁸ In the early 1960s, researchers found that plasma cortisol levels increased in groups of subjects exposed to war movies and decreased while they viewed Disney nature films.^{9,10} Mason later demonstrated that the initiation of the GAS depended on psychologic factors surrounding the stressors.¹¹ He also showed that various factors, such as degrees of discomfort or unpleasantness or the suddenness of the stress, could account for the presence or absence of **physiologic stress responses**.¹¹

Although the term *stress* was used by many disciplines and with numerous disagreements over its definition, in recent years, **stress** was defined as a *transactional* or *interactional concept*. Transactionally, stress is viewed as the state of affairs arising when a person relates to (i.e., interacts or transacts with) situations in certain ways. People are not disturbed by situations per se but by the ways they appraise and react to situations. In general, a person experiences stress when a demand *exceeds* a person's coping abilities, resulting in reactions such as disturbances of cognition, emotion, and behavior that can adversely affect well-being. Moreover, psychologic stressors can elicit reactive or anticipatory stress responses. The **reactive response** is a physiologic response derived from psychologic stressors. For example, the stress of an examination may produce an increased heart rate and dry mouth in the unprepared student. The anticipatory response occurs when physiologic responses develop in anticipation of disruption of the optimal steady-state, also known as **homeostasis**. These **anticipatory responses** can be generated either by species-specific innate programs, such as reacting to the presence of predators and

unfamiliar situations, or by experience-dependent memory programs created by conditioning.¹² Anticipatory responses are learned responses under fine control by regions located in the brain regions most frequently associated with learning and memory and include the hippocampus, amygdala, and prefrontal cortex. In order for these regions to elicit a stress response, the paraventricular nucleus (PVN) of the hypothalamus must be stimulated. These brain structures interact with the PVN through intermediary neurons, some of which are primarily used for the reactive response.

In a **conditional response** one learns that specific stimuli (i.e., objects or situational context) are associated with danger, and as such anticipation of subsequent encounters with the stimulus produces a physiologic stress response. For example, a child abused by a parent may experience a physiologic stress response in anticipation of further abuse when the parent enters the room. Under some circumstances these memory programs may become so strong that psychologic disorders, such as phobias, develop. In a similar fashion, some persons develop **posttraumatic stress disorder (PTSD)** in response to the memory, as opposed to the anticipation of traumatic events. PTSD is characterized by flashback memories, sleep disturbances, depression, and other symptoms. These symptoms have the potential to greatly compromise normal activities, such as employment, personal relationships, and quality of life. Today, evidence implicates stress as a precipitating factor across a range of diseases and health conditions. The term **allostasis**, as opposed to *homeostasis*, is currently used in stress research as a better way to understand how stress influences the development of disease. Unlike having a set point and physiologic equilibrium in Selye's homeostasis view of physiologic stress systems, the allostasis view proposes that physiologic systems are dynamic and capable of changing set-points after exposure to stress. This change in physiologic set point (e.g., chronic stress-induced elevation in cortisol secretion) may be the culprit underlying pathophysiologic conditions. **Allostatic load** (Fig. 11.4) is the individualized cumulative effects of stressors that exist in people's lives and influence their physiologic responses. Allostatic load may

result from a vulnerable physiologic/genetic makeup, lifestyle (including damaging health behaviors), daily stressful encounters, and extraordinary events (such as disasters).^{2,13} Over time this load exacts a toll on people's bodies (i.e., "wear and tear"). Because the brain is a key player in deciding what is stressful, it is influential in determining when they feel toxic allostatic overload. Under conditions of allostatic overload, the parasympathetic system may decrease its restraint of the sympathetic system, resulting in increased or prolonged inflammatory responses.^{2,14} Furthermore, in response to acute and chronic stress some regions of the brain (the hippocampus, amygdala, and prefrontal cortex) may respond by undergoing structural remodeling, which can alter behavioral and physiologic responses (such as cognitive impairment or depression).² The adult brain and the developing brain possess structural and functional plasticity in response to stress, including neuronal replacement, dendritic remodeling, and synapse turnover.¹⁵ Many intra- and intercellular mediators and processes are involved in changing the brain during stress and recovery from stress experiences. Examples of molecules that are necessary or permissive for brain remodeling include brain-derived neurotrophic factor (BDNF), tissue plasminogen activator (tPA), corticotropin releasing hormone (CRH), the secreted protein Lipocalin-2, and endocannabinoids (eCBs).¹⁶ Stress causes an imbalance of neural circuitry that serves cognition, decision-making, and anxiety and mood that can disrupt behavioral states.¹⁶ The imbalance can then affect systemic physiology through neuroendocrine, autonomic, immune, and metabolic mediators.¹⁶ Key mediators and biomarkers of **allostatic overload** (exaggerated pathophysiologic responses to stress) include the glucocorticoid cortisol, catecholamines (released from sympathetic nervous system activation), and proinflammatory cytokines. A prevalent example is sleep deprivation resulting from excessive stress. Sleep deprivation has significant damaging effects, including elevated evening cortisol level; elevated insulin and blood glucose levels; increased blood pressure; reduced parasympathetic activity; increased levels of proinflammatory cytokines; and increased concentrations of the gut

hormone ghrelin, which stimulates appetite. Altogether, these physiologic alterations induced by the cumulative effects of insomnia can lead to increased caloric intake, depressed mood, cognitive problems, and a host of other potential health issues.¹⁷

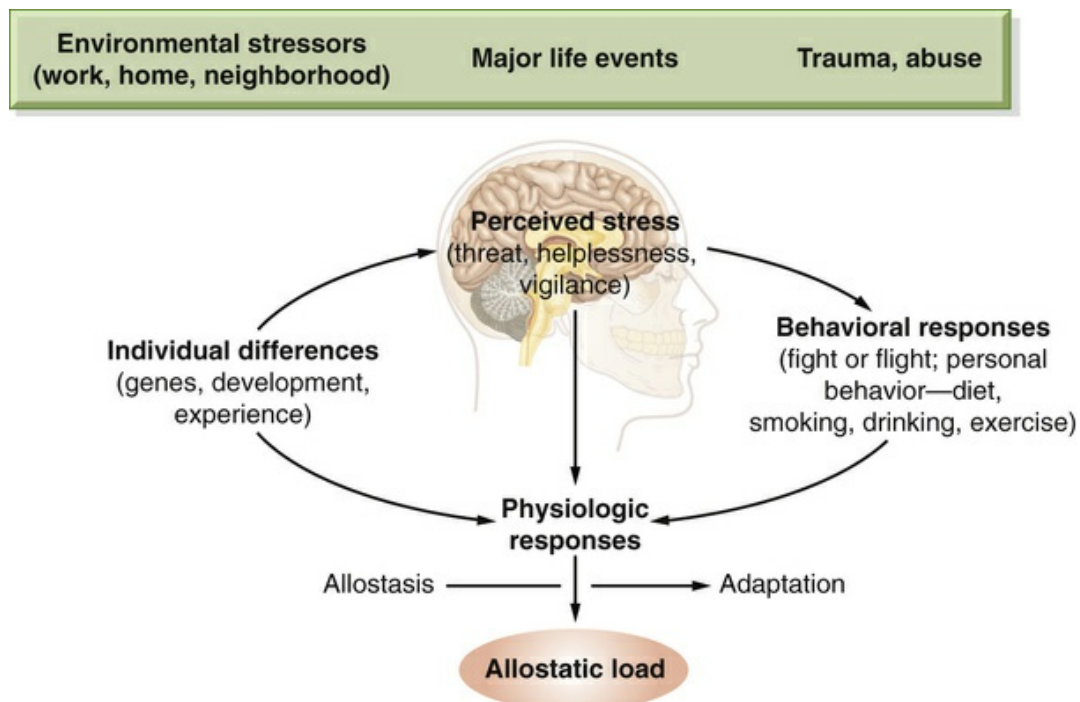

FIGURE 11.4 Physiologic and Behavioral Stress Responses. Stress processes arise from bidirectional communication patterns between the brain and other physiologic systems (autonomic, immune, neural, and endocrine). Importantly, these bidirectional mechanisms are protective, promoting short-term adaptation (allostasis). Chronic stress mechanisms, however, can lead to long-term dysregulation and promote behavioral responses and physiologic responses that lead to stress-induced disorders/diseases (allostatic load) that compromise health. (From McEwen BS: *Eur J Pharmacol* 583[2–3]:174–185, 2008.)

As studies point increasingly to the important role that stress plays in certain disease processes, research has begun to focus on the mechanisms and interactions among social, psychological, biologic, and behavioral risk factors responsible for these mind-body interactions. Molecular biologists, immunologists, neurologists, clinicians, and behavioral scientists are now exploring the role of the other half of the mind-body (dualistic) model—that is, the mind. What is emerging is a more holistic and complex model of health and disease states. This

model involves the biochemical relationships of the central and autonomic nervous systems, the endocrine system, and their relationships to stress-elicited coping behaviors that can modify the integrity of the immune system. Discoveries of these complex links have led to the creation of the field of psychoneuroimmunology.

Psychoneuroimmunologic Mediators of Stress

Psychoneuroimmunology (PNI) is the study of how the consciousness (*psycho*), the brain and spinal cord (*neuro*), and the body's defenses against infection and abnormal cell division (*immunology*) interact. Psychoneuroimmunology assumes that all immune-mediated diseases result from interrelationships among psychosocial, emotional, genetic, and behavioral factors with the neurologic, endocrine, and immune systems.¹⁸⁻²⁰ The immune system is integrated with other physiologic processes and is sensitive to changes in CNS and endocrine functioning that accompany psychologic states. **Stressors** (e.g., infection, noise, decreased oxygen supply, pain, malnutrition, heat, cold, trauma, prolonged exertion, radiation, responses to life events [including anxiety, depression, anger, fear, loss, and excitement], obesity, old age, drugs, disease, surgery, and medical treatment) can elicit the stress response through the action of the nervous and endocrine systems.

The field of PNI has generated a large body of research, some of which has led to strenuous scientific debate. For example, mouse models suggest a strong link between stress and breast cancer progression, yet this effect is not consistently found in humans,^{21,22} especially with respect to the causal role of personality in cancer mortality and morbidity.²¹ Current understanding in the PNI field is that hormones released by stress influence many metabolic systems and corresponding physiologic events. Furthermore, data now suggest that psychosocial stressors or interventions modulate the immune system to impact health outcomes.^{2,14,17,23-37} Studies support the link between psychosocial stressors and health outcomes for infectious disease and wound healing.³⁸⁻⁴³ A meta-analysis of 10 studies conducted among persons living in England found that any

level of psychologic distress is associated with increased mortality and increased risk of death from cardiovascular disease, external causes, and cancer (albeit only at higher levels of distress); 68,000 persons were used in this study and personal factors, such as age, smoking, and alcohol use, were adjusted accordingly.⁴⁴ Investigators studied workplace stressors and health outcomes.⁴⁵ Using meta-analysis of 228 studies they found that job insecurity increases the odds of reporting poor health by about 50%, high job demands raise the odds of having a diagnosed illness by 35%, and long work hours increase mortality by almost 20%.⁴⁵ Work-related stress can cause both behavioral and psychosocial problems. The World Health Organization (WHO) report focuses on the stress and health outcomes from work.⁴⁶ Fig. 11.5 summarizes psychosocial hazards that may affect both psychologic and physical health directly or indirectly through the experience of stress and risks for work-related stress.

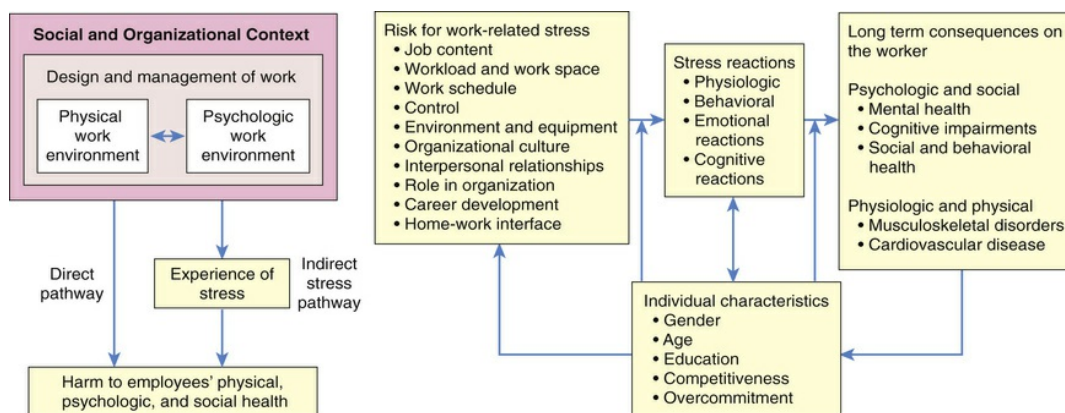

FIGURE 11.5 Psychosocial Work Environment and Work-Related Stress (Data from Leka S, Jain A: *Health impact of psychosocial hazards at work: An overview*, Geneva, 2010, Institute of Work, Health & Organizations, University of Nottingham, World Health Organization.)

Stress Response

The perception of stress initiates a series of events in the central and peripheral nervous systems (see Fig. 11.1). In the brain, stress elicits an anticipatory response that activates the limbic system; the brain area

responsible for motivation, emotions, and cognition. The limbic system also indirectly elicits both an endocrine stress response by stimulating neural pathways responsible for receiving sensory information and the release of norepinephrine from the locus ceruleus (LC). Norepinephrine release promotes arousal, increased vigilance, and anxiety, as well as other protective emotional responses. The fast-acting sympathetic adrenal medullary system in the periphery releases the catecholamines norepinephrine and epinephrine and the slower-acting HPA system culminates in the secretion of cortisol. The activation of these two stress systems redirects adaptive energy to the CNS and peripheral body sites to cope with stress (see [What's New? Insights into How the Mind Affects the Body](#)).

What's New?

Insights into How the Mind Affects the Body

Walter Cannon recognized nearly a century ago that stress or threat triggers the sympathetic nervous system to rapidly prepare the body for the *fight-or-flight* response. This adaptive activation of the sympathetic nervous system to effectively fight or flee from a dangerous situation involves, to name a few, increased blood flow to the heart and viscera, elevated metabolism, and pupil dilation. Catecholamine secretion from the adrenal medulla into the circulatory system plays a major role in facilitating this myriad of physiologic effects. Although the adrenal medulla is well-known to be connected to sympathetic neurons that project from the thoracic spinal cord to stimulate release of epinephrine and norepinephrine, until recently how the brain influences this adrenal-medullary system has been a mystery.

Using a technique to trace the pathways from the primate cerebral cortex that are linked to the adrenal medulla, Dunn and colleagues found cortical motor areas of the frontal lobe and somatosensory cortex also are involved in facilitating visceromotor and skeletomotor output. This cortical pathway coordinates the

body's motor system required to cope with stress with increased metabolism through adrenal medulla catecholamine secretion. Another pathway from the medial prefrontal cortex plays a role in regulating cognitive and emotional processing. Cognitive control over a stressful situation determines the degree or intensity of adrenal medulla secretion of catecholamines. Failure to assess or cope with a stressful situation may then lead to uncontrolled emotional states, heightened activation of the sympathetic nervous system, and the onset disorders, such as posttraumatic stress disorder or chronic psychosomatic illness. In summary, this study identifies key cortical brain regions involved in coordinating motor, cognitive, and emotional functions with adrenal medulla catecholamine secretion. This research offers insights into the mind-body connection underlying health and psychosomatic illness.

Sympathetic Nervous System

Catecholamines

Stress activates the **sympathetic nervous system (SNS)** to stimulate the release of **catecholamines** (epinephrine and norepinephrine) from the adrenal medulla into the bloodstream and nerve endings that innervate peripheral organs and tissues. The adrenal medulla is an extension of the SNS because preganglionic fibers from the splanchnic nerve terminate in the medulla to innervate chromaffin cells that produce catecholamines. These adrenergic effector molecules have multiple effects on gene expression and cellular function in the nervous, endocrine, cardiovascular, gastrointestinal, respiratory, reproductive, and immune systems. Each adrenergic system regulates cellular functions through distinct receptors (α_1 , α_2 , β_1 , β_2 , β_3) coupled to G-protein-mediated signal transduction pathways. For example, acute fight-or-flight responses increase heart rate by activating β_1 -adrenergic receptors in the heart muscle; blood from superficial

tissues is redistributed to long muscles by activating vascular α_1 - and β_2 -adrenergic receptors; respiratory rate is increased by activating bronchial α_1 - and β_2 -adrenergic receptors; energy is mobilized by activating β_2 - and β_3 -adrenergic receptors in adipose tissue and the liver; and immune cells, such as natural killer (NK) cells, are mobilized into circulation by activating β_2 -adrenergic receptors on leukocytes.⁴⁷ The physiologic effects of the catecholamines on organs and tissues are summarized in [Table 11.1](#) and [Fig. 11.2](#).

TABLE 11.1

PHYSIOLOGIC EFFECTS OF CATECHOLAMINES*

ORGAN/TISSUE	PROCESS OR RESULT
Brain	Increased blood flow; increased glucose metabolism
Cardiovascular system	Increased rate and force of contraction Peripheral vasoconstriction
Pulmonary system	Bronchodilation
Skeletal muscle	Increased glycogenolysis Increased contraction Increased dilation of muscle vasculature Decreased glucose uptake and utilization (decreases insulin release)
Liver	Increased glucose production Increased glycogenolysis
Adipose tissue	Increased lipolysis Decreased glucose uptake
Skin	Decreased blood flow
Gastrointestinal and genitourinary tracts	Decreased protein synthesis Decreased smooth muscle contraction Increased renin release Increased gastrointestinal sphincter tone
Lymphoid tissue	Acute and chronic stress inhibits several components of innate immunity, particularly decreasing number of natural killer cells
Macrophages	Inhibit and stimulate macrophage activity Depend on availability of type 1/proinflammatory cytokines, presence or absence of antigenic stressors, and peripheral corticotropin-releasing hormone (CRH)

*Some of these responses require glucocorticoids (e.g., cortisol) for maximal

activity (see text for explanation).

Data from Elenkov IJ, Chrousos GP: *Ann N Y Acad Sci* 966:290–303, 2002;
Granner DK: Hormones of the adrenal medulla. In Murray RK et al, editors:
Harper's biochemistry, ed 25, New York, 2000, McGraw Hill.

Epinephrine is rapidly transported to and acts on several organs, but it is metabolized quickly, making it short-acting. Metabolically, epinephrine causes transient hyperglycemia (high blood glucose level), decreases glucose uptake in the muscles and other organs, and decreases insulin release from the pancreas. This is accomplished by activating enzymes whose actions promote glucose formation (gluconeogenesis) and glycogen breakdown (glycogenolysis) in the liver, while inhibiting glycogen formation. This prevents glucose from being taken up by peripheral tissue and preserves it for the CNS. Further, very little adrenal norepinephrine reaches distal tissue; thus the effects caused by norepinephrine during the stress response are primarily elicited from the SNS.^{48,49}

Epinephrine has a greater influence on cardiac action and is the principal catecholamine involved in metabolic regulation. Epinephrine enhances myocardial contractility (inotropic effect), increases heart rate (chronotropic effect), and increases venous return to the heart, all of which increase cardiac output and blood pressure. Epinephrine dilates blood vessels of skeletal muscle, allowing for greater oxygenation. Epinephrine in the liver and skeletal muscles is rapidly metabolized and dilates blood vessels supplying skeletal muscles, allowing for more oxygenation. Epinephrine also mobilizes free fatty acids and cholesterol by stimulating lipolysis, freeing triglycerides and fatty acids from fat stores, and by inhibiting the degradation of circulating cholesterol to bile acids. The metabolic actions of epinephrine aid the metabolic actions of cortisol, which are similar.

Table 11.2 summarizes the actions of the two subclasses of adrenergic receptors. Epinephrine binds to and activates both α - and β -adrenergic receptors. Norepinephrine at physiologic concentrations binds primarily to α -adrenergic receptors.⁵⁰

TABLE 11.2**PHYSIOLOGIC ACTIONS OF α - AND β -ADRENERGIC RECEPTORS**

RECEPTOR	PHYSIOLOGIC ACTIONS
α_1	Increased glycogenolysis; smooth muscle contraction (blood vessels, genitourinary tract)
α_2	Smooth muscle relaxation (gastrointestinal tract); smooth muscle contraction (some vascular beds); inhibition of lipolysis, renin release, platelet aggregation, and insulin secretion
β_1	Stimulation of lipolysis; myocardial contraction (increased rate, increased force of contraction)
β_2	Increased hepatic gluconeogenesis; increased hepatic glycogenolysis; increased muscle glycogenolysis; increased release of insulin, glucagon, and renin; smooth muscle relaxation (bronchi, blood vessels, genitourinary tract, gastrointestinal tract)

Catecholamines can modify the numbers of cells of the immune system circulating in the blood.⁵¹ Injection of epinephrine into healthy human subjects is associated with a transient increase of the number of lymphocytes (e.g., T cells and natural killer [NK] cells) in the peripheral blood. Specifically, the levels of T cytotoxic and especially NK cells increase,⁵¹ whereas little change occurs in the levels of B lymphocytes. Qualitatively, lymphocyte responsiveness of T and B lymphocytes is reduced. Similar quantitative and qualitative changes are found 5 to 6 minutes after exposure to a psychologic or physical stressor.⁵² However, the effects of acute elevation of catecholamine levels on the alteration of lymphocyte function are short-lived, lasting only about 2 hours.⁵³

Catecholamines also increase proinflammatory cytokine production, for example, causing increased heart rate and blood pressure. Glucocorticoids are known to inhibit this proinflammatory production; however, inhibition depends on dose and cell or tissue type.³¹ More simply, glucocorticoids can also promote inflammation depending on dose and cell type.¹⁴ The possibility that chronic and dysfunctional HPA axis stimulation (as may occur during chronic inflammation) increases inflammation in the brain and other tissue may contribute to other diseases, including osteoporosis, metabolic disease (diabetes, obesity), and cardiovascular disease.³² Additionally, these interactions are nonlinear and are very complex (Fig. 11.6).

Staying on the Good Side of the Stress Spectrum

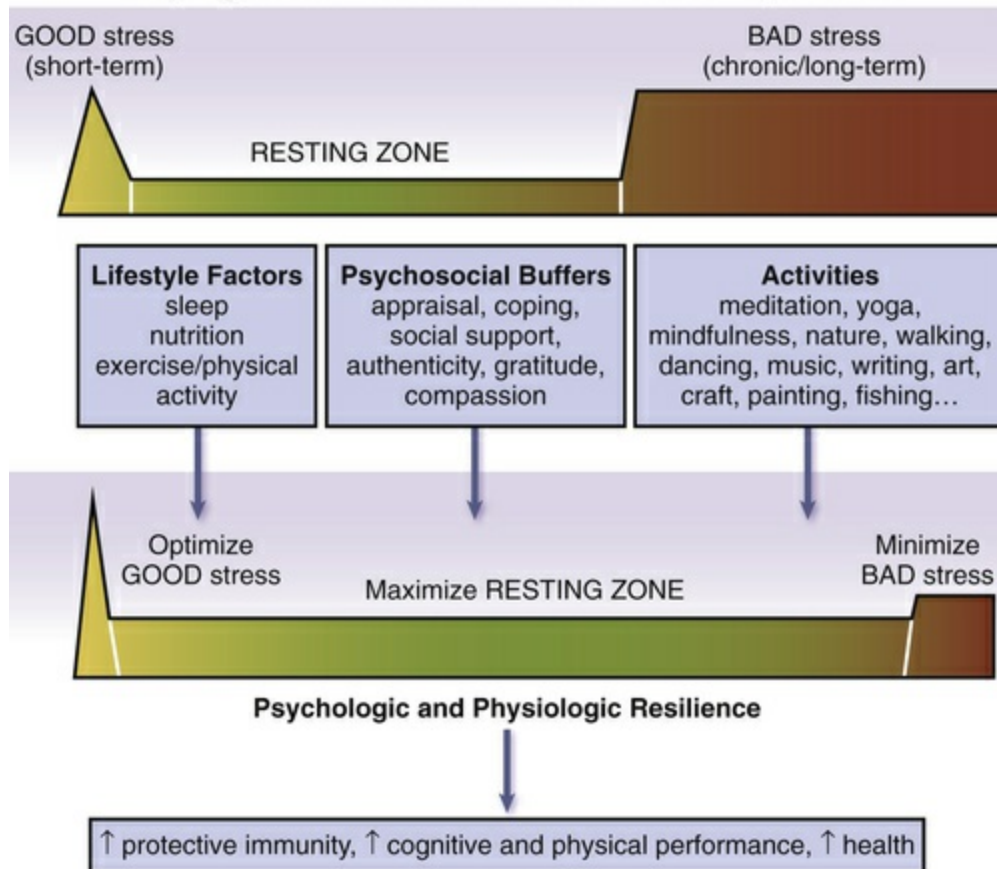

FIGURE 11.6 Stress Interactions Are Nonlinear and Complex. GOOD stress is shown on the left of the spectrum and involves a rapid biologic response to the stressor, followed by a rapid shutdown of the response upon cessation of the stressor. These responses support physiologic conditions that are likely to enhance protective immunity, cognitive and physical performance, and overall health. BAD stress, represented on the right of the spectrum, involves exposure to chronic or long-term biologic changes that are likely to result in dysregulation or suppression of immune function, a decrease in cognitive and physical performance, and an increased likelihood of disease. Short- and/or long-term stress is generally superimposed on a psychophysiological RESTING ZONE of low/no stress that also represents a state of health maintenance/restoration. To maintain health, one needs to optimize GOOD stress, maximize the RESTING ZONE, and minimize BAD stress. Achieving psychologic and physiologic resilience involves a multipronged approach. Sleep of a quality and duration that helps one feel rested in the morning, a moderate and healthy diet, and consistent and moderate exercise or physical activity are three *Lifestyle Factors* that are likely to enable one to stay on the “good” side of the stress spectrum. Effective appraisal and coping mechanisms, genuine gratitude, social support, and compassion toward others and oneself are likely to provide *Psychosocial Buffers* against bad stress and enable one to stay on the “good” side of the stress spectrum. Additionally, depending on individual preferences, *Activities*, such as, meditation, yoga, being in nature, exercise/physical activity, music, art, craft, dance, fishing, painting, also may reduce BAD stress, extend The RESTING ZONE, and optimize GOOD stress. Such personal activities are likely to involve different strokes

for different folks and need not always be meditative or reflective in nature. (Adapted from Dhabhar FS, McEwen BS: Bidirectional effects of stress on immune function: possible explanations for salubrious as well as harmful effects. In Ader R, editor: *Psychoneuroimmunology IV*, San Diego, 2007, Elsevier.)

Parasympathetic System

The parasympathetic system balances the sympathetic nervous system and, thus, it influences adaptation or maladaptation to stressful events. The parasympathetic system also has antiinflammatory effects and opposes the sympathetic (catecholamine) responses, for example, by slowing the heart rate.¹⁴ Researchers evaluate the relative balance of the parasympathetic and sympathetic nervous systems using a technique known as heart rate variability (the measurement of R wave variability from heartbeat to heartbeat).

Neuroendocrine Regulation

Hypothalamic-Pituitary-Adrenal System

In sequence, the PVN of the hypothalamus secretes **corticotropin-releasing hormone (CRH)**, which binds to specific receptors on anterior pituitary cells that, in turn, produce **adrenocorticotrophic hormone (ACTH)**. ACTH is then transported through the blood to the adrenal glands located on the top of the kidneys. After binding to specific receptors on the adrenal glands, the glucocorticoid hormones (primarily cortisol; from the adrenal cortex) are released. **Cortisol** (*hydrocortisone* is a synthetically produced but chemically identical version of cortisol) initiates a series of metabolic changes (see the following section [Glucocorticoids: Cortisol](#)); however, these hormones overall are thought to enhance immunity during acute stress and suppress immunity during chronic stress because of prolonged exposure and increased concentration.¹ Cortisol also sends a negative feedback signal to the pituitary and hypothalamus to terminate the HPA stress response.²³ Cortisol reaches *all* tissues, including the brain; easily penetrates cell membranes; and reacts with numerous intracellular glucocorticoid receptors. Because they spare almost no

tissue or organ and influence a large proportion of the human genome, they exert significant diverse biologic actions.²³

Glucocorticoids: Cortisol

Cortisol circulates in the plasma, both protein-bound and free. The main plasma-binding protein is called **transcortin** or **corticosteroid-binding globulin**. The unbound, or free, fraction is approximately 8% of the total plasma cortisol and is biologically active.⁵⁰ Cortisol mobilizes substances needed for cellular metabolism. One of the primary effects of cortisol is the stimulation of gluconeogenesis, or the formation of glucose from noncarbohydrate sources, such as amino acids or free fatty acids in the liver. In addition, cortisol enhances the elevation of blood glucose level promoted by other hormones, such as epinephrine, glucagon, and growth hormone. This action by cortisol is said to be *permissive* for the actions of other hormones. Cortisol also inhibits the uptake and oxidation of glucose by many body cells. The overall action of cortisol increases blood glucose concentration, thereby enabling the body to combat the stressor. The physiologic effects of cortisol are summarized in [Table 11.3](#).

TABLE 11.3

PHYSIOLOGIC AND ACUTE EFFECTS OF CORTISOL

FUNCTIONS AFFECTED	PHYSIOLOGIC EFFECTS
Carbohydrate and lipid metabolism	Diminishes peripheral uptake and utilization of glucose; promotes gluconeogenesis in liver metabolism cells; enhances gluconeogenic response to other hormones; promotes lipolysis in adipose tissue
Protein metabolism	Increases protein synthesis in liver and decreases protein synthesis (including immunoglobulin synthesis) in muscle, lymphoid tissue, adipose tissue, skin, and bone; increases plasma level of amino acids; stimulates deamination in liver
Antiinflammatory effects (systemic effects)	High levels of cortisol used in drug therapy suppress inflammatory response; inhibit proinflammatory activity of many growth factors and cytokines; however, over time some individuals may develop tolerance to glucocorticoids, causing an increased susceptibility to both inflammatory and autoimmune disease

Proinflammatory effects (possible local effects)	Cortisol levels released during stress response may increase proinflammatory effects
Lipid metabolism	Lipolysis in extremities and lipogenesis in face and trunk
Immune effects	<i>Treatment</i> levels of glucocorticoids are immunosuppressive; thus they are valuable agents used in numerous diseases; the T-cell or innate immunity system is particularly affected by these larger doses of glucocorticoids with suppression of Th1 function or innate immunity; <i>stress</i> can cause a different pattern of immune response; these nontherapeutic levels can suppress innate (Th1) and increase adaptive (Th2) immunity—the so-called <i>Th1 to Th2 shift</i> ; several factors influence this complex physiology and include long-term adaptations, reproductive hormones (i.e., overall, androgens suppress and estrogens stimulate immune responses), defects of hypothalamic-pituitary-adrenal axis, histamine-generated responses, and acute vs. chronic stress; thus stress seems to cause a Th2 shift <i>systemically</i> whereas <i>locally</i> , under certain conditions, it can induce proinflammatory activities and by these mechanisms may influence onset or course of infections and autoimmune/inflammatory, allergic, and neoplastic diseases
Digestive function	Promotes gastric secretion
Urinary function	Enhances excretion of calcium
Connective tissue function	Decreases proliferation of fibroblasts in connective tissue (thus delaying healing)
Muscle function	Maintains normal contractility and maximal work output for skeletal and cardiac muscle
Bone function	Decreases bone formation
Vascular system/myocardial function	Maintains normal blood pressure; permits increased responsiveness of arterioles to constrictive action of adrenergic stimulation; optimizes myocardial performance
Central nervous system function	Somehow modulates perceptual and emotional functioning; essential for normal arousal and initiation of daytime activity
Possible synergism with estrogen in pregnancy?	Suppresses maternal immune system to prevent rejection of fetus?

Cortisol also affects protein metabolism. It has an anabolic effect; that is, it increases the rate of synthesis of proteins and ribonucleic acid (RNA) in the liver. The anabolic effect of cortisol, however, is countered by its catabolic effect on protein stores in other tissues. Protein catabolism acts to increase levels of circulating amino acids, and chronic exposure to excess cortisol can severely deplete protein stores in muscle, bone, connective tissue, and skin. Further, cortisol

acts to reduce protein synthesis in nonhepatic tissues, a loss for which dietary protein cannot compensate. Some evidence suggests that cortisol depresses transport of amino acids into muscle cells while enhancing their uptake into the liver. Finally, cortisol promotes gastric secretion in the stomach and intestines, potentially causing gastric ulcers. This could account for the gastrointestinal ulceration observed by Selye. In contrast, norepinephrine reduces gastric secretion.

Chronic Stress–Induced Effects of Glucocorticoids.

Chronic secretion of glucocorticoids, along with catecholamines and the immune system, contributes to the development of the metabolic syndrome and the pathogenesis of obesity (Box 11.1). Elevated secretion of cortisol, norepinephrine (NE), epinephrine, and interleukin-6 (IL-6) promotes insulin release and decreases levels of growth and sex hormones. Over time, visceral fat increases accompanied by the loss of muscle mass (sarcopenia) and bone mass (osteoporosis).⁵⁴ The increase in adipose tissue is accompanied by the secretion of IL-6 and other cytokines. As a result, a low-grade, systemic inflammatory state emerges that induces insulin resistance and the onset of type 2 diabetes mellitus, tumor growth, atherosclerosis, and neurodegeneration.^{55,56}

Box 11.1

Glucocorticoids, Insulin, Inflammation, and Obesity

The signs and symptoms of Cushing syndrome (e.g., excess glucocorticoids [GCs]) include truncal obesity, relatively thin extremities, a “moon face,” and a “buffalo [neck] hump.” In such individuals the possibility of associated hypertension is high as well as increased risk of infection and metabolic syndrome or frank type 2 diabetes. In addition, the likelihood of an elevated ratio of intraabdominal subcutaneous fat mass to nonabdominal fat mass is high because the glucocorticoids mediate the redistribution of

stored calories into the abdominal region. The specific increase in abdominal fat stores is a consequence of elevated levels of glucocorticoids combined with increased insulin action. However, the increased levels of glucocorticoids need not be present in the circulation, but can be generated locally in fat by conversion of inactive cortisone to active cortisol through the action of the isoenzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) type-1. This conversion is referred to as “pre-receptor” metabolism of cortisol. The active steroid is secreted directly to the liver through the portal vein. In vitro insulin synthesis and secretion from the pancreas are inhibited by the glucocorticoids. However, increasing levels of glucocorticoids in vivo are associated with increasing insulin secretion possibly because of an antiinsulin effect on the liver, which appears to be vulnerable to the negative effects of glucocorticoids on insulin action. Hepatic insulin resistance is strongly associated with abdominal obesity.

Recent data reveal that the plasma concentration of inflammatory mediators, such as tumor necrosis factor-alpha (TNF- α) and interleukin-6 (IL-6), is increased in the insulin-resistant states of obesity and type 2 diabetes. Two mechanisms might be involved in the pathogenesis of inflammation: (1) glucose and macronutrient intake (i.e., which can be mediated through chronic stress) causes oxidative stress; and (2) the increased concentrations of TNF- α and IL-6 associated with obesity and type 2 diabetes might interfere with insulin signal transduction. This interference might promote inflammation. Chronic overnutrition (obesity) might thus be a proinflammatory state with oxidative stress.

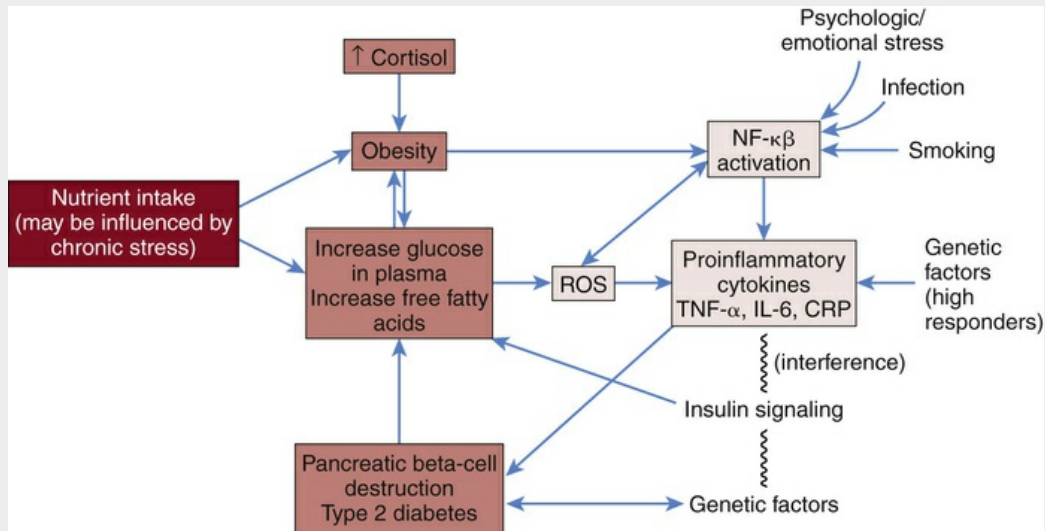

FIGURE Stress, Inflammation, Obesity, and Type 2 Diabetes. The induction of reactive oxygen species (ROS) generation and inflammation through the proinflammatory transcription factor, NF- κ B, activate most proinflammatory genes. Macronutrient intake, obesity, free fatty acids, infection, smoking, psychologic stress, and genetic factors increase the production of ROS. Interference with insulin signaling (insulin resistance) leads to hyperglycemia and proinflammatory changes. Proinflammatory changes increase the levels of TNF- α and IL-6, and also lead to the inhibition of insulin signaling and insulin resistance. Inflammation in pancreatic beta cells leads to beta-cell dysfunction, which in combination with insulin resistance leads to type 2 diabetes. *CRP*, C-reactive protein.

Epidemiologic evidence suggests that prenatal stress or elevations in levels of glucocorticoids may increase the subsequent risk of disease in offspring.⁵⁷ One study reported that high maternal cortisol concentration during pregnancy was associated with low birth weight.⁵⁸ This cortisol-induced low birth weight increases the offspring's risk of disease in later life, for example, obesity; cardiovascular conditions, such as hypertension; and behavioral disorders attributed to altered brain structure.^{35,58,59} Thus abnormal glucocorticoid elevation in utero dramatically affects human pathophysiology and, consequently, longevity.^{2,23,60}

The inhibitory effects of chronic glucocorticoid secretion on the growth axis are caused, in part, by elevated CRH secretion, which increases somatostatin, the inhibitor of growth hormone (GH) from the pituitary. Evidence linking the role of the HPA system to growth

is found in studies showing that children who experienced abuse may have decreased levels of GH and short stature, which is reversed when removed from the abusive, stressful environment and in children with Cushing syndrome where chronic exposure to glucocorticoids leads to arrested growth.⁶¹

The brain is a target of glucocorticoids and neurotransmitters that alters physiologic, behavioral, cognitive, and immune functions. When exposed to chronic stress, specific brain regions that have glucocorticoid (GC), catecholamine, and excitatory amino acid receptors may undergo dendritic retraction or expansion, cell death, or inhibition of neurogenesis to alter the brain functions.

GCs are involved in stress and circadian regulation and produce actions through the GC receptor (GR). GR can function as a nuclear transcription factor.⁶² Just like the nuclear genome, the mitochondria contain a small genome, the mitochondrial DNA (mtDNA), that encodes 13 polypeptides. Recent work has found that in the brain and other systems, GR is translocated from the cytosol to the mitochondria and that stress and corticosteroids have a direct influence on mtDNA transcription and mitochondrial physiology.⁶² Investigators also found that both acute and chronic stress and GC were linked with changes in the function of brain mitochondria.⁶²

The hippocampus has GRs that support the HPA negative feedback systems. Activation of hippocampal GRs by moderate stress also may lead to temporary hippocampal dendritic shrinkage and loss of spines. However, chronic stress may lead to cell death and inhibit neurogenesis. The loss of hippocampal neurons compromises the HPA negative feedback system and promotes the chronic increase in glucocorticoid secretion. This elevated, prolonged stress-induced increase in glucocorticoids is linked to cognitive deficits and major depression.¹⁶ Furthermore, chronic stress-induced elevations to glucocorticoids may be a risk factor for Alzheimer disease.⁶³ Middle-aged women exposed to heightened stress are at increased risk of developing Alzheimer disease.⁶⁴ An animal study showed that stress and glucocorticoid secretion impaired memory and increased Tau kinases and hyperphosphorylated Tau in the hippocampus and

prefrontal cortex.⁶⁵ This study provides insight into how the cumulative effects of stress and glucocorticoid exposure over time may progress to Alzheimer disease through the onset of Tau, which mediates the pathogenic actions of amyloid β .

Another brain region influenced by stress is the amygdala, a major site linked to fear and anxiety. Here, chronic stress expands the dendritic field and the synthesis of CRH neurons. The increase in amygdala CRH neurons is associated with increased fear and autonomic and HPA functioning found in anxiety disorders, such as posttraumatic stress disorder.¹⁶

The prefrontal cortex modulates higher order cognitive functions, such as abstract thinking, executive decision-making processing, and goal-directed behavior. Exposure to chronic stress causes dendritic shrinkage in the medial prefrontal cortex, which may lead to cognitive rigidity or inflexible thinking. However, another region, the orbitofrontal cortex, shows neurons with an expanded dendritic field that may lead to increased fear vigilance. These alterations in the prefrontal cortex disrupt the balance between the fear-generating amygdala and cognitive control or coping with stress.^{16,66} People exposed to high levels of stress have high levels of HPA hormones and catecholamines, impairments in working memory, and the ability to switch to flexible goal-directed behavior. Of relevance to mental disorders, stress may exacerbate the onset of schizophrenia. In addition, stress may facilitate the conversion from euthymia to bipolar disorder.

In summary, the stress-induced alterations in the brain associated with emotional and cognitive disorders may develop because of an inability of the brain to readily induce synaptic changes that promote recovery and resilience. Effective clinical treatments may be unlocking these inflexible neuronal functions and brain circuits and returning the brain to a functional state capable of generating adaptive cognitive and behavioral programs.

Glucocorticoids, Stress, and the Immune System.

Glucocorticoids or cortisol secretion during stress exerts beneficial

effects by inhibiting initial inflammatory effects, for example, vasodilation and increased capillary permeability.³² Cortisol also promotes resolution and repair. These actions are mainly accomplished by facilitating the effects of GR, namely, the transcription of genetic material (through DNA binding) within leukocytes.³² Because GR is so widely expressed, glucocorticoids influence virtually all immune cells. However, whether cortisol-induced effects are adaptive or destructive may depend on the intensity, type, and duration of the stressor; the tissue involved; and the subsequent concentration and length of cortisol exposure. Finally, glucocorticoids are shown to induce T-cell apoptosis.³²

Cortisol acts to suppress the activity of Th1 cells, which leads to a decrease in innate immunity and the proinflammatory response. Cortisol also stimulates the activity of Th2 cells, which increases adaptive immunity and the antiinflammatory response. Epinephrine and norepinephrine have a similar effect: a decrease in Th1 activity and an increase in Th2 activity.

Initially, immune responses are regulated by cells of *innate immunity* called *antigen-presenting cells (APCs)*, such as monocytes/macrophages, dendritic cells, and other phagocytic cells, and by Th1 and Th2 lymphocytes (cells involved in *adaptive immunity*). These cells secrete chemical messengers, called **cytokines**, that regulate innate and adaptive immune responses. Cytokines, such as interferons, interleukins, and tumor necrosis factors, can stimulate or inhibit various components of the immune system. Antigen-presenting cells also release cytokines that induce T cells to differentiate into Th1 cells. Th1 cells and APC cytokines work together to stimulate the activity of cytotoxic T cells, natural killer cells, and activated macrophages—the major components of innate immunity. These cytokines also stimulate the synthesis of nitric oxide and other inflammatory mediators that increase chronic delayed-type inflammatory responses. Because of this effect, these cytokines are sometimes referred to as proinflammatory cytokines.

The cytokines secreted by the Th2 cells act to inhibit Th1 cells and can promote adaptive immunity by stimulating the growth and

activation of mast cells and eosinophils, as well as the differentiation of B-cell immunoglobulins. Thus these cytokines are sometimes referred to as antiinflammatory cytokines⁶⁷ (Fig. 11.7). Moreover, cytokines can act synergistically, antagonistically, or reciprocally. However, the roles of cytokines are highly complex and much remains unknown. Regardless, the decrease in Th1 activity and the increase in Th2 activity are sometimes called a **Th1 to Th2 shift**. Individuals experiencing a Th1 to Th2 shift are more likely to experience allergic responses, infections, and temporary worsening of autoimmune conditions such as arthritis.

FIGURE 11.7 Effect of Corticotropin-Releasing Hormone (CRH)—Mast Cell—Histamine Axis, Cortisol, and Catecholamines on the Th1/Th2 Balance—Innate and Adaptive Immunity. Adaptive immunity provides protection against multicellular parasites, extracellular bacteria, some viruses, soluble toxins, and allergens. Innate immunity provides protection against intracellular bacteria, fungi, protozoa, and several viruses. Type 1 cytokines or proinflammatory cytokines include IL-12, interferon-gamma (IFN- γ), and tumor necrosis factor-alpha (TNF- α). Type 2 cytokines or antiinflammatory cytokines include IL-10 and IL-4. Solid lines (*black*) represent stimulation, whereas dashed lines (*blue*) represent inhibition (i.e., Th1 and Th2 are mutually inhibitory, IL-12 and IFN- γ inhibit Th2, and vice versa; IL-4 and IL-10 inhibit Th1 responses). Stress and CRH modulate inflammatory/immune and allergic responses by stimulating cortisol (glucocorticoid), catecholamines, and peripheral (immune) CRH secretion and by changing the production of regulatory cytokines and histamines. *CRH* (peripheral, immune), *CRH*, Corticotropin-releasing hormone; *IL*,

interleukin; *NE*, norepinephrine; *NK*, natural killer cell; *Tc*, cytotoxic T cell; *Th*, helper T cell. *Dashed lines*, decreased (inhibited); *solid lines*, increased (stimulation). (Redrawn from Elenkov IJ, Chrousos GP: *Trends Endocrinol Metab* 10[9]:359–368, 1999.)

The preceding description of the effect of stress hormones on the Th1-Th2 balance may not be accurate for certain local responses.^{67,68} That is, the release of catecholamines (epinephrine and norepinephrine) can cause certain epithelial cells of the lung to release cytokines that promote recruitment of leukocytes, potentially enhancing inflammation and worsening lung function. This paradoxical stress-induced potentiation of inflammation in the lungs may explain why “acute respiratory distress syndrome” often develops in individuals with major infections associated with profound activity of the stress response.⁶⁹

For years, stress hormones, especially glucocorticoids (cortisol), have been used therapeutically as powerful antiinflammatory/immunosuppressive agents. The synthetic forms of glucocorticoid hormones (exogenous types of antiinflammatory glucocorticoids administered for a pharmaceutical reaction) are poorly metabolized when compared to endogenous glucocorticoids, leading to a longer half-life and no circadian rhythm for these compounds. Moreover, these synthetic compounds bind to different targets, so each has a unique effect.¹⁴ Therapeutic levels of glucocorticoids inhibit the accumulation of leukocytes at the site of inflammation and inhibit the release of substances involved in the inflammatory response (i.e., kinins, plasminogen-activating factor, prostaglandins, and histamine) from the leukocytes. Glucocorticoids inhibit fibroblast proliferation and function at the site of an inflammatory response. This inhibition accounts for the poor wound healing, increased susceptibility to infection, and decreased inflammatory response that often are noted in individuals with chronic glucocorticoid excess.

Paradoxically, elevated levels of glucocorticoids and catecholamines (epinephrine and norepinephrine)—both endogenous and exogenously administered—may decrease innate immunity and increase autoimmune responses. These effects, which can accentuate inflammation in general and potentially increase neuronal death (e.g.,

in stroke victims),¹⁴ may explain the seemingly contradictory stress response of immunosuppression and the increased risk of infection (decreased innate immunity) with a heightened antibody response and autoimmune disease (increased adaptive immunity).

A perioperative risk factor for cancer recurrence is psychologic distress, beginning with the cancer diagnosis and following surgical and adjuvant treatment, when individuals experience stress, anxiety, and depression.^{70,71} Psychologic stress was reported to down-regulate cellular immune factors, including natural killer (NK) and cytotoxic T lymphocyte (CTL) activity, macrophage motility, and phagocytosis.⁷²⁻⁷⁵ Stress hormones, catecholamines, opioids, and glucocorticoids were relatedly shown in animal experiments to causally promote metastatic progression.^{76,77} Importantly, from animal experiments a single exposure to stress or stress hormones during a critical period of tumor progression could increase cancer mortality.⁷⁶ Surgery, itself, profoundly suppresses cell-mediated immunity.⁷⁸ Surgery, and associated neuroendocrine and paracrine responses, increased secretion of cortisol, leading to immune suppression and decreases in the number and function of NK, Th1, and CTL cells.^{79,80} These responses begin before surgery, are increased following surgery, and dissipate during the first few postoperative days or weeks.^{80,81} Immunosuppression during the perioperative period can increase long-term cancer recurrence rates (Fig. 11.8).^{77,82}

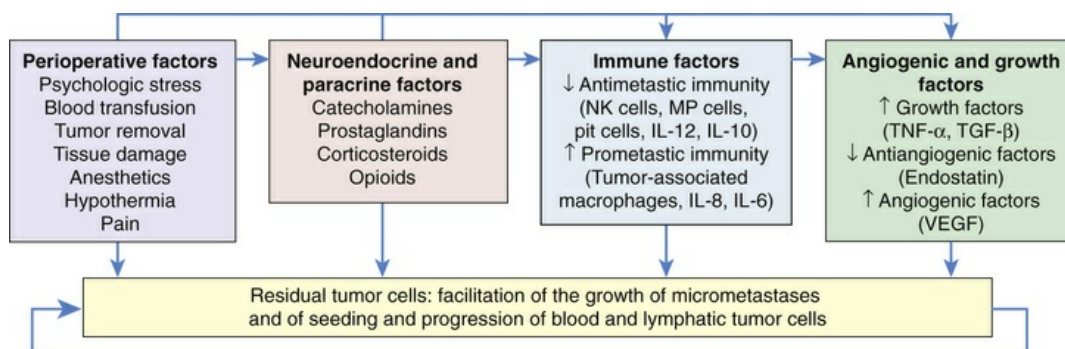

FIGURE 11.8 The Perioperative Period and the Excision of the Primary Tumor Can Promote the Development of Metastases. The perioperative timeframe is critical in determining long-term cancer outcomes. Various aspects of surgery, with the consequent paracrine and neuroendocrine responses and immunologic changes, can directly and indirectly affect

malignant tissue. The cancer outcome is affected by surgery-related anxiety and stress, nutritional status, anesthetics and analgesics, hypothermia, blood transfusion, tissue damage, and levels of sex hormones. *IL*, Interleukin; *MP*, mononuclear phagocyte cells; *NK*, natural killer cells; *TGF*, transforming growth factor; *VEGF*, vascular endothelial growth factor. (Data from Horowitz M et al: *Nat Rev Clin Oncol* 12:213–226, 2015.)

Corticotropin-Releasing Hormone (CRH)

CRH influences the immune system indirectly by the activation of cortisol (glucocorticoids) and catecholamines. CRH is secreted by the hypothalamus and also peripherally at inflammatory sites (called **peripheral [immune] CRH**).^{26,67} Peripheral (immune) CRH is proinflammatory, causing an increase in vasodilation and vascular permeability.⁸³ Therefore it appears that mast cells are the target of peripheral CRH. Mast cells release histamine, a well-known mediator of acute inflammation and allergic reactions (see [Fig. 11.7](#)). Recent evidence suggests that immune cells have histamine receptors and that histamine may have an effect similar to that of catecholamines. This finding suggests that histamine induces acute inflammation and allergic reactions while suppressing Th1 activity (decreasing innate immunity) and promoting Th2 activity (increasing adaptive immunity).^{69,83,84} A number of stress factors initiate CRH production, including high levels of interleukin-1 (IL-1) and IL-6. Increased CRH secretion facilitates cortisol secretion, which in turn inhibits further cytokine release by macrophages and monocytes. The observation that IL-1 can elicit changes in the nervous and endocrine systems by stimulating CRH production in the hypothalamus is part of a growing body of evidence demonstrating immune-induced regulation of the CNS. The release of the immune inflammatory mediators IL-6, tumor necrosis factor-alpha (TNF- α), and interferon is triggered by bacterial or viral infections, cancer, and tissue injury that in turn initiate a stress response through the HPA pathway. Enhanced systemic production of these cytokines also induces other CNS and behavior changes during the acute phase of an infectious episode, acting either directly in a distant, systemic “endocrine” way or indirectly through the

mediation of neuropeptides. These effects include pyrogenesis (fever), induction of slow-wave sleep, and anorexia, which together are adaptive responses to infection and possibly cancer. Slow-wave sleep is associated with enhanced release of growth hormone (GH) and a reduction in levels of cortisol, which is beneficial for tissue repair and enhanced immune response.

In summary, stress can activate an excessive immune response and, through cortisol and catecholamines, suppress the Th1 response, causing a Th1 to Th2 shift. Locally, stress can exert proinflammatory or antiinflammatory effects depending on the chemicals that are released in the local environment and the way that cells of the local environment respond to those chemicals. Moreover, different types of stressors may have variable effects on the immune response. Thus *systemic responses to stress* may cause a decrease in innate immunity and an enhancement in adaptive immunity, whereas *local responses to stress*, under certain conditions, may induce proinflammatory activities that influence the onset and cause of infectious, autoimmune/inflammatory, allergic, and neoplastic diseases.

Other Hormones

The immune system is integrated with other physiologic processes and is sensitive to changes in CNS and endocrine functioning, such as those that accompany psychologic states. For example, **neuropeptide Y (NPY)**, a sympathetic neurotransmitter and growth factor for many cells, is a stress-mediator implicated in atherosclerosis and tissue remodeling.⁵¹ Other hormones that influence the stress response are listed in [Table 11.4](#). Neuropeptides and hormones have a significant effect on the immune response. This effect on immune function depends on the type of factor secreted, with some factors enhancing activity, some suppressing activity, and some both enhancing and suppressing activity, depending on the concentration and length of exposure, the target cell, and the specific immune function studied.

TABLE 11.4

OTHER HORMONES THAT INFLUENCE THE STRESS RESPONSE

OTHER HORMONES THAT INFLUENCE THE STRESS RESPONSE

HORMONE	SOURCE	ACTION
β -Endorphins (endogenous opiates)	Pituitary and hypothalamus	Activates endorphin (opiate) receptors on peripheral sensory nerves, leading to pain relief or analgesia Hemorrhage increases levels to inhibit blood pressure or delay compensatory changes that would increase blood pressure ¹
Growth hormone (GH, somatotropin)	Anterior pituitary gland	Affects protein, lipid, and carbohydrate metabolism Counters effects of insulin Involved in tissue repair May participate in growth and function of immune system ² Levels increase after a variety of stressful stimuli (cardiac catheterization, electroshock therapy, gastroscopy, surgery, fever, physical exercise) Increased levels associated with psychologic stimuli (taking examinations, viewing violent or sexually arousing films, certain psychologic performance tests) Prolonged stress (chronic stress) suppresses growth hormone
Prolactin	Anterior pituitary gland; numerous extrapituitary tissue sites	Increases in response to many stressful stimuli (including procedures such as gastroscopy, proctoscopy, pelvic examination, and surgery) ³ Requires more intense stimuli than those leading to increases in catecholamine or cortisol levels Levels show little change after exercise
Oxytocin	Hypothalamus	Promotes bonding and social attachment In animals it is associated with reduced hypothalamic-pituitary-adrenal (HPA) activation levels and reduced anxiety ⁴
Testosterone	Leydig cells in testes	Regulates male secondary sex characteristics and libido Levels decrease after stressful stimuli (anesthesia, surgery, marathon running, mountain climbing) ⁵ Decreased by psychologic stimuli; however, some data indicate that psychologic stress associated with competition (e.g., pistol shooting) increases both testosterone and cortisol levels, especially in athletes older than 45 years ⁶ Markedly reduced in individuals with respiratory failure, burns, and congestive heart failure ⁷ Decreased levels occur during aging and are associated with a lower cortisol responsiveness to stress-induced inflammation ⁸
Estrogen	Ovaries	Works in concert with oxytocin, exerting a calming effect

		during stressful situations ⁹
Melatonin	Produced by pineal gland	Increases during stress response; release is suppressed by light and increased in the dark; receptors have been identified on lymphoid cells, possibly higher density of receptors on T cells than B cells; suppression of lymphocyte function by trauma was reversed by melatonin ¹⁰
Somatostatin (SOM)	Produced by sensory nerve terminals found in and released from lymphoid cells and hypothalamus	Natural killer (NK) function and immunoglobulin synthesis are decreased by SOM; growth hormone secretion decreased by SOM
Vasoactive intestinal peptide (VIP)	Found in neurons of central nervous system (CNS) and in peripheral nerves	VIP increases during stress; VIP-containing nerves are located in both primary and secondary lymphoid tissues, around blood vessels, and in gastrointestinal tract; VIP receptors are on both T and B cells; VIP may influence lymphocyte maturation; cytokine production by T cells is modified by VIP; B cells and antibody production are influenced by VIP
Calcitonin gene-related peptide (CGRP)	Found in spinal cord motor neurons and in sensory neurons near dendritic cells of skin and in primary and secondary lymphoid tissues	CGRP receptors are present on T and B lymphocytes; thus it is likely that CGRP can modulate immune function; CGRP may enhance acute inflammatory response because it is a vasodilator; maturation of immune B lymphocytes is inhibited by CGRP; IL-1 is inhibited by CGRP, which is important for activation of T cells; it has been shown to interfere with lymphocyte activation
Neuropeptide Y (NPY)	Present in neurons of CNS and in neurons throughout body; co-localized in nerve terminals in lymphatic tissues with norepinephrine	Lymphocytes have receptors for NPY and thus may modulate their function; ¹¹ several lines of evidence suggest that NPY is a neurotransmitter and neurohormone involved in stress response; increased levels of NPY occur in plasma in response to severe or prolonged stress; it may be responsible for stress-induced regional vasoconstriction (splanchnic, coronary, and cerebral); it may also increase platelet aggregation ²
Substance P (SP)	Produced by a neuropeptide classified as tachykinin (increases heart rate subsequent to lowering blood pressure) found in brain, as well as nerves innervating secondary lymphoid	SP increases in response to stress; receptors for SP are found on membranes of both T and B cells, mononuclear phagocytic cells, and mast cells; proinflammatory activity induces release of histamine from mast cells during stress response; causes smooth muscle contraction, causes macrophages and T cells to release cytokines, and increases antibody production

Hormones of the Female Reproductive System.

The HPA axis exerts powerful, multilevel effects on the female reproductive system. Stress generally inhibits the female reproductive system (Fig. 11.9), primarily through the HPA axis by (1) CRH suppression of hypothalamic gonadotropin-releasing hormone (GnRH) secretion and CRH stimulation of β -endorphin release; (2) cortisol-inhibited secretion of luteinizing hormone (LH), estradiol, progesterone, and possibly testosterone;^{85,86} and (3) cortisol-induced target tissue resistance by estradiol.^{87,88} The locus ceruleus–norepinephrine (LC/NE) system provides positive input to the reproductive system, which is frequently altered by the stress-activated HPA axis. Sexual stimulation and GnRH neuron activation, however, may cause the gonadal axis to be resistant to suppression by the HPA axis. Table 11.5 presents potential pathologic effects of central and peripheral CRH in women.

FIGURE 11.9 Stress and the Female Reproductive System. Interactions of the reproductive system with the hypothalamic-pituitary-adrenal (HPA) axis and locus ceruleus–norepinephrine system (LC/NE). Corticotrophic cells of the pituitary gland express proopiomelanocortin (POMC) peptides. Stress generally inhibits the female reproductive system primarily through the HPA by (1) suppressing hypothalamic gonadotropin-releasing hormone (GnRH) secretion by corticotropin-releasing hormone (CRH) and CRH-induced β -endorphins; (2) inhibiting GnRH, pituitary luteinizing hormone (LH), and ovarian estradiol (E₂) secretion by cortisol; and (3) enhancing cortisol-induced target tissue resistance to estradiol. The LC/NE system provides positive input to the reproductive system, which can be overridden by the stress-activated HPA. Estradiol can cause the reproductive system to stimulate the stress system by stimulating CRH secretion and inhibiting reuptake and catabolism of catecholamines. *ACTH*, Adrenocorticotropic hormone; *FSH*, follicle-stimulating hormone. Dashed lines refer to inhibitory pathways. Solid lines refer to direct stimulatory pathways. (Adapted from Chrousos GP et al: *Ann Intern Med* 129[3]:229–240, 1998.)

TABLE 11.5

POTENTIAL PATHOLOGIC EFFECTS OF CENTRAL AND PERIPHERAL CORTICOTROPIN-RELEASING HORMONE (CRH) IN WOMEN

CHANGES	ALTERATIONS
Central CRH	
Increased secretion	Hypercortisolism

	Melancholic depression Eating disorders Chronic active alcoholism Chronic active exercise Consequences: osteoporosis, visceral obesity, infertility Tau protein misfolding-Alzheimer disease?*
Decreased secretion	Atypical depression Seasonal affective disorder Chronic fatigue and fibromyalgia syndromes Rheumatoid arthritis Postpartum blues, depression, and autoimmunity Premenstrual tension syndrome Menopausal depression
Peripheral CRH	
Increased secretion of immune CRH	Inflammatory disorders
Increased secretion of placental CRH	Premature labor
Decreased secretion of placental CRH	Delayed labor
Decreased secretion of ovarian CRH	Ovarian dysfunction Anovulation Defective corpus luteum function
Increased secretion of ovarian CRH	Early menopause
Decreased secretion of endometrial CRH	Infertility Early spontaneous abortion

*New line of investigation: Filipcik P et al: *Cell Mol Neurobiol* 32(5):837–845, 2012.

Data from Chrousos GP et al: *Ann Intern Med* 129(3):229–240; Kalantaridou SN et al: *J Reprod Immunol* 62(1–2):61–68, 2004.

Estrogen stimulates the HPA axis, and HPA responsiveness is greater in women than in men.⁸⁸ Estrogen directly stimulates the CRH gene promoter and the central NE system, which may explain the effects of estradiol fluctuations on adult women's slight hypercortisolism, increases in affective anxiety and eating disorders, mood cycles, and vulnerability to autoimmune and inflammatory disease. Estradiol down-regulates glucocorticoid receptor binding in the anterior pituitary, hypothalamus, and hippocampus, which tends to *increase* HPA activity by interfering with glucocorticoid-negative feedback, whereas progesterone opposes these effects.⁸⁹ Thus alterations in estradiol levels during normal menses, perimenopause (including increases as well as decreases), and menopause modify the

regulatory feedback loop, and adaptations over time develop as a new equilibrium is established in the relationship (see Fig. 11.9). Over time, these changes increase the incidence of mood alterations, eating disorders, anxiety, depression, weight alterations, and inflammatory and immune disorders.

Endorphins and Enkephalins.

Endorphins and enkephalins (endogenous opiates) are released into the blood as part of the response to stressful stimuli. These proteins found in the brain have pain-relieving capabilities. Stressful stimuli include traumatic injury and an acute, intense stress situation, such as first-time parachute jumping. In inflamed tissue, immune cell-derived endorphins activate endorphin receptors on peripheral sensory nerves, leading to pain relief or analgesia.⁹⁰ Hemorrhage increases β -endorphin levels, which inhibits blood pressure increases or delays compensatory changes that increase blood pressure.⁹¹ Thus endogenous opiates modulate blood pressure instability and neuroendocrine and cytokine responses to blood losses.^{92,93}

In conditions or activities when endogenous opiate activity increases, people not only experience insensitivity to pain but also report increased feelings of excitement, positive well-being, or euphoria. In addition, cells of the immune system synthesize and release opioids when lymphoid cells are activated.⁹⁴ T and B lymphocytes and mononuclear phagocytic cells have receptors for opioids. Endorphins may play a role in the excitement and exhilaration produced by dancing, contact sports, and combat. Little direct evidence, however, links the endorphin system to most of these activities.

Prolactin.

Prolactin is released from the anterior pituitary gland as well as numerous extrapituitary tissue sites. It is necessary for lactation and breast development. Prolactin receptors are present in many different tissues, including the liver, kidney, intestine, and adrenals. Prolactin is also produced by lymphoid cells.⁹⁵ Prolactin is necessary for lactation

and breast development. Plasma prolactin levels also increase after exposure to a variety of stressful stimuli, including gastroscopy, proctoscopy, pelvic examination, and surgery; after taking examinations; and after receiving various sexual stimuli, for example, stimulation of the nipple or areola in women. Unlike GH, prolactin levels show little change after exercise. However, similar to GH, prolactin secretion appears to require more intense stimuli than those leading to increases in catecholamine or cortisol levels. Immune cells also are influenced by prolactin. Prolactin acts as a second messenger for IL-2 and has a positive influence on B-cell activation and differentiation. Several classes of lymphocytes have receptors for prolactin, suggesting a direct effect of prolactin on immune function.

Oxytocin.

Oxytocin, a peptide hormone and neurotransmitter produced in the hypothalamus, is well-known to be secreted by the posterior pituitary in females to induce parturition and lactation. In the brain, oxytocin acts on brain circuits, including the amygdala, HPA, and sympathetic nervous systems, to modulate or buffer fear and anxiety and attenuate the HPA stress response.⁹⁶ Animal studies further indicate that oxytocin stimulates prosocial behavior, such as maternal or parental care and mother-infant bonding. In humans, oxytocin facilitates interpersonal gaze; social support; maternal care;^{97,98} and, when secreted during orgasm in both sexes, the prosocial hormone may promote bonding and social attachment. Some but not all studies further suggest oxytocin may have a role in promoting trust.⁹⁸ In summary, oxytocin is increasingly recognized as a prosocial hormone that strengthens social relationships, social support, and protection and also attenuates psychosocial stressful events.

Testosterone.

Testosterone, a hormone secreted by Leydig cells, regulates male secondary sex characteristics and libido. Testosterone levels decrease after stressful stimuli. This decrease in testosterone level occurs after stimuli such as ether or anesthetic administration, surgery, marathon

running, and mountain climbing. The mechanism causing decreased levels of testosterone is thought to be exerted by cortisol and β -endorphin.

Psychologic stimuli also lead to a decrease in testosterone levels. Men engaged in rigorous combat training and those engaged in the first several weeks of officer candidate school experience significant drops in testosterone levels.^{99,100} However, other data have shown that the psychologic stress associated with some types of competition (e.g., pistol shooting) *increases* both testosterone and cortisol levels, especially in athletes older than 45 years.¹⁰¹ Moreover, individuals with acute illness, such as respiratory failure, burns, and congestive heart failure, show a marked reduction in plasma testosterone level.¹⁰²

The direct immunologic effects of sex hormones contribute to the sexual dimorphism seen in the incidence of autoimmune disease¹⁰³ and the greater susceptibility to sepsis and mortality in males following injury.¹⁰⁴ Estrogens generally are associated with a depression of T-cell–dependent immune function and an enhancement of B-cell functions, and androgens suppress both T- and B-cell responses.¹⁰² In injury, however, males produce greater amounts of proinflammatory cytokines, a profile that is associated with poor outcome.¹⁰⁵ Additionally, androgens appear to induce a greater degree of immune cell apoptosis following injury, a mechanism that may elicit a greater immunosuppression in injured males vs. females.¹⁰⁶ (A list of other hormones, including melatonin, substance P, neuropeptide Y, calcitonin gene–related peptide, somatostatin, and vasoactive intestinal peptide, is contained in [Table 11.4](#).)

Stress, Illness, and Coping

Cortisol secretion during stress may be beneficial for several reasons. Gluconeogenesis prompted by cortisol ensures an adequate source of glucose (energy) for body tissues, and nerve cells in particular. The pooling of amino acids from catabolized proteins may ensure amino acid availability for protein synthesis in certain cells. The redistribution of protein to sites where replacement is critical, such as

muscle or cells of damaged tissue, would be beneficial. Short-term, cortisol-induced alterations in immune cell distribution (e.g., traffic) patterns may be adaptive, with a decrease in peripheral blood cell numbers as effector cells locate to sites of injury or inflammation. In addition, decreased immune cell activity by cortisol is beneficial in some situations because it prevents immune-mediated tissue damage by prolonged cell exposure to high levels of certain cytokines. Whether cortisol-induced effects are adaptive or destructive may depend on the intensity, type, and duration of the stressor, and the subsequent concentration and length of cortisol exposure that target cells of the individual experience.

Extreme physiologic stressors, such as severe burn injury, represent a predictable stimulus for the stress responses described previously. A less severe and defined event or situation, however, can be a stressor for one person and not for another. Many stressors, such as fasting or temperature changes, do not necessarily cause a physiologic stress response if psychologic factors are minimized. Stress itself is not an independent entity but a system of interdependent processes that are moderated by the nature, intensity, and duration of the stressor and the perception, appraisal, and **cop**ing efficacy of the affected individual, all of which in turn mediate the psychologic and physiologic response to stress. Further, adjustment to repetitive stressors is based on a person's appraisal of a situation.¹⁰⁷ Illustrating the influence of an individualized stress appraisal on physiologic processes, a meta-analysis of the relationships between stressors and immunity found that a higher *perception* of stress was associated with reduced T-cytotoxic (Tc) cell cytotoxicity although not with levels of circulating Th or Tc lymphocytes.¹⁰⁸ Appraisals of highly threatening stressors also are coupled to intense cognition rumination and greater inflammatory stress responses.^{109,110} Of relevance to the importance of mental well-being in the context of overall health, a recent study reported that after adjusting for age, sex, follow-up year, all psychiatric and physical conditions, and socioeconomic factors, individuals who perceived higher levels of stress were at increased risk of requiring hospitalization or rehospitalization.¹¹¹

Psychosocial distress may be predictive of psychological and physical health outcomes. In **psychologic distress**, the individual feels a general state of unpleasant arousal after exposure to life events that manifest as physiologic, emotional, cognitive, and behavioral changes. Periods of depression and emotional upheaval often are associated with adverse life events and place the affected individual at risk for immunologic deficits, increasing the risk of ill health.¹¹² An older meta-analysis of studies demonstrates the longstanding relationship between depression and reduction in lymphocyte proliferation and NK cell activity.¹¹³ Multiple moderating factors may be important in immune modulation in depressed individuals, including comorbidities such as alcoholism. Adverse life events having the most negative effect on immunity are characterized as uncontrollable, undesirable, and overtaxing the individual's ability to cope.

Low socioeconomic status (SES), as indicated in terms of income, education, or occupation, is found to be associated with higher rates of mortality and morbidity. People of lower SES may be confronted with situations characterized by uncontrollable exposure to psychosocial stress or allostatic overload that increase the risk for disease by continuously activating the sympathetic and HPA systems.¹¹⁴ Indeed, low SES individuals exhibit higher basal levels of cortisol and catecholamines than those with higher income and education.¹¹⁵ This association between SES and physiologic measures was independent of race, age, gender, and body mass.

Evidence also points to the emerging connection between early stressful life events and a range of chronic illnesses in later life. Childhood adversity (e.g., abuse, neglect, a dysfunctional family lifestyle, low SES) increases the risk of developing cardiovascular disease, type 2 diabetes, cancer, and a number of somatic disorders. Exposure to stress-induced dysregulation of the immune system in vulnerable children may be a major factor responsible for the subsequent onset of chronic diseases and premature death¹¹⁶ (see *What's New? How Childhood Poverty Compromises Adaptive Body and Brain Functions* located on the Evolve site).

It should be further noted that the developing HPA axis is

hypothesized to be influenced by parental rearing styles. Inconsistent parental discipline and monitoring are related to a flatter diurnal cortisol slope (e.g., lower morning and elevated evening cortisol secretion), problem behavior of children characterized by aggression and defiance,¹¹⁷ and decreased physical and mental health.¹ This altered diurnal cortisol secretion pattern is reported to be a reflection of chronic exposure to stress occurring in young children.¹¹⁸

Animal studies reported that stress contributes to the initiation, growth, and metastasis of certain tumors.¹¹⁹ In humans, stress affects important processes in cancer including antiviral responses, deoxyribonucleic acid (DNA) repair, and aspects of cellular aging.¹¹⁹ The role of epigenetics and stress is an emerging field with strong implications for the intersection between stress and disease. A very recent study suggests that breast cancer bone metastases may be influenced by chronic stress by increasing the levels of Receptor Activator of Nuclear Factor κ B Ligand (RANKL) that are expressed by osteoblasts, a known chemoattractant for RANK-expressing breast cancer cells.¹²⁰ However, the overall evidence is mixed from prospective studies linking stress with cancer incidence and progression. Although stress may influence the progression and recurrence of cancer, critical prospective studies have not always been supportive.¹²¹ Studies examining impairments in antiviral immunity and chronic activation of hormonal responses (e.g., HIV-related tumors, hepatocellular carcinoma, and cervical cancer) may be more successful for defining the stress-related mechanisms.¹¹⁹ Previous and current evidence show a relationship between immune stimulation and heart disease.¹²² The relationship between stress and cardiovascular health may be mediated by stress-induced changes in immune function, which may potentiate proinflammatory processes and permit alterations leading to heart disease.¹²³ A new study of heart disease and inflammation demonstrates that monocytes and splenic macrophages invade atherosclerotic plaques after an initial myocardial infarction (heart attack), rendering them unstable and as such contribute to secondary heart attacks.¹²⁴

In the past decade, evidence has accumulated linking severe

psychosocial stress resulting from negative life events to a chronic syndrome with mental and physical consequences. Posttraumatic stress disorder (PTSD) has been described in many populations.¹²⁵⁻¹²⁷ A cascade model has been proposed to describe the pathogenesis and clinical course illustrating the clinical, epidemiologic, neurobiologic, and psychosocial components of PTSD.¹²⁸ The study of PTSD has contributed to the knowledge concerning mechanisms involved in the chronic stress and disease relationship. Recently an appreciation of the association of chronic stress with high levels of cortisol production and paradoxical bioavailability (i.e., bound to plasma protein and therefore not bioavailable) of cortisol has been gained.¹²⁹

Another well-documented finding is that exposure to major stressful life events, such as interpersonal loss (e.g., death of spouse, job termination) or the advent of serious health-threatening issues (e.g., cancer diagnosis, cardiovascular disease), increases the risk of major depressive disorder.¹³⁰ Furthermore, studies suggest that stressors dramatically disrupt the person's life plans and goals and not only promote major depression but also increase the likelihood of developing diverse health problems that may be mediated and exacerbated at least, in part, by inflammation, such as asthma, rheumatoid arthritis, chronic pain, certain cancers,^{1,131-133} and cardiovascular disease, the leading cause of death in major depression.¹³⁴

This complex interplay connecting stress, depression, and inflammation may be understood in the context that stress is known to up-regulate proinflammatory cytokines.^{133,135} One mechanism involving proinflammatory cytokines on major depression is the effects of TNF- α , IL-2, and IL-6 in breaking down tryptophan, the essential amino acid of serotonin synthesis.¹³⁶⁻¹³⁸ IL-6 and TNF- α also may deplete serotonin levels by metabolizing to 5-hydroxyindoleacetic acid. Over time, stress-induced proinflammatory cytokines reduce serotonin synthesis or increase serotonin degradation that together contribute to alterations in mood, emotion, and motivational states and the eventual onset of major depression.

Another contributing factor that increases the risk of stress-induced

inflammation and depression is oxidative stress, which potentially damages or shortens the telomeres and accelerates cellular aging.^{139,140} Telomeres are DNA-protein complexes that cap the chromosomal DNA ends to protect the chromosome from damage. Although telomere shortening is part of the normal aging process, chronic stress accelerates telomere shortening and over time increases the risk of a number of age-related diseases, including cancer, cardiovascular disease, diabetes, obesity, Alzheimer disease, and early death.^{141,142} Toxic exposure to glucocorticoids and catecholamines that promote oxidation, inflammation, and telomere shortening also is linked to depression, bipolar, and possibly anxiety disorders, especially when exposed to childhood maltreatment or trauma.¹⁴³⁻¹⁴⁵

The influence of repetitive but episodic stress on cancer survivors demonstrates a connection between events such as mammography and activation of the HPA axis. Early research with breast cancer survivors by Cordova and colleagues¹⁴⁶ demonstrated a link between sympathetic activity and HPA axis activation, noting that some women reported symptoms of PTSD (heart palpitations, panic, shakiness, nausea) during thoughts of recurrence triggered by events such as finding themselves near the hospital where they received initial treatment.¹⁴⁶ HPA axis activation also influences organs and tissues that enable bidirectional communication processes (feedback loops) between neuroendocrine and immune processes.¹⁴⁷ For example, among breast cancer survivors 3 to 5 years post diagnosis, elevated baseline cortisol levels and blunted cortisol reactivity were reported in response to the anticipation of a real, regularly scheduled mammogram, and alterations in cortisol level and heart rate variability were reported in women simulating the threat of cancer with a controlled laboratory stressor.^{148,149} Further, Ma and colleagues¹⁴⁸ reported that the threat of cancer recurrence (using a simulated mammography event as a stressor to elicit thoughts of cancer recurrence) elicited greater alterations in heart rate variability when compared with another simulated controlled stressor. These studies suggest activation of the autonomic nervous system to events, such as mammography, that occur repeatedly throughout breast

cancer survivorship, although the timing of onset of these autonomic activation responses to a stressor is unclear. Similar ANS activation may occur in association with events particular to the management of many other types of chronic illnesses as well as interactions with the healthcare system (see [What's New? Attenuating the Effects of Stress on Cancer](#)).

What's New?

Attenuating the Effects of Stress on Cancer

Chronic exposure to psychosocial stress can compromise health by increasing inflammation and promoting the development of diseases including cancer. Preclinical research demonstrates that prolonged stress-induced activation of the sympathetic nervous system (SNS) increases the progression of tumors by recruiting inflammatory cells to tumors and forming blood vessels that provide routes for tumor cell transport. In addition, the lymphatic system, which is innervated by the SNS and involved in immune function, also may influence cancer progression by providing a means for tumor cells to disperse through the lymphatic vasculature and a source of chemokines that promote the invasion of tumor cells.

Of interest, a preclinical study by Le and colleagues recently showed the effects of stress on tumor lymphatic vasculature and tumor breast cancer cell progression. In this study, investigators using an animal model of chronic stress reported an increase in intratumoral lymphatic vessel density (LVD), as well as increased dilation of lymphatic vessels that drain metastatic tumor cells into the lymphatic circulation. The investigators then examined whether blocking the stress-induced effects of norepinephrine on β -adrenoceptors, which are present on both tumor and inflammatory cells, will attenuate the increase in intratumoral LVD. Mice treated with the beta-blocker propranolol, a drug used clinically to treat hypertension, reduced stress-induced intratumoral LVD and tumor

cell dissemination. The potential benefits of using propranolol treatment to limit LVD were then investigated in 956 people who had breast cancer. Analysis revealed that beta-blocker treatment significantly reduced the risk of lymph node metastasis. Thus inhibition of SNS signaling through the norepinephrine β -adrenoceptor attenuates in animal models the effects of chronic stress on intratumoral LVD and metastasis in people with breast cancer. The researchers conclude the results offer a promising treatment strategy to reduce the adverse effects of stress-induced SNS signaling on lymphatic vascular remodeling and the progression of cancer.

Data from Cole SW et al: *Nat Rev Cancer* 15:563–572, 2015; Le CP et al: *Nat Comm* 7:10634, 2016.

These additional stresses may affect the course of illness as well as interfere with the efficacy of the medical intervention. Identifying and reducing stress in the clinical setting have particular applicability in both disease prevention and illness management. In addition to medical procedures, patient-provider communication also provides an important area for future research. Recent studies of cancer communication and patient-provider interaction have demonstrated a link between communication events and emotional outcomes, such as uncertainty and mood state in breast cancer survivors.^{150,151} Although a logical extension, it remains to be seen if these emotional outcomes affect physiologically based health outcomes caused by activation of the HPA axis and subsequent immune processes.

As indicated previously, coping can be considered as adaptive or maladaptive. Adaptive coping strategies, especially those that are problem focused and those that encourage seeking social support, are beneficial during stressful experiences. The extent to which an individual responds to distress, using effective positive coping strategies, determines the degree of successful moderation of the stress challenge. Conversely, ineffective negative coping attempts may exacerbate the effects of distress on health, thus augmenting the

potential for illness. Mediating factors that may influence stress susceptibility or resilience include age, socioeconomic status, gender, social support status, personality and lifestyle, self-esteem, genetics, life events, past experiences, and current health status.¹⁵² Evidence suggests that effective intervention may result in greater stress resilience and improved psychologic and physiologic outcomes. In a study of nursing home residents randomly assigned to control or social support intervention groups, improved psychologic measures and immune function (NK cell activity) were observed in the experimental group at 6 weeks.¹⁵³ In another study, women with recurrent metastatic breast cancer were given either routine follow-up (routine care) or weekly support group sessions. Survival in the support treatment group was an average of 19 months longer than in the routine care group, suggesting a mediating influence of additional support for these women.^{26,154} The importance of social support for seriously ill individuals has focused attention on the health and well-being of family members who function as caregivers. Significant stress manifested as depression, anxiety, and fatigue has been noted in family caregivers of those with cancer, Alzheimer disease, and burn trauma.¹⁵⁵ A recent study reported that a substantial percentage of spousal or common law caregivers may be at risk of clinical depression or suffer from psychologic health, especially in caregivers without a sense of control, social support, and low socioeconomic income.¹⁵⁶ Individuals and caretakers exhibited suppression of various measures of immune function, with improved function associated with better perceived social support.¹⁵⁷⁻¹⁵⁹ Gender-based coping differences may be attributed, in part, to the hormonal milieu of the individual, with females more likely to offer social support, a behavior with an oxytocin/estrogen association.⁹⁴

Interventions to prevent or manage stress-related psychologic or physical problems include both short- and long-term coping strategies. Stress management consists of educational components specific to the individual's problems and relaxation techniques, which may include meditation, imagery, massage, and biofeedback. These approaches may be used on an individual or a support group basis.

Incorporation of these approaches into clinical training facilitates their use in the clinical arena. Research should focus on the efficacy of such approaches with various populations (*What's New? Stress and Resilience*).

What's New?

Stress and Resilience

People encounter many stressful experiences in modern society. In some people, stress may induce maladaptive coping behavior accompanied by pathophysiologic disorders, whereas other people are able to overcome adversity and keep in check adaptive psychologic and physiologic functioning. This latter group of individuals is considered to be resilient to the negative, toxic effects of stress and recent studies are investigating the basis of resilience.

A hypothesized neuroprotective factor underlying resilience is neuropeptide Y (NPY), a neurotransmitter that modulates stress. Higher plasma NPY levels were found in Special Forces soldiers than in non-Special Forces people and predicted better psychologic performance under stressful training situations. Another factor contributing to resilience may be testosterone. Secretion of testosterone is elevated in dominant male animals and in men who won an athletic competition. The hormone is associated with feelings of success and positive mood. In contrast, low blood levels of testosterone are found in men with posttraumatic stress disorder (PTSD) and major depressive disorder. Of further interest, testosterone may have resilient effects in men compared to women who are more likely to develop PTSD and depression. Other protective hormones may include dehydroepiandrosterone (DHEA) and DHEA sulfate ester (DHEAS). These hormones, secreted by the adrenal cortex, are some of the most abundant steroid hormones and suggested to modulate fat, mineral metabolism, and sexual functioning along with antigluccorticoid, antiinflammatory, and antioxidant effects. Studies show that soldiers undergoing

underwater navigation stress tests performed physically and cognitively better when DHEA levels are elevated or when the DHEA-to-cortisol ratio in blood is high. DHEA and DHEAS may serve to buffer the potential deleterious effects of stress and lead to superior performance effects. Another example of the potential basis of resilience is the serotonin transporter promoter polymorphism (5HTTLPR). Carriers of the “short” (S) variant, which is less transcriptionally efficient than the “long” (L) variant, are vulnerable to major depression and anxiety. In contrast, people with the L allele are better able to cope and recover from stress. An L genetic variation in 5HTTLPR appears to promote emotional resilience.

Studies also demonstrate that people with high cognitive control that is associated with increased prefrontal cortex activity exhibit more appropriate emotional responses compared to people diagnosed with PTSD. Volunteers with high trait resilience show insula and amygdala activation only to aversive pictures compared to low-trait resilience participants. Resilient people appear better able to appropriately appraise and adjust the level of emotional resources required to meet the demands of stressful situations. Programs are currently offered to train and prepare people (e.g., firefighters, soldiers) who are likely to encounter dangerous situations by developing stress management skills, such as relaxation training. This type of training involves developing skills to manage the thoughts and perception that one will recover from stressful life events. Mindfulness-based stress reduction (MBSR) is another resilience program associated with higher levels of physical and mental health and is used as a potential treatment for PTSD, anxiety and depression disorders, and chronic pain. MBSR focuses awareness on present mental processes, such as sensations, thoughts, and feelings, in order to reduce negative emotions and improve health and coping. Overall, cognitive-based training programs play a proactive role in promoting the development of skills to become resilient to the long-term negative effects of stress disorders.

Aging and Stress: Stress-Age Syndrome

A set of neurohormonal and immune alterations, as well as tissue and cellular changes, sometimes develops with aging. These changes, which recently have been defined as stress-age syndrome, include the following:^{152,160}

- Alterations in the excitability of structures of the limbic system and hypothalamus
- Increase of the blood concentrations of catecholamines, antidiuretic hormone (ADH), ACTH, and cortisol
- Decrease of the concentrations of testosterone, thyroxine, and others
- Alterations of opioid peptide concentration
- Alterations in immunodepression and patterns of chronic inflammation
- Alterations in levels of lipoproteins
- Hypercoagulation of the blood
- Free radical damage of cells

Some of the alterations are adaptational, whereas others are potentially damaging. These stress-related alterations of aging can influence the course of developing stress reactions and lower adaptive reserve and coping.¹⁵²

In summary, it is clear that the mind and body are connected

through a multitude of complex physical and emotional interactions. Understanding the complexity of these interactions is a challenge for many researchers. Areas of promise include investigating relationships between the potential for illness with respect to stressors, as well as developing effective stress management techniques and approaches that can be easily and cost-effectively employed.

Summary Review

Historical Background and General Concepts

1. Modern society is full of stress.
2. In general, a person experiences stress when a demand exceeds a person's coping abilities.
3. Hans Selye identified three structural changes in rats subjected repeatedly to noxious stimuli (stressors): enlargement of the cortex of the adrenal gland, atrophy of the thymus gland and other lymphoid tissues, and ulceration of the gastrointestinal tract.
4. Selye believed that the three changes were caused by a nonspecific physiologic response to any long-term stressor. He called this response the general adaptation syndrome (GAS).
5. The GAS occurs in three stages: the alarm stage, the stage of resistance or adaptation, and the stage of exhaustion. Diseases of adaptation develop if the stage of resistance or adaptation does not restore homeostasis.
6. Selye identified three components of physiologic stress: the stressor, the physiologic or chemical disturbance produced by the stressor, and the body's adaptational response to the stressor.
7. It is now known that, while important, the physiologic view of stress as outlined in the GAS is an oversimplified model of stress responses.
8. The stress response is currently viewed as the product of the

interaction of the mind and body and how the cumulative effects of stress or allostatic overload may lead to disease and mental disorders. Allostatic overload refers to how long-term functional changes in the stress-related hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system (SNS) may compromise the immune system and health of the individual.

Concepts of Stress, Homeostasis, and Allostasis

1. Psychologic stress may cause or exacerbate (worsen) several disease states. Stress is related to the severity of symptoms and the outcomes of diseases and conditions. Research is focused on the mechanisms responsible for these mind-body interactions.
2. Stress has been defined as the state of affairs arising when a person relates to (i.e., interacts or transacts with) situations in a certain way. The way a person appraises and reacts to situations has a profound impact on stress.
3. The nonspecific physiologic response consists of interaction among the sympathetic branch of the autonomic nervous system (ANS) and other neural signals that activate the endocrine system, known as the hypothalamic-pituitary-adrenal (HPA) axis.
4. The nonspecific physiologic response is a common residual response and can be elicited with diverse agents such as cold, heat, x-rays, adrenaline, insulin, tubercle bacilli, and muscular exercise. Although the reactions of these stages are nonspecific, evidence supports the coexistence of highly specific, adaptive reactions to any of these agents.
5. As with a physically mediated stress response, psychologic stressors can elicit a reactive stress response; that is, a physiologic response can be derived from psychologic stressors.
6. Another type of psychologic-mediated stress response is the

anticipatory response.

7. In a conditioned response, the organism learns that specific stimuli are associated with danger and anticipation of subsequent encounters with that particular stimulus produces a physiologic stress response (e.g., PTSD).
8. Psychoneuroimmunology (PNI) is the study of the interaction of consciousness (*psycho*), the brain and spinal cord (*neuro*), and the body's defense against external infection and abnormal cell division (*immunology*).
9. Psychoneuroimmunology assumes that all immune-related disease is multifactorial. The immune system is integrated with other physiologic processes and is sensitive to changes in CNS and endocrine functioning, such as those that accompany psychologic states.
10. CRH is released centrally from the brain and peripherally at inflammatory sites.

Stress Response

1. The stress response is initiated by the CNS and endocrine system. Where the stress response begins depends on whether the stressor is perceived or real.
2. Perceived stressors elicit an anticipatory response that usually begins in the limbic system of the brain. The limbic system elicits an endocrine stress response indirectly by stimulating neural pathways responsible for receiving sensory information and elicits a central response directly by stimulating the LC to release LC/NE.
3. Real stressors elicit a reactive response that can begin either in the limbic system or in the brain in response to specific sensory information. This information is then relayed to the paraventricular nucleus (PVN). The PVN stimulates the LC and both central and endocrine stress responses.
4. The neuroendocrine response to stress consists of sympathetic stimulation of the adrenal medulla to secrete catecholamines

(norepinephrine and epinephrine) and stressor-induced stimulation of the hypothalamus to secrete CRH, which in turn stimulates the pituitary to secrete ACTH, which then stimulates the adrenal cortex to secrete steroid hormones, particularly cortisol.

5. In general, the catecholamines prepare the body to act, and cortisol mobilizes energy stores (e.g., glucose) and other substances needed to fuel the action.
6. Epinephrine exerts its chief effects on the cardiovascular system. Epinephrine increases cardiac output and increases blood flow to the heart, brain, and skeletal muscles by dilating vessels that supply these organs. It also dilates the airways, thereby increasing delivery of oxygen to the bloodstream.
7. Norepinephrine's chief effects complement those of epinephrine. Norepinephrine constricts blood vessels of the viscera and skin; this has the effect of shifting blood flow to the vessels dilated by epinephrine. Norepinephrine also increases mental alertness.
8. CRH influences the immune system indirectly by the activation of glucocorticoids (cortisol) and catecholamines. Peripheral CRH is proinflammatory, causing vasodilation and vascular permeability. It appears that the mast cells are the target of peripheral CRH.
9. Cortisol's chief effects involve metabolic processes. By inhibiting the use of metabolic substances while promoting their formation, cortisol mobilizes glucose, amino acids, lipids, and fatty acids and delivers them to the bloodstream.
10. Glucocorticoids or cortisol secretion during stress exerts beneficial effects by inhibiting inflammation and promoting resolution and repair. Paradoxically, elevated levels of glucocorticoids and catecholamines (epinephrine and norepinephrine), administered both endogenously and exogenously, can decrease innate immunity and increase autoimmune (adaptive) responses. These immunosuppressive effects can accentuate inflammation in general and potentially

increase neuronal death (e.g., in stroke victims). In addition, chronic exposure to stress alters adaptive functions throughout the body and brain to increase the risk of developing a host of diseases including obesity, the metabolic syndrome, cardiovascular disease, and cognitive impairments, such as Alzheimer disease, and mental disorders, such as major depression, schizophrenia, and posttraumatic stress disorder.

11. The nervous, endocrine, and immune systems communicate through the common use of signal molecules and their receptors, which in turn regulate the behavior of cells in each system during stress challenge.
12. There are direct and indirect pathways of influence among the nervous, endocrine, and immune systems. Neuropeptides have direct effects on immune cells, as well as indirect influences through neuromediated endocrine modulation of immune function. Endocrine products (cortisol) also influence nerve cell behavior. Immune cell products affect both nerve and endocrine cell function, reflecting an adaptive role for the immune system as a “signal” organ to alert other systems of threatening stimuli.
13. Other hormones are affected by the stress response and include increased circulating levels of β -endorphins, growth hormone, prolactin, and oxytocin and a decrease in antidiuretic hormone level with extreme stress. Concentrations of luteinizing hormone, estradiol, progesterone, and possibly testosterone decrease during the stress response.

Stress, Illness, and Coping

1. Stress is a system of interdependent processes that are moderated by the nature, intensity, and duration of the stressor and the coping efficacy of the affected individual, all of which in turn mediate the psychologic and physiologic response to stress.

2. Many studies have linked psychologic distress with altered immune function, and evidence strengthens the association of stress with potential for illness in humans, especially in vulnerable young children who are unable to control the adverse effects of stress, such as poor housing and negative parental rearing conditions.
3. Adaptive coping strategies, especially those that are problem focused and those that encourage seeking social support, are beneficial during stressful experiences.

Aging and Stress: Stress-Age Syndrome

1. With aging, sometimes a set of neurohormonal and immune alterations develop; these changes have been defined as stress-age syndrome.
2. These stress-related alterations of aging can influence the course of developing stress reactions and lower adaptive reserve and coping.

Cancer is a leading cause of suffering and death in the developed world. Over the past 35 years intensive research has led to a significantly enhanced understanding of this complex and frightening disease. It is now understood that cancer is a collection of more than 100 different diseases, each caused by a specific and often unique age-related accumulation of genetic and epigenetic alterations. Environment, heredity, and behavior interact to modify the risk of developing cancer and the response to treatment. Improvements in treatment strategies and supportive care, coupled with new, often individualized therapies based on advances of the basic pathophysiology of malignancy, have contributed to an increasing number of effective options for these diverse, often lethal, disorders collectively called *cancer*.

Cancer Characteristics and Terminology

Any discussion of cancer must start with a definition of what it is and what it is not. Although most readers may have an intuitive understanding of this disorder, composing an exact definition that encompasses this broad category is more challenging.

The term *cancer* derives from the Greek word for crab, *karkinoma*, which the physician Hippocrates used to describe the appendage-like projections extending from tumors. The word **tumor** originally referred to any swelling that was caused by inflammation, but is now generally reserved for describing a new growth, or **neoplasm**, resulting from an abnormal growth following uncontrolled proliferation and serving no physiologic purpose. Not all tumors or neoplasms, however, are cancer. The term **cancer** refers to a *malignant* tumor and is not used to refer to *benign* growths, such as lipomas or hypertrophy of an organ. The National Cancer Institute (NCI) of the National Institutes of Health (NIH) defines **cancer** as “diseases in

which abnormal cells divide without control and are able to invade other tissues.”¹ The definitions of benign vs. malignant are presented in the following text and shown in [Fig. 12.1](#).

FIGURE 12.1 Comparison Between a Benign Tumor and a Malignant Tumor of the Same Origin. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

Tumor Classification and Nomenclature

Proper identification of a cancer is important for many reasons. Different cancers will have different causes, different rates and patterns of progression, and different responses to treatment. The classification starts with knowing the tissue and organ of origin, the extent of distribution to other sites, and the microscopic appearance of the lesion. Increasingly, it also includes a detailed description of the critical genetic changes in the cancer.

Benign tumors, which are not referred to as cancers, are usually encapsulated with connective tissue and contain fairly well-differentiated cells and well-organized stroma (see [Fig. 12.1](#)). They

retain recognizable normal tissue structure and do not invade beyond their capsule, nor do they spread to regional lymph nodes or distant locations. Mitotic cells are very rarely present during microscopic analysis. Benign tumors are generally named according to the tissues from which they arise with the suffix “-oma,” which indicates a tumor or mass. For example, a benign tumor of the smooth muscle of the uterus is a *leiomyoma*, and a benign tumor of fat cells is a *lipoma*. Benign tumors of the colon or stomach usually present as colonic or gastric polyps, and those of melanocytes present as dark-colored nevi (e.g., birthmark, mole). It is important to understand that benign tumors can become extremely large and, depending on their location in the body, can cause morbidity or be life-threatening by compressing normal tissue, preventing blood flow to the region (ischemia), or causing necrotic death of normal tissue. For example, a benign meningioma at the base of the skull may cause symptoms by compressing adjacent normal brain tissue. Benign tumors of endocrine organs may lead to overproduction of hormones.

Some tumors initially described as benign can progress to cancer and then are referred to as **malignant tumors**, which are distinguished from benign tumors by more rapid growth rates and specific microscopic alterations, including loss of differentiation and absence of normal tissue organization (Fig. 12.2). One of the microscopic hallmarks of cancer cells is **anaplasia**, the loss of cellular differentiation. Malignant cells are also **pleomorphic**, with marked variability of size and shape. They often have large darkly stained nuclei, and mitotic cells are common. Malignant tumors may have a substantial amount of stroma, but it is disorganized, with loss of normal tissue structure. Malignant tumors lack a capsule and grow to invade nearby blood vessels, lymphatics, and surrounding structures. The most important and deadliest characteristic of malignant tumors is their ability to spread far beyond the tissue of origin, a process known as **metastasis**.

FIGURE 12.2 Loss of Cellular and Tissue Differentiation During the Development of Cancer. The cells of a benign neoplasm (B) resemble those of the normal colonic epithelium (A), in that they are columnar and have an orderly arrangement. Loss of some degree of differentiation is evident in that the neoplastic cells do not show much mucin vacuolization. Cells of the well-differentiated malignant neoplasm (C) of the colon have a haphazard arrangement and although gland lumina are formed, they are architecturally abnormal and irregular. Nuclei vary in shape and size, especially when compared with those illustrated in A. Cells in the poorly differentiated malignant neoplasm (D) have an even more haphazard arrangement, with very poor formation of gland lumina. Nuclei show greater variation in shape and size compared with the well-differentiated malignant neoplasm in C. Cells in anaplastic malignant neoplasms (E) bear no relation to the normal epithelium, with no recognizable gland formation. Tremendous variation is found in the size of cells and their nuclei, with very intense staining (hyperchromatic nuclei). Not knowing the site of origin would make it impossible to classify this tumor by microscopic appearance alone. Well-differentiated tumors often resemble their cell of origin, as shown in the example of a benign tumor of smooth muscles (F). (From Stevens A, Lowe J: *Pathology*, ed 2, London, 2000, Mosby.)

Unlike benign tumors, which are named related to the tissue of origin, cancers are generally named according to the cell type from

which they originate. Cancers arising in epithelial tissue are called **carcinomas**, and if they arise from or form ductal or glandular structures are named **adenocarcinomas**. Hence, a malignant tumor arising from breast glandular tissue is a **mammary adenocarcinoma**, whereas an example of a benign breast tumor is a fibroadenoma. Cancers arising from mesenchymal tissue (including connective tissue, muscle, and bone) usually have the suffix **sarcoma**. For example, malignant cancers of skeletal muscle are known as *rhabdomyosarcomas*. Cancers of lymphatic tissue are called **lymphomas**, whereas cancers of blood-forming cells are called **leukemias**. However, many cancers, such as Hodgkin disease and Ewing sarcoma, are named for historical reasons that do not follow this nomenclature convention.

Carcinoma in situ (often abbreviated **CIS**) refers to preinvasive epithelial tumors of glandular or squamous cell origin. Cancers develop incrementally, as they accumulate specific genetic mutations. Careful surveillance for cancer often detects abnormal growths in epithelial tissues that have atypical cells and an increased proliferation rate compared with normal surrounding tissues. These early stage cancers are localized to the epithelium and have not penetrated the local basement membrane or invaded the surrounding stroma. Based on these characteristics, they are not malignant but are often called CIS. CIS occurs in a number of sites, including the cervix, skin, oral cavity, esophagus, and bronchus. In glandular epithelium, in situ lesions occur in the stomach, endometrium, breast, and large bowel. In the breast, ductal carcinoma in situ (DCIS) fills the mammary ducts but has not progressed to local tissue invasion. CIS lesions can have one of the following three fates: (1) they can remain stable for a long time, (2) they can progress to invasive and metastatic cancers, or (3) they can regress and disappear. CIS can vary from low-grade to high-grade dysplasia, with the high-grade lesions having the highest likelihood of becoming invasive cancers. The time that such preinvasive lesions remain in situ before becoming invasive is unknown. Some carcinomas of the cervix appear as preinvasive lesions in situ for several years before they progress to invasive

carcinoma and metastatic tumors (Fig. 12.3). Knowing how to best treat low-grade CIS lesions is challenging because the proportion that progress to cancer vs. the proportion that will never cause clinical problems is usually not known. Although most persons prefer removal of any CIS as opposed to “watchful waiting,” this topic continues to be a source of great debate.

FIGURE 12.3 Progression from Normal to Neoplasm in the Uterine Cervix. A sequence of cellular and tissue changes progressing from low-grade to high-grade intraepithelial neoplasms (also called *carcinoma in situ*) and then to invasive cancer is seen often in the development of cancer. In this example of the early stages of cervical neoplastic changes, the presence of anaplastic cells and the loss of normal tissue architecture signify the development of cancer. The high rate of cell division and the presence of local mutagens and inflammatory mediators all contribute to the accumulation of genetic abnormalities that lead to cancer. (From Alberts B et al: *Molecular biology of the cell*, ed 5, New York, 2002, Garland.)

The Biology of Cancer Cells

In two seminal publications, Drs. Douglas Hanahan and Robert Weinberg^{2,3} described what they considered the hallmarks of cancer. Both articles stimulated considerable discussion and, especially,

debate. The original publication contained six hallmarks, but with time and new research findings, increased to eight hallmarks and two traits that enable cancer progression. Their analysis remains the leading overview of why a cell is malignant. The following discussion is organized in the context of those 10 hallmarks/enablers (Fig. 12.4). Two fundamental concepts are the foundation for understanding the biology of cancer. Cancer is a complex genetic disease, and the microenvironment of a tumor is a heterogeneous mixture of cells, both cancerous and benign.

FIGURE 12.4 Hallmarks of Cancer. (Adapted from Hanahan D, Weinberg RA: *Cell* 144(5):646–674, 2011. Found in Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

Cancer is a disease of cumulative genetic changes during aging. The fraction of individuals who develop cancer increases dramatically with age. Genetic changes may occur by both mutational and epigenetic mechanisms. Mutation generally means an alteration in the DNA sequence affecting expression or function of a gene (Fig. 12.5). Mutations include small-scale changes in DNA, such as **point mutations**; the alteration of one or a few nucleotide base pairs (see Chapter 4). This type of mutation can have profound effects on the

activity of resultant proteins. **Chromosome translocations** are large changes in chromosome structure in which a piece of one chromosome is translocated to another chromosome. **Gene amplification** is the result of repeated duplication of a region of a chromosome, so that instead of the normal two copies of a gene, tens or even hundreds of copies are present. Gene expression also may be altered indirectly by **epigenetic** effects including **DNA methylation**, histone acetylation, or altered expression of **non-coding RNA** (see [Chapter 6](#)).⁴ Some mutations, referred to as **driver mutations**, “drive” the progression of cancer. There may be as many as 140 different driver mutations, although some are more critical than others, and a relatively small number of these are present in an individual cancer. Not all mutations in cancer contribute to the malignant phenotype. Some are just random events, and are referred to as **passenger mutations**; they are just along for the ride. After a critical number of driver mutations have occurred, the cell becomes cancerous. The cancer cell has a selective advantage over its neighbors; its progeny can accumulate faster than its nonmutant neighbors. This is referred to as **clonal proliferation** or **clonal expansion** ([Fig. 12.6](#)). As a clone with mutations proliferates, it may become an early stage tumor, for example, a carcinoma in situ or a benign colonic polyp. The increasingly rapid cell division and impaired DNA repair mechanisms of cancer cells result in a continuing accumulation of mutations throughout the progression to the most aggressive metastatic lesion. Thus **malignant transformation**, the process by which a normal cell becomes a cancer cell, is directed by progressive accumulation of genetic changes that alter the basic nature of the cell and drive it to malignancy. The process of tumor development is a form of Darwinian evolution; cells with a heritable change that confers a survival advantage out-compete their neighbors. Each cancer cell may develop its own set of mutations resulting in a genomically *heterogeneous* mixture of cancer cells with subsets that have accumulated more and more mutations that increase the cell's malignant potential.⁵ The degree of intratumor mutational heterogeneity may vary considerably among tumors. For instance,

melanomas have a rather high degree of genetic homogeneity, whereas pancreatic cancers are more heterogeneous and appear to arise from independent mutational events in the pancreas. Thus many cancer cells that do not accumulate a critical set of mutations lose the competition and die during this process.

FIGURE 12.5 Oncogene Activation Mechanisms. Cellular genes may become cancerous oncogenes as a result of (A) point mutations that alter one or a few nucleotide base pairs, causing the production of a protein that is activated as a result of the altered sequence (e.g., *ras*); (B) amplification of the cellular gene, resulting in higher levels of protein expression (e.g., *N-myc* in neuroblastoma); or (C) chromosomal translocations that either lead to the juxtaposition of a strong promoter, causing increased protein expression (*c-myc* in Burkitt lymphoma), or produce a novel fusion protein that is derived from gene fragments normally present on different chromosomes (*BCR-ABL* in chronic myeloid leukemia). (From Haber DA: *Molecular genetics of cancer*. In *ACP medicine*, Danbury, CT, 2004, WebMD.)

FIGURE 12.6 Clonal Proliferation Model of Neoplastic Progression in the Colon. During clonal proliferation, progressively altered populations of colon cells (colonocytes) arise over time. As genetic and epigenetic changes occur, different subclones (indicated by different color cells) coexist for a time. Clones that grow the fastest out-compete other clones, producing even more malignant, and abnormal-appearing, growths. The sequential accumulation of mutations has been well studied in the progression from a normal colon cell to a benign intestinal polyp to a malignant colon cancer. One of the earliest mutations in colon cancer is loss of the tumor-suppressor gene *APC*. Additional mutations (often in the oncogene *RAS*), activation of *COX-2*, and loss of the tumor suppressors *DCC* and *TP53* occur as the lesion progresses from a benign polyp to an invasive carcinoma. *APC*, Adenomatous polyposis coli; *COX-2*, cyclooxygenase-2; *DCC*, deleted in colon cancer; *TP53*, *p53* gene. (Modified from Mendelsohn I et al: *The molecular basis of cancer*, ed 2, Philadelphia, 2001, Saunders; and Kumar V et al: *Basic pathology*, ed 6, Philadelphia, 1997, Saunders.)

The processes occurring during the development of cancer are, in many ways, analogous to wound healing. The initial proliferation of cancer cells and enlargement of the tumor elicit the synthesis of proinflammatory mediators by the cancer cells and adjacent nonmalignant cells. As with wound healing, mediators recruit inflammatory/immune cells (primarily T lymphocytes and macrophages, but also B cells and neutrophils) and cells normally associated with tissue repair (fibroblasts, adipocytes, mesenchymal stem cells, endothelial cells, and pericytes). These cells form the **stroma** (tumor microenvironment) that surrounds and infiltrates the tumor⁶ (Fig. 12.7). In some conditions, stromal cells may make up 90% of the tumor mass. Extensive paracrine signaling among the stromal and cancer cells affects both populations; cancer cells increase proliferation and become more heterogeneous during tumor growth, and several populations of stromal cells undergo evolution to

phenotypes that promote cancer progression and metastatic potential. **Cancer heterogeneity** arises from ongoing proliferation and mutation. Tumor-associated endothelial cells, fibroblasts, and inflammatory cells develop different and distinct gene expression profiles with unique cell surface molecules and patterns of secreted molecules. During this process there is generally a great deal of cancer cell death, but the surviving cells are more aggressive and many take on a metastatic phenotype. Because continuing somatic mutations may be random, cancer cells in different regions of the tumor may be genetically diverse. Additionally, a population of cancer stem cells may arise, the origin of which is still unclear. Many of the hallmarks of cancer are consequences of cancer-stromal interactions (discussed later).

FIGURE 12.7 Cancers Live in a Complex Microenvironment. Cancer cells

express tumor-specific antigens that ideally can be recognized by cells of the immune system and inflammatory systems (natural killer cells, antitumor M1 macrophages, T-cytotoxic cells) and destroyed by apoptosis or undergo growth suppression by type I cytokines. However, successful cancers produce a variety of cytokines and chemokines that are chemoattractants for stromal cells that infiltrate the tumor and undergo change to pro-tumor phenotypes. These include tumor-associated M2 macrophages (TAMs), cancer-associated fibroblasts (CAFs), mesenchymal stem cells (MSCs), and immune suppressor cells of T-cell origin (T-regulatory cells) and myeloid origin (myeloid-derived suppressor cells). Through multiple receptor-mediated interactions between other stromal cells and the cancer cells, the stromal cells, as well as the cancer cells, collectively produce a battery of additional cytokines (e.g., TGF- β , type II cytokines), chemokines (e.g., CXCL5), growth factors (e.g., VEGF, EGF, CSF-1, FGF, PDGF), and proteases (e.g., MMPs) and secrete components of the extracellular matrix (ECM). The stromal reaction promotes tumor progression, including new blood vessel growth (angiogenesis), tumor cell proliferation and differentiation, suppression of immune rejection and tumor cell apoptosis, invasion, and commitment to metastasis. *CAF*, Cancer-associated fibroblast; *CSF-1*, colony-stimulating factor-1; *CXCL5*, C-X-C motif chemokine 5; *ECM*, extracellular matrix; *EGF*, epidermal growth factor; *FGF*, fibroblast growth factor; *MSC*, mesenchymal stem cell; *MMP*, matrix metalloproteinase; *NK*, natural killer cell; *PDGF*, platelet-derived growth factor; *TAM*, tumor-associated macrophage; *TGF- β* , tumor growth factor-beta; *T_{reg}*, T-regulatory cell; *VEGF*, vascular endothelial cell growth factor. (Modified from Quail DF, Joyce JA: Microenvironmental regulation of tumor progression and metastasis, *Nat Med* 19[11]:1423–1437, 2013.)

Several of the hallmarks/enablers are primarily genomic alterations that initiate and maintain development of cancer. These will be discussed first and include sustained proliferative signaling, evading growth suppression, genomic instability, and replicative immortality (see Fig. 12.4). Other hallmarks/enablers are cellular adaptations secondary to genomic change and include inducing angiogenesis and reprogramming energy metabolism. A third group, tumor resistance to destruction by the host's protective mechanisms, includes resisting apoptotic cell death, promoting tumor inflammation, and avoiding immune destruction. The last hallmark is the culmination of the previous nine: activating invasion and metastasis.

Genomic Hallmarks

Sustained Proliferative Signaling

The first and foremost hallmark of cancer is uncontrolled cellular proliferation. Normal cells generally only enter proliferative phases in

response to growth factors that bind to specific receptors (receptor tyrosine kinases [RTKs]) on the cell surface. The cytoplasmic components of the receptors are associated with signaling molecules that undergo activation and in turn activate intracellular signaling pathways leading to induction/activation of regulatory factors affecting DNA synthesis, entrance into the cell cycle, and changes in expression of other genes related to cell metabolism for optimal growth (Fig. 12.8). One example is initiation of cell proliferation by epidermal growth factor (EGF). EGF binds and cross-links two EGF receptors (EGFRs) on the cell surface.⁷ The cytoplasmic portions of the receptors are tyrosine kinases that attach phosphorus to tyrosine in neighboring proteins, including each other (autophosphorylation). Phosphorylation allows the receptor to attach to bridging protein, which links the EGF receptors to plasma membrane-associated inactive RAS. **RAS** is an acronym for “rat sarcoma,” where it was found originally. Inactive RAS is associated with guanine diphosphate (GDP). Association between the EGF receptor and inactive RAS modifies the binding of GDP, which is replaced with guanine triphosphate (GTP). GTP activates RAS, which is a GTPase that converts GTP to GDP, during which it can activate signaling pathways such as the **mitogen-activated protein kinase pathway (MAPK pathway)** and the **phosphatidylinositol-3-kinase pathway (PI3K pathway)**. These signaling pathways phosphorylate other cytoplasmic proteins and affect activity and nuclear localization of transcription factors, such as MYC (myelocytomatosis viral oncogene homolog), that govern the transcription of cell cycle regulators, such as cyclins, and entrance into cellular proliferation. Proliferation can be discontinued through this pathway by decreased levels of growth factors in the environment or inactivation of signaling pathway components.

FIGURE 12.8 Growth Factor Signaling Pathways in Cancer. Growth factor receptors, RAS, PI3K, MYC, and D cyclins are oncoproteins that are activated by mutations in various cancers. GAPs apply brakes to RAS activation, and PTEN serves the same function for PI3K. GAP, GTPase-activating protein; GDP, guanosine diphosphate; GTP, guanosine triphosphate; MAPK, mitogen-activated protein kinase; PI3K, phosphatidylinositol-3-kinase; PTEN, phosphatase and tensin homolog. (From Kumar V et al: Robbins and Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Saunders.)

The genes that encode components of receptor-mediated pathways designed to regulate normal cellular proliferation are collectively called **proto-oncogenes**. Cancerous cells characteristically express mutated or overexpressed proto-oncogenes, which are referred to as

oncogenes. Oncogenes are independent of normal regulatory mechanisms; thus the cell is driven into a state of unregulated constitutive expression of proliferation signals and uncontrolled cell growth. Oncogenes can affect any portion of the growth factor pathways, such as described for EGF. For instance, most growth factors originate from neighboring cells, but some cancers acquire the ability to secrete growth factors that stimulate their own growth, a process known as **autocrine stimulation**. As described later in this chapter, noncancerous stromal cells within a tumor are frequently modified to benefit the cancer. In some instances, stromal cells produce excessive growth factors that drive the proliferation of cancer cells. Other cancers increase the expression of RTKs; for example, in breast cancer production of the **human epidermal growth factor receptor 2 (HER2)**, also known as the *epidermal growth factor receptor gene [ERBB-2]* is up-regulated and is hyperresponsive to low levels of EGF. Some breast and lung cancers are effectively treated by inhibitors of HER2 and other EGF receptors that block this pathway.

Oncogenes may lead to constitutive activation of the signal cascade from the cell surface receptor to the nucleus. Up to a third of all cancers have an activating mutation in the *RAS* gene resulting in a continuous cell growth signal even when growth factors are missing (see [Fig. 12.8](#)). Other mutations in the EGF receptor pathway include excessive proliferation signaling by hyperactivation of the PI3 kinase.

Several types of genetic events can activate oncogenes. A point mutation that is frequently observed in lung cancer results in continuous activation of the EGF **receptor tyrosine kinase**. A point mutation in the *RAS* gene converts it from a regulated proto-oncogene to an unregulated oncogene. Activating point mutations in *RAS* are found in many cancers, especially pancreatic and colorectal cancer. Specialized tests, such as direct DNA sequencing, can detect such point mutations in clinical samples.

Translocations can activate oncogenes in one of two distinct mechanisms ([Fig. 12.9](#)). First, a translocation can cause excess and inappropriate production of a proliferation factor. One of the best examples is the t(8;14) translocation found in many Burkitt

lymphomas; t(8;14) designates a chromosome that has a piece of chromosome 8 fused to a piece of chromosome 14 (see [Chapter 30](#)). Burkitt lymphoma is an aggressive cancer of B lymphocytes. The *Myc* proto-oncogene found on chromosome 8 is normally activated at low levels in proliferating lymphocytes and is inactivated in mature lymphocytes. If the t(8;14) translocation occurs (reciprocal translocation[t] or exchange of genetic material between chromosomes designated t[8, for chromosome 8, and 14, for chromosome 14]) the *Myc* gene is aberrantly placed under the control of a B-cell immunoglobulin gene (*IG*) present on chromosome 14. The *IG* gene is very active in maturing B lymphocytes. The t(8;14) translocation alters the control of *MYC*; its normal low-level expression is switched to high levels, as directed by an *IG* gene promoter. Hyperproduction of **MYC protein** drives proliferation and blocks differentiation.

FIGURE 12.9 Examples of Chromosomal Translocations and Associated Oncogenes. See text for further explanation. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

Second, chromosome translocations can lead to production of novel proteins with growth-promoting properties. In chronic myeloid leukemia (CML) a specific chromosome translocation is almost always present. This translocation, t(9;22), was first identified in association

with CML in Philadelphia in 1960 and is often referred to as the **Philadelphia chromosome**. Translocation fuses two chromosomes in the middle of two different genes: *Bcr* (break point cluster region gene) on chromosome 9 and *Abl* (Abelson gene) on chromosome 22. The result is production of a BCR-ABL fusion protein containing the first half of BCR and the second half of ABL (a nonreceptor tyrosine kinase). BCR-ABL is an unregulated protein tyrosine kinase that promotes growth of myeloid cells. Imatinib, a drug that specifically targets this tyrosine kinase, represents the first successful chemotherapy targeted against the product of a specific oncogenic mutation. Imatinib and related tyrosine kinase inhibitors (TKIs) are highly effective in the treatment of CML and, because of their specificity, lack the toxic side effects noted with nonspecific anticancer drugs. However, imatinib is not effective in cancers that do not have the t(9;22) translocation or related mutations. In modern personalized cancer therapy, knowledge of the specific genetic alteration can dictate the optimal drugs for the individual.

Oncogenes also may be activated by gene amplification (Fig. 12.10). Gene amplification results in increased expression of an oncogene, or in some cases drug resistance genes. The N-Myc oncogene, a member of the Myc family, is amplified in 25% of childhood neuroblastomas and confers a poor prognosis. The HER2 gene (*ERBB2*) is amplified in 20% of breast cancers.

FIGURE 12.10 N-Myc Gene Amplification in Neuroblastoma. (A) The N-Myc gene is present on chromosome 2, becomes amplified, and is seen either as extra chromosomal double minutes or as a chromosomal

homologous staining region. The N-Myc gene is detected in human neuroblastoma cells using a technique called FISH (fluorescent in situ hybridization). (B) A single pair of N-Myc genes is detected in normal cells and in low-grade neuroblastoma. (C) Multiple, amplified copies of the N-Myc gene are detected in some cases of neuroblastoma. Amplification of the N-Myc gene is strongly associated with a poor prognosis in childhood neuroblastoma. (A from Kumar V, et al: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders; B, C courtesy Arthur R. Brothman, PhD, FACMG, University of Utah School of Medicine, Salt Lake City, UT.)

Evading Growth Suppressors

Uncontrolled cancer cell proliferation also is related to inactivation of tumor-suppressor genes. **Tumor-suppressor genes** normally regulate the cell cycle, inhibit proliferation resulting from growth signals, stop cell division when cells are damaged, and prevent mutations. Hence, they also have been referred to as *anti-oncogenes*. Whereas oncogenes are *activated* in cancers, tumor suppressors must be *inactivated* to allow cancer to occur (Table 12.1 and Fig. 12.11). A single genetic event can activate an oncogene because it can act in a dominant manner in the cell. However, each individual has two copies of each tumor-suppressor gene, one from each parent. Both copies must be inactivated; therefore two mutations are necessary.

TABLE 12.1

COMPARISON OF CANCER GENE TYPES

GENE TYPE	NORMAL FUNCTION	MUTATION EFFECT
Caretaker	DNA and chromosome stability	Chromosome instability and increased rates of mutation
Dominant oncogenes*	Encode proteins that promote growth (e.g., growth factors)	Overexpression or amplification causes gain of function
Tumor suppressors (recessive oncogenes)	Encode proteins that inhibit proliferation and prevent or repair mutations	Requires loss of function of both alleles to increase cancer risk

* Nonmutant state referred to as proto-oncogene.

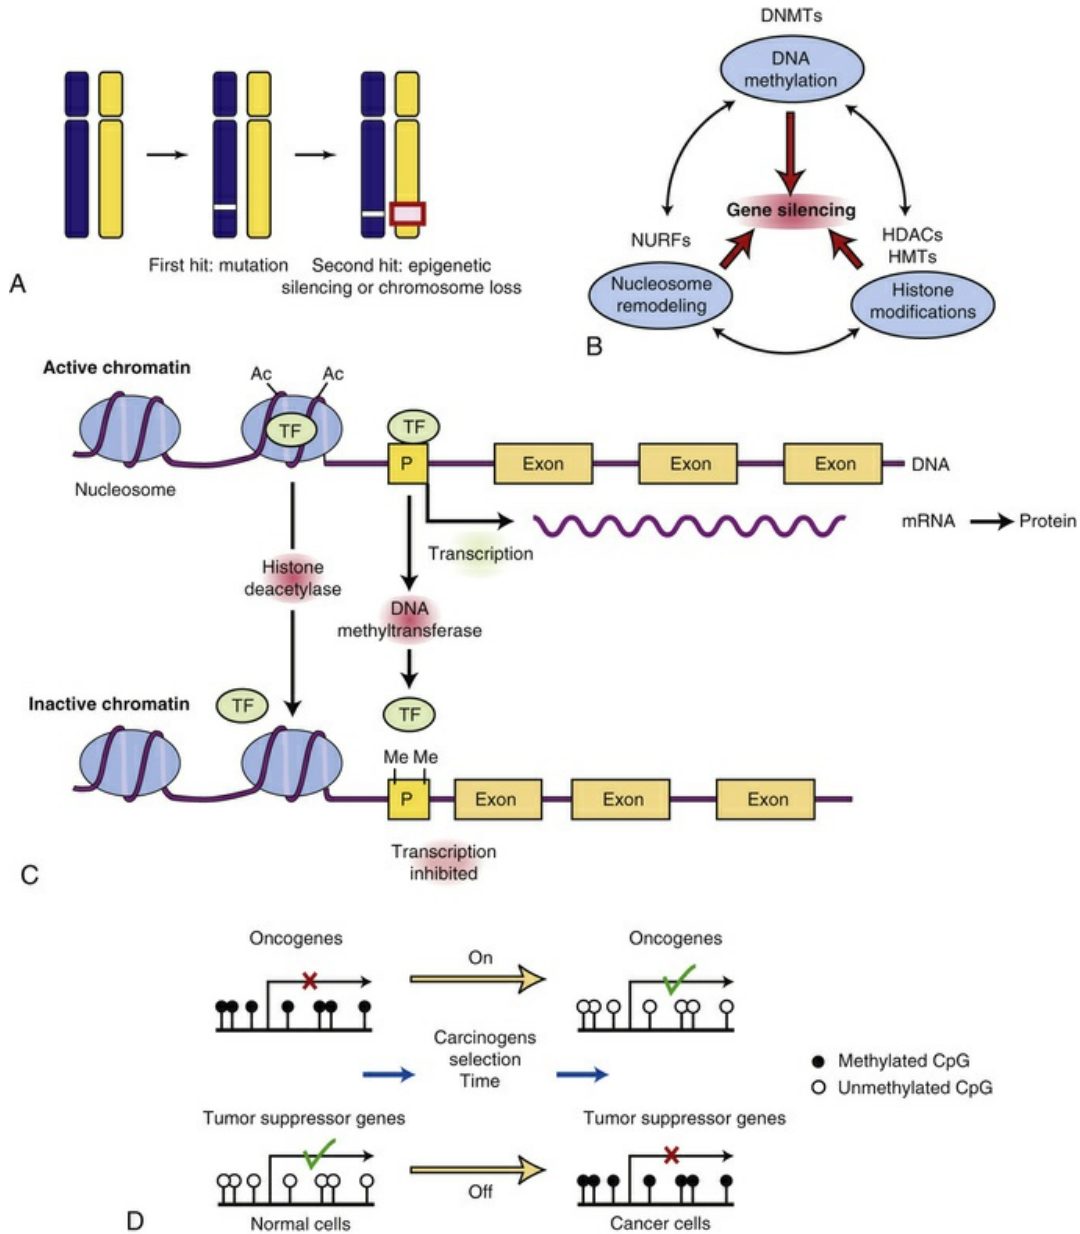

FIGURE 12.11 Silencing Tumor-Suppressor Genes by Epigenetic Alterations. Tumor-suppressor genes can be turned off by a variety of mechanisms. **A**, In this example, the first hit is a point mutation in a tumor-suppressor gene (*white box*), followed by either epigenetic silencing or chromosome loss of the second allele (*red box*). **B**, Genes can normally be silenced by a variety of interacting processes including DNA methylation, histone modifications, nucleosome remodeling, and microRNAs (not shown). A number of cellular enzymes contribute to these modifications, including DNA methyltransferases (*DNMTs*), histone deacetylases (*HDACs*), histone methyltransferases (*HMTs*), and complex nucleosomal remodeling factors (*NURFs*). Gene silencing is essential for normal development and differentiation. **C**, Histone modification and promoter methylation regulate gene expression. Genes are transcribed when chromatin is modified by addition of acetyl (*Ac*) groups to specific lysine groups in histones. Gene expression can be turned off when specific acetyl groups are removed by HDACs or when the CpG-rich promoter regions of

genes are modified by direct DNA methylation (by DNA methyltransferase). In addition, small endogenous RNA molecules (microRNAs or miRNA) can bind to mRNA and reduce gene expression. D, Changes in promoter methylation turn cancer genes off and on. Oncogenes can be turned on by promoter hypomethylation, and tumor-suppressor genes can be turned off by promoter hypermethylation. Each of these changes can produce selective growth and survival advantage for the cancer cell. (B adapted from Jones PA, Baylin SB: *Cell* 128:683–692, 2007; C from Gluckman PD et al: *N Engl J Med* 359[1]:66, 2008; D from Shames DS, Minna JF, Gazdar AF: *Curr Mol Med* 7:85–102, 2007.)

A prototypical tumor-suppressor gene is the **retinoblastoma (*RB*) gene**. Normal cells receive diverse “antigrowth” signals from their normal environment. Contact with other cells, with basement membranes, and with some soluble factors normally signal cells to stop proliferating. Tumor-suppressor genes, such as *RB*, monitor antigrowth cellular signals and block activation of the growth/division phase in the cell cycle; thus mutations in *RB* lead to persistent cell growth. Antiproliferative activity of *RB* depends on the degree of protein phosphorylation. Low levels of phosphorylation (hypophosphorylation) result in *RB* binding to and inhibiting transcription factors that regulate genes controlling passage through the cell cycle. Growth factor–regulated kinases increase phosphorylation (hyperphosphorylation) and inactivation of *RB*. A variety of genetic mutations in cancers also inactivate *RB*, resulting in unregulated and continuous cellular proliferation. *RB* is mutated in childhood retinoblastoma, and in many lung, breast, and bone cancers as well. The *RB* gene resides on chromosome 13, in a region referred to as q14 (13q14). Most individuals with *RB* mutations have a subtle mutation, such as a point mutation, in one allele. The *RB* gene in the other chromosome may be inactivated through loss of the 13q14 region or epigenetic mechanisms.

Another classic tumor-suppressor gene is the **p53 tumor-suppressor gene (TP53)**. The protein p53 has been called the *guardian of the genome*. TP53 monitors intracellular signals related to stress and activates **caretaker genes**—genes that are responsible for the maintenance of genomic integrity (Fig. 12.12). Many types of cellular stress (e.g., anoxia, oncogene expression, nuclear damage) produce intracellular signals (e.g., levels of nucleotides and glucose, degree of

oxygenation, DNA damage, and other indicators of cellular abnormalities) detectable by p53. Normally p53 is in an inactive complex with inhibitor molecules. Stress activates kinases that phosphorylate p53 into an active suppressor of cell division and activator of caretaker genes. Caretaker genes encode proteins that are involved in repairing damaged DNA, such as with errors in DNA replication, mutations caused by ultraviolet or ionizing radiation, and mutations caused by chemicals and drugs. The p53 protein also controls initiation of cellular senescence or apoptosis, and suppresses cell division until DNA repair is complete or other effects of stress are corrected. If not corrected, the cell enters senescence or apoptosis, thus preventing further DNA damage and mutations. Loss of function of TP53 or caretaker genes leads to increased mutation rates and cancer.

FIGURE 12.12 The Role of p53 in Maintaining the Integrity of the Genome. Activation of normal p53 by DNA-damaging agents or by hypoxia leads to cell cycle arrest in G₁ by up-regulation of the cell cycle inhibitor p21 and induction of DNA repair transcriptional up-regulation of the cyclin-dependent kinase inhibitor *CDKN1A* (encoding the cyclin-dependent kinase inhibitor p21) and the *GADD45* genes. Successful repair of DNA allows cells to proceed with the cell cycle. If DNA repair fails, p53 triggers either apoptosis or senescence. In cells with loss or mutation of the p53 gene, DNA damage does not induce cell cycle arrest or DNA repair, and genetically damaged cells proliferate, giving rise eventually to malignant neoplasms. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

Because inactivation of tumor-suppressor genes requires at least two mutations (one in each allele), a single mutation in the germline cells (sperm or egg) results in the transmission of cancer-causing

genes from one generation to the next, producing families with a high risk for specific cancers. These inherited mutations that predispose to cancer are almost invariably in tumor-suppressor genes because only a single additional mutation is needed to inactivate completely the tumor-suppressor gene (Table 12.2).

TABLE 12.2

SOME FAMILIAL CANCER SYNDROMES CAUSED BY LOSS OF TUMOR-SUPPRESSOR GENE FUNCTION

SYNDROME	GENE
Retinoblastoma	<i>RB1</i>
Li-Fraumeni syndrome	<i>p53</i> (TP53)
Familial melanoma	<i>p16^{INK4a}</i> (<i>CDKN2A</i>)
Neurofibromatosis	<i>Neurofibromin</i> (<i>NF1</i>)
Familial adenomatous polyyps	<i>APC</i>
Breast cancer	<i>BRCA1</i>

An example of increased risk for cancer that can be inherited is the familial form of retinoblastoma. A mutation in one *RB* allele is inherited so that only one additional mutation in the normal allele will lead to cancer. Approximately half of children with retinoblastoma have the inheritable form and most will develop tumors in both eyes (bilateral retinoblastoma). Also, Li-Fraumeni syndrome is a very rare inheritable loss-of-function mutation in TP53 in one allele resulting in a 25-fold increase of developing malignancy at early age (<50 years of age). These malignancies may include breast cancer, brain tumors, acute leukemia, soft tissue sarcomas, bone sarcoma, and adrenal cortical carcinoma. Other familial cancers with inheritable mutations in tumor-suppressor genes include Wilms tumor, a childhood cancer of the kidney (*WT1* gene); neurofibromatosis (*NF1* gene); and familial polyposis coli or adenomas of the colon (*APC* gene). Characterization of cancer-causing genes and other genetic factors helps identify individuals prone to developing cancer and contributes to the understanding of sporadic cancers. Individuals known to carry mutations in tumor-suppressor genes are offered targeted cancer

screening to facilitate early cancer detection and therapy.

Genomic Instability

Genomic instability refers to an increased tendency of alterations—mutability—in the genome during the life cycle of cells. Inherited and acquired mutations in caretaker genes that protect the integrity of the genome and DNA repair increase the level of genomic instability and risk for developing cancer.⁸ Acquired mutations in “guardians of the genome,” such as TP53, that detect DNA damage and activate repair mechanisms result in an increasing accumulation of mutations. Xeroderma pigmentosum is a defect in the repair of DNA pyrimidine dimers created by ultraviolet (UV) light that increases the risk for skin cancers. Hereditary nonpolyposis colorectal cancer results from an inherited defect in repairing DNA base pair mismatches that occur occasionally during DNA replication. Affected individuals have an increased rate of small insertions and deletions in DNA, leading to a high rate of colon and other cancers. Some inherited mutations threaten the integrity of entire chromosomes. Bloom syndrome, caused by mutations in a DNA helicase, presents with an increased risk of several forms of cancer, and those with Fanconi aplastic anemia, caused by loss of function for repairing DNA double-strand breaks, have a particularly increased risk of acute myelogenous leukemia. These examples are autosomal recessive disorders in which affected individuals demonstrate marked chromosomal instability.

Genomic instability also may result from increased **epigenetic silencing** or modulation of gene function ([Chapters 4 and 6](#)). Many cancers have increased methylation of DNA in the promoter region of tumor-suppressor genes. They also have associated changes in the modification of histones in the chromatin, often correlated with methylation of DNA. These changes alter the promoter regions of genes, leading to their silencing or altered gene expression.

Changes in gene regulation can affect not just single genes, but also entire intracellular signaling networks. Gene expression networks can be regulated by changes in **microRNAs (miRNAs, or miRs)** and other non-coding RNAs (ncRNAs). **miRs** regulate diverse signaling

pathways; the miRs that stimulate cancer development and progression are termed **oncomirs**. miRs decrease the stability and expression of other genes by pairing with mRNA.

Mutations in *BRCA1* and *BRCA2* (breast cancer 1 and 2, early onset genes, respectively) are currently of clinical importance. Both are tumor-suppressors and caretaker genes that repair double-stranded DNA breaks. Inherited mutations in either gene greatly increase the risk for a variety of tumors, especially breast cancer in both women and men, and ovarian or prostate cancers.⁹ Approximately 12% of women generally will develop breast cancer within their lifetime, whereas about 60% of women with a high-risk *BRCA1* mutation and 45% with a *BRCA2* mutation will develop cancer by age 70.¹⁰ Ovarian cancer occurs in approximately 1.4% of the general population, but about 39% of women with an inherited mutation in *BRCA1* and about 15% with a mutation in *BRCA2* will develop ovarian cancer by age 70. At-risk women are currently offered prophylactic surgery to reduce the risk of cancer.

In addition to specific gene mutations and abnormal epigenetic silencing, **chromosome instability** also appears to be increased in malignant cells, resulting in a high rate of chromosome loss, as well as loss of heterozygosity and chromosome amplification. The underlying mechanism of this instability is not clear but may be caused by malfunctions in the cellular machinery that regulates chromosome segregation at mitosis.

Enabling Replication Immortality

A hallmark of cancer cells is their immortality, in that they seem to have an unlimited life span and will continue to divide for years under appropriate laboratory conditions. One of the most commonly used laboratory cell lines, HeLa cells, was derived from a cervical cancer specimen obtained in 1951 that continues to grow and divide in laboratories around the world.¹¹ Most normal cells are not **immortal** and can divide only a limited number of times (known as the *Hayflick limit*) before they either enter senescence (cease dividing) or enter crisis (apoptosis) and die. One major block to unlimited cell division

(i.e., immortality) is the size of a specialized structure called the telomere. **Telomeres** are protective ends, or caps, of repeating hexanucleotides (six nucleotide units) on each chromosome and are placed and maintained by a specialized enzyme called **telomerase** (Fig. 12.13). As one might expect, telomerase is usually active only in germ cells (in ovaries and testes) and in stem cells. All other cells of the body lack telomerase activity. Therefore when non-germ cells begin to proliferate abnormally their telomere caps shorten with each cell division. Short telomeres normally signal the cell to cease cell division. If the telomeres become critically small, the chromosomes become unstable and fragment, and the cells die.

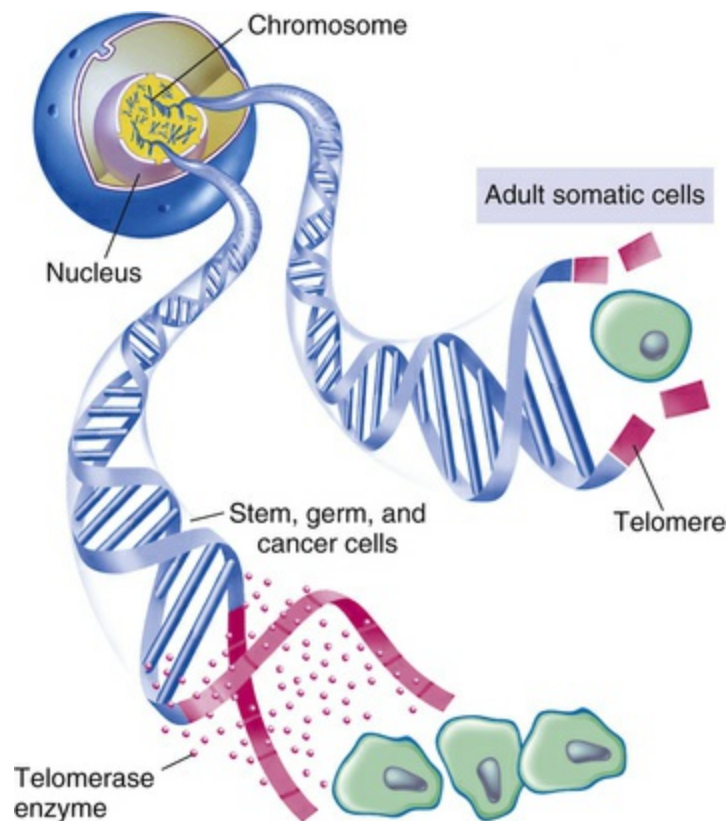

FIGURE 12.13 Control of Immortality: Telomeres and Telomerase. Normal adult somatic cells cannot divide indefinitely because the ends of their chromosomes are capped by telomeres. In the absence of the telomerase enzyme, telomeres become progressively shorter with each division until, when they are critically short, they signal the cell to stop dividing. In germ cells, adult stem cells, and cancer cells the telomerase gene is “switched on,” producing an enzyme that rebuilds the telomeres. Thus, like germ cells, the cancer cell becomes immortal and able to divide indefinitely without losing its telomeres.

Cancer cells are very heterogeneous and many cells die as the cancer develops. When they reach a critical age, most cancer cells activate telomerase to restore and maintain their telomeres, thereby allowing continuous division.¹² The trigger for reexpression of telomerase activity remains unclear, but seems to require expression of specific oncogenes, such as *RAS* or *Myc*, and loss of function of certain tumor-suppressor molecules, such as p53 and RB. Telomerase activity is restored in about 90% of cancers. The remaining cancers appear to recruit or originate from stem cells, becoming cancer stem cells that maintain levels of telomerase activity characteristically found in somatic stem cells. Because telomerase is specifically activated in cancer cells, and potentially in cancer stem cells, it is an attractive therapeutic target.

Cellular Adaptations

Inducing Angiogenesis

A major component of wound healing is the process of establishing new blood vessels within the tissue undergoing repair (called **neovascularization** or **angiogenesis**). Access to a blood supply also is obligatory to the growth and spread of cancer. Without a blood supply to deliver oxygen and nutrients, growth of a tumor is limited to about a millimeter in diameter.

Angiogenic factors and **angiogenic inhibitors** normally control development of new vessels. In cancerous tumors several mechanisms increase and maintain secretion of angiogenic factors by the cancer cells, as well as prevent release of angiogenic inhibitors. **Hypoxia-inducible factor-1 α (HIF-1 α)**, an oxygen-sensitive transcription factor, is a major regulator of angiogenesis in normal tissue; HIF-1 α is stabilized under hypoxic conditions and induces expression of pro-angiogenic factors, such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF).¹³ Inactivation of tumor-suppressor genes (e.g., *p53*) or increased expression of oncogenes (e.g., *HER2*) leads to increased expression of HIF-1 α -regulated angiogenic

factors and increased vascularization. Increased expression of HIF-1 α also is related to increased resistance to chemotherapy, increased tumor cell glycolysis, increased metastasis, and a poor prognosis. These effects may likely occur through an autocrine mechanism by which VEGF activates tumor-associated VEGF receptors. For instance, in soft tissue sarcomas VEGF induces increased expression of anti-apoptotic proteins (e.g., Bcl-2) and activation of intracellular survival signal pathways. The use of angiogenic inhibitors targeting VEGF signaling can inhibit angiogenesis and diminish tumor growth.

Other routes of angiogenic factor induction include mutations in cancer oncogenes (e.g., *RAS*, *Myc*) that increase transcription of VEGF by cancer cells. Most cells in the tumor microenvironment also secrete VEGF, including tumor-infiltrating monocytes, endothelial cells, adipocytes, and cancer-associated fibroblasts. Angiogenesis inhibitors, such as **thrombospondin-1 (TSP-1)**, normally bind to cellular surface receptors on inflammatory cells and negatively regulate angiogenesis in wound healing and tissue remodeling. The expression of angiogenesis inhibitors is under the control of p53, which is suppressed in cancer cells, thus diminishing the control of stromal inflammatory cell secretion of angiogenic factors.

Cancer cells and stromal cells may increase production of **matrix metalloproteinases** (e.g., MMP-9)¹⁴ (Fig. 12.14). MMPs are zinc-dependent proteases that digest the surrounding extracellular matrix (ECM). The ECM contains stored latent (inactive) forms of some angiogenic factors (e.g., bFGF, transforming growth factor-beta [TGF- β]). MMPs activate the stored forms into functional angiogenic factors.

FIGURE 12.14 Tumor-Induced Angiogenesis. Malignant tumors secrete angiogenic factors and tissue-remodeling matrix metalloproteinases (*MMPs*) that actively induce formation of new blood vessels. New blood vessels are formed from both local endothelial cells and circulating precursor cells recruited from the bone marrow. Circulating platelets can also release regulatory proteins into the tumor. *bFGF* and *bFGFR*, Basic fibroblast growth factor and its receptor, respectively; *PDGF* and *PDGFR*, platelet-derived growth factor and its receptor, respectively; *VEGF* and *VEGFR*, vascular endothelial growth factor and its receptor, respectively. (Adapted from Folkman J: *Nat Rev Drug Discov* 6[4]:273–286, 2007.)

The vessels formed within tumors differ from those in healthy tissue. They originate from endothelial sprouting from existing capillaries and irregular branching, rather than regular branching seen

in healthy tissue. The interendothelial cell contact is less tight so the vessels are more porous and prone to hemorrhage, as well as allowing passage of tumor cells into the vascular system.

Reprogramming Energy Metabolism

Cancer cells live in a distinct environment from normal cells and have different nutritional requirements from nonproliferating cells. The successful cancer cell divides rapidly, with the consequent requirement for the building blocks to construct new cells. Nonmalignant cells in the presence of adequate oxygen normally generate adenosine triphosphate (ATP) by mitochondrial oxidative phosphorylation (OXPHOS), generating 36 ATP molecules from each glucose molecule that is broken down to water and carbon dioxide. In the absence of sufficient oxygen (hypoxia) normal cells perform glycolysis (anaerobic glycolysis), generating only two ATP molecules per molecule of glucose, with lactic acid and pyruvate as byproducts.

Even in the presence of adequate oxygen, cancer cells may not use OXPHOS, but are reprogrammed to glycolysis (Warburg effect) (Fig. 12.15). Thus the **Warburg effect** is the use of glycolysis under normal oxygen conditions, hence the name **aerobic glycolysis**.¹⁵ Although aerobic glycolysis was postulated to arise from cancer-specific mitochondrial dysfunction, it is now apparent that this is instead a highly regulated and beneficial adaptation for cancer cells. The shift from OXPHOS to glycolysis allows lactate and other products of glycolysis to be used for the more efficient production of lipids, nucleosides, amino acids, and other molecular building blocks needed for rapid cell growth.

FIGURE 12.15 Cancers Have Altered Metabolism. Normal tissues use oxidative phosphorylation (OXPHOS) to turn glucose into CO₂ and energy (in the form of ATP). Cancers take a different approach; even in the presence of oxygen, usually they do not use OXPHOS. Instead, they consume large quantities of glucose to make cellular building blocks, supporting rapid proliferation. ATP, Adenosine triphosphate. (From Van der Heiden MG, Cantley LC, Thompson CB: *Science* 324:1029–1033, 2009.)

A new model, the **reverse Warburg effect**, may play a role in certain cancers. Cancer cells may continue using OXPHOS to generate large amounts of ATP. However, they also may manipulate the **cancer-associated fibroblasts (CAFs)**, perhaps by inducing oxidative stress, to undergo aerobic glycolysis and secrete metabolites (e.g., lactate, pyruvate) that the cancer cells can use in the citric acid cycle (Krebs cycle) to feed OXPHOS and produce ATP. A secondary consequence would be induction of autophagy in the CAFs, resulting in consumption of the CAFs and release of materials needed by the cancer cell in the synthesis of new organelles.

Promoters of aerobic glycolysis are activated by oncogenes and mutated tumor-suppressor molecules. Up-regulation of GLUT1 (glucose transporter 1) under the control of oncogenes (e.g., *RAS*, *Myc*)

and mutant tumor suppressors (e.g., TP53) increases transport of glucose into the cytoplasm. These and other oncogenes or mutant tumor-suppressor genes inhibit OXPHOS and promote the aerobic glycolytic pathway and related metabolic pathways that support the rapid growth of cancers.

Clinically the high glucose utilization of a cancer can be exploited for its detection. ^{18}F -Fluorodeoxyglucose (FDG) is incorporated into cells in the same way as glucose, with two key differences. Because it is missing a key hydroxyl group it cannot be broken down by glycolysis and, thus, FDG accumulates in cells. Because it is tagged with ^{18}F , it can be imaged by a positron emission tomography (PET) scan. Small metastatic tumor masses that are consuming huge amounts of glucose can readily be detected with this imaging method (Fig. 12.16).

FIGURE 12.16 Intense Glucose Requirement Aids in Diagnosis of Metastatic Non-Small Cell Lung Cancer. This 54-year-old woman had a non-small cell lung cancer (NSCLC) resected from the left upper lobe. Five years later, these studies were obtained. The positron emission tomography (PET) scan using 18-fluorodeoxyglucose (FDG) shows metastatic lesions in the brain, right shoulder, and mediastinal and cervical lymph nodes, as well as in the liver, left pelvis, and proximal femur. *PET whole-body image (left):* Representative coronal image from the whole-body FDG-PET/CT-fused image of the same patient (*right*). The fused

image consists of the computed tomography (CT) image with the metabolic information superimposed in color. The pattern of spread is most likely from the primary tumor to the large mediastinal lymph nodes, followed by lymphatic spread to cervical nodes. Blood-borne dissemination produced the bone, brain, and liver metastases. Normally, only the heart, brain, and bladder show a strong signal in PET scans. Resistance to Destruction

Resisting Apoptotic Cell Death

Programmed cell death (**apoptosis**) is a mechanism by which individual cells can self-destruct under conditions of tissue remodeling or as a protection against aberrant cell growth that may lead to malignancy. Two pathways may trigger apoptosis ([Fig. 12.17](#)). The intrinsic pathway (mitochondrial pathway) monitors cellular stress. Cellular stress may include DNA damage, genomic instability, aberrant proliferation, loss of adhesion to extracellular matrix or to adjacent cells, and other causes and characteristics of abnormal cellular physiology. The extrinsic pathway is activated through a plasma membrane receptor complex linked to intracellular activators of apoptosis (known as the *death receptor*).

FIGURE 12.17 Extrinsic and Intrinsic Pathways of Apoptosis and Mechanisms Used by Tumor Cells to Evade Cell Death. (1) Loss of p53 leading to reduced function of proapoptotic factors, such as BAX. (2) Reduced egress of cytochrome c from mitochondria as a result of up-regulation of antiapoptotic factors, such as BCL-2. (3) Loss of apoptotic peptidase-activating factor 1 (APAF-1). (4) Up-regulation of inhibitors of apoptosis (IAP). (5) Reduced CD95 levels. (6) Inactivation of death domain signaling complex (FADD). (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

The balance between proapoptotic (e.g., Bcl-2-associated X protein

[BAX] and Bcl-2-homologous antagonist/killer [BAK]) and anti-apoptotic (e.g., BCL2 [B-cell lymphoma 2]) members of the Bcl-2 family regulates apoptosis. Both groups regulate mitochondrial release of proapoptotic molecules (e.g., cytochrome *c*). As mentioned previously, expression of the tumor-suppressor gene TP53 is affected by intracellular stress, particularly DNA damage. If DNA damage is irreparable, p53 is activated by phosphorylation and induces transcription of proapoptotic factors.

The extrinsic pathway is relatively dormant until the death receptor is activated. The principal apoptotic receptor is called Fas/CD95 (the CD95 nomenclature is an alternative for Fas) (see [Fig. 12.17](#)). Fas is a receptor for Fas ligand (FasL) and similar molecules, such as tumor necrosis factor (TNF). Cytotoxic T lymphocytes and NK cells express surface and soluble FasL and can produce TNF, thus inducing apoptosis in target cells. The Fas receptor is linked to a complex of intracellular proteins (FADD, the Fas-associated death domain signaling complex) that triggers apoptosis.

Both pathways activate a series of intracellular effector enzymatic molecules (caspases). Proapoptotic molecules released by mitochondria in the intrinsic pathway activate caspase 9, which in turn activates caspase 3. Caspase 3 cuts DNA and other substrates, leading to cell death. Activation of the extrinsic pathway activates caspase 8, which can directly activate caspase 3.

Apoptotic pathways are dysregulated in most cancers. Most commonly, loss-of-function mutations to the TP53 gene suppress activation of apoptosis during DNA damage. The balance between pro- and anti-apoptotic molecules also can be affected by overexpression of anti-apoptotic molecules or diminished expression of anti-apoptotic molecules resulting from mutations. Overexpression of Bcl-2 occurs in the vast majority of follicular B-cell lymphomas. Excess expression of other anti-apoptotic members of the Bcl-2 family also may provide increased resistance to chemotherapeutic drugs, many of which act through induction of apoptosis. Other mechanisms of providing resistance to apoptosis include downregulation of caspases or production of caspase inhibitors. Whichever mechanism,

or combination of mechanisms, is used successful cancers suppress apoptotic pathways and increase resistance to cell death.

Tumor-Promoting Inflammation

Historically, an immune/inflammatory response to cancer was considered a detrimental condition that successful tumors evolved methods of evading. It is now realized that the relationship between a cancer and the inflammatory system is much more complex. The inflammatory response may contribute to the onset of cancer and be manipulated throughout the process to benefit tumor progression and spread.

Chronic inflammation has been recognized for close to 150 years as being an important factor in the development of cancer. Chronic inflammations may result from many causes, for example, solar irradiation, asbestos exposure (mesothelioma), pancreatitis, and infection (Table 12.3). Additionally, some organs appear to be more susceptible to the oncogenic effects of chronic inflammation (e.g., the gastrointestinal [GI] tract, prostate, thyroid gland). Individuals who have suffered with ulcerative colitis for 10 years or more have up to a 30-fold increase in the risk of developing colon cancer. Chronic viral hepatitis caused by hepatitis B virus (HBV) or hepatitis C virus (HCV) infection markedly increases the risk of liver cancer.

TABLE 12.3

CHRONIC INFLAMMATORY CONDITIONS AND INFECTIOUS AGENTS ASSOCIATED WITH NEOPLASMS

INFLAMMATORY CONDITIONS	ASSOCIATED NEOPLASM(S)
Inflammatory Conditions	
Asbestosis, silicosis	Mesothelioma, lung carcinoma
Bronchitis	Lung carcinoma
Cystitis, bladder inflammation	Bladder carcinoma
Gingivitis, lichen planus	Oral squamous cell carcinoma
Inflammatory bowel disease, Crohn disease, chronic ulcerative colitis	Colorectal carcinoma

Lichen sclerosus	Vulvar squamous cell carcinoma
Chronic pancreatitis, hereditary pancreatitis	Pancreatic carcinoma
Reflux esophagitis, Barrett esophagus	Esophageal carcinoma
Sialadenitis	Salivary gland carcinoma
Sjögren syndrome, Hashimoto thyroiditis	MALT lymphoma
Skin inflammation	Melanoma
Infectious Agent (Nonviral)	
<i>Helicobacter pylori</i>	Gastric adenocarcinoma, MALT lymphoma
Chronic bacterial cholecystitis	Gallbladder cancer
Schistosomiasis	Bladder, liver, rectal carcinoma; follicular lymphoma of spleen
Liver flukes	Cholangiocarcinoma
Infectious Agent (Viral)	
Human immunodeficiency virus type 1 (HIV-1)	Non-Hodgkin lymphoma, squamous cell carcinomas, Kaposi sarcoma
Hepatitis B and hepatitis C	Hepatocellular carcinoma
Epstein-Barr virus	B-cell non-Hodgkin lymphoma, Burkitt lymphoma, nasopharyngeal carcinoma
Kaposi sarcoma-associated herpesvirus (KSHV/HHV8)	Kaposi sarcoma
Human Papilloma Virus (HPV)-16, -18, -31, others	Cervical, anogenital warts
Human T-cell lymphotropic virus 1 (HTLV-1)	Adult T-cell leukemia/lymphoma

MALT, mucosa-associated lymphoid tissue.

Modified from Kuper H et al: *J Intern Med* 248(3):171–183, 2000.

A specific example is the association between gastric inflammation induced by infection with the bacterium *Helicobacter pylori* (*H. pylori*) and the risk for gastric cancer. *H. pylori* is a bacterium that infects more than half of the world's population. Chronic infection with *H. pylori* is an important cause of peptic ulcer disease and is strongly associated with gastric carcinoma, a leading cause of cancer deaths worldwide. It also is associated with a less common cancer, gastric mucosa-associated lymphoid tissue (MALT) lymphomas. *H. pylori* infection is often acquired in childhood and disproportionately affects lower socioeconomic classes. Although most infections are

asymptomatic, prolonged chronic inflammation can lead to increased gastric acid secretion, atrophic gastritis, and duodenal ulcers, or benign cellular proliferation that can in a small fraction of individuals progress to dysplastic changes and finally gastric adenocarcinoma. *H. pylori* infection can both directly and indirectly produce genetic and epigenetic changes in cells of infected stomachs, including mutations in TP53 and alterations in the methylation of specific genes. Eradication of *H. pylori* from infected individuals before the development of dysplasia may prevent the development of cancer. However, there is no expert consensus on the value of population screening and treatment strategies. The MALT lymphomas associated with chronic *H. pylori* infections may depend on chronic inflammation and antigenic stimulation associated with infections, and therefore treatment with antibiotics may be useful even in cases of early lymphoma.

Once cells with malignant phenotypes have developed, additional complex interactions occur between the tumor and the surrounding stroma and cells of the immune and inflammatory systems. Cancers disrupt the environment, initiate or enhance inflammation, and in turn recruit local and distant cells (macrophages, lymphocytes, and other cellular components of inflammation). The acute inflammatory response is initially designed to eliminate infection, but evolves to initiate and direct the healing process (see [Chapter 7](#)). Successful tumors appear capable of manipulating cells of the inflammatory response from a rejection response toward the phenotypes associated with wound healing and tissue regeneration; a process that includes induction in the damaged tissue of cellular proliferation, neovascularization, and local immune suppression. These activities benefit cancer progression, as well as increase resistance to chemotherapeutic agents.

One of the key cells that promote tumor survival is the **tumor-associated macrophage**, or **TAM**. Tumors commonly produce cytokines and chemokines that are chemotactic factors for monocytes/macrophages (e.g., colony-stimulating factor-1 [CSF1; also known as *macrophage colony stimulating factor* or M-CSF], the

chemokine ligand 2 [CCL2; also known as *monocyte chemoattractant protein-1* or MCP-1]). Levels of CCL2 in human breast cancer and cancers of the esophagus are related to the degree of macrophage infiltration and progression of the tumor. Most tumors have large numbers of TAMs, whose presence frequently correlates with a worse prognosis. Thus monocytes are attracted from the blood and into the tumor, where they mature into macrophages. Monocytes have the capacity to differentiate into several macrophage phenotypes, depending upon the conditions in the microenvironment. The classic proinflammatory macrophage (M1) is the primary macrophage in the acute inflammatory response and is responsible for removal and destruction of infectious agents. During healing, however, a different phenotype (M2) produces antiinflammatory mediators to suppress ongoing inflammation and induce cellular proliferation, angiogenesis, and wound healing. TAMs appear to phenotypically mimic the M2 phenotype.

TAMs have diminished cytotoxic response, and develop the capacity to block T-cytotoxic cell and NK-cell functions and produce cytokines that are advantageous for tumor growth and spread. TAMs secrete cellular growth factors (e.g., TGF- β and fibroblast growth factor-2 [FGF-2]) that favor tumor cell proliferation, angiogenesis, and tissue remodeling, similar to their activities in wound healing. They also secrete angiogenesis factors (e.g., VEGF) that induce neovascularization and matrix metalloproteinases (MMPs) that degrade intercellular matrix. The overall effect is increased tumor growth, invasion of the blood vessels, increased oxygen to the tumor, and invasion through the degraded matrix into the local tissue.

Cancer-associated fibroblasts (CAFs) synthesize the extracellular matrix that surrounds and permeates the tumor. Cytokines and growth factors stored in the matrix as well as growth factors, metalloproteases, proteoglycans, and other molecules secreted by CAFs contribute greatly to cancer progression, local spread, and metastasis.¹⁶

Evading Immune Destruction

Many cancers express cell surface antigens that are not generally found on normal cells from the same tissue. **Tumor-associated antigens** include products of oncogenes, antigens from oncogenic viruses, oncofetal antigens (expressed in embryonic tissues and tumors), and altered glycoproteins and glycolipids. Viral and tumor antigens are processed by the tumor cell and presented on the cell surface by MHC class I molecules and are targets of CD8⁺ T-cytotoxic cells (Tcyto) (see [Chapter 8](#)). NK cells recognize altered cell surface glycoproteins and glycolipids. Thus cancer cells should be recognized as foreign and destroyed by the immune system. In the laboratory, T lymphocytes and NK cells recognize and kill cancer cells. This observation gave rise to two concepts—*immune surveillance* and *immunotherapy*. The **immune surveillance hypothesis** predicts that most developing malignancies are suppressed by an efficient immune response against tumor-associated antigens. The rationale for **immunotherapy** predicts that the immune system could be used to target tumor-associated antigens and destroy tumors clinically. Immunotherapy could be either active, by immunization with tumor antigens to elicit or enhance the immune response against a particular cancer, or passive, by injecting the individual with cancer with antibodies or lymphocytes directed against the tumor antigens. However, the interactions between cancer and the immune system are more complex than originally envisioned and both hypotheses remain controversial.

What is the role of the immune system in protecting against cancer? The most clearly documented effective immune response is prophylactic and directed against oncogenic viruses. Several viruses have been associated with human cancer; human papillomavirus (HPV), Epstein-Barr virus (EBV; also known as HHV4), Kaposi sarcoma herpesvirus (KSHV; also known as HHV8), and hepatitis B and C viruses (HBV, HCV) are associated with about 15% of all human cancers worldwide.¹⁷ Cancer of the cervix and hepatocellular carcinoma account for approximately 80% of virus-linked cancer cases.

Virtually all cervical cancer is caused by infection with specific

types of HPV, which infects basal skin cells and commonly causes warts. There are more than 120 HPV types, but only about 40 can infect human mucosal tissue, and only a few (HPV-16, -18, -31, and -45) are associated with the highest risk for developing cervical, anogenital, and penile cancer. Most HPV infection is handled effectively and rapidly by the immune system and does not cause cancer. Cancer is more common in people with prolonged infection with HPV (a decade or more), during which the viral DNA becomes integrated into the genomic DNA of the infected basal cell of the cervix and directs the persistent production of viral oncogenes. Early oncogenic HPV infection is readily detected by the Papanicolaou (Pap) test, an examination of cervical epithelial scrapings. Early detection of atypical cells in a Pap test alerts healthcare providers to the possibility of cervical carcinoma in situ, which can be effectively treated. The Pap test is probably the most effective cancer-screening test developed to date. For women age 30 to 65 years old, additional testing for HPV infection of cervical cells (HPV test) should be added. Vaccines protecting against the common oncogenic HPV types (HPV-16 and HPV-18 [types that cause 70% of cervical cancers] and HPV-6 and HPV-11 [types that cause 90% of genital warts]) were approved for clinical use beginning in 2006; if these vaccines are administered to young women and men before an initial HPV infection, this is likely to prevent many cases of cervical cancer.

Chronic hepatitis B infections are common in parts of Asia and Sub-Saharan Africa and confer up to a 200-fold increased risk of developing liver cancer. Chronic hepatitis C infections have become increasingly recognized in Western countries. Up to 80% of liver cancer cases worldwide are associated with chronic hepatitis caused either by HBV or by HCV. The initial infection with hepatitis B or C is not associated with cancer; instead, it is acquisition of a chronic viral hepatitis that markedly increases cancer risk. In both cases, it appears that a lifetime of chronic liver inflammation predisposes to the development of hepatocellular carcinoma. Widespread use of the HBV vaccine is expected to significantly decrease the incidence of chronic hepatitis B and hence hepatocellular carcinoma. Unfortunately, a

vaccine for HCV is not yet available.

For most other human tumor viruses, immunoprophylaxis is not yet available. EBV and HHV8 are members of the Herpesviridae family. More than 90% of adults have been infected with EBV, usually as children and without symptoms. EBV infection during adolescence may cause infectious mononucleosis. The virus infects B lymphocytes and stimulates their limited proliferation and usually becomes latent throughout the individual's life. If the individual is immunosuppressed because of HIV infection or because of drugs given for an organ transplant, persistent EBV infection can lead to the development of B-cell lymphomas. EBV infection also is associated with Burkitt lymphoma in areas of endemic malaria and with nasopharyngeal carcinoma, a cancer endemic in Chinese populations in Southeast Asia. HHV8 is linked to the development of Kaposi sarcoma, a cancer that was once seen primarily in older men but now occurs in a markedly more virulent form in immunosuppressed individuals, especially those with acquired immunodeficiency syndrome (AIDS). HHV8 also has been linked to several rare lymphomas. **Human T-cell lymphotropic virus type 1 (HTLV-1)** is an oncogenic retrovirus linked to the development of adult T-cell leukemia and lymphoma (ATLL). HTLV is transmitted vertically (that is, inherited by children from infected parents) and horizontally (e.g., by breast-feeding, sexual intercourse, blood transfusions, and exposure to infected needles). Infection with HTLV may be asymptomatic, and only a small fraction of infected individuals develop ATLL, often many years after acquiring the virus.

Thus immunization has proven beneficial in preventing viral-induced cancers. The immune surveillance hypothesis, however, would predict that components of the immune system, especially T cells, monitor the body and destroy most nascent tumors, even those not caused by viruses. If the immune surveillance hypothesis is correct, compromise of the immune system by immunosuppressive drugs or development of genetic or acquired immune deficiencies would result in increased incidences of all types of cancer. However, defective immune responses generally only increase the risk for

lymphoid cancers, many of which are associated with viral infections. For instance, individuals taking chronic powerful immunosuppressive drugs, such as those given for kidney, heart, or liver transplant, have a much higher risk of developing viral-associated cancers, with a 10-fold increased risk of non-Hodgkin lymphoma (caused by EBV) and up to a 1000-fold increased risk of Kaposi sarcoma (caused by HHV8). The same immunosuppressed individuals, however, have only a slight increase in the risk of common cancers such as lung and colon cancer (and this could well be because of increased inflammation at those sites), and no increase in the risk of breast or prostate cancer.

However, many tumors have an abundance of **tumor-infiltrating lymphocytes (TILs)**. Although the immune cells frequently found in tumors were once thought to be futile attempts at an antitumor response, instead it appears that cancers actively recruit an immune and stromal response to assist in remodeling of tissues, formation of new blood vessels, and promotion of metastasis. NK cells are generally in low amounts in tumors. The predominant TILs are T-regulatory (Treg) cells. Treg cells are CD4⁺ cells that differentiate under the control of specific cytokines, primarily TGF- β . The role of Treg cells during wound healing is to control or limit the immune response to protect the host's own tissues against autoimmune reactions. Their role in tumors is manipulated to prevent a destructive antitumor immune response and provide cytokines that facilitate tumor cell proliferation and spread.¹⁸ Treg cells and TAMs, as well as other stromal cells, produce very high levels of TGF- β and interleukin-10 (IL-10). IL-10 is an immunosuppressive cytokine, which generally decreases T-helper cell 1 (Th1) and Th2 activity, suppresses antigen recognition and cell proliferation by Th cells, and suppresses the capacity of CD8⁺ T-cytotoxic (Tcyto) cells to recognize, proliferate, and kill tumor cells. The goal of current immunotherapy regimens is to reverse this relationship and facilitate T-cell-mediated cancer cell death (discussed later in this chapter).

The release of immunosuppressive factors into the tumor microenvironment also increases resistance of the tumor to chemotherapy and radiotherapy. Increased levels of Treg cells in

blood and lymph nodes and infiltrating the tumor correlate with poor outcomes in breast and GI tumors. In advanced non-small cell lung cancer an elevated ratio of Treg to Tcyto cells is related to a poor response to platinum-based chemotherapy. Immunosuppressive cytokines additionally lower the cancer cell's sensitivity to immune-mediated death (Fig. 12.18). With increasing heterogeneity of cells within the tumor, subpopulations of antigen-negative cancer cell variants may selectively outgrow more immune-sensitive cells. Variants may suppress the production of particular antigens or suppress levels of antigen-presenting MHC class I. Other cytokines appear to increase the cancer cells' resistance to apoptosis. For example, the Th2 cytokine IL-4 increases the resistance of thyroid cancer to chemotherapy; IL-6 produced by Th cells, adipocytes, and fibroblasts activates survival pathways in breast cancer leading to resistance to radiotherapy; and adipocytes enhance the transcription of the anti-apoptotic factor Bcl-2 in leukemia cells.

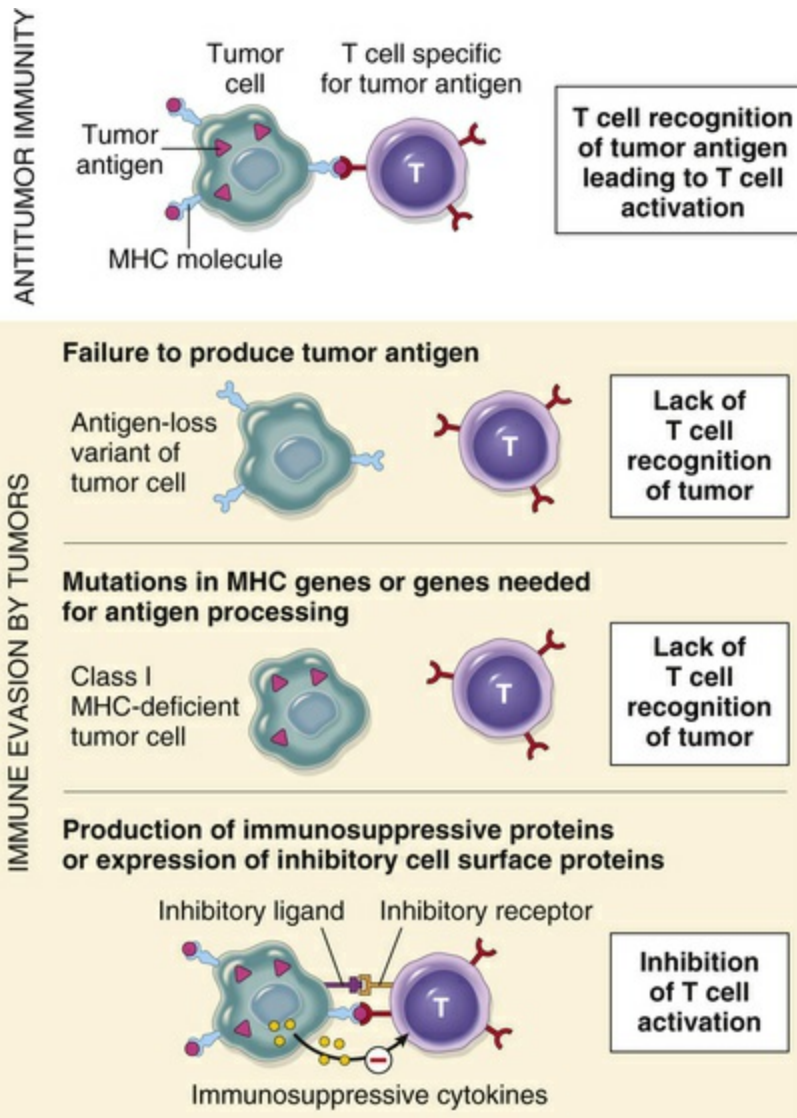

FIGURE 12.18 Mechanisms by Which Tumor Cells Evade the Immune System. Tumors may evade the immune response by losing expression of antigens or major histocompatibility complex (MHC) molecules or by producing immunosuppressive cytokines or ligands for inhibitory receptors on T cells. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

Activating Invasion and Metastasis

Metastasis is the spread of cancer cells from the site of the original tumor to distant tissues and organs through the body. Metastasis is a defining characteristic of cancer and is the major cause of death from cancer. Cancer that has not metastasized can often be cured by a combination of surgery, chemotherapy, and radiation. These same

therapies are frequently ineffective against cancer that has metastasized. For example, in appropriately treated women with localized low-stage breast cancer, the 5-year survival rate is often greater than 90%. Tragically, less than 30% of women with metastatic breast cancer are still alive 5 years after diagnosis. A growing body of basic and clinical research is defining the biologic principles of metastasis, with the hope that this improved understanding will lead to novel diagnostic approaches and better therapies to prevent and treat metastatic cancers.

How do cancer cells develop the ability to metastasize? Metastasis is a highly inefficient process. Cancer cells must surmount multiple physical and physiologic barriers in order to spread, survive, and proliferate in distant locations, and the destination must be receptive to the growth of the cancer. Changes in the tumor microenvironment initiate the metastatic process and may include stromal cell adaptation to increase tumor mass and intratumor hypoxia. As this diversity increases within the changing tumor microenvironment, some cancer cells evolve with multiple new abilities that can facilitate metastasis. The model for transition to metastatic cancer cells is called *epithelial-mesenchymal transition*.

Epithelial-mesenchymal transition (EMT) has been most extensively described for carcinomas, which originate from highly differentiated and polarized epithelial cells that form structured sheets stabilized by multiple adherences to neighboring cells and to a basement membrane (an extracellular meshwork of collagens and other connective tissue proteins) along the cell's basal surface.¹⁹ Although the degree of malignant transformation resulting in a primary carcinoma may be adequate for local expansion of the tumor, neoplastic cells usually retain some epithelial-like characteristics that prevent dissociation from the extracellular matrix and preclude successful metastasis to distal sites. A greater degree of cellular “dedifferentiation” is necessary to produce the phenotype that can separate from the primary tumor and flourish in a potentially hostile secondary site. This results from a programmed transition of the still partially epithelial-like carcinoma to a more undifferentiated

mesenchymal-like phenotype (Fig. 12.19). A similar process occurs with tumors of endothelial origin (endothelial-mesenchymal transition).

FIGURE 12.19 Epithelial-Mesenchymal Transition and Metastasis. The microenvironment supports metastatic dissemination and colonization at secondary sites. Stromal cells (e.g., mesenchymal stem cells [MSCs]), possibly facilitated by a relative decrease in oxygen levels in the tumor, contribute to the epithelial-to-mesenchymal transition (EMT) through which tumor cells develop a metastatic phenotype characterized by suppression of adhesion molecules and reduced adherence to adjacent cells and extracellular matrix, increased local invasion, and access to the blood and lymphatic circulations. One major mediator of this process is TGF- β , which is secreted by the tumor stroma. Intravasation of tumor cells into the circulation is facilitated by protumorigenic TAMs, and CAFs tend to cluster at the leading edge of the invading cancer cells and secrete matrix metalloproteinases that promote digestion and remodeling of the

surrounding ECM. Survival in the circulation is promoted by association with platelets and clotting factors that shield the cancer cells from cytotoxic immune cells (T-cytotoxic cells and NK cells) that are also suppressed by myeloid-derived suppressor cells (*MDSCs*). Potential metastatic sites are prepared by induction of fibronectin, which provides a site for the influx of hematopoietic progenitor cells (*HPCs*) that have receptors for VEGF. *HPCs* appear essential for establishment of a metastatic site. At a metastatic site, cancer cells will adhere to local vascular endothelium, undergo extravascularization facilitated by the effects of ATP on the endothelium, and undergo mesenchymal-to-epithelial transition (*MET*). The premetastatic niche may have been prepared by molecular signaling from the cancer and initiation of a favorable microenvironment. *CAF*, Cancer-associated fibroblast; *ECM*, extracellular matrix; *NK*, natural killer cell; *PDGF*, platelet-derived growth factor; *TAM*, tumor-associated macrophage; *TGF- β* , tumor growth factor-beta; *Treg*, T-regulatory cell; *VEGF*, vascular endothelial cell growth factor. (Modified from Quail DF, Joyce JA: *Nat Med* 19[11]:1423–1437, 2013.)

EMT is a process that occurs normally in embryonic development, as well as wound healing and tissue repair. Generally, cells that have transitioned into a mesenchymal-like phenotype have suppressed expression of adhesion molecules with a loss of polarity, increased migratory capacity, and elevated resistance to apoptosis, and have demonstrated the potential to redifferentiate into other cell types. The transition to a mesenchymal-like phenotype is, in most cases, driven by cytokines and chemokines produced within the tumor microenvironment. IL-8 is an effective driver of carcinoma cells into EMT.

Invasion, or local spread, is a prerequisite for metastasis. In its earliest stages local invasion may occur by direct tumor extension. Eventually, however, cells migrate away from the primary tumor and invade the surrounding tissues (see [Fig. 12.19](#)). Invasion is a multistep process within EMT that includes diminished cell-to-cell adhesion, digestion of the surrounding extracellular matrix, and increased motility of individual cancer cells. *TGF- β* induces changes in expression of **E-cadherin** (an integral component of tight junctions) and of β_4 -integrin in mammary gland tumor cells. The loss of E-cadherin in particular allows cells to detach from extracellular matrix and migrate more readily.

Recruitment of TAMs and other cell types is critical for invasion. Cells are normally attached to the extracellular matrix (ECM). TAMs and other stromal cells secrete proteases and protease activators, such

as the MMPs and plasminogen activators, which promote digestion of connective tissue capsules and other structural barriers. Degradation of the surrounding ECM creates pathways through which cells can move, while releasing bioactive peptides as digestion products that further stimulate tumor growth and mobility.

Normal cells, when separated from their ECM, undergo **anoikis**, a form of apoptosis. Tumor cells adapted to a hypoxic environment have already been selected for resistance to apoptosis, often by loss of normal cell death pathways. The process of EMT frequently increases resistance to apoptosis. For example, neuroblastomas with loss of the proapoptotic caspase 8 genes are able to avoid apoptosis after loss of integrins, and are more able to metastasize than the same cells with normal levels of caspase 8. Accordingly, individuals whose neuroblastomas have low levels of caspase 8 have a poor prognosis.

To transition from local to distant metastasis, the cancer cells must also be able to invade local blood and lymphatic vessels, a task facilitated by stimulation of neoangiogenesis and lymphangiogenesis by factors such as VEGF. After release from the ECM and digestion of basement membranes, mobile cancer cells gain access to the circulation, perhaps facilitated by the leaky newly made vessels and attraction of the cells because of chemoattractants coming from these new vessels. Once in the circulation, metastatic cells must be able to withstand the physiologic stresses of travel in the blood and lymphatic circulation, including high shear rates and exposure to immune cells. One mechanism is for tumor cells to bind to blood platelets, giving them a protective coat of nonmalignant blood cells that both shields the tumor cells and creates a small tumor embolus, or cancer clot, that can promote cancer cell survival in distant locations.

Cancer cells spread through vascular and lymphatic pathways. The **neovascularization** of a cancer offers malignant cells direct access into the venous blood and draining lymphatic vessels. The venous and lymphatic drainage networks associated with the primary tumor frequently determine the pattern of metastasis. Single cells, clumps, and even tumor fragments can disseminate by these routes. Anatomic

patterns of lymphatic and venous blood flow help determine how colon cancers spread to the liver, liver cancers spread through the portal vein to the lungs, lung cancers spread through the systemic circulation to the brain, and breast cancer spreads through the lymphatics to axillary lymph nodes (Fig. 12.20). Cancers often spread first to regional lymph nodes through the lymphatics and then to distant organs through the bloodstream.

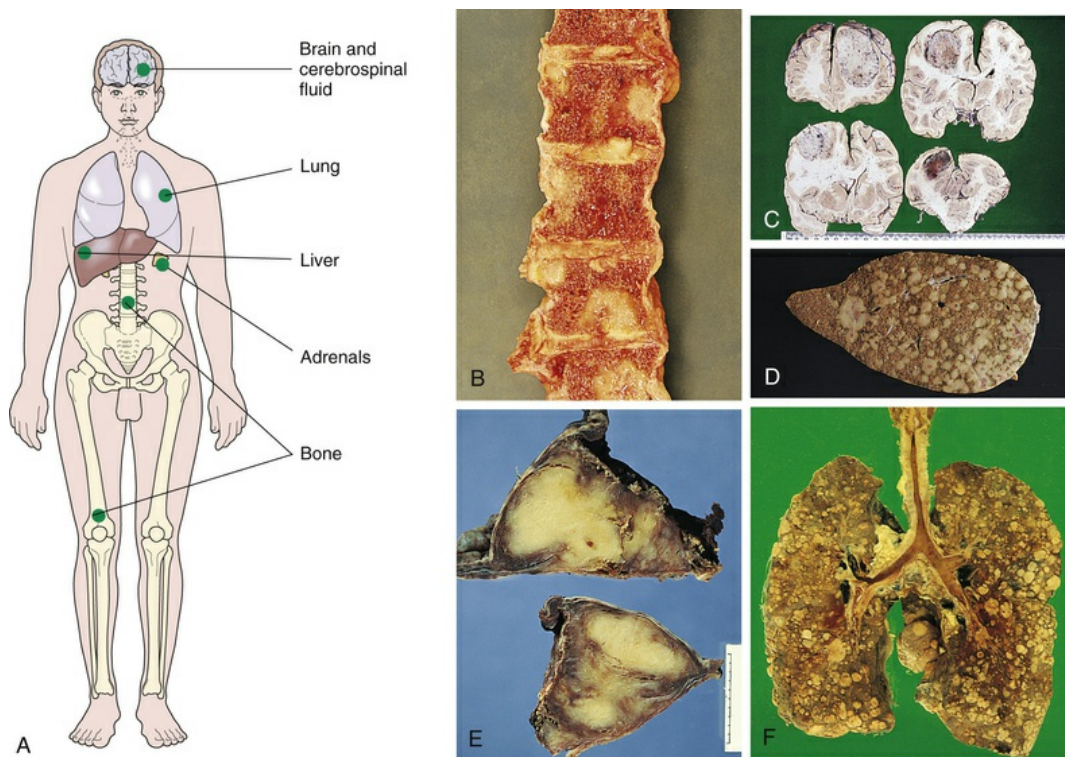

FIGURE 12.20 Patterns of Metastatic Spread. A, Sites of hematogenous metastasis. Blood-borne tumor metastasis leads to growth of secondary tumors in several main sites. The macroscopic appearance of bone metastasis is shown in B, where lesions are seen in vertebrae. C, Numerous metastases from a neoplasm of the stomach are seen in the brain. D, The liver is the most common site for metastases from tumors in the gastrointestinal tract that arose from a colonic neoplasm. E, Metastatic tumor has replaced both adrenal glands, as is commonly seen with spread from lung and breast tumors. F, The lung is the most common site for blood-borne metastases from tumors outside the spinal tract, particularly mesenchymal tumors.

There also is a major yet poorly understood selectivity of different cancers for different sites. Metastatic breast cancer often spreads through the bloodstream to bones but rarely to kidney or spleen,

whereas lymphomas often spread to the spleen but uncommonly spread to bone. In a key study, different types of cancer cells were injected into the carotid artery of mice.²⁰ In spite of identical blood flow-mediated distribution of the cancer cells, each cell type produced cancers in very different parts of the brain. This tissue selectivity is likely caused by specific interactions between the cancer cells and specific receptors on the small blood vessels in different organs. Experimental metastasis studies in mice are beginning to reveal additional molecular reasons for this tissue specificity. Examples include interaction between $\alpha3\beta1$ integrins binding to laminin-5 receptors in the lung, and the chemokine receptor CXCR4 on breast cancer cells promoting homing to lung tissues expressing the ligand CXCL12.

A cancer's ability to establish a metastatic lesion in a new location requires that the cancer survive in the specific environment and be capable of forming complex and heterogeneous tumors. In some cases, these tumor-initiating cells are very rare. Human cancers transplanted into special immune-deficient mice will grow and can metastasize. Experiments have been performed to determine how few cancer cells are capable of establishing a tumor; only 1 in 10,000 human colon cancer cells are able to re-form a complex and heterogeneous colon cancer in mice; however, in human melanomas 1 in 4 cells can initiate a complex tumor in the appropriate mouse model. Thus the number of potentially metastatic cells may vary greatly with the particular cancer.

The degree of dedifferentiation may be variable, but most cells undergoing EMT acquire stem cell traits that facilitate initial growth in a new microenvironment. The EMT is not a stable transition; after taking residence in the metastatic site, the tumor tends to regain some characteristics of the primary tumor, thus reverting to some extent to its epithelial origins. Because metastasis requires successful completion of each and every step, there may be many opportunities to interrupt this potentially lethal pathway.

However, metastasis does not universally result in proliferation at a new site. Some cancer cells survive at a new site but do not proliferate

to form a clinically relevant metastatic site. These cancer cells appear to exist in a state of *dormancy*. **Cellular dormancy** is cellular quiescence—a stable, nonproliferative state that is reversible. Cells may remain quiescent for years before initiating proliferation. About two-thirds of breast cancer deaths occur after a 5-year disease-free interval. In other conditions, solitary tumor cells can be detected in the blood years after a complete clinical remission in individuals, and many people with detectable micrometastases will not develop clinically obvious metastases. Cancer cell dormancy may be extremely common, even without a history of clinical cancer. Studies of deceased individuals without any history of cancer suggest that most individuals have dormant cancer cells that never adjusted to form a malignant tumor.

The causes of dormancy and, more importantly, escape from dormancy and development of malignant cancer are unknown. Dormancy may result from features of the cell or the environmental niche, or both. Individuals with clinical cancers may shed disseminated tumor cells very early from premetastatic lesions. These early cells may have developed inadequately to a metastatic phenotype and thus cannot recruit cells into a supportive stroma or initiated angiogenesis. Another consideration is the niche itself. It is not clear whether a developing cancer secretes factors that enter the bloodstream and prepare potential metastatic niches. If so, early disseminated cancer cells may encounter nonsupportive niches that foster dormancy. A clear understanding of dormancy is needed because existing cancer therapies do not address this condition.

Clinical Manifestations of Cancer

Paraneoplastic Syndromes

Paraneoplastic syndromes are symptom complexes that are triggered by a cancer but are not caused by direct local effects of the tumor mass. They are most commonly caused by biologic substances released from the tumor (e.g., hormones) or by an immune response

triggered by the tumor. For example, a small fraction of carcinoid tumors release hormones, including serotonin, into the bloodstream that cause flushing, diarrhea, wheezing, and rapid heartbeat. A number of cancers trigger an antibody response that attacks the nervous system, causing a variety of neurologic disorders that can precede other symptoms of cancer by months.

Although infrequent, paraneoplastic syndromes are significant because they may be the earliest symptom of an unknown cancer and, in affected individuals, can be serious, often irreversible, and sometimes life-threatening. [Table 12.4](#) presents the classifications of paraneoplastic syndromes. Other clinical manifestations of cancer are summarized in [Box 12.1](#) and [Table 12.5](#).

TABLE 12.4

PARANEOPLASTIC SYNDROMES

CLINICAL SYNDROMES	MAJOR FORMS OF UNDERLYING CANCER	CAUSAL MECHANISM
Endocrinopathies		
Cushing syndrome	Small cell carcinoma of lung Pancreatic carcinoma Neural tumors	ACTH or ACTH-like substance
Syndrome of inappropriate antidiuretic hormone (SIADH) secretion	Small cell carcinoma of lung; intracranial neoplasms	Antidiuretic hormone or atrial natriuretic hormones
Hypercalcemia	Squamous cell carcinoma of lung Breast carcinoma Renal carcinoma Adult T-cell leukemia/lymphoma Ovarian carcinoma	Parathyroid hormone-related protein (PTHrP), TGF- α , TNF, IL-1
Hypoglycemia	Fibrosarcoma Other mesenchymal sarcomas Hepatocellular carcinoma	Insulin or insulin-like substance
Carcinoid syndrome	Bronchial adenoma	Serotonin, bradykinin

	(carcinoid) Pancreatic carcinoma Gastric carcinoma	
Polycythemia	Renal carcinoma Cerebellar hemangioma Hepatocellular carcinoma	Erythropoietin
Nerve and Muscle Syndrome		
Myasthenia	Bronchogenic carcinoma	Immunologic
Disorders of central and peripheral nervous systems	Breast carcinoma	
Dermatologic Disorders		
Acanthosis nigricans	Gastric carcinoma Lung carcinoma Uterine carcinoma	Immunologic; secretion of epidermal growth factor
Dermatomyositis	Bronchogenic, breast carcinoma	Immunologic
Osseous, Articular, and Soft Tissue Changes		
Hypertrophic osteoarthropathy and clubbing of the fingers	Bronchogenic carcinoma	Unknown
Vascular and Hematologic Changes		
Venous thrombosis (Trousseau phenomenon)	Pancreatic carcinoma Bronchogenic carcinoma Other cancers	Tumor products (mucins that activate clotting)
Nonbacterial thrombotic endocarditis	Advanced cancers	Hypercoagulability
Anemia	Thymic neoplasms	Unknown
Others		
Nephrotic syndrome	Various cancers	Tumor antigens, immune complexes

ACTH, Adrenocorticotrophic hormone; *IL*, interleukin; *TGF*, transforming growth factor; *TNF*, tumor necrosis factor.

Box 12.1

Common Side Effects of Cancer and Cancer

Therapy

Anemia: Commonly associated with malignancy, with 20% of persons diagnosed with cancer having hemoglobin concentrations less than 9 g/dL (normal value = 15 g/dL). Mechanisms of anemia include chronic bleeding (resulting in iron deficiency), severe malnutrition, cytotoxic chemotherapy, and malignancy in blood-forming organs. Chronic bleeding and iron deficiency can accompany colorectal or genitourinary malignancy. Iron also is malabsorbed in individuals with gastric, pancreatic, or upper intestinal cancer.

Bone Density Loss: Osteoporosis, or less severe osteopenia, may occur secondary to hormone treatment, such as used for breast cancer and prostate cancer, or in individuals treated with steroids.

Cachexia: A syndrome that includes many symptoms including anorexia, early satiety (filling), weight loss, anemia, asthenia (marked weakness), taste alterations, and altered protein, lipid, and carbohydrate metabolism. It is the most severe form of malnutrition associated with cancer and results in wasting, emaciation, and decreased quality of life. Cytokines and metabolites from the tumor may contribute to cachexia.

Cardiac and Pulmonary Damage: Chemotherapy and localized radiation can damage the heart and lungs, resulting in increased risk for heart failure and decreased pulmonary function.

Fatigue: Severe fatigue is the most frequently reported and persistent symptom of cancer and cancer treatment, particularly chemotherapy. Suggested causes include sleep disturbances, chronic inflammation, anemia, depression, level of activity, nutritional status, and other environmental and physical factors.

Gastrointestinal Tract (GI): Rapidly proliferating cells of the

GI tract are particularly sensitive to radiation and chemotherapy, leading to oral ulcers (stomatitis), malabsorption, and diarrhea, as well as increased risk for infection from the individual's own microbiome.

Hair Loss (Alopecia) and Skin: Some chemotherapy generally affects hair follicles, whereas radiation is more localized. It is usually temporary, although hair may regrow with a different texture initially. Decreased renewal rates of the epidermal layers in the skin may lead to skin breakdown and dryness, altering the normal barrier protection against infection. Radiation therapy may cause skin erythema (redness) and contribute to breakdown.

Infection: The most significant cause of complications and death in people with malignant disease is infection. Immune suppression, lymphopenia, and granulocytopenia may result from the underlying cancer or secondary to treatment increasing the risk of serious microbial (bacterial and fungal) infections. (Factors that predispose individuals with cancer to infection are summarized in [Table 12.5](#).) The prevalence of hospital-acquired (nosocomial) infections increases because of indwelling medical devices, inadequate wound care, and the introduction of microorganisms from visitors and other individuals.

Infertility: Male or female infertility may be secondary to the cancer, surgical treatment, or treatment with chemotherapy or radiation. Many infertility clinics will freeze sperm, eggs, or embryos before initiation of therapy.

Leukopenia and Thrombocytopenia: Causes can include many chemotherapeutic drugs and radiation therapy because they are toxic to the bone marrow, often causing granulocytopenia and thrombocytopenia. Thrombocytopenia is a major cause of hemorrhage in people with cancer and is often treated with platelet transfusions.

Lymphedema: Accumulation of fluid in the tissues results from damage to the lymphatic system from lymphoid cancer or

metastatic disease, surgery, or radiation treatment.

Pain: Pain may occur during the early stages of malignant disease but intensifies with disease progression. Direct pressure, obstruction, invasion of a sensitive structure, stretching of visceral surfaces, tissue destruction, infection, and inflammation all can cause pain. Chronic pain may result from nerve damage secondary to surgery, chemotherapy, or radiation.

TABLE 12.5

FACTORS PREDISPOSING INDIVIDUALS WITH CANCER TO INFECTION

FACTOR	BASIS
Age	Many common malignancies occur mostly in older age. Immunologic functions decline with age. General debility reduces immunocompetence. Immobility predisposes to infection. Far-advanced cancer often results in immobility and general debility that worsen with age. Elderly persons are predisposed to nutritional inadequacies. Malnutrition impairs immunocompetence.
Tumor	Nutritional derangements can result. Sites and circumstances favorable to growth of microorganisms (obstruction, serous or blood effusion, ulceration) can be created. Far-advanced disease predisposes individuals to debility and immobility. Humoral or cellular immune defects may result. Metastasis to bone marrow may cause leukopenia or other defects in immunity.
Leukemias	Inadequate granulocyte production can occur (e.g., neutropenia, impaired phagocytosis). Thrombocytopenia (bleeding) can occur. Late effect: chronic lung disease from <i>Pneumocystis carinii</i> pneumonia can develop during therapy.
Lymphomas and other mononuclear phagocyte malignancies	Humoral and cellular immune defects (anergy, altered immunoglobulin production) result. Late effect: splenectomy in children can cause increased susceptibility to infection.
Surgical treatment	Invasive procedure interrupts first lines of defense. Radical nature of surgery (removal of large blocks of tissue in lengthy procedures) causes hemorrhage, decreased tissue perfusion, creation of dead spaces, and tissue necrosis. Procedure may be "dirty" surgery (bowel, infected, or contaminated areas). Surgery patients are often older and at poor risk. Long preoperative hospitalization often precedes surgery. Patients may have received previous adrenocorticosteroid therapy. Patients may have infections at sites remote from the operative area. Nutritional derangements (especially important in head and neck surgery) may result. Lymph node dissection

may predispose patient to local infection and impair containment to area. Gynecologic surgery may result in fistulae. Lung surgery may cause bronchopleural fistulae. Debility and immobility may result.

Molecular Mechanisms of Cachexia

Cachexia is a multiorgan syndrome that has been discussed as a type of energy balance disorder where energy intake is decreased and energy expenditure is increased (Fig. 12.21). Energy intake and expenditure depends on the tumor type and its growth phase. Because individuals who are being administered total parenteral nutrition still lose weight, increased resting energy expenditure may be the cause of the wasting syndrome. Investigators are studying the role of both mitochondria and sarcoplasmic reticulum (SR) in muscle function and its relationship to cachexia. Hypotheses related to these functions include increased production of peroxisome proliferator-activated receptor- γ co-activator-1 α (PGC1 α), which can activate a mitochondrial protein (mitofusin-2 [MFN2]) that interacts with muscle SR and controls interorganelle calcium (Ca⁺⁺) signaling. Therefore one hypothesis is the overexpression of PGC1 α can activate MFN2 expression, leading to Ca⁺⁺ deregulation, which is closely associated with muscle wasting. Muscle weakness and fatigue is related to loss of myofibrillar proteins in muscle cells. Abnormalities in protein and amino acid metabolism are noted in cachectic muscle (Fig. 12.22).

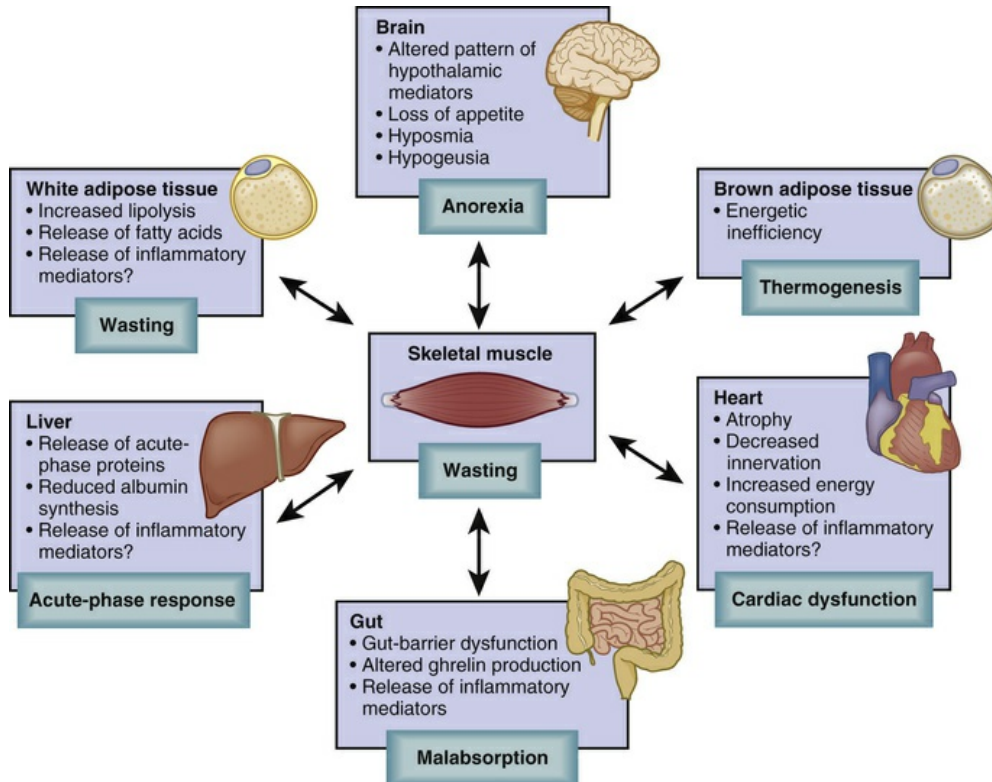

FIGURE 12.21 Cachexia: A Multiorgan Syndrome. Loss of skeletal muscle and adipose tissue are major contributors to cachexia. But many other organs have a role in the cachexia syndrome and the wasting that takes place in muscle may be dependent on alterations in these other organs or tissues. Changes in hypothalamic function and activation of brown adipose tissue, as well as alterations in liver and heart function, also are involved in the syndrome. Recent studies support a role for gut microbiota in cancer cachexia and the possibility of a gut–microbiota–skeletal muscle relationship. Recent data suggest that the conversion of white adipose tissue to brown adipose tissue is triggered by both humoral inflammatory mediators, such as interleukin-6 (IL-6), and tumor-derived compounds, such as parathyroid hormone–related protein (PTHrP). (From Bindels LB, Delzenne NM: *Int J Biochem Cell Biol* 45:2186–2190, 2013; Bindels LB et al: *PLoS One* 7[6]:e37971, 2012.)

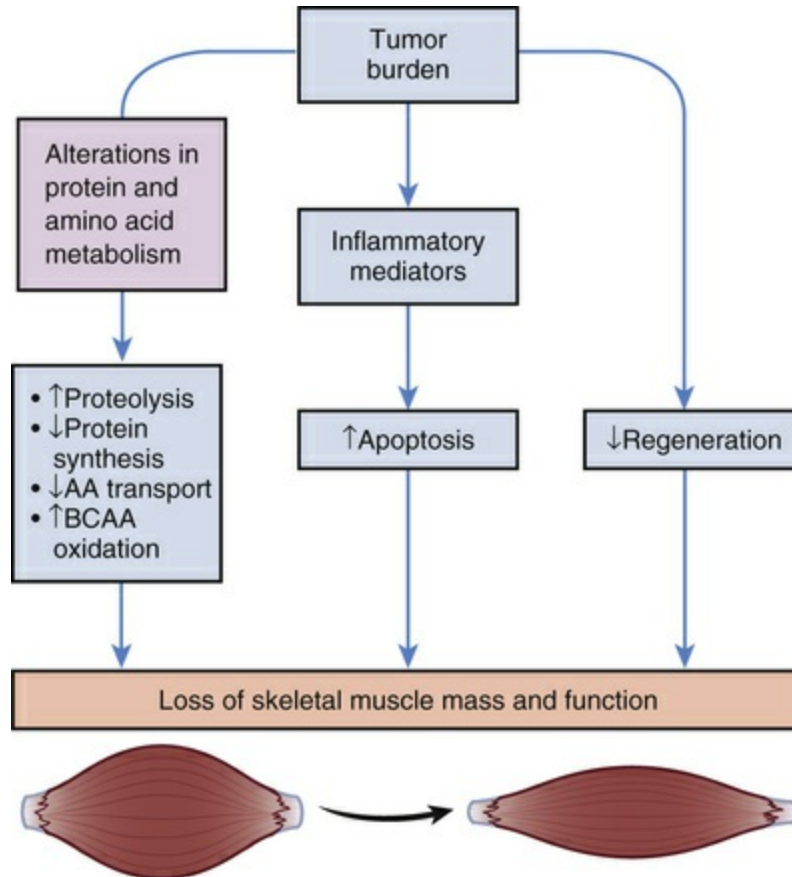

FIGURE 12.22 Wasting of Skeletal Muscle. Inflammation plays a major role in muscle wasting and is linked to alterations in protein and amino acid metabolism, activation of muscle cell apoptosis, and decreased regeneration. AA, amino acids; BCAA, branched-chain amino acids. (Adapted from Argilés JM et al: *Nat Rev Cancer* 14[11]:754–762, 2014.)

Contributing further to muscle wasting are an increase in apoptosis and an impaired capacity for regeneration. Many signaling pathways are involved in protein turnover leading to the wasting process and are activated by inflammatory mediators including cytokines, myostatin, and tumor-derived factors. In addition to muscle wasting, miRNAs may be involved in stimulating the breakdown of adipose tissue. In cancer cachexia, skeletal muscle loss includes major loss of **white adipose tissue (WAT)**. The WAT loss is thought to be caused by (1) increased lipolysis, (2) decreased activity of lipoprotein lipase (LPL), and (3) decreased new or de novo lipogenesis in adipose tissue. New data show that WAT cells undergo a “browning” process during cancer cachexia where they change to beige cells called *BAT-like cells*. Browning is associated with increased thermogenesis. Tumor-derived

compounds, such as IL-6 (which also may be released by immune cells) and parathyroid hormone–related protein (PTHrP), may be the drivers of thermogenesis.

An unusual and frustrating component of cancer care is the person's early satiety, or a sense of being full after only a few mouthfuls of food. Brain mediators are involved in the regulation of food intake and include appetite, satiation, taste, and smell of food. Therefore the brain is an important organ in anorexia and consequently altered energy balance. Profoundly altered are both **orexigenic** (appetite-stimulating) and **anorexigenic** (appetite-suppressing) **brain pathways**. (Cytokines are discussed in detail in [Chapters 7](#) and [8](#).)

Diagnosis and Staging of Cancer

Histologic Staging

Cancer can be discovered in many ways: after screening tests, from routine examinations, and after investigation of symptoms. The symptoms a cancer produces are as diverse as the types of cancer. The location of the cancer can determine symptoms by physical pressure, obstruction, and loss of normal function or a cancer can cause problems far away from its source by pressing on nerves or secreting bioactive compounds. Whatever the initial complaint, once the diagnosis is suspected and a tumor has been identified, it is essential that tumor tissue be obtained to establish a definitive diagnosis and correctly classify the disease. Various methods of obtaining tissue are described in [Table 12.6](#).

TABLE 12.6

OBTAINING TISSUE—THE BIOPSY

PROCEDURE	PURPOSE	EXAMPLE
Excisional biopsy	Complete removal, usually with a margin of normal tissue	Full resection (e.g., mastectomy, partial colectomy)
Incisional	Removal of a portion of a lesion	Lymph node biopsy, muscle

biopsy		mass biopsy
Core needle biopsy	Often performed with direct vision, or guided with ultrasound or computed tomography (CT)	Needle biopsy of prostate or liver mass
Fine-needle aspiration	Obtains dissociated cells for cytologic study but does not preserve tissue structure	Thyroid, breast mass
Exfoliative cytology	Cells shed from the surface, for example, from cervix, sputum (lung), or urine	Brushings from lung or colon endoscopy

If the diagnosis of cancer is established, it is critical to determine if the cancer has spread, known as the **stage of the cancer**. **Cancer staging** initially involves determining the size of the tumor, the degree to which it has locally invaded, and the extent to which it has spread (metastasized) (Fig. 12.23). Specific molecular tests are increasingly used in staging as well. Diverse schemes are used for staging different tumors. In general, a four-stage system is used, with carcinoma in situ regarded as a special case. Cancer confined to the organ of origin is stage 1; cancer that is locally invasive is stage 2; cancer that has spread to regional structures, such as lymph nodes, is stage 3; and cancer that has spread to distant sites, such as a liver cancer spreading to lung or a prostate cancer spreading to bone, is stage 4. One common scheme for standardizing staging is the World Health Organization's TNM system: *T* indicates tumor spread, *N* indicates node involvement, and *M* indicates the presence of distant metastasis. The prognosis generally worsens with increasing tumor size, lymph node involvement, and metastasis. Staging also may alter the choice of therapy, with more aggressive therapy being delivered to more invasive disease.

FIGURE 12.23 Tumor Staging by the TNM System. Example of staging for breast cancer.

Tumor Markers

During surveillance or diagnosis of cancer as well as following therapy, specific biochemical markers of tumors have proven to be helpful. These **tumor markers** are substances produced by both benign and malignant cells that are either present in or on tumor cells or found in blood, spinal fluid, or urine. Some tumor markers have been known for many decades. Tumor markers include hormones, enzymes, genes, antigens, and antibodies. If the tumor marker itself has biologic activity, then it can cause symptoms, such as those described in [Table 12.7](#). For example, the adrenal medulla normally secretes the catecholamine epinephrine (adrenaline). Benign tumors of the adrenal medulla (pheochromocytoma) can produce catecholamines (e.g., adrenaline) in vast excess, leading to rapid pulse rate, high blood pressure, diaphoresis (i.e., sweating), and tremors. Detection of elevated blood or urine levels of catecholamines helps to confirm the diagnosis, and treatment of the disease relieves the symptoms. Tumor markers can be used in three ways: (1) to screen and identify individuals at high risk for cancer; (2) to help diagnose the specific type of tumor in individuals with clinical manifestations

relating to their tumor, as in adrenal tumors or enlarged liver or prostate; and (3) to follow the clinical course of a tumor.

TABLE 12.7

EXAMPLES OF TUMOR MARKERS IN BODY FLUIDS

MARKER NAME	NATURE	TYPE OF TUMOR
Adrenocorticotrophic hormone (ACTH)	Peptide hormone	Pituitary adenomas
Alpha fetoprotein (AFP)	70-kDa protein	Hepatic, germ cell
Beta-2-microglobulin (β 2M)	11-kDa protein	Multiple myeloma, CLL
Beta-human chorionic gonadotropin (β -hCG)	Glycopeptide hormone β -chain	Germ cell, choriocarcinoma
CA15-3/CA27-29	Large MW glycoproteins	Breast
CA-125	Large MW glycoprotein	Ovary
CA19-9	201-kDa glycoprotein	Pancreas, gallbladder, bile duct, gastric
Calcitonin	3.4-kDa polypeptide hormone	Thyroid
Carcinoembryonic antigen (CEA)	200-kDa glycoprotein	GI, pancreas, lung, breast, etc.
Catecholamines	Epinephrine and precursors	Pheochromocytoma (adrenal medulla)
CD20	33–36-kDa glycosylated phosphoprotein	Non-Hodgkin lymphoma
Chromogranin A (CgA)	48-kDa protein	Neuroendocrine
Homovanillic acid/vanillylmandelic acid (HVA/VMA)	Catecholamine metabolites	Neuroblastoma
Prostate-specific antigen (PSA)	33-kDa glycoprotein	Prostate
Urinary Bence-Jones protein	Ig light chain	Multiple myeloma

CLL, Chronic lymphocytic leukemia; *GI*, gastrointestinal; *Ig*, immunoglobulin; *kDa*, kilodalton(s); *MW*, molecular weight.

To date, no tumor marker has proven satisfactory to screen populations of healthy individuals for cancer. Testing large populations will always detect a few normal individuals with test results at the high end of the normal distribution (the “false positives”), which can lead to expensive and invasive additional tests, and unnecessary concern. Similarly, some individuals with disease

will have test results in the normal range (“false negatives”). More importantly, some nonmalignant conditions also can produce tumor markers. The presence of an elevated tumor marker therefore may suggest a specific diagnosis, but it is not used alone as a definitive diagnostic test. For instance, prostate tumors secrete *prostate specific antigen (PSA)* into the blood. However, enthusiasm has waned for routine testing for PSA levels. Most men (approximately 75%) with elevated levels of PSA do not have cancer upon biopsy.²¹ A taskforce to study the use of PSA detection concluded that for every 1000 men (ages 55 to 69) screened repeatedly, only 0 to 1 prostate cancer-related deaths would be avoided, 100 to 120 men would undergo unnecessary biopsies with some complications, and 110 men would be diagnosed with prostate cancer (frequently slow growing and not life threatening) and 50 of these would have major complications related to treatment. However, falling levels of PSA after radiation or surgical therapy may indicate successful treatment for prostate cancer, and a later rise may indicate a recurrence. Identification of ideal sensitive and specific tumor markers that are elevated early in the course of common cancers remains a high priority because the early detection of cancer often improves the treatment outcome.

Immunohistochemical and Genetic Analysis

Because knowledge about the cellular and molecular alterations in individual cancers can influence the choices of therapy, it becomes increasingly important for clinicians to accurately classify each cancer. The classification, and hence the treatment decisions, of cancers was originally based on gross and light microscopic appearance, and is now commonly accompanied by immunohistochemical analysis of protein expression. Increasingly, this is supplemented by a more extensive genetic analysis of the tumors. The range of genetic analysis is expanding rapidly. A single gene may be examined (for example, to determine if there is a characteristic chromosomal translocation diagnostic of chronic myelogenous leukemia [CML]) or a panel of genes and proteins may be examined (e.g., in breast cancer) to determine if the tumor expresses estrogen receptor, progesterone

receptor, and the epidermal growth factor (EGF) receptor HER2 or if there are mutations in specific genes that modify response to therapy. In a research setting and increasingly in clinical settings, global gene expression and mutation analysis can be measured using polymerase chain reaction (PCR), microarray, or advanced DNA sequencing technology. These analyses can be used to classify tumors more precisely and may predict the most effective therapy.²² This detailed analysis of each tumor is a form of **personalized medicine** that offers therapy based on a very detailed knowledge of the characteristics of each individual's specific cancer. This enhanced molecular characterization subdivides cancers into therapeutically and prognostically relevant smaller groups. As an example, breast cancers can now be subclassified into over four types (luminal A, luminal B, basal-like, and others) based on their expression of specific markers, such as estrogen receptor, HER2/Neu, and other specific genes and proteins. Each subtype has a different response to therapy and a different prognosis.

Treatment of Cancer

Until late in the last century the mainstays of cancer therapy have been surgery, chemotherapy, and radiation therapy. These approaches have been highly successful for certain types of cancer, but have many limitations. Immunotherapy has been the Holy Grail of cancer therapists, but successes have been few. Cancer therapy is now in a process of rapid evolution. Armed with a clearer understanding that cancer is in fact multiple diseases that share general hallmarks/enablers and that the specific mechanisms underlying each hallmark may vary considerably among cancers (e.g., the large variety of oncogenes that may be used to differentiate cancers), modern cancer therapy is reaching a stage where complete genetic analysis of an individual cancer may determine the appropriate combination of therapies. Thus effective therapy may include a combination of reagents targeting several hallmarks and under constant modification to target the evolving cancer cells.

Classic Approaches

Surgery

Surgery plays many roles in the care of individuals with cancer. The multiple approaches to obtaining tissue for diagnosis have been discussed. Surgery is often the definitive treatment of cancers that do not spread beyond the limits of surgical excision. If melanoma can be diagnosed when localized to the skin, surgical removal can result in a cure rate of 98%.²³ Cancers detected early in the prostate, testis, or thyroid have cure rates of 99%, 95%, and 98%, respectively.

Surgery also is indicated for the relief of symptoms, for instance, those caused by tumor mass obstruction. In selected high-risk diseases, surgery plays a role in the prevention of cancer. For example, individuals with familial adenomatous polyposis because of germline mutations of the *APC* gene have close to a 100% lifetime risk of colon cancer, so a prophylactic colectomy is indicated. Similarly, women with *BRCA1/2* mutations have a markedly increased risk of breast and ovarian cancer, and often choose prophylactic mastectomy or bilateral salpingo-oophorectomy (removal of ovaries and fallopian tubes), or both.

Key principles apply specifically to cancer surgery, including obtaining adequate surgical margins during a resection to prevent local recurrences and obtaining adequate tissue specimens during biopsies so that the pathologist can be confident of the diagnosis. Additionally, the surgeon provides critical staging information by inspection, sampling, and removal of local and regional lymph nodes during procedures.

Radiation Therapy

Radiation therapy is used to kill cancer cells while minimizing damage to normal structures. Ionizing radiation damages cells by imparting enough energy to cause molecular damage, especially to DNA. The damage may be lethal, in which the cell is killed by radiation; potentially lethal, in which the cell is so severely affected by radiation that modifications in its environment will cause it to die; or

sublethal, in which the cell can subsequently repair itself. Areas with rapidly renewing cells are more radiosensitive. Effective cell killing by radiation also requires good local delivery of oxygen, something not always present in large cancers. Radiation produces slow changes in most cancers and irreversible changes in normal tissues as well. Because of these irreversible changes, each tissue has a maximum lifetime dose of radiation it can tolerate. Radiation is well suited to treat localized disease in areas that are hard to reach surgically, for example, in the brain and pelvis. A number of radiation delivery methods are available, with external beam being the most common. Radiation sources, such as small ^{125}I -labeled capsules (also called *seeds*), can also be temporarily placed into body cavities, a delivery method termed **brachytherapy**. Brachytherapy is useful in the treatment of cervical, prostate, and head and neck cancers.

Chemotherapy

The era of modern chemotherapy began with the observation in World War II that mustard gas exposure caused suppression of the bone marrow. Related compounds, such as nitrogen mustard and cyclophosphamide, were then tested and produced clinical responses in hematologic malignancies, including lymphomas. Also in the late 1940s, based on the remarkable clinical observation that the vitamin folic acid could *increase* leukemia growth, antifolate drugs were developed (leading ultimately to methotrexate) that produced remissions in previously untreatable leukemia.

All chemotherapeutic agents attack pathways that exist in rapidly dividing normal cells, but cancer cells utilize more and are severely affected. Antimetabolites, such as methotrexate and L-asparaginase, block normal growth pathways in all cells, but leukemia and other cancer cells are exquisitely sensitive to folic acid and asparagine deprivation, whereas nonmalignant cells are far less sensitive. Similarly, some cancer cells are highly sensitive to DNA-damaging agents, such as cyclophosphamide and anthracyclines, because of the oncogenic mutations that accelerate the cell cycle and DNA synthesis. Cellular checkpoints prevent normal cells treated with microtubule-

directed drugs, such as vincristine and the taxanes, from undergoing mitosis, whereas cancer cells treated with these agents lack normal checkpoints, continue through mitosis, and undergo mitotic catastrophe.

Single chemotherapeutic agents often shrink cancers, but these drugs given alone rarely, if ever, provide a cure. Hence, chemotherapy drugs are usually given in combinations designed to attack a cancer from many different weaknesses at the same time and to limit the dose and therefore the toxicity of any single agent. Cancers contain a very large number of cells, and commonly a small fraction of those cells may be resistant to a particular drug. However, those cells are likely to be sensitive to the second or third drug in a chemotherapy cocktail. Scheduling of drug administration is also very important, with many studies showing cancers are more likely to develop drug resistance if there are significant delays between planned courses of chemotherapy.

Induction chemotherapy seeks to cause shrinkage or disappearance of tumors, but success depends greatly on the type of tumor, the stage, and the individual's age at diagnosis. In Hodgkin lymphoma, for example, chemotherapy alone can be used in some cases to cure the disease. If used as part of a drug cocktail, treated individuals have a 5-year cure rate of 86%.²³ In other settings, chemotherapy may shrink the tumor and improve symptoms without ultimately providing a cure. **Adjuvant chemotherapy** is given after surgical excision of a cancer with the goal of eliminating micrometastases. **Neoadjuvant chemotherapy** is given before localized (surgical or radiation) treatment of a cancer. As with induction chemotherapy, the effectiveness of neoadjuvant therapy can be determined by measuring the size of the tumor. Neoadjuvant therapy can shrink a cancer so that surgery may spare more normal tissue. For example, in the bone cancer osteogenic sarcoma, neoadjuvant therapy often converts a large tumor mass into a much smaller mass, allowing the surgeon to perform a limb-sparing excision rather than an amputation.

Some leukemia is very effectively treated with chemotherapy. Acute lymphoblastic leukemia (ALL) is most common in children and

adolescents. Primarily using chemotherapy, the 5-year cure rate is about 90%.²³ Acute myelogenous leukemia (AML) and chronic lymphoblastic leukemia (CLL) occur in children, but more often in adults. Chemotherapy of AML may lead to 5-year cure rates of 65%, but it is not as effective in adults (about 40% in adults younger than 60 years, but only about 10% in adults older than 60 years). CLL occurs more in the elderly (median age of 71 at diagnosis), and chemotherapy results in a 82% 5-year cure rate.²³

A major complication of chemotherapy is death of rapidly dividing cells that are not cancer, such as those of the bone marrow. Hematopoietic growth factors also have been used to counter the effects of chemotherapy on bone marrow cells, for example, erythropoietin to increase numbers of red blood cells, IL-11 to increase platelet levels, and colony-stimulating factors to increase granulocytes (G-CSF) or both granulocytes and monocytes (GM-CSF).

Immunotherapy

The expression of unique antigens on cancer cells that can be targeted by T cells has driven the quest for effective therapies to initiate an immune response, boost a currently inadequate immune response, or convert a tumor-protective immune response to a destructive one.²⁴ Since the 1950s this quest has been characterized by promises and frustrations.

Tumor cell vaccines were one of the first attempts at immunotherapy for cancer. Vaccines have been extremely effective in protecting individuals against infective agents. Killed whole tumor cell vaccines prepared from an individual's own cancer (autologous) or from cancers from other individuals (allogeneic) were attempted. Several allogeneic cancer cell vaccines using protein extracts or peptides continue to be tested, but so far none have been shown to be effective enough to be licensed.²⁵

One innovative approach using sipuleucel-T has been approved by the Food and Drug Administration (FDA) for the treatment of metastatic prostate cancer that is resistant to conventional therapy. One therapy is sipuleucel-T using dendritic cells obtained from an

individual with prostate cancer and incubated with a protein resulting from the fusion of prostatic acid phosphatase (a cancer antigen found in 95% of prostate cancers) and granulocyte-macrophage colony-stimulating factor (GM-CSF, an immune cell-stimulating cytokine). The dendritic cells process and present the antigen and are infused back into the individual. In clinical trials, treatment with sipuleucel-T extended the lives of individuals by 4.1 months. These results may not seem spectacular, but were meaningful in this group with very advanced and terminal disease. Other similar vaccine approaches against B-cell lymphoma and melanoma have shown promising results.

Passive immunotherapy using lymphocytes against cancer cell antigens has been attempted, with limited success, since the early 1970s. In recent years, passive administration of tumor-targeting lymphocytes (adoptive cell therapy, ACT) treated ex vivo with cytokines seems promising. The use of cytokines or adoptive cell therapy assumes the individual with cancer has remaining cancer-specific Tc cells and NK, which may not be true. Cytokines have been injected into individuals with cancer to enhance T-cell function. The cytokines IL-2 and Interferon-alfa (trade name for interferon-alpha, IFN- α) increase proliferation and cytotoxic activity of Tc and NK cells and have been approved by the FDA to treat metastatic kidney cancer and melanoma. Lymphocytes that have infiltrated the tumor (TILs) are more likely to contain active tumor-specific Tc and NK cells. TILs can be obtained from excised tumor tissue and further activated in the laboratory. Treatment of TILs with IL-2 before reinjection has been successful in some individuals. This approach is being improved by engineering T-cell receptors (TCRs) to increase the effectiveness of cancer-specific killing (see *What's New? Engineering T Cells for Better Anticancer Killing*).

What's New?

Engineering T Cells for Better Anticancer Killing

The specificity and function of T-cytotoxic cells (Tc cells) is controlled by three signals: (1) the T-cell receptor (TCR) that binds antigen and is associated with a complex of transmembrane signaling molecules (CD3) (see [Chapter 7](#)); (2) the transmembrane co-receptor CD8 that binds to class I major histocompatibility complex (MHC) that is presenting antigen, resulting in proximity of CD3 with the intracellular portion of CD8 leading to activation of a signaling molecule; and (3) transmembrane accessory molecules, such as CD28, that bind to ligands on the target cell surface and provide an additional activation signal ([Fig. A](#)). Cancers have developed multiple mechanisms for escaping the cytotoxic effects of Tc cells, among which are suppression of antigen presentation, reduction of CD3 expression, and inhibition of the CD28 signal by expression of soluble CTLA-4, which competes for binding to the CD28 ligand. Thus recognition of cancer-associated antigens by the Tc cell may be completely suppressed.

FIGURE A

A variety of approaches have been designed to bypass

suppression of the TCR. Initial attempts included cloning Tc cells expressing high-affinity TCRs for tumor antigen. However, suppression of antigen presentation by the tumor prevented recognition by these Tc cells. This has led to a unique approach of engineering T cells with chimeric antigen receptors (CAR T cells). Early success with these novel cells has led to further sophisticated approaches to constructing more complex CARs.

The process involves collection of circulating white blood cells from the blood of an individual with cancer using leukapheresis. The lymphocytes are enriched, induced to proliferate, and transfected by a virus containing the genetically engineered CAR. The CAR T cells are cloned in bulk, verified for expression of the CAR, and cryopreserved. When used, the cells are thawed and infused into the individual with cancer.

The CAR receptors are V_H and V_L regions cloned from monoclonal antibodies and inserted in tandem into the CAR gene. Because tumors suppress MHC presented antigen, the CAR receptors are designed against other surface molecules that do not require presentation. The CAR gene also contains information for hydrophobic transmembrane regions, followed by genetic information for costimulatory signals. Initially the costimulatory signals included the cytoplasmic portions of CD28 and CD3, but more recently developed CARs include multiple costimulatory signaling peptides. Thus binding of the receptor to a cancer-related molecule activates linked intracellular signaling peptides, such as CD3, CD28, and others, contained sequentially in the CAR gene.

Targets for CAR T cells have included CD19, CD20, and CD22 on hematologic cancers and HER2, EGFR, and others on solid tumors. The most notable success has been treatment of CD19-positive B-cell malignancies. CD19 is expressed on cancer cells at a very high level related to normal B cells. Infusion of CAR T cells has led to remissions of greater than 80% of people with ALL and about 50% of those with CLL. Success against solid tumors has been less spectacular.

The next generation of CAR T cells is in development. These

include the addition of more costimulatory signals, simultaneous expression of two CAR molecules on the T cell (both targeted to the same cancer-related molecule, but one CAR providing a strong TCR-like signal and the second providing a costimulatory signal), CARs directed to apoptosis-inducing molecules or cytokine receptors, and the use of engineered allogeneic T cells. The use of allogeneic T cells would accelerate treatment by circumventing the current 2- to 3-week process of preparing CAR T cells from the individual's own cells.

ALL, acute lymphocytic leukemia; *CLL*, chronic lymphocytic leukemia.

A family of monoclonal antibodies are currently approved for use against cancer. One group is designed to directly bind to and damage cancer cells. Dinutuximab is a monoclonal antibody against ganglioside GD2. It reacts with CD2-expressing tumor cells, such as malignant melanoma, neuroblastoma, osteosarcoma, and small cell carcinomas of the lung, and induces complement-mediated cytotoxicity or provides a site for NK cells and others with Fc receptors to bind and initiate antibody-dependent cellular cytotoxicity (ADCC) (see [Chapter 7](#)). Bispecific monoclonal antibodies have been created that, unlike other antibodies, are engineered to express two different antigen binding sites on the same molecule. One example is an antibody in which one binding site is specific for CD19 and the other is against CD3; thus the antibody bridges CD19-positive ALL cells and CD3-positive T cells, facilitating T-cell killing of these leukemia cells.

A group of highly effective monoclonal antibodies are called **immune checkpoint inhibitors**. Immune checkpoints are where signals from costimulatory molecules may suppress or allow T-cell-mediated cytotoxicity, thus protecting normal cells. These antibodies are directed against the costimulatory molecules involved in

repressing T-cell immune responses (see [Chapter 8](#)). Ipilimumab was the first immune checkpoint inhibitor approved by the FDA for treatment of advanced melanoma. This monoclonal antibody blocks the costimulatory molecule cytotoxic T-lymphocyte–associated protein-4 (CTLA-4) on the surface of Tc cells so they retain tumor-killing capacity. Two other approved drugs block protein cell death protein-1 (PD-1) on the surface of Tc cells (nivolumab) and the respective ligand (PD-L1 and PD-L2) on the surface of tumor cells (pembrolizumab). These have been approved for treatment of advanced melanoma, urothelial carcinoma, non–small cell lung cancer, and renal cell carcinoma.

Targeted Disruption of Cancer

As discussed previously, cancers appear to share a variety of hallmarks that contribute to the malignant phenotype. Recent molecular and genetic analyses of groups of cancer can classify an individual's cancer by the spectrum of mutations underlying the cancer phenotype. Targeted cancer therapy is designed to address unique growth characteristics of a specific class of tumor and directly interfere with that process. Tumor growth and progression are dependent on a variety of mutations leading to expression of oncogenes, inactivation of tumor-suppressor molecules, and interactions with inflammatory cells in the tumor microenvironment that foster angiogenesis, resistance to apoptosis and immune-mediated cancer cell death, altered tumor cell metabolism, and metastasis. A more efficacious therapeutic approach, therefore, may be a combination of drugs highly targeted to cancer hallmarks.²⁶ More than 25 drugs are listed at the National Cancer Institute as cancer-targeting agents that inactivate oncogenes, block angiogenesis, and affect cancer cell metabolism. For instance, imatinib mesylate is a competitive inhibitor of tyrosine kinases, primarily the BCR-ABL tyrosine kinase. It is highly effective in treating CML and ALL that expresses the Philadelphia chromosome but ineffective in virtually all other cancers.

Some monoclonal antibodies have been effective in delivering targeted cancer therapy. Monoclonal antibodies against the CD20 antigen (rituximab) expressed on some non-Hodgkin lymphomas and those against CD52 (alemtuzumab) on CLL can induce apoptosis of the cancer cell. Monoclonal antibodies against the epidermal growth factor (EGF) receptor on colon cancers and head and neck cancers and also the HER2 EGF receptor on breast cancer have been relatively successful. Bevacizumab inhibits tumor angiogenesis by targeting the interaction between VEGF secreted by tumor cells and the VEGF receptor.

Monoclonal antibodies also have been used as targeted carriers (immunoconjugates) of radioactive molecules or toxins. Examples include ^{90}Y -ibritumomab, a monoclonal antibody that targets CD20 on non-Hodgkin lymphoma cells to deliver yttrium-90; and ado-trastuzumab emtansine that delivers the drug DM1 (inhibits cell proliferation) to HER2-positive breast cancer cells. These drugs are so tightly targeted they have much less toxicity than conventional chemotherapies that have targets in virtually all cells.
